Abstract

Background: Psychoeducation has the potential to support students experiencing distress and help meet the demand for support; however, there is a need to understand how these programs are experienced. Web-based diaries are a useful activity for psychoeducation because of their therapeutic benefits, ability to capture naturalistic data relevant to well-being, and appropriateness for text analysis methods.

Objective: This study aims to examine how university students use electronic diaries within a psychoeducation program designed to enhance mental well-being.

Methods: The Science of Happiness course was administered to 154 undergraduate students in a university setting (the United Kingdom). Diaries were collected from the students for 9 weeks. Baseline well-being data were collected using the Short Warwick-Edinburgh Mental Wellbeing Scale (SWEMWBS). The percentage of negative and positive emotion words used in diaries (emotional tone) and use of words from five life domains (social, work, money, health, and leisure) were calculated using the Linguistic Inquiry and Word Count 2015 software. Random effects (generalized least squares) regression models were estimated to examine whether time, diary characteristics, demographics, and baseline well-being predict the emotional tone of diaries.

Results: A total of 149 students participated in the diary study, producing 1124 individual diary entries. Compliance with the diary task peaked in week 1 (n=1041, 92.62%) and was at its lowest in week 3 (n=807, 71.81%). Compared with week 1, diaries were significantly more positive in their emotional tone during week 5 (mean difference 23.90, 95% CI 16.89-30.90) and week 6 (mean difference 26.62, 95% CI 19.35-33.88) when students were tasked with writing about gratitude and their strengths. Across weeks, moderate and high baseline SWEMWBS scores were associated with a higher percentage of positive emotion words used in diaries (increases compared with students scoring low in SWEMWBS were 5.03, 95% CI 0.08-9.98 and 7.48, 95% CI 1.84-13.12, respectively). At week 1, the diaries of students with the highest levels of baseline well-being (82.92, 95% CI 73.08-92.76) were more emotionally positive on average than the diaries of students with the lowest levels of baseline well-being (59.38, 95% CI 51.02-67.73). Diaries largely focused on the use of social words. The emotional tone of diary entries was positively related to the use of leisure (3.56, 95% CI 2.28-4.85) and social words (0.74, 95% CI 0.21-1.27), and inversely related to the use of health words (−1.96, 95% CI −3.70 to −0.22).

Conclusions: We found evidence for short-term task-specific spikes in the emotional positivity of web-based diary entries and recommend future studies examine the possibility of long-term impacts on the writing and well-being of students. With student well-being strategies in mind, universities should value and encourage leisure and social activities.

Introduction

Background

There is mounting concern regarding increases in the number of young people (aged 16-24 years) reporting long-standing mental health difficulties [1]. Rising university attendance among school-leavers approaching the end of adolescence has been observed globally [2], making universities an increasingly advantageous setting for providing mental health and well-being interventions [3]. Alongside treatment-based approaches for managing mental ill-health, there is a need to better understand the use of more accessible preventative approaches that equip students with resources to protect and promote their well-being [4].

Student Mental Health and Well-being

The mental health of university students has been a priority in the higher education sector for at least a century [5]. In the last decade, however, academics have described a growing crisis in university students' mental health [6,7]. For many students, university education is undertaken at a crucial period of transition into adulthood, associated with social, psychological, and developmental challenges across multiple life domains [8,9]. The World Health Organization's World Mental Health International College Student project in 8 countries found that 31% of students had experienced a mental health disorder (such as anxiety or depression) within the previous 12 months [10]. As demand from students for counseling support continues to exceed supply, there is growing pressure to invest in strategies with the potential to prevent students from reaching the point where high-intensity one-on-one support is required [11].

Embedding Psychoeducation in University

Psychoeducation, which involves the provision of information, tips for self-management, and guidance for staying well [12], may be one method for embedding well-being–enhancing interventions within university life. In a framework adapted from World Health Organization guidelines, experts have highlighted that alongside formal specialized treatment for severe mental ill-health problems, there is a need for structured and unstructured support for students experiencing varying levels of distress [13]. In line with this model, psychoeducation interventions can be used to facilitate social support networks and provide space for students to engage in self-care strategies. Research into university-based psychoeducation continues to expand [14,15], and there is a need to understand how students, with varying levels of well-being, experience and engage with these interventions.

Practical and Methodological Use of Diaries

Diaries are a promising tool for integration into psychoeducation programs because of their potential for both therapeutic benefit and data collection [16]. Diaries offer writers a naturalistic space to reflect on experiences, and provide researchers with a depth of detail that is difficult to accurately achieve when relying on tools that require participants to retrospectively recall events from their past [17].

One of the earliest diary studies examining well-being in university found that common worries included academic stress and common sources of happiness included friendships [18]. Previous research with students has also indicated that participation in writing tasks about positive life events may lead to improvements in mood [19]. In a study where students were asked to write about their thoughts and feelings in relation to starting university, students who screened positive for depression (Beck Depression Index scores above 14) used significantly more negative emotion words than students without depression (scores below 7) [20]. These studies highlight a link between the emotional content of writing and how students report feeling about their mental health and well-being. Less is known about the balance between negative and positive feelings [21] and the emotional tone (balance of positive and negative words) of writing [22].

Technological Developments in Diary Methodology

The availability and progression of technology has been critical in the ongoing advancement of diary-based research. In the field of diary analysis, researchers have used technology to identify prospective participants on the web [23], automatically prompt participants with poor compliance to diary completion tasks [24], and automatically monitor the time of day when respondents choose to complete their diaries [25].

Significant advancement has also been made in the analysis of open-text data contained within diaries. Natural language processing methods are being increasingly used to automate the analysis of diaries, as seen in a web-based eating disorder intervention [26]. Statistical models have been developed to predict depression severity based on the use of emotional words within social media posts [27]. The use of technology to enhance aspects of the research process, however, should not be undertaken without careful consideration. For example, where tasks are automated, it remains crucial to understand how the process is undertaken and be mindful of any trade-offs involved in generating these efficiencies.

This Study and Research Questions

This study aims to examine how university students use electronic diaries within a psychoeducation program designed to develop mental well-being skills (Science of Happiness course). Longitudinal diary data enabled us to examine how the program was experienced and how the proportion of positive and negative emotion words (emotional tone) within diaries fluctuated over time. Automated text analysis methods were used to analyze the written content of the diaries. This study has 5 key research questions:

1. How compliant are students to the web-based diary task across weeks?
2. How does the proportion of positive and negative emotion words (emotional tone) within the diaries develop over time?
3. How are time, sociodemographics, diary characteristics, and baseline self-reported well-being related to the emotional tone of diaries? (model 1)
4. Is the trajectory of emotional tone within diaries dependent on baseline levels of well-being? (model 2)
5. Which life domains do students discuss most in their diaries, and how do these topics relate to the emotional tone of diary entries? (model 3)

Methods

Participants

The sample consisted of 154 university undergraduate students at a university in the UK. The *Science of Happiness* course was offered to students on 14 undergraduate courses in their first year of study (including *study abroad programs*) in exchange for academic credits. The course began in the first semester of the study (September 2019) and involved weekly lectures, weekly group tasks, and weekly diary entries (the focus of this research). The main evaluation examining the impact of the intervention is presented in a publication submitted separately [28].

Data Collection

Sociodemographic characteristics and well-being data were collected at baseline. Parallel to the intervention, linked anonymized diary entries were collected digitally on a weekly basis at 9 time points.

Each student was assigned a study participant number, and no personally identifiable data were included in the research data set. Diary data were extracted from the web platform they were submitted to (Blackboard) and deposited in a Microsoft Excel spreadsheet stored on a secure server. Within the software, students were only able to submit one diary entry per week. The study obtained ethical approval from the University of Bristol Faculty Ethics Review Committee (reference: 27061987862).

Electronic Diaries

The diaries we collected were *solicited*, given that they were requested by us for this study, rather than being spontaneous [29]. Students were able to submit their diary entries on the web via a desktop or laptop or smartphone. Students were prompted to write in their diaries about events in the week that had influenced their well-being or they were given guidance to write about their well-being in relation to specific topics such as their goals for the future. These tasks are described in Multimedia Appendix 1. Although this imposed some structure on the task, care was taken to encourage open responses and space for respondents to reflect without excessive constraints [29].

Measures

A brief sociodemographic survey was used to capture data on gender, age, nationality, and ethnicity. Mental well-being was measured using the 7-item Short Warwick-Edinburgh Mental Wellbeing Scale (SWEMWBS) [30]. The original full-length Warwick-Edinburgh Mental Wellbeing Scale has demonstrable content validity, structural validity, criterion validity, internal consistency, and test-retest reliability across a UK nationally representative sample of adults and a specific sample of students in 2 UK universities [31]. The shortened 7-item version of the scale has been found to be internally consistent [30], and data on UK national norms have since been published to aid in interpreting scores [32]. Responses to the SWEMWBS are scored on a 5-point scale ranging from 1 (none of the time) to 5 (all of the time). Total scores were transformed, and higher scores indicated greater levels of mental well-being. In the regression analysis, well-being was recoded into a 3-level variable representing scores in the first (low), second (moderate), and third (high) tertiles of scores.

Text Analysis

This study used a *dictionary method* approach to text analysis. This deductive approach involved automating the analysis of diary content based on a predetermined dictionary-based coding scheme [33].

Data Processing and Cleaning

All diaries were completed in the English language. Text data were stored in Microsoft Excel in a wide format (one participant per row and 1 week of diary entries per column). Typos were managed using guidance developed by the Language Use and Social Interaction lab [34]. A manual rather than an automated process was selected to preserve as much of the text as possible in its original form.

All diaries were manually scanned for typos, and words such as *roominate* were changed to *ruminate* to ensure the text analysis software was able to correctly identify the words used. Words such as *kinda* were not corrected because of the ability of text analysis software to recognize and correctly classify *slang text-speech*. In total, 892 words were manually corrected during the data cleaning process.

Linguistic Inquiry and Word Count Text Analysis Variables

Linguistic Inquiry and Word Count (LIWC) 2015 is a stand-alone piece of software that has been empirically validated to analyze the linguistic, social, and psychological content of text data [35]. LIWC 2015 uses an internal dictionary of almost 6400 words coded into different categories and counts the frequency of words used within any target text data. The software is now in its fourth major revision [22]. In a sample of 117,779 pieces of text data (novels, tweets, natural speech,

expressive writing, and Twitter), LIWC 2015 correctly classified an average of 85.18% of words (SD 5.36%) [22]. In this study, we generated 7 LIWC text variables: positive emotions (eg, love, nice, and sweet), negative emotions (eg, hurt, ugly, and nasty), social (eg, mate, talk, and they), work (eg, job, class, and boss), health (eg, clinic, flu, and pill), leisure (eg, cook, TV, and movie), and money (eg, audit, cash, and owe). Each variable reflects the total number of words within each diary entry that falls into these prespecified categories of the LIWC's internal dictionary. We also used LIWC to automatically calculate the word count of each diary. Using these variables builds on the use of sentiment analysis approaches in dictionary-based text analysis [33].

Emotional Tone

We also used the emotional tone variable generated by the LIWC software. This reflects the ratio of positive and negative emotion words. If a diary entry contained 100 words and 5 of its words were found in the *negative emotion* section of LIWC's internal dictionary and 5 of its words were found in the *positive emotion* section of LIWC's internal dictionary, the *positive emotion* score would be 5, the *negative emotion* score would be 5, and the *emotional tone* score would be 50. Higher scores on the emotional tone variable indicate a greater ratio of positivity within the text of diary entries, with scores above 50 indicating a greater proportion of positive words and scores below 50, indicating a greater proportion of negative words.

Statistical Analysis

Data were analyzed using STATA 16 (StataCorp LLC) [36]. Sociodemographic characteristics (age, gender, ethnicity, and nationality) and diary characteristics (word count, diary entries, and emotional tone) were summarized descriptively for the whole sample. Participants' characteristics were compared descriptively according to levels of compliance to the diary task. Diaries were also subgrouped based on word count to compare the characteristics of students who wrote the most and least.

The trajectory of emotional tone across weeks is displayed in line graphs. The trajectory of emotional tone seen in the whole data set (available-case analysis) was compared with the trajectory seen for the subsample with full compliance to diary entry (complete-case analysis).

We applied 4 models using random effects generalized least squares with an autoregressive disturbances regression approach (Table 1). This method was selected because the diaries in our data set are clustered around repeated measures from the same individuals and are thus not independent and because of the need for a method that is robust to variations in the number of repeated measures collected across individuals. Model 1 addressed research question 3, model 2 addressed research question 4, and model 3 addressed research question 5. Model 0 (a basic model with only week effects) was only estimated to establish whether our main model (model 1) had an improved statistical model fit (Wald chi-square) following the addition of sociodemographics, diary characteristics, and baseline well-being variables.

Table 1. Random effects generalized least squares with autoregressive disturbances regression models estimated.

Model	Sample (n=154), n (%)	Diaries (n=1124), n (%)	Dependent variable	Independent variables
Model 0: investigating the role of week effects only on the emotional tone of diary entries	110 (71.43)[a]	855 (76.07)	Emotional tone	Time (weeks)
Model 1: investigating the role of week effects, sociodemographics, diary characteristics, and baseline well-being on the emotional tone of diary entries	110 (71.43)	855 (76.07)	Emotional tone	Time (weeks), gender, age, diary word count, total diary entries, and baseline well-being
Model 2: investigating interaction effects between baseline well-being and week (Multimedia Appendix 2)	110 (71.43)	855 (76.07)	Emotional tone	Time (weeks), gender, age, diary word count, total diary entries, baseline well-being, and interactions between baseline well-being and time
Model 3: investigating the relationship between word use in 5 life domains on the emotional tone of diary entries	120 (77.92)	927 (82.47)	Emotional tone	Time (weeks), social words, work words, health words, money words, leisure words, gender, age, diary word count, and total diary entries

[a]Sample of respondents with complete data on variables in model 1 to enable Wald chi-square model fit comparisons (Multimedia Appendix 3).

Results

Sociodemographic and Diary Characteristics

A summary of the sample characteristics is provided in Table 2. Of a total sample of 154 participants, 149 (96.8%) participated in the diary completion activity, resulting in a total of 1124 diary entries. Participants had a mean age of 19.29 years (SD 1.47 years) and were predominantly female (93/124, 75.0%). The sample mainly consisted of White (100/123, 81.3%) and UK nationality students (96/121, 79.3%). Participants, on average, completed a mean of 7.54 diary entries (SD 1.47), and diary entries had a mean word count of 209.63 (SD 165.79). The text analysis software LIWC correctly captured 92% of the 235,621 words analyzed in this study, which is in line with expectations from previous LIWC analyses. The mean emotional tone of diary entries was 75.15 (SD 28.60).

Table 2. Total sample sociodemographics.

Sample characteristics	Values
Age (years; n=124), mean (SD)	19.29 (1.47)
Gender (n=124), n (%)	
Female	93 (75.0)
Male	29 (23.4)
Prefer not to say	2 (1.6)
Ethnicity (n=123), n (%)	
Asian or Asian British	12 (9.8)
Black, African, Caribbean, or Black British	3 (2.4)
Mixed or multiple ethnic groups	5 (4.1)
Other ethnic group	3 (2.4)
White	100 (81.3)
Nationality (n=121), n (%)	
British	96 (79.3)
All other nationalities	25 (20.7)
Diary characteristics (n=149), mean (SD)	
Word count	209.63 (165.79)
Diary entries	7.54 (1.47)
Emotional tone	75.15 (28.60)

From 855 diaries, the SWEMWBS scores were recoded by tertiles for the diaries of students with low well-being (range 14.08-19.98; n=296), moderate well-being (range 20.73-22.35; n=345), and high well-being (range 23.21-25.03; n=214).

Compliance with the diary task by week is displayed in Figure 1, which indicates that week 1 (138/149, 92.6%) and week 5 (136/149, 91.3%) had the highest compliance rates, whereas week 3 (107/149, 71.8%) and week 9 (108/149, 72.5%) had the lowest compliance rates.

Figure 1. Compliance with diary completion activity.

Diary Entry Compliance—Subgroup Analysis

Participants were grouped by those who completed all 9 entries (44/149, 29.5%), 8 entries (45/149, 30.2%), 7 entries (32/149, 21.5%), or fewer than 6 entries (28/149, 18.8%). Descriptive statistics for the characteristics of participants across the 4 levels of diary compliance are presented in Table 3. Participants who were fully compliant with the diary activity (9 entries) had higher diary word counts (mean 242.96, SD 201.88) than participants who completed 6 or fewer diary entries (mean 175.00, SD 160.59). Furthermore, participants who were fully compliant had the highest levels of baseline well-being (mean 22.16, SD 2.57) compared with students with 6 of fewer diary entries (mean 20.78, SD 2.69). The emotional tone and percentage of females was highest for participants in the most compliant group; however, the pattern across levels of compliance was less clear.

Table 3. Key sample and diary characteristics by diary-compliance subsamples.

Characteristics	Diary compliance			
	9 entries	8 entries	7 entries	≤6 entries
Diaries (n=149), n	396	360	224	396
Word count (n=149), mean (SD)	242.96 (201.88)	213.00 (142.24)	167.53 (112.14)	175.00 (160.59)
Age (years; n=124), mean (SD)	19.26 (1.38)	19.26 (1.54)	19.04 (0.74)	19.74 (2.10)
Gender, female (n=124), n (%)	35 (28.2)	25 (20.2)	20 (16.1)	13 (10.5)
Baseline well-being (n=119), mean (SD)	22.16 (2.57)	20.91 (2.45)	21.46 (3.33)	20.78 (2.69)
Emotional tone (n=149), mean (SD)	77.39 (26.27)	75.33 (28.95)	70.68 (30.88)	75.53 (29.67)

Word Count—Subgroup Analysis

There were no clear patterns in the age of respondents or emotional tone of diary entries based on the 4 word count categories (Table 4). Longer diary entries had the highest proportion of female respondents (155/281, 55.2% for diaries of *0-103.5* word count length and 195/280, 69.6% for diaries of *265+* word count).

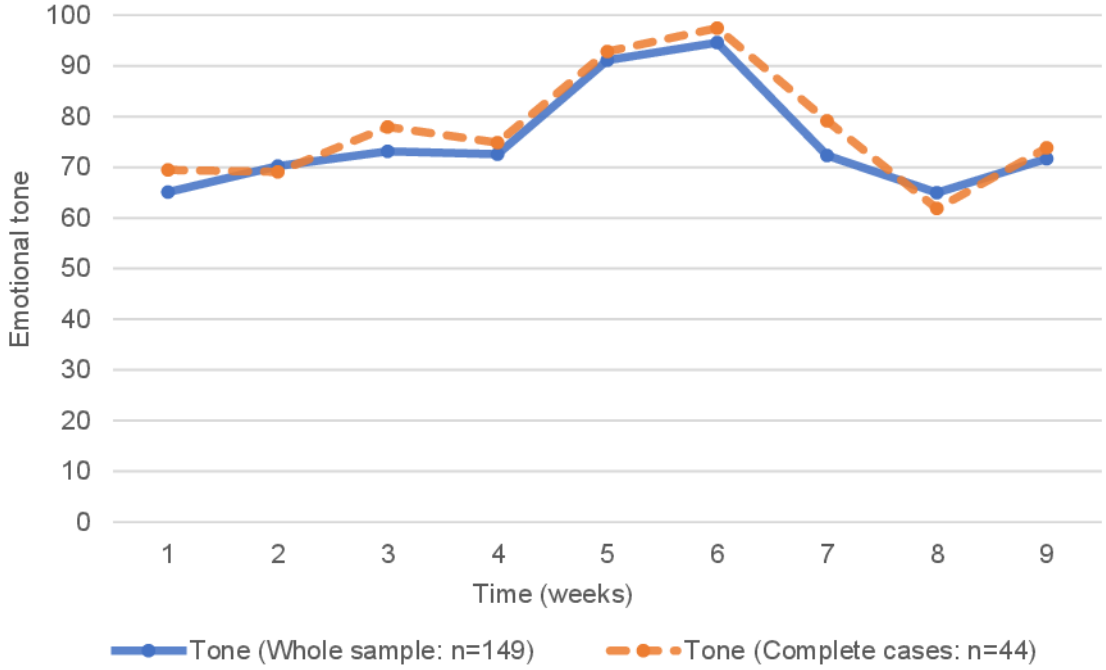
Table 4. Key sample and diary characteristics by diary-compliance subsamples.

Characteristics	Word count (percentile range)			
	265+ (75-100)	163-265 (50-75)	103.5-163 (25-50)	0-103.5 (0-25)
Diary entries, n (%)	280 (24.9)	281 (25.0)	282 (25.1)	281 (25.0)
Age (years), mean (SD)	19.56 (1.56)	19.09 (1.21)	19.07 (1.20)	19.36 (1.64)
Gender (female), n (%)	195 (69.6)	182 (64.8)	178 (63.1)	155 (55.2)
Emotional tone, mean (SD)	72.48 (26.97)	79.33 (26.91)	74.13 (28.50)	74.67 (31.47)

Trajectory of Diary Emotional Tone

The pattern of scores for the available-case analysis and the complete-case analysis followed an inverted U shape (Figure 2), with a peak between weeks 5 and 6 when students are completing the gratitude and signature strengths diaries, respectively. Given the similarity in the trajectory pattern of emotional tone, whether complete case data or all available data were used, subsequent analyses in this paper are presented using the whole data set diary data (available-case analysis).

Figure 2. Trajectory of mean emotional tone within diaries for whole sample (and participants with complete data for all 9 weeks).



Factors Determining the Emotional Tone of Diaries (Model 1)

The results from the random effects generalized least squares regression examining the role of week effects, sociodemographics, diary characteristics, and baseline levels of well-being in determining the emotional tone of diary entries are presented in Table 5. The emotional tone of diary entries in weeks 5 and 6 were, on average, higher by 23.90 (95% CI 16.89-30.90; *P*<.001) and 26.62 (95% CI 19.35-33.88; *P*<.001), respectively, in comparison with the emotional tone of diary entries in week 1. The mean emotional tone did not significantly differ from week 1 for the remaining 6 weeks. As the age of students increased by 1 year, the emotional tone of diary entries was higher, on average, by 1.98 (95% CI 0.51-3.46; *P*=.008). Students with both moderate (5.03, 95% CI 0.08-9.98; *P*=.046) and high (7.48, 95% CI 1.84-13.12; *P*=.009) levels of baseline well-being had diaries with significantly higher emotional tone compared with students with low baseline well-being. Gender and diary characteristics had no clear effects.

Table 5. Model 1: random effects generalized least squares regression examining the role of time (week effects), sociodemographics (age and gender), diary characteristics (word count and entries), and baseline well-being (moderate and high well-being, compared with low well-being) in determining the emotional tone of diary entries.[a]

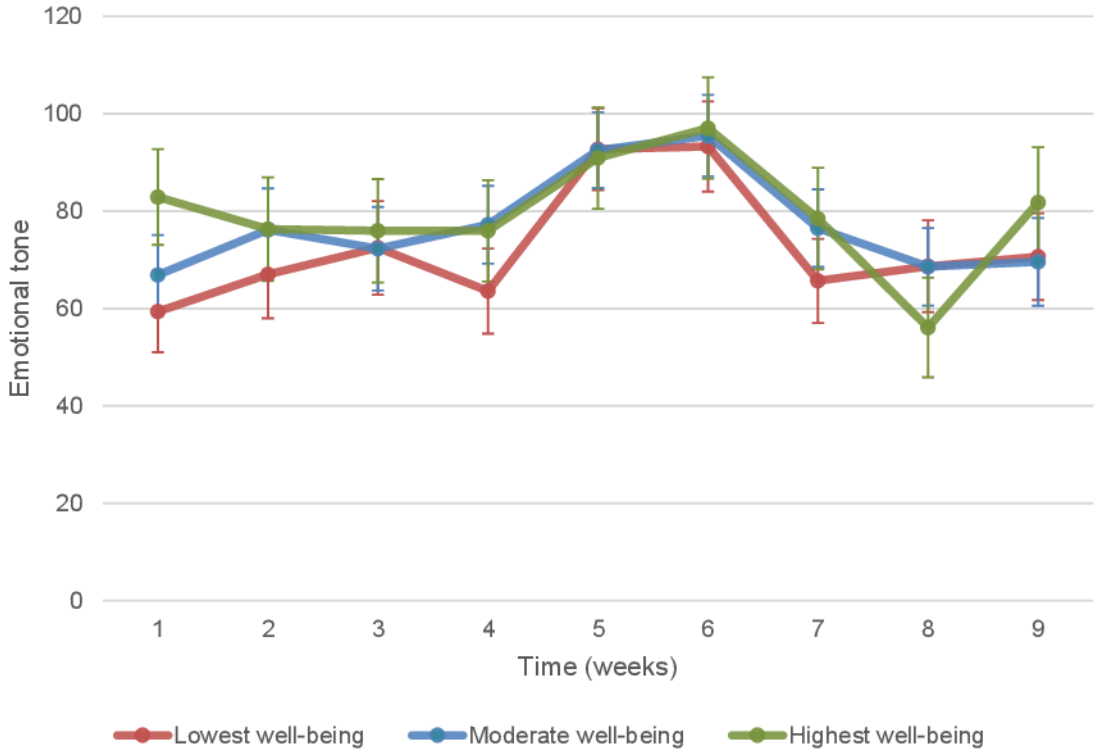
Differences in Emotional Tone Across Weeks for Students With the Highest and Lowest Levels of Baseline Well-being (Model 2)

As a secondary analysis, we tested whether adding an interaction effect between baseline well-being (tertiles for the lowest, moderate, and highest scores) and time (weeks) improved the fit of the model (Multimedia Appendix 2). Adding this interaction to the model produced a significantly higher Wald chi-squared value (*P*=.03), indicating a better fitting model. To examine how the pattern of emotional tone differed between students with the lowest and highest well-being across the weeks, we plotted the mean emotional tone for students with the highest and lowest levels of well-being (adjusted for age, gender, word count, and total diary entries; Figure 3). The difference in the pattern was most substantial in the first week, where students with the lowest levels of baseline well-being started out with markedly lower average emotional tone of their diary entries. Furthermore, students with the highest levels of baseline well-being demonstrated a marked drop in the emotional tone of their diaries during week 8 when they were asked to write about their goals for the future.

Figure 3. Trajectory of emotional tone for students with low, moderate, and high baseline well-being, adjusted for age, gender, word count, and total diary entries.



Life Domain Analysis (Social, Health, Leisure, Money, and Work; Model 3)

The use of words from 5 life domains (mean percentage of words per diary entry) across the 9 weeks is presented in Figure 4. Social topics were the most discussed topic apart from in week 8 (when participants were asked to diary about their goals) when work was the most dominant life domain discussed. A peak in the discussion of social topics was observed for week 5 (when participants were asked to diary about gratitude). Money was the least discussed topic of diaries for all 9 weeks.

Figure 4. Use of life domain–specific terms in diary entries across weeks.

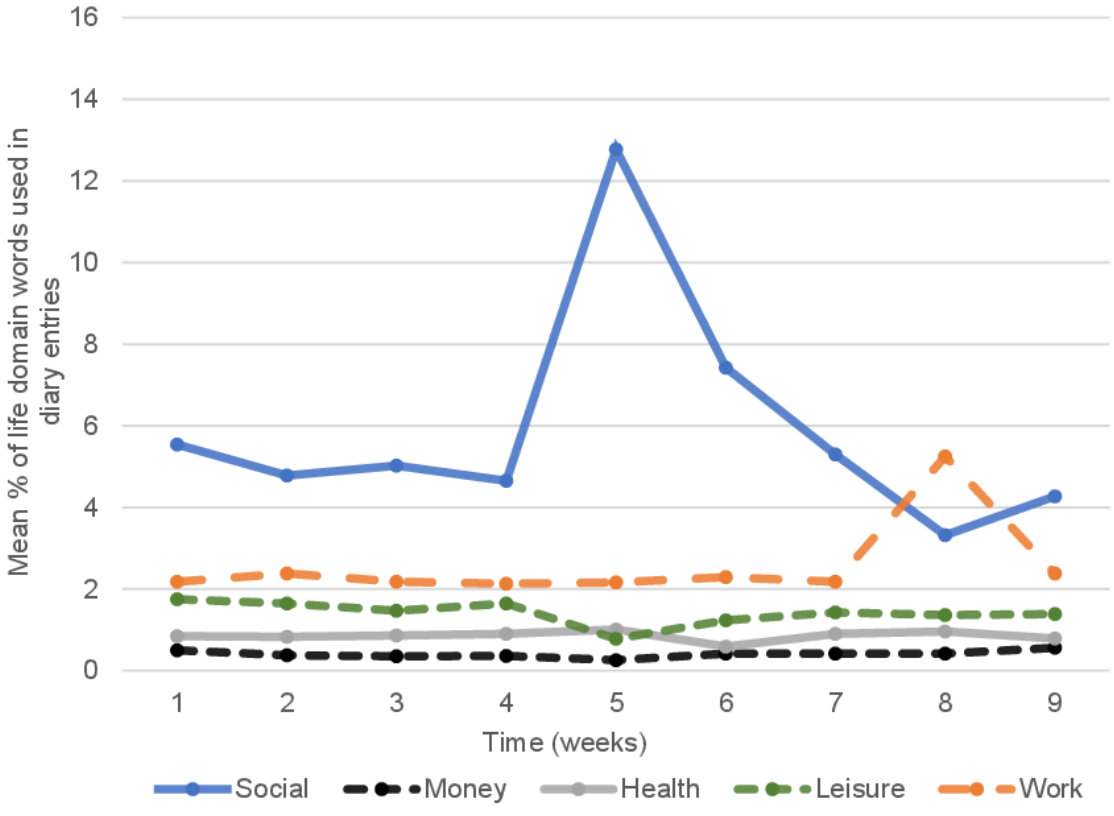


Table 6 presents the results of the random effects generalized least squares regression examining how the use of words in the 5 life domains relates to the emotional tone of diary entries. As the percentage of *social* words in diaries increased by 1, the emotional tone of diaries increased by an average of 0.74 (95% CI 0.21-1.27; *P*=.006). As the percentage of *leisure* words in diaries increased by 1, the emotional tone of diaries increased on average by 3.56 (95% CI 2.28-4.85; *P*<.001). Finally, as the percentage of *health* words in diaries increased by 1, the emotional tone of diaries was more negative by an average of 1.96 (95% CI −3.70 to −0.22; *P*=.03). The relationships between *work*- and *money*-related words and the emotional tone of diary entries were nonsignificant.

Table 6. Model 3: random effects generalized least squares regression examining how the use of words from 5 life domains (social, health, leisure, work, and money) relates to the emotional tone of diary entries, controlling for week effects (time), sociodemographics (age and gender), and diary characteristics.[a]

Discussion

Principal Findings

Compliance with the diary task peaked in week 1 (1041/1124, 92.62%) and the fewest diaries were completed in week 3 (807/1124, 71.81%). Students with the most completed diaries had the highest diary word counts, highest levels of baseline well-being, and on average had diaries with the highest emotional tone. Compared with week 1, diaries were significantly more positive in their emotional tone during weeks

5 and 6 when diary tasks involved writing about gratitude and strengths, respectively. This improvement in emotional tone was not observed at the end of the course, indicating a short-term rather than a lasting improvement in the emotional tone of writing. Higher levels of baseline well-being were associated with more emotionally positive diary entries, and the pattern of emotional tone within diaries across the weeks seen for students with low, moderate, and high baseline well-being was distinct. Diaries predominantly focused on social topics throughout the weeks, and the emotional tone of diaries was positively related to the use of leisure and social words and negatively related to the use of health words.

Existing Literature

The dominant focus on social topics within well-being–oriented diaries reinforces findings from previous research, indicating that a lack of social connectedness predicted higher levels of related mental distress (anxiety and depression) in a cross-sectional study of UK university students [37]. In this study, students with the lowest levels of baseline well-being used on balance more negative words in their diaries (emotional tone), in line with findings linking experiences of depression with the use of negative words [20]. Our findings indicate a strong link between writing about leisure and the use of positive emotion words complements a recent study in China that reported when students were asked to draw their happiest moments, they often depicted leisure activities [38]. Despite links in the literature between financial circumstances and well-being among university students [39,40], our work indicated that in some student samples, money worries may not necessarily factor into the weekly well-being experiences of students.

Implications

The analysis of word use across life domains highlights the importance of social factors and leisure in the lives of university students. As such, attempts to tackle student well-being concerns should continue to experiment with the utility of peer support networks, engaging familial support and responsible use of social media. In terms of the important role leisure plays in student well-being, universities are encouraged to ensure multiple options for leisure are readily available, and students are encouraged to select activities that are personally satisfying [41]. The promotion of leisure among students also has the potential to encourage participation in health-promoting behaviors, such as physical activity [42].

These findings also have implications for the ongoing development of the Science of Happiness course. We present evidence for students' acceptance and willingness to engage in a reasonably rigorous schedule of weekly web-based written diary tasks. It is also noteworthy that one of the weeks with lower compliance to the diary entry task occurred when students were on a break from study (week 3), which provides us important insight into the level of engagement to expect when students are disengaged from university academic activities. This work also provides data-driven guidance as to which students may be more prone to disengage from the task (ie, males and students with lower levels of baseline well-being).

There are wider implications for how student data are used as technology develops. The text analysis methods described in this paper could readily be applied to routinely collected information from students, for example, in written requests for well-being support, to estimate levels of distress based on the use of emotional words. Any developments in this area should reflect on the ethical questions about privacy and student preferences raised by experts working in the area of learning analytics [43]. Students should be involved in these discussions, and work should be undertaken to determine the risks, benefits, and opportunities provided by increased analytic involvement in how students are supported.

Limitations

This study has several limitations. Participants in this study were self-selected; therefore, the respondents in this study may not be representative of the wider student population. Available national data indicate that the UK university population is slightly more female and two-thirds of White ethnicity [44]; however, in our sample, both demographics were overrepresented. This means that the observed gender differences need to be interpreted with caution. Furthermore, the study may not have attracted students who did not believe they have any difficulties with their well-being. As the course was only offered to first-year undergraduate students, these results may not be generalizable to other undergraduate years, postgraduates, and PhD graduate students. Separately, as diary data were collected without the presence of researchers, we were unable to follow up with participants to explore any specific points raised in depth. Finally, without a control group also completing weekly diaries, in this study, we were unable to test whether specifically the diary task had a positive impact on the self-reported well-being of participants. However, on balance students demonstrated a high level of compliance with the diary task, the course generated novel data, and we were able to flexibly apply the LIWC software to analyze the content and underlying emotional tone of the available text data.

Future Research

In this study of undergraduate students, diaries predominantly focused on social topics; however, future research could examine whether different patterns, such as a focus on money or health, are observed in nonstudent samples of young adults. This study could build on attempts to investigate how distinct the challenges experienced by students are to university populations [45,46]. Separately, it would be valuable to investigate whether money was more of a focus within the diaries of subgroups with different financial circumstances [47]. Although leisure was discussed less frequently than social topics, the use of leisure words was related to the emotional positivity of diary entries. Building on work that has theorized about the many dimensions of leisure in university settings [48], it would be valuable to conduct more in-depth research with students to examine how and when different forms of leisure contribute to their well-being.

Given the noticeable spike in emotional tone observed when students were tasked with writing diaries about gratitude, a future iteration of the course could focus solely on this subject [49]. Future research could examine the sources of gratitude for

university students and explore whether repeated engagement in this task has a positive and sustained impact on the emotional positivity of writing and self-reported well-being. The more we understand about the relationship between what students write and how they feel, the better informed we will be to decide how far the use of these methods should be extended. We also recognize that a future analysis of unsolicited diaries would enrich our understanding of how diaries are used in nonexperimental settings.

One explanation for why compliance with the diary task fell to 72.5% (108/149) in week 9 is that this time point marked the conclusion of the course. Exploring this phenomenon and broader motivations for participation in the course would expand our understanding of how the course is interpreted and experienced. In future research, it would be informative to examine the acceptability of automated digital prompts designed to encourage the use of the web-based diaries, especially for participants who are willing yet have simply forgotten to complete the task.

Conclusions

This study demonstrated the informative power of web-based diaries, the flexibility of computerized text analysis methods, and differential experiences of students with varying levels of baseline well-being engaged in psychoeducation. Students used their diaries with a high level of compliance and wrote with the highest proportion of positive emotion words during weeks where diaries focused on gratitude and strengths. Further research is needed to explore the importance of leisure to well-being the longer-term impact of diaries on well-being, and suggestions are provided for how the science of happiness could be adapted in the future. We present support for previous studies highlighting the importance of social factors and leisure for student well-being, and echo recommendations that universities should ensure these activities are facilitated and encouraged.

Acknowledgments

The authors would like to thank Prof Laurie Santos for developing the original course on which the Science of Happiness course was based. This work was supported by the Elizabeth Blackwell Institute, University of Bristol, and the Development and Alumni Relations Office, University of Bristol.

Authors' Contributions

MAL designed the study with the support of all the coauthors. SJ and BH collected data. MAL performed the data analysis using RM. MAL drafted the manuscript, and all coauthors helped edit the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The COVID-19 pandemic has led to a notable increase in telemedicine adoption. However, the impact of the pandemic on telemedicine use at a population level in rural and remote settings remains unclear.

Objective: This study aimed to evaluate changes in the rate of telemedicine use among rural populations and identify patient characteristics associated with telemedicine use prior to and during the pandemic.

Methods: We conducted a repeated cross-sectional study on all monthly and quarterly rural telemedicine visits from January 2012 to June 2020, using administrative data from Ontario, Canada. We compared the changes in telemedicine use among residents of rural and urban regions of Ontario prior to and during the pandemic.

Results: Before the pandemic, telemedicine use was steadily low in 2012-2019 for both rural and urban populations but slightly higher overall for rural patients (11 visits per 1000 patients vs 7 visits per 1000 patients in December 2019, *P*<.001). The rate of telemedicine visits among rural patients significantly increased to 147 visits per 1000 patients in June 2020. A similar but steeper increase (*P*=.15) was observed among urban patients (220 visits per 1000 urban patients). Telemedicine use increased across all age groups, with the highest rates reported among older adults aged ≥65 years (77 visits per 100 patients in 2020). The proportions of patients with at least 1 telemedicine visit were similar across the adult age groups (n=82,246/290,401, 28.3% for patients aged 18-49 years, n=79,339/290,401, 27.3% for patients aged 50-64 years, and n=80,833/290,401, 27.8% for patients aged 65-79 years), but lower among younger patients <18 years (n=23,699/290,401, 8.2%) and older patients ≥80 years (n=24,284/290,401, 8.4%) in 2020 (*P*<.001). There were more female users than male users of telemedicine (n=158,643/290,401, 54.6% vs n=131,758/290,401, 45.4%, respectively, in 2020; *P*<.001). There was a significantly higher proportion of telemedicine users residing in relatively less rural than in more rural regions (n=261,814/290,401, 90.2% vs n=28,587/290,401, 9.8%, respectively, in 2020; *P*<.001).

Conclusions: Telemedicine adoption increased in rural and remote areas during the COVID-19 pandemic, but its use increased in urban and less rural populations. Future studies should investigate the potential barriers to telemedicine use among rural patients and the impact of rural telemedicine on patient health care utilization and outcomes.

Introduction

Access to health care services in rural communities has proven challenging among individuals for many reasons. There is a scarcity of health care professionals serving rural populations, and consequently, rural residents face barriers to health care access, such as long travel times, limited public transportation and associated costs, and time away from work. Ontario is Canada's most populous province with over 14,000,000 people, and, at >1,000,000 km^2, it has a larger area than Texas and Montana combined. While most of Ontario's population is situated in the southern region of the province in urban areas, approximately 10% of the population resides in rural areas [1], including the northern regions of the province. The Ontario Telemedicine Network (OTN) is an organization funded by the provincial government, which aimed to initially increase health care access among the rural population by facilitating 2-way videoconferencing between patients and care providers [2]. However, prior to the COVID-19 pandemic, telemedicine adoption was modest in Ontario [3], in part owing to strict requirements for both the patient and the physician, such as attending a virtual visit at an OTN facility, and using an OTN-approved communication platform [4]. A prepandemic study from Ontario revealed that Northern Ontario, a predominantly rural region in the province, saw markedly higher annual rates of telemedicine use than the mostly urban Southern Ontario, and even within Northern Ontario, rates of telemedicine use were higher in the "very rural" than in the "less rural" populations [5].

The COVID-19 pandemic has posed a unique challenge for rural patients—particularly those who are more susceptible to the disease—such as older adults and those with chronic diseases. In particular, there has been a need to balance chronic disease management with the risk of virus transmission, either during health care consultations or when traveling from rural to urban areas [6]. In order to reduce virus transmission in the health care setting, the Ontario Health Insurance Plan (OHIP)—the government health insurer across the province—introduced temporary billing codes that broadened the range of modalities eligible for reimbursement beyond OTN-approved videoconferencing platforms, including telephone calls and many other types of technology [7]. While a limited number of studies have reported substantial increases in the use of telemedicine during the pandemic, there are currently no published data on the use of telemedicine in rural communities or on the potential differences in telemedicine uptake between rural and urban populations during the pandemic. An understanding of rural telemedicine uptake and how it has been affected by the COVID-19 pandemic can provide insight into the utility of telemedicine in rural areas, particularly among vulnerable and at-risk populations; moreover, this information can contribute to the development of targeted approaches to increase telemedicine access where uptake was limited.

This study aimed to measure the utilization of telemedicine in rural and urban populations and among at-risk patient groups in rural Ontario prior to and during the COVID-19 pandemic, and to describe the characteristics of rural patients who have used telemedicine.

Methods

Study Design and Data Sources

We conducted a population-based, repeated cross-sectional study of monthly and quarterly rural ambulatory telemedicine visits in Ontario, Canada, beginning prior to the COVID-19 pandemic (January 1, 2012) and extending to June 30, 2020, using data from the following administrative databases: (1) OHIP, which records all health services delivered by physicians to Ontario residents and (2) Registered Persons Database, which contains demographic information of all patients covered under OHIP. We linked each patient's postal code of residence to census-based neighborhood income measures and then stratified patients across the province into neighborhood income quintiles. To understand telemedicine uptake among patients with various chronic conditions, we defined individual patient cohorts on the basis of select chronic ambulatory care conditions, using the Discharge Abstract Database, which records all in-patient hospital admissions, the National Ambulatory Care Reporting System, which contains data on all hospital- and community-based ambulatory care (including emergency department visits), and various Institute for Clinical Evaluative Sciences (ICES)–validated disease-specific registries. ICES is an independent, nonprofit research institute whose legal status under Ontario's health information privacy law allows it to collect and analyze health care and demographic data without consent for health system evaluation and improvement. Databases were linked using unique encoded identifiers and analyzed at the ICES. The use of these databases for the purpose of this study was authorized under clause 45 of Ontario's Personal Health Information Protection Act [8], which does not require review by a research ethics board.

Population

We identified all patients residing in the rural regions of Ontario by using the rurality index for Ontario (RIO) and their ambulatory visits through telemedicine through relevant physician billing codes (Multimedia Appendix 1). The RIO score has been established by the Ministry of Health and Long-Term Care as a method to fairly and consistently measure a community's degree of rurality based on its postal code in order to allocate governmental funding for rural health programs. The RIO score is derived from three measures: population density, distance from a basic referral center, and distance from an advanced referral center [9]. A higher RIO score indicates a higher degree of rurality, with a maximum score of 100. Rural residents have been defined as patients with a RIO score of ≥40, which is a standard cut-off used by the provincial government [10]. We compared the rates of rural telemedicine visits to those of urban visits, the latter defined with a RIO score of <40. We excluded claims for any patient who was a nonresident of Ontario or had an invalid or missing health card number.

We further identified patients diagnosed with chronic disease including chronic obstructive pulmonary disease, congestive heart failure, asthma, hypertension, and diabetes mellitus from the existing established ICES registries and algorithms [11].

Patients with serious mental illness were identified from at least 2 outpatient or 1 inpatient claims with the corresponding International Classification of Diseases, 9th revision or 10th revision codes for schizophrenia, psychotic disorders, or bipolar disorder in the past 12 months. Patients with angina were identified by at least one emergency department visit with the aforementioned relevant disease codes in the past 12 months (Multimedia Appendix 1).

Statistical Analysis

For each month in our study period (January 1, 2012, to June 30, 2020), we reported the rate of telemedicine visits per 1000 patients in rural Ontario. Given the markedly high population of older adults in rural Ontario [12], we also calculated quarterly rates separately among patients aged ≥65 years and compared them with those of other age groups (visits per 100 patients). Chi-square tests were conducted to assess the distribution of various characteristics of patients who have used telemedicine (age category, sex, region of residence, neighborhood income quintile, level of rurality, and chronic disease diagnosis) across 2012, 2016, and 2020. We selected 2012 as the first year of the study period, 2016 as the middle period, and 2020 as the pandemic period. We also compared quarterly telemedicine utilization across chronic disease subgroups (visits per 100 patients). A *P* value less than .05 was considered significant. All analyses were performed using SAS (version 9.4, The SAS Institute).

Results

We compared the characteristics of rural patients who used telemedicine across the calendar years of 2012 and 2016 and the first half of 2020. The number of rural patients who received at least one telemedicine visit increased from 2012 (n=14,666/1,017,546, 1.4%) to 2020 (n=290,401/1,033,271, 28.1%). Prior to the pandemic, a greater proportion of adults aged 18-49 years used telemedicine (n=4965/14,666, 33.9% in 2012) compared to the other age groups (n=4140/14,666, 28.2% for patients aged 50-64 years and n=3716/14,666, 25.3% for patients aged 65-79 years), but after the onset of the pandemic, we observed similar proportions of telemedicine users among the older age groups as well (n=82,246/290,401, 28.3% for patients aged 18-49 years; n=79,339/290,401, 27.3% for patients aged 50-64 years, and n=80,833/290,401, 27.8% for patients aged 65-79 years). In 2012 and 2016, there was an approximately equal proportion of male and female telemedicine users; however, in 2020, there were more female users than male users (n=158,643/290,401, 54.6% vs n=131,758, 45.4%, respectively). Prior to the COVID-19 pandemic, most users were based in Northern Ontario (n=10,431/14,666, 71.1% in 2012 and n=15,702/27,145, 57.8% in 2016), but after the onset of the pandemic, there was a more balanced distribution of users across all regions, with the highest proportion of users in Eastern Ontario (n=98,008/290,401, 33.7% in 2020). These results are summarized in Table 1. Similarly, in 2012, the highest rate of telemedicine visits was observed among patients residing in Northern Ontario; however, the Central and Eastern regions recorded the highest rates in 2020 (Multimedia Appendix 2). Smaller shifts were reported in telemedicine use across income quintiles, with more patients in the lower-income quintiles using telemedicine in 2012 (n=3270/14,666, 22.3% for quintile 1 and n=3013/14,666, 20.5% for quintile 2) and 2016 (n=6012/27,145, 22.1% for quintile 1 and n=6770/27,145, 24.9% for quintile 2) but more users in the middle-income quintiles in 2020 (n=67,172/290,401, 23.1% in quintile 2 and n=65,128/290,401, 22.4% in quintile 3). In 2012, we observed a higher proportion of telemedicine users living in less rural areas (lower RIO score) than in more rural areas (n=8709/14,666, 59.4% vs n=5957/14,666, 40.6%, respectively). This difference further increased across the years, with the largest difference observed in 2020 (n=261,814/290,401, 90.2% vs n=28,587/290,401, 9.8%, respectively). While the absolute number of telemedicine users with chronic disease has increased significantly over the years, for most chronic disease groups, the proportion of users with the disease appeared to decrease slightly (eg, 1041 of 14,666 [7.1%] patients had heart failure in 2012 as opposed to 12,580 of 290,401 [4.3%] in 2020; *P*<.001). Among the health conditions of interest in this study, hypertension was the most frequently diagnosed condition (n=112,297/290,401, 38.7% in 2020), followed by diabetes (n=52,830/290,401, 18.2% in 2020).

We observed a significant increase in the rate of telemedicine visits among both rural and urban patients after the start of the COVID-19 pandemic. Prior to the pandemic, this rate was consistently higher among rural patients than among urban patients (11 visits per 1000 patients vs 7 visits per 1000 patients in December 2019, respectively; *P*<.001). During the pandemic, both urban and rural telemedicine usage rates increased significantly, but utilization rates among rural patients were lower than those among urban patients (147 visits per 1000 patients vs 220 visits per 1000 patients in June 2020, respectively; *P*=.15). These findings are illustrated in Figure 1.

Among physicians who provided telemedicine consultations to rural patients, there was a large shift from mostly in-person visits in 2012 and 2016 to telemedicine visits in 2020. The highest proportion of telemedicine providers in 2020 were from family or general practice (n=9044/17,601, 51.4%) (Multimedia Appendix 3).

The rate of telemedicine visits increased significantly from before to during the COVID-19 pandemic among patients with various chronic disease conditions, with the highest rates observed among patients in the mental illness subgroup (126 visits per 100 patients in in second quarter of 2020), followed by those in the congestive heart failure (116 visits per 100 patients), chronic obstructive pulmonary disease (110 visits per 100 patients), angina (96 visits per 100 patients), diabetes (92 visits per 100 patients), hypertension (80 visits per 100 patients), and asthma (65 visits per 100 patients) subgroups. These trends are shown in Figure 2.

Prior to the pandemic, the rates of telemedicine visits were low and stable; however, the onset of the pandemic led to a surge in telemedicine use across all age groups. The highest rates were reported among adults aged ≥65 years, approaching 77 visits per 100 patients in the second quarter of 2020 as opposed to 4 visits per 100 patients in the fourth quarter of 2019. The next highest telemedicine usage rates during the pandemic was observed among patients aged 51-64 years (53 visits per 100

patients), followed by those aged 31-50 years (42 visits per 100 patients), and those aged 18-30 years (32 visits per 100 patients). The lowest rates of telemedicine use were observed among the youngest group of patients (aged 0-17 years, 16 visits per 100 patients). These findings are illustrated in Figure 3.

Table 1. Characteristics of rural patients who received at least 1 telemedicine visit in 2012, 2016, and 2020.

Variables	Number of patients, n (%)			*P* value

Discussion

Principal Findings

In this population-based study, we sought to quantify the impact of the COVID-19 pandemic on rural telemedicine use across a large, geographically and demographically diverse region. While telemedicine use before the COVID-19 pandemic was higher in rural areas than in urban areas of Ontario, the use of telemedicine was modest. Broad telemedicine usage in Ontario was low in part owing to the lack of billing codes for many types of telemedicine services outside of the government-operated videoconferencing platform. With the initiation of these temporary fee-codes allowing reimbursement for other forms of telemedicine visits during the pandemic, usage increased rapidly, with the temporary visit codes comprising the vast majority of telemedicine visits. The onset of the pandemic led to a rapid increase in telemedicine usage in both rural and urban areas of Ontario, with high adoption of telemedicine among patients in urban areas and those in less rural areas, compared to those in the most remote regions of Ontario. We speculate that higher rates of urban telemedicine use during the pandemic coincide with generally higher rates of urban health care use as telemedicine became ubiquitous. We note that the slight reduction or plateau in the telemedicine usage rates among both urban and rural populations from April to June 2020 coincided with the loosening of lockdown restrictions after the first wave of the COVID-19 pandemic and may have resulted from an increase in in-person visits during this period.

Telemedicine usage increased rapidly among all age groups in rural areas, although the usage rate increased with age. Older adult patients used telemedicine at the highest rate during the pandemic and children and adolescents used telemedicine the least. Telemedicine usage varied among patients with different chronic diseases, those with mental illness and with congestive heart failure making maximum use of telemedicine, and those with other ambulatory sensitive chronic conditions making substantial use of telemedicine. This study is the first to quantify the rates of telemedicine use in rural populations, particularly among older patients and those with chronic diseases.

Health care access has been a major challenge for rural patients in many jurisdictions, particularly for chronic disease management and access to specialist care. Previous studies have described the increasing trend of telemedicine use specifically among rural beneficiaries even prior to the pandemic [13]. Numerous advantages are associated with the adoption of telemedicine in rural regions, such as saving of time and costs associated with traveling, reduction of hospital readmissions, prevention of emergency department visits, and increasing the availability of inpatient beds for patients requiring critical care [14]. Rural telemedicine has been shown to improve health care access and quality in various areas, ranging from trauma and critical care [15-17], family medicine [18], pediatrics [19], and cancer care [20]. In fact, several randomized controlled trials have reported that telemedicine-based care can lead to similar

and potentially better outcomes compared to in-person care among rural patients [21,22].

Furthermore, previous studies have reported that populations overall have increased their use of telemedicine and virtual care during the pandemic [23] to avail of both urgent and nonurgent care [24], and benefits have been observed within various subspecialties [25,26]. Telemedicine allows health care professionals to safely deliver care by reducing the risk of potential exposure to the care provider and the patient, preserving personal protective equipment, and lessening patient loads at hospitals and facilities [27]. This proves especially useful in rural settings, where a significant proportion of the population are older adults and are at a higher risk of COVID-19.

Telemedicine uptake has surged across several groups of patients with chronic diseases, potentially highlighting the importance of remote management of chronic conditions. This finding is concurrent with published data on the use of telemedicine among patients with various chronic diseases, such as diabetes [28] and congestive heart failure [29], and particularly among patients residing in rural or remote areas [30]. Although rates of telemedicine use increased among patients with chronic disease, the proportion of telemedicine users with chronic disease appeared to decrease slightly over the years, suggesting a potentially increased uptake of telemedicine overall. We hypothesize that with the widespread use of telemedicine, a greater proportion of healthier patients used telemedicine for their health care needs. Longitudinal studies on the changes in the trends of telemedicine usage, particularly in the postpandemic period, are needed.

Despite evidence on the effectiveness of virtual ambulatory care for older adults [31], some studies have reported the challenges of adopting telemedicine in this population, owing to barriers such as disabilities or lack of devices, proper internet connectivity, and experience with technology [32,33]. However, our study shows that telemedicine usage increased significantly among older adult patients during the pandemic. This was likely a result of the new COVID-19 billing codes, which allowed for the reimbursement of telephone visits, as telephone calls may be easier to access for older adults than videoconferencing. Our findings are concurrent with those of a similar study we conducted, which focused on the rates of telemedicine visits in the entire patient population in Ontario, and we previously reported that the increase in telemedicine usage rates from before the pandemic to during the pandemic was similar across age groups, with older adults showing the highest rates of telemedicine use during the pandemic [3].

Limitations

The limitations of this study include a shortage of data comparing different modalities of communication technology, specifically telephone versus video visits. The new COVID-19 billing codes reimburse for telemedicine delivered through various modalities, and the type of modality used is not available in administrative data sets. The lack of clinical granularity that accompanies the use of administrative data also implies our inability to deduce the reasons for telemedicine use and assess the quality of care in our study population.

Conclusions

Our study investigates the trend in telemedicine use among patients residing in rural Ontario before and during the COVID-19 pandemic. Rural patients globally face many barriers to care, and telemedicine has proved important in helping patients access the health care services they need. Uptake of telemedicine services increased after the onset of the pandemic for the rural patient population of Ontario and across various subgroups, including those who are older or those with chronic disease. Telemedicine use appears to have increased more significantly among patients residing in less rural areas compared to those residing in more rural areas during the pandemic. Further studies are required to assess the potential barriers to telemedicine experienced by rural populations compared to those experienced by urban populations and the impact of telemedicine compared to that of in-person care on other forms of health care utilization, outcomes, and quality of care among vulnerable and at-risk patient groups in the rural population.

Abstract

Background: Telemedicine use in chronic disease management has markedly increased during health emergencies due to COVID-19. Diabetes and technologies supporting diabetes care, including glucose monitoring devices, software analyzing glucose data, and insulin delivering systems, would facilitate remote and structured disease management. Indeed, most of the currently available technologies to store and transfer web-based data to be shared with health care providers.

Objective: During the COVID-19 pandemic, we provided our patients the opportunity to manage their diabetes remotely by implementing technology. Therefore, this study aimed to evaluate the effectiveness of 2 virtual visits on glycemic control parameters among patients with type 1 diabetes (T1D) during the lockdown period.

Methods: This prospective observational study included T1D patients who completed 2 virtual visits during the lockdown period. The glucose outcomes that reflected the benefits of the virtual consultation were time in range (TIR), time above range, time below range, mean daily glucose, glucose management indicator (GMI), and glycemic variability. This metric was generated using specific computer programs that automatically upload data from the devices used to monitor blood or interstitial glucose levels. If needed, we changed the ongoing treatment at the first virtual visit.

Results: Among 209 eligible patients with T1D, 166 completed 2 virtual visits, 35 failed to download glucose data, and 8 declined the visit. Among the patients not included in the study, we observed a significantly lower proportion of continuous glucose monitoring (CGM) and continuous subcutaneous insulin infusion (CSII) users (n=7/43, 16% vs n=155/166, 93.4% and n=9/43, 21% vs n=128/166, 77.1%, respectively; *P*<.001) compared to patients who completed the study. TIR significantly increased from the first (62%, SD 18%) to the second (65%, SD 16%) virtual visit (*P*=.02); this increase was more marked among patients using the traditional meter (n=11; baseline TIR=55%, SD 17% and follow-up TIR=66%, SD 13%; *P*=.01) than among those using CGM, and in those with a baseline GMI of ≥7.5% (n=46; baseline TIR=45%, SD 15% and follow-up TIR=53%, SD 18%; *P*<.001) than in those with a GMI of <7.5% (n=120; baseline TIR=68%, SD 15% and follow-up TIR=69%, SD 15%; *P*=.98). The only variable independently associated with TIR was the change of ongoing therapy. The unstandardized beta coefficient (B) and 95% CI were 5 (95% CI 0.7-8.0) (*P*=.02). The type of glucose monitoring device and insulin delivery systems did not influence glucometric parameters.

Conclusions: These findings indicate that the structured virtual visits help maintain and improve glycemic control in situations where in-person visits are not feasible.

Introduction

Background

The COVID-19 pandemic has restricted access to medical clinics in order to prevent the risk of infection. In this context, routine care for patients with chronic diseases such as diabetes has emerged as a major challenge. Several strategies have been implemented to support patients with type 1 diabetes (T1D) and type 2 diabetes during the COVID-19 pandemic and to provide adequate assistance to avoid disease exacerbation [1-4]. Patients with diabetes have been recommended to follow general guidelines on infection risk reduction, blood glucose monitoring, taking medication, injecting insulin and noninsulin drugs adequately, and maintaining a healthy lifestyle (through diet and physical activity) [5].

Furthermore, experts have strongly suggested implementing the practice of downloading glucose data with dedicated software and sharing information with the health care providers to facilitate the provision of remote assistance [6]. More generally, the efficacy of virtual visits through telephone calls, text messages, mobile apps, or electronic visits—outside the context of the COVID-19 pandemic—has been described in some studies and systematic reviews. The current evidence is not univocal, and text messages seem more effective than web-based interventions [7-10]. Despite the number of published articles reporting a consensus on video consultations and guidelines for managing diabetes in the COVID-19 setting, no prospective evidence is available regarding the efficacy of teleassistance as an alternative to ambulatory visits during the pandemic [1,2,5,6]. Indeed, most studies, with a relevant number of patients, are retrospective and have analyzed data remotely with specific software that download glucose data without contacting the patients.

Aim and Hypothesis

As a necessary measure, we have implemented remote medical examination of patients with T1D during the lockdown period (March 10 to June 3, 2020). In this study, we assessed new glucometric parameters collected during 2 different virtual visits. We hypothesized that the COVID-19 pandemic might affect metabolic control in patients with diabetes owing to limited access to diabetes care centers and poor compliance to lifestyle recommendations. We accordingly designed a pilot study to prospectively analyze the effectiveness of 2 structured virtual visits (video or telephone consultations) on the basis of the time in range (TIR), time above range (TAR), time below range (TBR), mean daily glucose, glucose management indicator (GMI), and glycemic variability [11].

Methods

Patients

Our pilot study is a prospective, single-arm, observational study including patients with T1D who completed 2 virtual visits (baseline and follow-up visits) from the start (March 10, 2020) to the end (June 3, 2020) of the lockdown period. The protocol was preliminarily submitted and approved by the local Ethical Committee “Regione Calabria, Area Centro” (approval# 79-2020). In total, 3 diabetes care centers at teaching hospitals were involved in this study. A nurse or physician contacted the patients through the telephone before the first virtual visit (first contact) to explain the study's purpose to them. Patients who provided verbal consent were enrolled. Baseline characteristics of patients who declined to participate in the study were collected and compared to those of patients who agreed to participate. During the telephone call, patients were informed about or instructed, if necessary, on how to download the data from continuous glucose monitoring (CGM) systems or a traditional meter into the cloud by using specific software, such as Clarity, Care Link, Eversense diabetes management system (DMS), Accu-Chek Connect DMS, and share the data through the cloud or email. They were also invited to send recent laboratory findings or reports from other specialists via email or mobile apps. Patients using traditional meters were strongly suggested to check their blood glucose levels before each meal and in the presence of symptoms suggestive of hypoglycemia. During the second contact (baseline virtual visit), the physician verified the clinical conditions, ongoing treatment, and adherence to healthy lifestyle recommendations. Blood glucose data were monitored, and treatment was changed accordingly. The second virtual follow-up visit (third contact) was decided on the basis of clinical conditions and glycemic control and completed as the baseline visit. All information collected during the virtual visit were uploaded in the electronic medical files, and the summary of the visits was shared via email.

Data Collection

For the present analysis, the following parameters were collected: TIR, TAR, TBR, and mean (SD) daily glucose levels determined 2 weeks before the baseline and follow-up visits. The coefficient of variation (CV)—an estimate of glycemic variability—and the GMI—an estimate of glycated hemoglobin levels—were determined using the following formulae if not automatically generated by the software analyzing glucose data [12]:

$$CV\ (\%) = [(SD/Mean\ Glucose) \times 100] \quad \textbf{(1)}$$

$$GMI\ (\%) = 3.38 + 0.02345 \times (Mean\ glucose\ in\ mg/dL) \quad \textbf{(2)}$$

Statistical Analyses

Statistical analyses were performed using SPSS for Macintosh (version 23, IBM Corp). Patients who declined to participate or complete 2 virtual visits were excluded from the analyses. For the statistical analyses, patients were grouped as follows: those included and excluded from the study, those using the sensor and injecting insulin with a pump (CGM + continuous subcutaneous insulin infusion [CSII]), those using the sensor and with multiple daily insulin injection (CGM+MDI), and

those testing blood glucose with a traditional meter (ie, self-monitoring blood glucose [SMBG]) and injecting insulin with a pump or through MDI (CSII or MDI+SMBG). Sensor users included patients using intermittently scanned CGM (isCGM) and real-time CGM (rtCGM). Variables including baseline mean daily glucose, GMI, and TBR were not normally distributed. Parametric and nonparametric tests were performed accordingly.

The 2-tailed *t* test for unpaired data and the Mann-Whitney *U* test were used to compare between-group differences. The 2-tailed *t* test for paired data and the Wilcoxon Signed-Rank test were used to compare variables between baseline and follow-up visits. The chi-square test was used to compare percentages (CGM or sensor use and MDI or CSII treatment) between groups. Multivariable regression analysis was performed to evaluate variables independently associated with the absolute difference in TIR between baseline and follow-up visits. Independent variables included in the model were age, disease duration, use of the sensor or pump, and therapy change. The absolute difference in TIR, calculated as the difference between the follow-up TIR and the baseline TIR, was not normally distributed and hence log-transformed before regression analysis.

Results

Characteristics of Patients

In total, 209 patients were scheduled for in-person visits during the lockdown, from March 10 to June 3, 2020. Of them, 43 (20.6%) patients declined to participate in the study. Furthermore, 35 (16.7%) patients stated difficulties in downloading or sharing data via email, and 8 (3.8%) did not attend the virtual visit. The remaining 166 (79.4%) patients were enrolled and assessed. The average mean interval between the 2 virtual visits was 11 weeks. The characteristics of patients included and excluded from the study are summarized in Table 1. The proportion of CGM and CSII users was significantly higher among included patients than among excluded patients (n=155/166, 93.4% vs n=7/43, 16%, respectively; *P*<.001). Among 166 patients included in this study, 11 (6.6%) monitored their blood glucose levels with SMBG, 20 (12.0%) used the isCGM, and 135 (81.3%) used rtCGM. Among the excluded 43 patients, only 7 (16%) were using CGM, while the remaining 36 (84%) were using SMBG. All patients monitoring blood glucose through the traditional meter used the Accu-Chek Connect DMS. All the patients included in the study had strips and sensors to monitor their glucose levels during the lockdown. The mean number of tests per day was 4.4 [SD 1.9] and 5.1 [SD 2.4] (*P*=.21) among patients using SMBG and 9.5 [SD 4.9] and 9.8 [SD 6.1] (*P*=.70) among those using isCGM at baseline and follow-up visits, respectively.

Table 1. Characteristics of patients with type 1 diabetes included and excluded from the analyses (N=209).

Variables	Patients included (n=166)	Patients excluded (n=43)	*P* value
Age (years), mean (SD)	40 (14)	37 (15)	N/A[a]
Males, n (%)	80 (48.2)	21 (49)	N/A
Disease duration (years), mean (SD)	20 (11)	17 (9)	N/A
SMBG[b] users, n (%)	11 (6.6)	36 (84)	<.001
CGM[c] (isCGM[d] + rtCGM[e]) users, n (%)	155 (93.4)	7 (16)	<.001

[a]N/A: not applicable.

[b]SMBG: self-monitoring blood glucose.

[c]CGM: continuous glucose monitoring.

[d]isCGM: intermittently scanned continuous glucose monitoring.

[e]rtCGM: real-time continuous glucose monitoring.

[f]MDI: multiple daily insulin injection.

[g]CSII: continuous subcutaneous insulin infusion.

Glucometric Characteristics at Baseline and Follow-up Visits

We compared glucometric parameters measured at the baseline and follow-up visits among all patients included in the study and grouped in accordance with different combinations of insulin delivery methods and glucose monitoring systems (CSII+CGM, MDI+CGM, and CSII or MDI+SMBG) (Table 2). The TIR significantly increased from the baseline to the follow-up visit in all patients with T1D (62%, SD 18% vs 65%, SD 16%, respectively; *P*=.02) and in the CSII or MDI+SMBG group (55%, SD 17% vs 66%, SD 13%, respectively; *P*=.01). Furthermore, the CSII or MDI+SMBG group displayed a significant improvement in the TAR at baseline and follow-up visits (40%, SD 18% vs 28%, SD 15%, respectively; *P*=.03), mean daily glucose (176 [SD 49] mg/dL vs 150 [SD 25] mg/dL; *P*=.04), GMI (7.5%, SD 1.1% vs 6.9% SD 0.6%; *P*=.04), and

CV (36%, SD 8% vs 42%, SD 9%; *P*=.04) compared to the other groups.

Based on the baseline GMI findings among all patients included in the study, we observed that the TIR significantly improved from baseline to follow-up visits among those with a GMI of ≥7.5% (n=46; 45%, SD 15% vs 53%, SD 18%; *P*<.01) compared to those with a GMI of <7.5% (n=120; 68%, SD 15% vs 69%, SD 15%; *P*=.98).

Table 2. Glucometric parameters at baseline and follow-up virtual visits in all patients and in those grouped in accordance with the insulin delivery method and glucose monitoring system (N=166).

Patient groups	Parameters		*P* value[a]

[a]Significant *P* values are shown in italics.

[b]CSII: continuous subcutaneous insulin infusion.

[c]CGM: continuous glucose monitoring.

[d]MDI: multiple daily insulin injection.

[e]SMBG: self-monitoring blood glucose.

In total, 104 (63%) patients were suggested a change of therapy during the baseline visit. Among them, 97 (93%) used CGM (isCGM or rtCGM), and 84 (81%) used CSII. These proportions were comparable with those of patients who were not suggested

a change of therapy (CGM: 93%; *P*=.60 and CSII: 71%; *P*=.10). The absolute difference in TIR between baseline and follow-up visits was significantly higher among patients who were suggested a changed of therapy (4%, SD 10%) than among those who were not suggested a change of therapy (0.1%, SD 10%) (*P*=.04). No significant difference was observed in the TBR, TAR, mean daily glucose, CV, and GMI between these 2 groups (data not shown).

None of the patients had diabetic ketoacidosis or severe hypoglycemia requiring hospitalization in the interval between the 2 virtual visits.

Multivariable regression analysis revealed that the change of therapy was the only variable independently associated with the absolute difference in TIR between baseline and follow-up visits. The unstandardized beta coefficient (B) and 95% CI were 5 (95% CI 0.7-8.0) (*P*=.02).

Discussion

Principal Findings

Our study shows that the structured virtual visits adequately maintain pre-existing glycemic control or improve the time spent in the target range among individuals with T1D during an emergency when in-person consultations are not permitted.

The benefits of virtual visits were discernible among patients using the traditional meters regardless of the type of insulin delivery modality (MDI or CSII) and among patients with a baseline GMI of ≥7.5%. These results suggest certain considerations. The telephone call preceding the baseline virtual visit may have encouraged patients using SMBG to download data from the meter into diabetes management systems, thus facilitating the subsequent interpretation of glucose data. In the actual scenario, it is common for patients using SMBG to not bring the meter along with them during in-person visits or to not have devices capable of connecting to the cloud, limiting appropriate adjustment of treatment. Patients using SMBG had higher values of GMI and a lower TIR, despite not presenting significant findings, than sensor users, which may have induced physicians to strengthen the more the general suggestions for diabetes management and convince patients to maintain a healthy lifestyle rather have a change of therapy. It could be argued that new metrics have been developed for glucose data collected by the sensor and that our results obtained from patients using the traditional meter might be due to chance. However, we have recently demonstrated that a strict correlation between TIR calculated by specific software, after downloading SMBG values, is significantly correlated with glycated hemoglobin levels. The strength of this association in our study was comparable to that between TIR calculated from CGM and glycated hemoglobin levels reported in other studies [13]. Patients using the meter reported a significant increase in CV compared to the other groups. This result can be explained by the higher daily fluctuation in the number of SMBG users compared to that of CGM users. Indeed, at the follow-up visit, mean glucose levels decreased by 11%, and the CV increased by 2.9%. This might be an unfavorable finding, if sustained in the long term. Some of the aforementioned considerations also apply to patients using CGM who had not experienced an exacerbation of glucose levels during the lockdown.

Patients with a GMI of ≥7.5% may have better managed their diabetes during the pandemic and may have had a healthy lifestyle. We believe that patients generally have had much more time available, owing to restrictions associated with stay-at-home orders. This may have stimulated a more in-depth analysis of glycemic data and potential interventions on incorrect habits.

Patients using the sensor or wearing the pump did not experience an exacerbation in glucose levels during the lockdown. In our opinion, this is a remarkable finding, given the current state of emergency. Sensor and pump users are in general well-educated and motivated to check and self-manage the disease. It is noteworthy that the proportion of pump and sensor users was very low among patients excluded from the study. The main limitation associated with patient recruitment was problems faced with downloading the glucose data.

Multivariable regression analysis revealed that a change of therapy during the virtual visit was the only variable independently associated with the absolute difference in TIR. Insulin therapy can be safely modified during a structured virtual visit. Indeed, none of the patients included in the teleassistance had a severe hypoglycemic episode or ketoacidosis.

Our results reinforce the evidence that virtual consultations may lead to appropriate care during a pandemic or when an in-person visit cannot be performed for any reason.

Comparison With Previous Studies

Recent case studies have reported that teleassistance can be provided safely and effectively for new-onset T1D and ketoacidosis, thus preventing hospital admission [14,15].

A retrospective study, including 13 adolescent patients with T1D, has reported that physical activity regularly performed during lockdown is associated with an improvement in the TIR [16]. Unfortunately, we did not collect information on physical activity from our patient cohort. However, we speculate that the patients included in our study stayed active at home in some way.

Another retrospective study, including 92 patients with T1D who use CGM systems, has reported an increase in the TIR from 59% to 63% during the lockdown. The study retrospectively reviewed glucose values downloaded into the cloud [17]. Similarly, a smaller study, including 33 patients with T1D who use the isCGM system that is connected to the clinic, has reported an increase in the TIR from 54% to 65% during the lockdown. However, that study did not indicate whether virtual contact was proposed during the lockdown [18].

We would like to remark on the potential educational role of virtual assistance. Indeed, a training session on the use of the pump and sensor and carbo-counting can be scheduled with specialists including nutritionists or nurses, favoring the access to technologies despite physical distancing [19].

Certain questions regarding teleassistance remain open, including those on cost, reimbursement, authorization, liability,

demographic characteristics of the people to be engaged, choice of the method for the virtual visit, involvement of the health care provider, duration of the visit, and adequate time interval between visits [20]. Furthermore, it is important to identify patients who need in-person visits despite the state of emergency, such as the current pandemic. Finally, it is important to consider patients with type 2 diabetes, who represent the majority of patients with diabetes and, in general, have limited access to technology and are less educated in self-managing diabetes. We should probably consider different strategies for type 2 diabetes.

Limitations

Our prospective study demonstrates the effectiveness of teleassistance in managing disease during the lockdown. Data sharing and remote visits help maintain or achieve adequate glycemic control through data analyses and therapy adjustment. However, our study has some limitations of note. For instance, the patient groups based on different therapeutic strategies are relatively small. Patients with T1D, who constitute the minority of patients with diabetes, frequently adopt personalized insulin delivery schedules and monitoring systems. It is therefore difficult to have large homogeneous patient groups. Furthermore, well-educated patients would have been more likely to provide their consent for virtual visits. This renders our study findings more reliable for patients who have received adequate therapeutic education and are cooperative. Ultimately, the selection criteria of our study were arbitrary; however, they were selected to include the largest number of patients, and we are confident that our findings are potentially applicable to most of our patients with T1D.

Conclusions

In conclusion, our results show that COVID-19 restrictions have provided an opportunity to bring teleassistance to the frontline in diabetes care. The advancement of technology and the development of new connected devices will further facilitate information exchange among patients, health care providers, and physicians.

Abstract

Background: Given the rapid ongoing progression of the internet and increase in health information available from disparate online sources, it is important to understand how these changes impact online health information-seeking behavior of the population and the way of managing one's health.

Objective: This paper aims at describing the evolution of internet use as a source of health information between 2010 and 2017, as well as the characteristics of online health information seekers, topics of interest, sources of information, and trust in retrieved information and potential impact on behavior.

Methods: Data from the French nationally representative surveys Health Barometers were used (N=4141 in 2010, 4811 in 2014, and 6255 in 2017). Evolutions over time were assessed using chi-square tests. Associations with sociodemographic characteristics and health status were evaluated using logistic regression models.

Results: The use of the internet as a source of health information rose between 2010 and 2014 (from 37.3% to 67.9%, *P*<.001) but decreased significantly in 2017 (60.3%, *P*<.001). Overall, the profile of health information seekers compared with nonseekers did not change over time. They were more likely to be women, to be younger, to have a higher educational level, to have a higher household income, and to be executives. Between 2014 and 2017, the proportion of those who did not pay attention to the source of information significantly increased to reach 39.7% (*P*<.001). In 2017 as in 2014, general health-related websites remained the first source of information (38.6%) while institutional websites were the third source (8.1%). Most information seekers trusted the information found online in 2010 (more than 80%), with a slight decrease between 2014 and 2017 (*P*=.048). Among individual characteristics, trust in the information was the main determinant of the way of managing one's health (odds ratio 4.06, 95% CI 3.26-5.06).

Conclusions: After a rapid growth in the internet use for seeking health information in the 2010 to 2014 period, a decrease was recorded in 2017, in parallel with a decrease in trust in the quality and reliability of information found online. These findings underline the need for public health authorities to increase citizens' eHealth literacy and to provide alternative trustworthy sources combining the popularity and accessibility of general health information websites.

KEYWORDS

internet; health information; information-seeking behavior; eHealth literacy

Introduction

In Europe, internet access is now democratized with 80% of the households using the internet for personal use [1]. Thus, over the last decade, the internet has become a major source of information including health-related information, with about 6 out of 10 Europeans reporting seeking health information online in the past year [1].

Using the internet as a health information source has many advantages. By offering quick, easy, timely, and low-cost access to the information, the internet tends to expand access to health messages [2], thus impacting citizens' management of their health. Providing the information is reliable, citizens may increase their health knowledge, better understand the risks and benefits of some treatments, and participate in their health care decision making [3,4]. The internet also provides the possibility of personalized feedback [2,5] and contributes to addressing issues of geographical or mobility isolation and anonymity [2,5]. Indeed, the privacy offered by online information is particularly valuable for individuals searching for information on sensitive topics [2,5,6]. However, these advantages can easily turn into disadvantages, since the quality and authority of health-related information is debatable, and identifying trustworthy versus not trustworthy sites is challenging [2]. In fact, the multiplication of health-related websites increasingly raised the issue of accessibility to accurate and trustworthy information [2,7-9]. In light of this, users must have appropriate capacities to access, understand, appraise, and use health-related information in a digital environment (ie, eHealth literacy) [10]. Previous studies have shown that a high level of eHealth literacy is associated with good management of one's health [11-13].

Online health information-seeking behavior depends on the characteristics of individual internet users, which might determine the reasons to search for health-related information online. Indeed, the literature has highlighted several predictors of online health information seeking, such as sociodemographic characteristics and overall health conditions [14]. Poor health, being female, being younger, having a diploma, and having higher income are associated with seeking health information online [15-19]. Similar trends were observed for eHealth literacy according to age and educational level. However, no significant difference has been reported between men and women [13,20].

A few studies have recently explored the trends in the use of the internet for health information seeking. The majority of them have been conducted in the United States [21-23] or have focused on specific population subgroups such as older people [24,25], pregnant women [26,27], children and adolescents [28-30], cancer survivors [31], or sexual minorities [32]. Two studies were conducted in Europe, in Finland [33] and Norway [34], but they considered data up to 2007 or 2009. In the European Union, eHealth literacy has been identified as a priority to address health inequalities in the eHealth Action Plan 2012-2020. The Eurobarometer on digital health literacy performed in 2014 supported this objective by assessing how Europeans use online information to help manage their own health. However, to our knowledge, no recent data exist on the evolution of such practice.

In addition, despite the rapid ongoing progression of the internet and overall perception of an increase in health information available from disparate online sources, the evolution of such sources used to seek information has been not documented so far. Finally, it is important to understand how these changes impact the online health information-seeking behavior of the population in order to offer appropriate solutions to disseminate reliable health messages.

The main objective of this article, therefore, was to describe, based on nationally representative surveys, the evolution of internet use as a source of health information between 2010 and 2017 in France. More specifically, this study was aimed at (1) describing the prevalence of internet use for health-related purposes and the characteristics of online health information seekers over time; (2) assessing the evolutions of topics of interest and sources of health-related information found online; and (3) investigating the attention paid to sources of information, the trust in retrieved information, and the potential impact on management of one's health.

Methods

Survey Methodology and Participants

Data were extracted from 3 national surveys (called Health Barometers) conducted in 2010, 2014, and 2017 by the French national public health agency (Santé publique France, formerly the French Institute for Prevention and Health Education or INPES) in consultation with the French Ministry of Health [20]. Health Barometers are cross-sectional surveys of random representative samples of the French population conducted using computer-assisted telephone interviewing. These surveys were designed to measure the evolution of key indicators regarding health-related behaviors, attitudes, and opinions in the general population. The questionnaires and the data collection methods are available on the official survey website [35,36]. Briefly, Health Barometers evaluate different health topics such as addiction (tobacco, alcohol, illegal drugs), mental health, sexuality, nutrition, or vaccination, as well as use of the internet for health. The full questionnaire is designed not to exceed 30 minutes completion time. The general part of the questionnaire, lasting 20 minutes, is addressed to all participants, and specific parts, lasting 10 minutes, are asked to different subsamples.

Health Barometers are based on a 2-stage random sampling design: sampling of telephone numbers covering all metropolitan French regions and random selection of one member of the household, using the method proposed by Kish [37]. In 2010, because of the increasing rate of households that had abandoned their landline telephones for cell phones, a cell-only sample was added (12% of the sample to keep the same rate as in 2010 in France). In 2014, since a section of the population including people also having a landline preferred using a mobile phone, 2 overlapping samples were constituted: one surveyed by landline and the other by mobile phone [38].

For households of the landline sample, one person was randomly selected among eligible persons living in the household (aged 15 to 75 years in 2014 and 2017 and 15 to 85 years in 2010, speaking French). In the cellular sample, selection was done

among persons sharing the cell telephone (when such sharing was reported).

If a household or individual refused to participate or could not be reached, they were not replaced in the study. For this reason, considerable efforts were made to reach households and increase the response rate: a formal request to participate explaining who was conducting the study and the goals of the survey was sent by electronic mail or letter to participant (when such information could be found using a national reverse directory). For every sampled number, up to 40 attempts were made to complete an interview. The calls were staggered over times of day and days of the week to maximize the chances of making contact with a potential respondent. When the selected individual was reached but unavailable, an appointment was made. Individuals unwilling to participate at first were contacted again by specialized interviewers in order to recruit them. Response rate of the 3 surveys was 53% in 2010, 61% in 2014, and 49% in 2017. All collected data were anonymous and self-reported. The survey was approved by the National Data Protection Authority and complied with the European Union General Data Protection Regulation.

Data Collection

Sociodemographic and Economic Characteristics and Health Status

Participants were asked to provide sociodemographic data, including gender (men, women), age in categories (18-24 years, 25-34 years, 35-44 years, 45-54 years, 55-54 years, 65-75 years, >75 years), educational level (primary, secondary, postsecondary), employment status (working, student, unemployed, retired, other), occupational category (farmers, artisans, executives, intermediate profession, employees, manual workers) and monthly income. Occupational category was reported for the respondent (using the last job position for unemployed and retired people) or for the reference person in the household if the respondent had never worked before (ie, student). Monthly household income was calculated per consumption unit (CU), where one CU is attributed for the first adult in the household, 0.5 CU for other persons aged 14 years or older, and 0.3 CU for children under 14 years, following national statistics methodology and guidelines [39]. Income categories were defined using the tertiles of the entire database, including the 3 years of data sets. In addition, participants were asked if they have a chronic disease (yes/no).

Internet Use for Health Information Seeking

In 2010, 2014, and 2017, participants were asked whether they had used the internet to search for health-related information or advice in the last 12 months (yes/no/no access to the internet). This question was used to identify health information seekers versus non–health information seekers. Only online health seekers were further asked about the trust they had in health-related information obtained on the internet. The responses were rated on a 4-point Likert scale ranging from 1 (not trustworthy at all) to 4 (totally trustworthy) and grouped into 2 categories (not trustworthy vs trustworthy). In order to understand the effect of using the internet on the doctor/patient relationship, individuals were asked whether the information and advice found on the internet had changed the way they were taking care of their health (4-point Likert scale from not at all to definitely yes, further grouped in 2 categories, yes vs no). In addition, they were asked if their use of the internet led them to visit their doctor more often, less often, or to the same extent as they did before using the internet for health purposes.

In 2014 and 2017, online health information seekers were also asked about the topics of their searches including (1) general health and illnesses, medical news, and treatments; (2) sexually-related health risk; (3) contraception and methods to avoid pregnancy; (4) nutrition, weight gain, or eating disorders; (5) pregnancy or maternity; (6) child health and illness; (7) alcohol; (8) tobacco; (9) cannabis and other drugs; and (10) electronic cigarettes (the latter assessed in 2017 only).

In 2014 and 2017, the questionnaire also included questions about the source of health information in general (forum, health information website, or did not pay attention to the information source) and the specific websites used for searching health information. Spontaneous reponses of participants were then categorized into different types of websites including general health-related websites; Doctissimo (a popular French website dedicated to general health mentioned by name by a large number of participants); social media; Wikipedia; institutional websites, Websites from health professional, patient association, scientific database; and others.

In 2010, questions were asked to assess why some people did not seek online health information (sufficiently informed, not interested in such information, better to ask these questions to a doctor, distrust in retrieved online information, do not think about it). Online health information seekers were also asked how often they seek online health information. However, since these variables were not assessed in 2014 and 2017, they were not analyzed in this article.

The list of the different variables and the corresponding questions asked each year are presented in Multimedia Appendix 1.

Ethical Consideration

According to French law, this study was not required to obtain the approval of a national ethics committee, as it is not legally considered research involving human beings and it relied on the collection of anonymous data only.

Statistical Analysis

Chi-square tests were used to compare the population characteristics over time, including gender, age, educational level, income, employment status, occupational category, and health status (chronic disease). Chi-square tests were also performed to assess the evolution of online health seekers over time and, between 2014 and 2017, of (1) health-related search topics, (2) sources of online health-related information, and (3) types of website used for these searches. The same tests were also used to describe the trends of the trust in health information found online and the potential impact on health management.

Multivariate logistic regression models were performed to investigate the profile of online health seekers versus non–health seekers (defined as the dependent variable), as well as the

evolution of the use of the internet for seeking health information over time. Independent variables included in the model were time, all sociodemographic variables, and health status. Interactions between all independent variables and time were assessed to evaluate potential differences in the profile of health seekers over time.

The same models including the same independent variables were performed to evaluate how individuals' characteristics and time are related with (1) the fact of not paying attention to the source of the health information found online, (2) trust in the information found online, and (3) the change in taking care of one's health.

Data were weighted by the number of telephone lines and eligible persons in the household. They were also adjusted to represent the French population structure (labor force survey 2008, 2012, and 2014) according to age, gender, educational level, region of residence, and level of urbanization [39].

Given that the maximum age limit was fixed at 75 years in 2014 and 2017 and the minimum at 18 years in 2017, participants aged 15 to 17 years in the 2010 and 2014 surveys and those aged 76 to 85 years in the 2010 survey were excluded in order to allow comparison over time. Given the low rate of missing values among the independent variables (ie, 1.3%), no specific imputation method was employed. Participants were therefore excluded if they had at least one missing value among the covariates used in the models. All tests of statistical significance were 2-sided, and the type I error was set at 5%. Statistical analyses were performed using Stata software version 13 (StataCorp LLC).

Results

The final sample comprised 15,277 individuals across the 3 time points, respectively 4141 in 2010, 4811 in 2014, and 6255 in 2017. A total of 581 participants were excluded because they were aged younger than 18 years or older than 75 years, and 202 because they had missing data.

Table 1 shows sociodemographic and economic characteristics and health status of included participants over time. Significant differences were found for age, educational level, income, occupational category, and chronic disease. Overall, figures showed that individuals tended to have higher educational levels and household incomes and more chronic diseases over time.

The evolution in internet access and use as a source of health information from 2010 to 2017 are presented in Figure 1. Although internet access increased steadily during this period, from 72.8% in 2010 to 92.4% in 2017 (an increase of 27%), the use of the internet as a source of health information rose between 2010 and 2014 (from 37.3% to 67.9%, $P<.001$) and decreased significantly in 2017 (60.3%, $P<.001$).

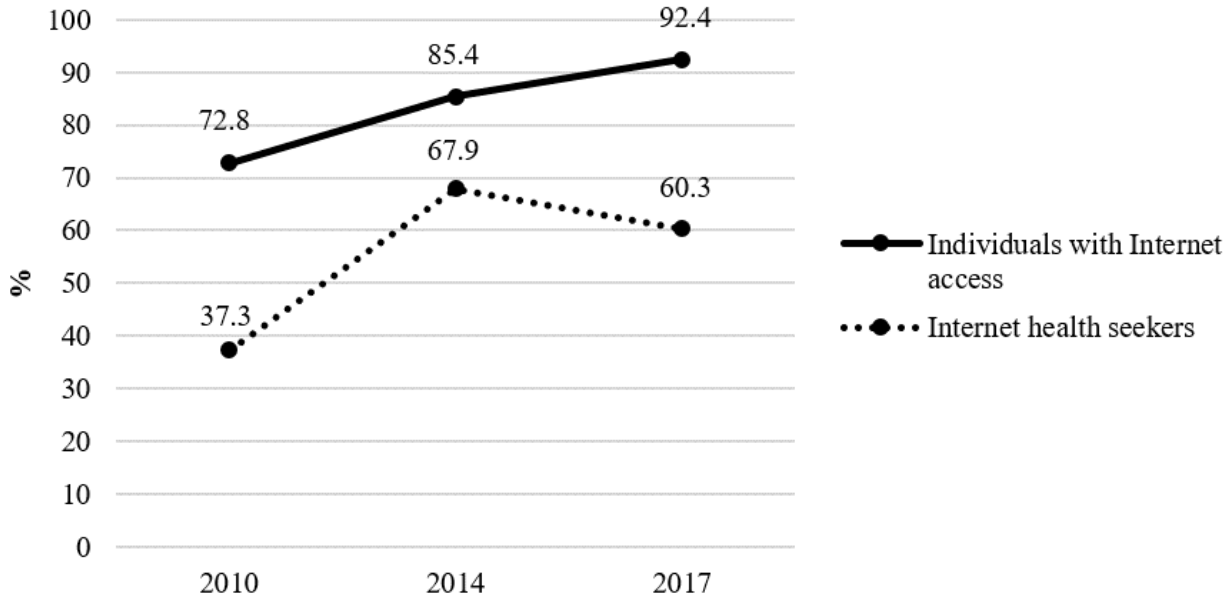
[d]CU: Household consumer units. One CU is attributed for the first adult in the household, 0.5 for other persons aged 14 years or older and 0.3 for children under 14 years.

Figure 1. Evolution in internet access and internet use as a source of health information from 2010 to 2017 (2010, N=4141; 2014, N=4881; 2017, N=6255).



Characteristics of online health information seekers across the 3 time points are presented in Table 2. Overall, health information seekers compared with nonseekers were more likely to be women, to be younger, to have a higher educational level, to have a higher household income, and to be executives. As regards the employment status, students and unemployed people were more likely to be health information seekers compared with the working group. Finally, individuals having a chronic disease were more likely to be health information seekers. Significant interaction with time was observed for age, educational level, and income. Results by the year of the survey were therefore explored (see Multimedia Appendix 2). Over time, the gap between generations seemed to be widening. In 2010, no differences in the use of the internet for seeking health information were found with people aged 45 to 54 years and younger, whereas this was the case in 2014 and 2017. As regards educational level, trends were comparable over time, but the odds of being online health seekers varied, in particular among those with a secondary education level. Finally, income was found to be less predictive of online seeking behavior after 2010, and particularly in 2014, since there was no more significant difference between the lower and intermediate income levels.

Table 2. Multivariate regression logistic models showing the association of internet use for seeking health information with time and individual characteristics (2010, N=4141; 2014, N=4881; 2017, N=6255).

[e]CU: consumption unit. One CU is attributed for the first adult in the household, 0.5 for other persons aged 14 years or older and 0.3 for children under 14 years.

Table 3 shows the topics of online health information research in 2014 and 2017, as well as the online sources of information and the type of websites used. Overall, the main topics searched online remained the same in 2014 and 2017 (ie, general health and illnesses; medical news and treatments; nutrition, weight gain, or eating disorders; and child health and illness). Nonetheless, while the percentage of respondents searching for information about general health and child health decreased over time, the percentage concerning nutrition-related topics remained constant. The most significant decreases were observed for searches about tobacco (–41%), alcohol (–70%), and cannabis and other drugs (–38%).

Overall, while the proportion of people using known health information websites and forums decreased, the proportion of those who did not pay attention to the source significantly increased (+12.1 percentage points). Thus, in 2017, this was the case for about 4 out of 10 internet health information seekers.

When focusing on the type of websites used for the last health-related internet searches by individuals who paid attention to the information source (48.7% in 2014 and 46.8% in 2017), figures indicates that between 2014 and 2017 general health-related websites remained the main source of information. Social media and commercial websites were the second source of information in 2014 as in 2017. And, in 2017, institutional websites were the third source. However, even if the visits to these institutional websites increased between 2014 and 2017, they remained at relatively low level, with only 8.1% of individuals declaring they used these sources.

Figure 2 shows the evolution of the trust in health information found on the internet and the change in taking care of one's health. Globally, the evolutions were symmetrical. While trust in the information increased from 2010 and 2014 ($P<.001$) and decreased slightly from 2014 to 2017 ($P=.048$), the change in health management rose between 2010 and 2014 ($P<.001$) but remained stable between 2014 and 2017. Nonetheless, the perception of health-related information found online was relatively positive, with at least 80% reporting that the most recent information found was trustworthy.

Table 3. Evolution between 2014 and 2017 among internet health seekers of (1) health-related search topics, (2) sources of online health-related information, and (3) types of websites used for internet health-related searches.

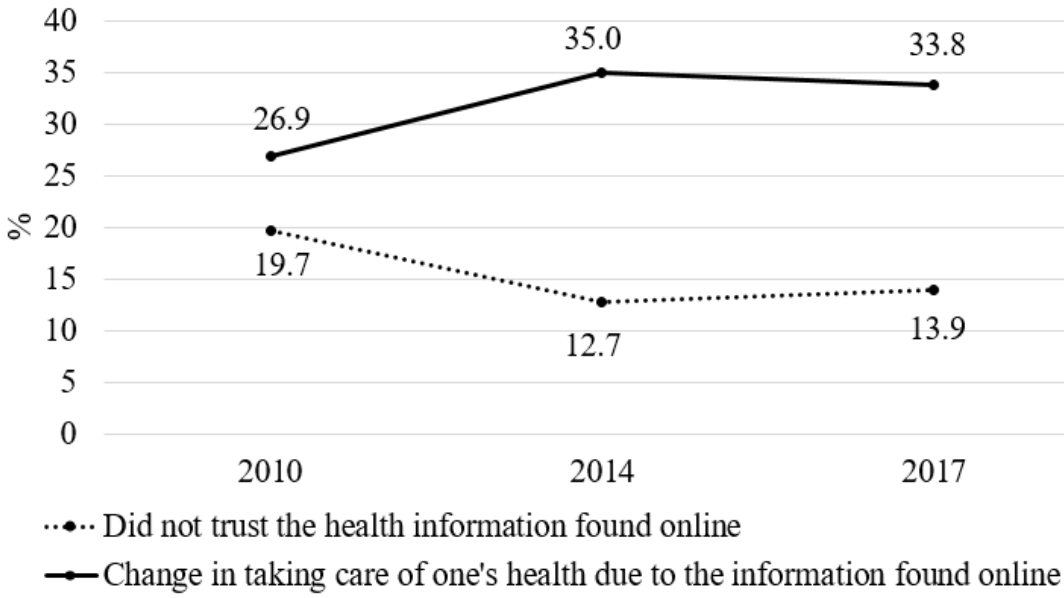
[e]A popular French website dedicated to general health mentioned by name by a large number of participants.

Figure 2. Evolution of the trust in health information found on the internet and the change in taking care of one's health from 2010 to 2017 (2010, N=1707; 2014, N=3582; 2017, N=3965).



The results of multivariate models showing how individuals' characteristics and time are related to (1) the fact of not paying attention to the source of the health information found online, (2) trust in the information found online, and (3) the change in taking care of one's health are shown in Table 4. Not paying attention to the health-related information source significantly increased between 2014 and 2017. Such practice was associated with a higher probability of having lower education levels and being artisans or manual workers. In turn, students were more likely to pay attention to the source of their searches.

Trust in the health information found online and change in taking care of one's health both significantly increased in 2014 and slightly decreased in 2017. Regarding the associations with sociodemographic characteristics, only individuals with higher educational levels were more likely to trust the information found online. This trust strongly influenced the way of managing one's health (odds ratio 4.07). Individuals aged 25 to 34 years were more likely to have changed the way they managed their health due to the information found online, whereas those aged 65 to 75 years were less likely to do so. Finally, those having higher educational levels and higher incomes were also less influenced by the information found online.

Table 4. Multivariate logistic regression models showing the association of individuals' characteristics and time with (1) the fact of not paying attention to the source of the health information found online (2014, N=1422; 2017, N=3965), (2) trust in the information found online, and (3) the change in taking care of one's health (both 2010, N=1707; 2014, N=3582; 2017, N=3965).

Characteristic	Not paying attention to information source (N=5313), OR[a] (95% CI)	*P* value[b]	Trust in the last health information found online, OR (95% CI)	*P* value[b]	Change in taking care of one's health, OR (95% CI)	*P* value[b]

[a]OR: odds ratio.

[b]Multivariate logistic regression adjusted for year, gender, age, educational level, household income, employment status, occupational category, and chronic disease.

[c]Not applicable.

[d]CU: consumption unit. One CU is attributed for the first adult in the household, 0.5 for other persons aged 14 years or older, and 0.3 for children under 14 years.

Discussion

Principal Findings and Interpretation

This was one of the first studies describing the evolution of online health information seeking in a European country, based on nationally representative time-series survey data. We observed an increase of the use of the internet for health-related information between 2010 and 2014 but a decrease between 2014 and 2017. In parallel, trust in the health information found online followed the same trend, thus suggesting a potential relationship between these 2 variables. Indeed, the growing phenomenon of misinformation and fake news might restrain citizens from using the internet for health-related information [40]. They might prefer consulting a health professional or just avoid looking for health information online [41]. However, promoting access to trustworthy information online represents a key lever to help people managing their health. Therefore, a growing body of research exists on the potential of interventions designed to develop eHealth literacy [42], which has been described as a necessary competence to mitigate health inequalities [43].

The rise in distrust was paradoxically complemented by a higher proportion of respondents reporting not paying attention to the information sources. This might be explained by the fact that it is often difficult to identify the source of information and assess its credibility. Apart from institutional health-related websites (eg, the website of the Ministry of Health, the website of a local hospital), determining the online source of information has become challenging and even frustrating [44]. On the other hand, general websites are easy to access and consult, while institutional websites remain less consulted, even if a slight increase was reported between 2014 and 2017 in our study. The complexity and density of the information they provide might explain their scarce use, despite their trustworthiness. Those who trusted more online contents were respondents having higher educational levels and incomes, which might be explained by the fact that they are supposed to have more developed eHealth literacy and technological skills, allowing them to better evaluate the accuracy of the information retrieved online [13,45]. These citizens were also less likely to change the management of their health based on health-related information found online, differentiating their information-seeking behavior from their health behavior [46].

Sociodemographic characteristics and health conditions of online health information seekers were similar to those found in previous studies [14,18,47]; being a woman, being younger, being an executive, having a higher educational level, having a higher household income, and having a chronic disease were all associated with use of the internet for health information seeking. Interestingly, our results showed that unemployed people were more likely to be health information seekers compared with other groups such as working or retired people. This result is in contrast with previous research [48,49] but in line with other studies [19,50] showing that this point is controversial and might depend on the specific characteristics of unemployed citizens when they are not taken into account in a model, like the fact of being a woman or having an illness, or rather on the country's unemployment rate or medical care coverage for these people. What can be said with more confidence is that higher educational levels are associated with higher use of the internet for health information seeking, independently from being employed or not, since eHealth literacy skills are higher among people having a diploma [51]. In our study, students, independently of the level of education, were more likely to be health information seekers compared with other people (eg, working, retired), which can be explained by the fact that they are used to seeking online information in general as part of their study curriculum.

Trends about searched topics were similar across time periods, with general health and illness being the most searched terms together with nutrition, weight gain, or eating disorders and child health and illness. The prevalence of these topics is explained by the characteristics of likely online health information seekers (ie, women aged 35 to 54 years). Gender differences have been frequently reported as relevant for health information seeking, including topics of interest [52]. Decreasing interest in topics like tobacco, alcohol, or other drug consumption might be explained by the fact that users prefer browsing the web for general health-related information, while for more specific problems like addiction, they prefer other sources of information. This is in line with the trustworthiness of online information and the risk of encountering fake news for sensitive topics like drug consumption and is also documented in previous research [53].

Strengths and Limitations

Strengths of this study included the use of large datasets from nationally representative surveys including the general population with various sociodemographic characteristics. The time-series design was also important to robustly assess the evolution of online health information-seeking patterns in the French population.

This study is not without limitations. First, while being based on large samples, the response rates were between 48.5% and 61%, which means that selection bias cannot be excluded and that some specific population groups like homeless people or immigrants were likely to be underrepresented. Second, as a population-based study specific to France, these results are not generalizable to other countries, although online health information-seeking behavior patterns are supposed to be similar in most of the European countries. Third, data on trust in the information found online were only available for the subsample of health information seekers: this prevented the evaluation of the association between trust and decrease in the use of the internet for health information seeking. Fourth, Health Barometer surveys do not report on important aspects related to online health information seeking such as technical skills and eHealth literacy. Finally, the reliability of some answers may be affected by a memory bias, and other data concerning online health information seeking were not assessed like the frequency of use and the use of social media or mobile apps providing health tips and information. A complete picture of online health information-seeking behaviors might benefit from more data on digital health use in general.

Conclusions

Our results showed a rapid growth in internet use in the 2010 to 2014 period with a decrease in the year 2017, in parallel with a decreasing trust in the quality and reliability of information found online. The trends in the use of and trust in online health information need to be constantly monitored, but our findings already underlined the need for alternative trustworthy sources of information on the internet. In particular, it is recommended that official health institutions promote initiatives to help citizens navigate health-related information available on the internet. These initiatives might range from interventions aimed at promoting citizens' eHealth literacy, such as educational programs, to official websites and online portals providing reliable but simple and usable information. Effective interventions should combine the popularity and accessibility of general health-related websites with the authority of the institutional websites.

Acknowledgments

We would like to acknowledge all participants in the 2010, 2014, and 2017 Health Barometers. We would also like to thank François Beck for coordinating the 2010 Health Barometer survey and Abdelkrim Zeghnoun for the statistical support. The 2010, 2014, and 2017 Health Barometers were funded by Santé publique France, the national public health agency (and formerly the National Institute for Health Prevention and Education, or INPES).

Authors' Contributions

The 2017 Health Barometer group participated in the design and implementation of the 2017 Health Barometer survey. JBR coordinated the 2010, 2014, and 2017 Health Barometers. JBR was responsible for the design and protocol of the study. PD conducted the literature review, performed the statistical analyses, and drafted the manuscript. IM, VNT, AJS, and JBR were involved in the interpretation of results and critically reviewed the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Work stress affects individual health and well-being. These negative effects could be mitigated through regular monitoring of employees' stress. Such monitoring becomes even more important as the digital transformation of the economy implies profound changes in working conditions.

Objective: The goal of this study was to investigate the association between computer mouse movements and work stress in the field.

Methods: We hypothesized that stress is associated with a speed-accuracy trade-off in computer mouse movements. To test this hypothesis, we conducted a longitudinal field study at a large business organization, where computer mouse movements from regular work activities were monitored over 7 weeks; the study included 70 subjects and 1829 observations. A Bayesian regression model was used to estimate whether self-reported acute work stress was associated with a speed-accuracy trade-off in computer mouse movements.

Results: There was a negative association between stress and the two-way interaction term of mouse speed and accuracy (mean −0.32, 95% highest posterior density interval −0.58 to −0.08), which means that stress was associated with a speed-accuracy trade-off. The estimated association was not sensitive to different processing of the data and remained negative after controlling for the demographics, health, and personality traits of subjects.

Conclusions: Self-reported acute stress is associated with computer mouse movements, specifically in the form of a speed-accuracy trade-off. This finding suggests that the regular analysis of computer mouse movements could indicate work stress.

KEYWORDS

work stress; psychological stress; stress indicator; computer mouse movements; human-computer interactions

Introduction

Stress in the workplace is responsible for over 120,000 deaths and US $187 billion in annual health care spending in the United States [1]. To mitigate this burden, work stress must be monitored and managed. The need for workplace stress management increases even further as the digital transformation of the economy implies profound changes in working conditions [2]. At the same time, digital transformation offers opportunities for better stress management. Human-computer interactions with ubiquitous digital devices could be used for real-time monitoring of work-related stress. In particular, it has been

shown that the computer mouse responds to changes in muscular activity as a result of stress [3-6]. Thus, previous studies have investigated the association between stress and the use of the computer mouse [7-11], for instance, by analyzing computer mouse movements [8,10,11]. However, the evidence from these studies is, so far, based on lab experiments using artificially designed computer tasks. Hence, it remains unclear whether an association between stress and the use of the computer mouse can also be observed in the field.

For this study, we hypothesized that there is an association between stress and computer mouse movements. Our hypothesized association is based on the theory of neuromotor noise [12-16]. Stress, induced by time pressure or multitasking, leads to higher neuromotor noise [15,16], which is the noise in control signals steering motor movements. Lower signal-to-noise ratios and limited capacity to process information lead to adaptive movement behavior [12]. For instance, if subjects are required to execute fast movements, then neuromotor noise will lead to greater variability in the direction of movement [15]. The reason for this is that high or low execution speeds induce neuromotor noise, which makes it more difficult to hit the intended target of the movement accurately and requires more or fewer corrections, respectively, along the trajectory [13,14]. That is, the accuracy of the movement has to adjust relative to the movement speed.

In short, the previous literature suggests that stress induces neuromotor noise, resulting in a speed-accuracy trade-off in motor movements. This trade-off is particularly documented in rapid aimed movements [13,14]; based on this, we can expect that it also applies to computer mouse movements. We tested our hypothesis with data from a longitudinal observational field study that included 70 subjects and 1829 observations. Thereby, we collected computer mouse movements and self-reported stress levels from employees during their regular office work for 7 weeks. Using a Bayesian regression model, we present findings that support our hypothesis that work stress is characterized by a speed-accuracy trade-off in computer mouse movements.

Methods

Study Design

A 7-week longitudinal field study was conducted at a large European technology company. The company's human resources director asked 496 employees from different service units (ie, accounting, human resources, information technology, marketing, quality management, logistics, and business development) to participate through an email invitation. The invitation described the study's objective of understanding the association between computer mouse movements and work stress.

Subjects were not offered financial incentives. However, they were invited to a debriefing event at the end of the study, where the aggregated results were presented. Further, their self-reports were made available to them through graphical diagrams so they could monitor their stress levels over the course of the study.

Among all invited employees, 71 subjects decided to participate. They installed our study software by clicking on a link in the invitation. When subjects first opened the study software, a tutorial explained how the software was used to report stress. During the 7-week study period, the study software asked subjects twice a day to report their stress level. The timings were randomly triggered by our software, namely, once between 9 AM and 11 AM and once between 2 PM and 4 PM. Prior to these self-reports, our software recorded all computer mouse movements for 30 minutes. If subjects were not using their computer at that time (eg, due to a meeting), then no data were recorded.

Data about subjects' computer mouse movements and self-reports were securely transferred to a server at the organization, from which they were gathered by our research team to perform subsequent analyses. At the beginning of the study, subjects were further asked to report their sociodemographics (ie, age, gender, and education), behavioral attributes regarding health and nutrition (ie, sports, nutrition, smoking, and drinking habits), and expression of the big five personality traits as measured by an established inventory [17]. All variables are described in Table 1.

Table 1. Variables and descriptions.

Variable	Description
Target variable	
Valence	Self-reported valence on a scale from 1 (low) to 7 (high)
Arousal	Self-reported arousal on a scale from 1 (low) to 7 (high)
Stress	Dummy with 1 if valence <4 and arousal >4 (stress), 0 otherwise (no stress)
Mouse movements	
Speed	Distance computer mouse is moved divided by the duration of the movement
Accuracy	Proportion of mouse events where the movement direction remained equal along the x-axis and y-axis
Mouse events	
Clicks	Proportion of mouse tracks with clicks in a recording
Wheels	Proportion of mouse tracks with wheels in a recording
Recording time	
Weekday	Categorical {1: Monday, 2: Tuesday, 3: Wednesday, 4: Thursday, 5: Friday, 6: Saturday and Sunday}
Daytime	Dummy with 1 if recording was in the morning, 0 otherwise (in the afternoon)
Sociodemographics	
Age	Subject age
Gender	Dummy with 1 if male, 0 otherwise (female)
Education	Dummy with 1 if university degree, 0 otherwise (ie, high school or lower)
Health and nutrition	
Sport	Hours of sport per week
Nutrition	Number of fruits or vegetables consumed per day
Alcohol	Categorical {1: never, 2: 2-4 times per month, 3: 2-3 times per week, 4: more than 4 times per week}
Smoking	Categorical {1: daily, 2: occasionally, 3: not anymore, 4: never smoked}
Personality traits	The big five personality traits, each measured on a scale from 1 (low expression of the trait) to 10 (high expression of the trait), based on an established inventory [17]

Processing Computer Mouse Movements

A Java application was developed to record computer mouse movements (ie, timestamp and x- and y-coordinates) and mouse events (ie, movement, click, and wheel). The application was built on the Windows operating system's standard software drivers with a sample rate of approximately 125 Hz. Computer mouse movements were recorded for 30 minutes and processed in the following way. Each recording was split into separate trajectories, where a trajectory started with a mouse movement and ended with a different mouse event (ie, a click or wheel). Thereby, trajectories were only considered if their duration was between 1 and 10 seconds. This approach was beneficial, as it omitted trajectories that were extremely short or included temporary phases where the mouse was not moving. For each trajectory, two variables were computed: (1) mouse speed, which is the average movement speed, and (2) mouse accuracy, which is the proportion of mouse events where the direction of the movement remained equal along the x- and y-axes (ie, the proportion of times the movement direction was *not* corrected). Both variables were then averaged over all trajectories. These provided the features that were inserted into our regression model.

Mouse speed was computed as the total distance the mouse moved between the start time t=1 of a trajectory and its end time T divided by the trajectory's total duration T. Hence, this yielded the following:

Mouse accuracy is the relative frequency of how often the movement in x- and y-directions was *not* changed. It is formalized by the following:

where the variable $eqdir_t$ indicates whether the movement in both x- and y-directions remained equal at time t. It returns a value of 1 if this is the case and 0 otherwise. Formally, it is specified by the following:

Accordingly, the larger the accuracy value is, the less the movement direction was altered. If the value for accuracy is 1, then the movement direction was never altered, and if the value for accuracy is 0, then the movement direction was always

altered. In other words, the more accurate movement was the one with fewer corrections. This directly relates our measure of accuracy to the theory of neuromotor noise, which predicts more corrections as the movement speed is increased.

The proportion of direction changes is commonly used as a measure of accuracy in related work [18,19]. Another measure for accuracy is the deviation from an optimal trajectory [19,20]. However, the theoretical model underlying the speed-accuracy trade-off predicts that higher movement speed leads to more corrective submovements [13,14], not necessarily to a larger deviation from the optimal line between the start and end point of the trajectory. For that reason, we specifically chose the proportion of direction changes as our measure of accuracy in this study.

Stress Measurement

Acute stress was measured according to the circumplex model of affect [21]. This model relates affective states to two underlying neurophysiological systems: valence, a pleasure-displeasure continuum, and arousal or alertness [22]. Both were collected using self-assessment manikins [23] on a 7-point Likert scale, with a value of 1 referring to a very negative valence (very low arousal) and a value of 7 indicating a very positive valence (very high arousal). Acute stress was then defined as a combination of low valence and high arousal, which has been shown to be related to work stressors in empirical research [24]. Specifically, stress is encoded as a dichotomous variable that equals 1 if subjects reported low valence and high arousal (ie, valence below the neutral midpoint of 4 and arousal above the neutral midpoint of 4) and 0 otherwise. Hence, our encoding translates into an analysis that focuses on distinguishing negative stress from positive or no stress.

Statistical Analysis

A logistic regression model was estimated with stress as the dichotomous outcome variable and with features from computer mouse movements as the independent variables. The model is specified as follows:

where $stress_{ik}$ is the dichotomous outcome variable for subject i=1,...,M and recording k=1,...,N. Subject-specific variation in average stress levels is captured by the varying intercept α_i. Note that subject-specific characteristics such as age or gender could explain between-subject variation of average stress levels, but beyond that, time-varying variables such as computer mouse movements are needed to explain within-subject variation of stress levels over time. The association of mouse speed and accuracy with stress is estimated by β_1 to β_3. In particular, the two-way interaction between mouse speed and accuracy (β_3) tests whether a speed-accuracy trade-off in computer mouse movements is associated with stress. Note that mouse speed and accuracy were centered and scaled by their empirical mean and standard deviation. By centering both variables, the sign of β_3 indicates the direction of the speed-accuracy trade-off. That is, a negative sign of β_3 would indicate that a simultaneous increase in mouse speed and decrease in mouse accuracy or a simultaneous decrease in mouse speed and increase in mouse accuracy is associated with a higher probability of stress.

Further independent variables were included in the above regression model as part of the sensitivity analysis. For instance, to control for mouse usage, we computed the number of events where the mouse was clicked or wheeled. Note that access to other human-computer interactions (eg, keyboard strokes) was not granted in this study due to privacy concerns.

Model Estimation

A Bayesian approach was used for model estimation. Compared to classical statistics, the Bayesian approach requires the specification of priors for all model parameters. When choosing flat priors, the classical and Bayesian approaches are the same. However, when choosing a Bayesian prior (eg, a normal prior), the results are different, and sign errors are less frequent with a Bayesian prior [25]. In other words, a Bayesian approach is less prone to making wrong claims about the sign of a parameter. In our study setting, this would most likely give more conservative estimates; hence, a Bayesian approach was used for data analysis. We chose weakly informative priors for all model parameters, thereby following recommendations on the choice of priors [26]. Our priors are as follows:

The model was estimated with Markov chain Monte Carlo using four chains. Each chain performed 2000 iterations divided into 1000 iterations for a warm-up and 1000 iterations for sampling. Samples were drawn with the No-U-Turn Sampler [27]. Thereby, it was ensured that all Markov chains converged successfully so that inference could be performed. In the Results section, we report the posterior distribution, the posterior mean, and the 95% highest posterior density interval (HPDI) of the estimated parameters.

Statistical analysis was performed with the programming language R, version 4.0.2 (The R Foundation), and the probabilistic programming language Stan, version 2.21.0 [28], using the interface provided by the R package brms, version 2.13.5 [29].

Data Inclusion and Exclusion

All participants deciding to participate were included in the study (ie, no additional inclusion or exclusion criteria were applied). Our raw data contained 2029 recordings from 71 subjects. The number of recordings per subject varied due to absences or because the subjects decided to stop participating. Further, recordings were excluded when no computer mouse movements were recorded (5 recordings), the recorded computer mouse movements contained tracking errors (ie, incorrect time

stamps) (92 recordings), or when the recordings contained less than 10 computer mouse trajectories (200 recordings). This led to the removal of 297 recordings from 62 subjects—between 1 and 12 per subject—and the exclusion of 1 subject from the study.

Data and Code Availability

Preprocessed data and a script to replicate all model results are provided [30]. Raw data may be used to identify individual study participants (eg, because mouse movements can be very specific to a person or may reveal sensitive information, such as passwords, when using a software keyboard) and, thus, cannot be made available; this decision was made by the research team and the institutional review board that evaluated the study.

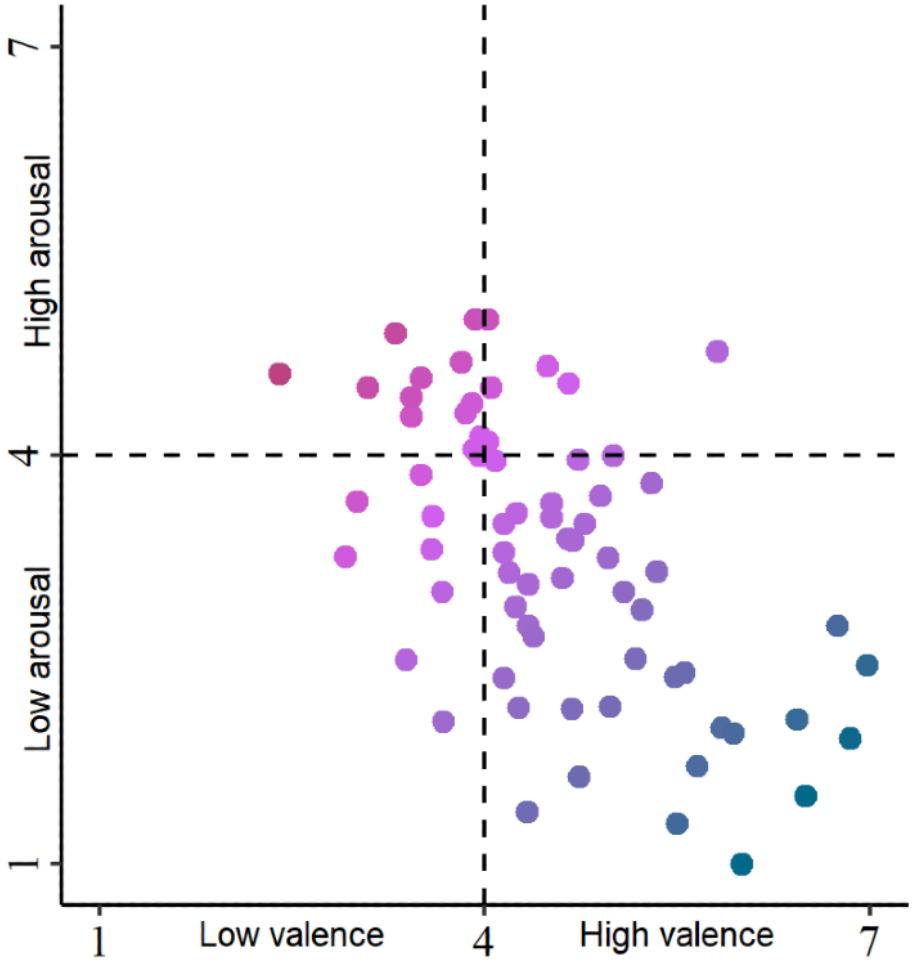
Results

Subject Statistics

Our results are based on 70 subjects and 1829 recordings (mean 26.13, SD 14.33). Subjects were between 20 and 61 years old, with a median age of 39.5 years (IQR 31.0-49.0). Further, 46% (32/70) of the participants were female, and 59% (41/70) held a university degree; all others had high school diplomas or lower. Recordings were roughly balanced by daytime hours (951/1829, 52.0% in the morning and 878/1829, 48.0% in the afternoon) and weekdays (329/1829, 18.0% to 384/1829, 21.0% per weekday and 18/1829, 1% on the weekend).

Both valence and arousal varied across subjects (see Figure 1). Average valence per subject was slightly above the neutral midpoint (mean 4.53, SD 0.98), and average arousal was slightly below the neutral midpoint (mean 3.28, SD 1.02). When averaged over the study period, a combination of low valence and high arousal (the top-left quadrant in Figure 1) was observed in 12 out of the 70 (17%) subjects. Applying our encoding of stress following the circumplex model of affect [21], 185 out of the 1829 self-reports (10.1%) were classified as stressful.

Figure 1. Perceived valence and arousal by subject. Shown are the average self-reported valence and arousal levels by subject in the field study. Red points indicate high levels and blue points indicate low levels of average stress.



Association Between Stress and Computer Mouse Movements

It was hypothesized that stress is characterized by a speed-accuracy trade-off. This trade-off is illustrated in Figure 2. When subjects perceived no stress, computer mouse movements were typically not characterized by a speed-accuracy trade-off. In contrast to that, when subjects perceive stress, computer mouse movements were typically characterized by a trade-off where the mouse was moved quickly but less

accurately (ie, many direction changes) or slowly but more accurately (ie, few direction changes). Descriptives for average mouse speed and accuracy are provided in Multimedia Appendix 1, Figure S1.

The estimated parameters of mouse speed and accuracy were as follows. The individual parameters of mouse speed (β_1) and accuracy (β_2) were not significant based on the observation that the 95% HPDIs include zero (see Figure 3). However, the parameter for the two-way interaction between speed and accuracy (β_3) was significant (mean −0.32, 95% HPDI −0.58 to −0.08). On average, a simultaneous 1 SD increase in mouse speed and 1 SD decrease in mouse accuracy, or vice versa, was associated with a change in the odds for perceiving stress by 1.53. In other words, work stress was characterized by a speed-accuracy trade-off.

Figure 4 depicts the partial dependence of both mouse speed and mouse accuracy on the probability of perceiving stress. Based on the plot, two findings can be derived. First, stress was more likely when there was a speed-accuracy trade-off. Second, this trade-off seemed slightly more prevalent for low mouse speed and high mouse accuracy, as indicated by a higher share of observations in the lower-right corner. This means that although both directions of the trade-off are present in our data, subjects perceiving stress were slightly more frequently increasing accuracy at the cost of speed.

Figure 2. Illustrative examples of the speed-accuracy trade-off in computer mouse movements. Shown are typical computer mouse movements (blue dot: beginning of movement; red dot: click) from the field study. Circles correspond to recordings at 125 Hz. When subjects perceived no stress, computer mouse movements were typically not characterized by a speed-accuracy trade-off. When subjects perceived stress, computer mouse movements were typically characterized by a speed-accuracy trade-off. Mouse speed and accuracy were standardized to indicate the direction of the trade-off; that is, high speed (+) and low accuracy (−) or low speed (−) and high accuracy (+).

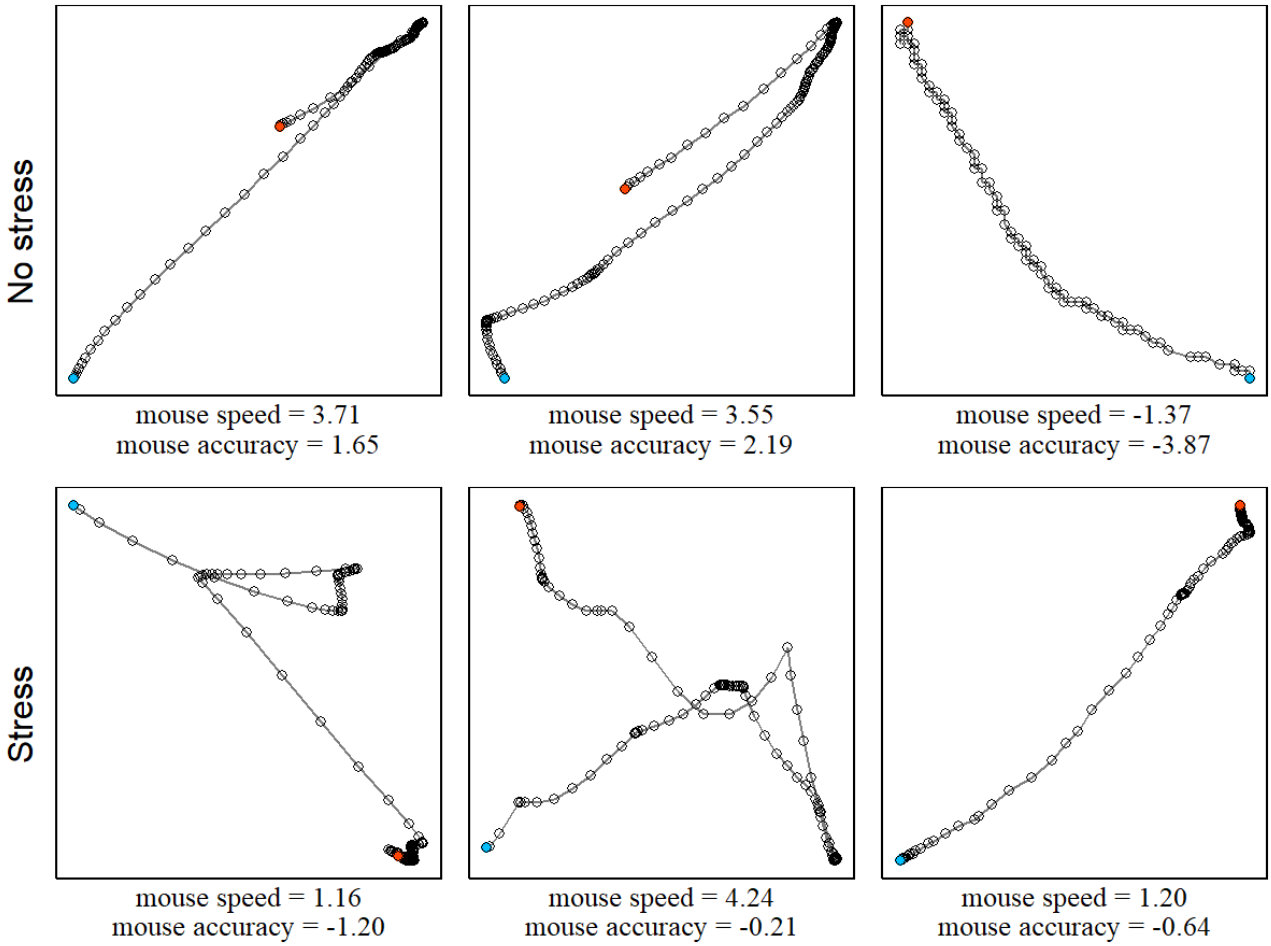


Figure 3. Association between work stress and computer mouse movements. Shown is the estimated effect (posterior and prior density and mean as solid and dashed grey lines, respectively, and 95% highest posterior density interval as shaded area) of mouse speed (β_1), mouse accuracy (β_2), and the two-way interaction between mouse speed and accuracy (β_2).

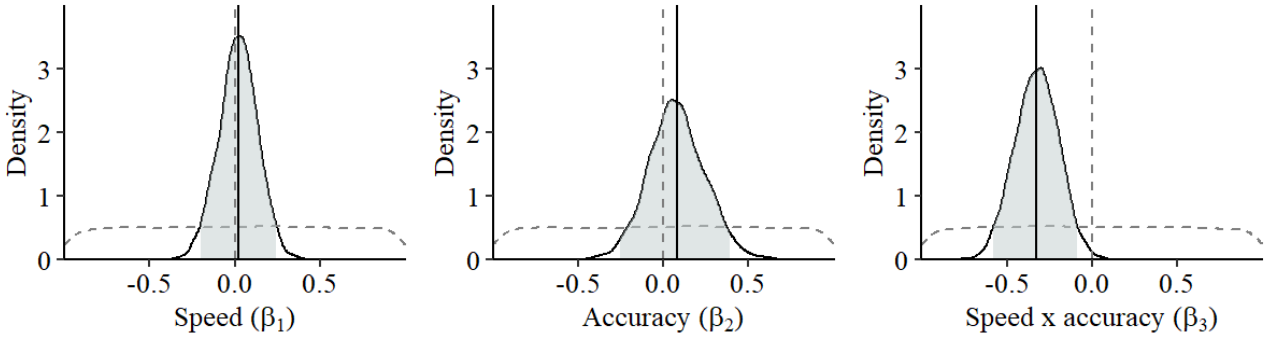

Figure 4. Probability (Prob.) of perceived stress based on mouse speed and accuracy. Shown is the partial dependence of stress on mouse speed and accuracy in the range of −2 SD to +2 SD. Red areas indicate high levels and blue areas indicate low levels of stress.

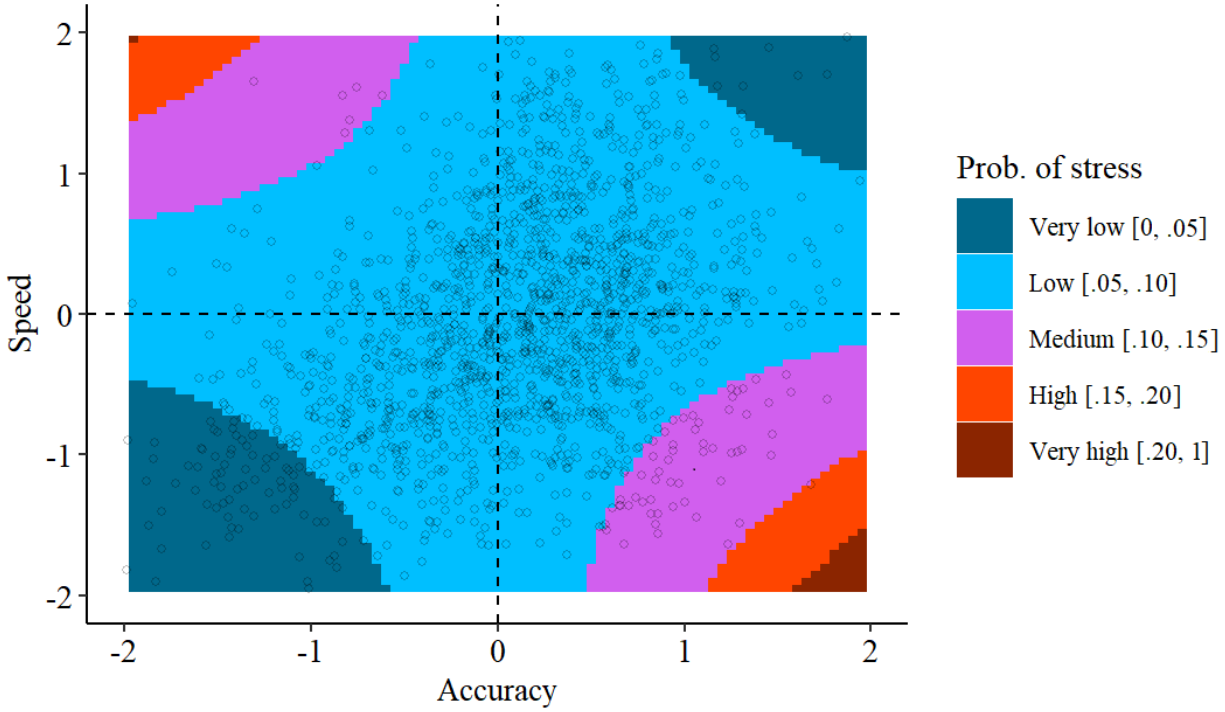

Sensitivity Analysis

The sensitivity of the estimated parameters was assessed in the following ways. First, different processing of the data led to conclusive findings. In the above analysis, recordings were removed when fewer than 10 computer mouse trajectories were counted over 30 minutes. When varying this number, the estimated parameter of the mouse speed-accuracy trade-off remained stable (see Multimedia Appendix 1, Figure S2). Similarly, the maximum duration for a trajectory was set to 10 seconds. When varying the maximum duration from 5 to 20 seconds, the estimated parameter of the mouse speed-accuracy trade-off also remained stable (see Multimedia Appendix 1, Figure S3). Furthermore, recordings from 2 subjects revealed unusually low mouse accuracy (see Multimedia Appendix 1, Figure S1). Excluding all recordings from these subjects slightly reduced the size of the estimated parameter for the trade-off (mean −0.22, 95% HPDI −0.42 to −0.03).

Second, the sensitivity of the estimated parameter for the speed-accuracy trade-off was assessed with respect to the inclusion of varying slopes for computer mouse movement variables and additional controls, such as mouse events and sociodemographics. Including varying slopes or adding more controls led to comparable estimates for the parameter of the mouse speed-accuracy trade-off (see Multimedia Appendix 1, Figure S4).

Third, the association of computer mouse movements with valence, arousal, and a discrete measure of stress (defined as arousal – valence + 6) was estimated. Results from Poisson regressions with the same model specification showed no significant associations but a tendency that arousal and the discrete measure of stress were negatively associated with the speed-accuracy trade-off (see Multimedia Appendix 1, Figure S5). However, the results from the regression with the discrete measure of stress as the outcome should be interpreted with caution, as an arousal level of 7 and valence level of 4 would

result in the equivalent level of stress as an arousal level of 5 and a valence level of 2, whereas only the second self-report would be labeled as stress according to the circumplex model of affect.

Fourth, the possibility of selection bias was investigated, with a statistical comparison between those subjects with few (n≤10) and many (n>10) recordings. The proportion of recordings with stress from subjects with few recordings (6/43, 14%) was higher than the proportion of recordings with stress from subjects with many recordings (188/1986, 9.5%). However, the difference was not statistically significant (χ^2_1=0.5, *P*=.47). This result suggests that participation intensity was not significantly related to stress. Other than that, it could not be investigated whether individuals outside this study were more or less stressed than the subjects participating in this study.

Discussion

Principal Findings

The goal of this study was to examine whether computer mouse movements indicate work stress. Data from a 7-week longitudinal field study supported the hypothesis. Despite the heterogeneity of computer tasks and the resulting complexity of computer mouse movements, we found a significant association with work stress. That is, work stress was characterized by a speed-accuracy trade-off in computer mouse movements.

Comparison With Prior Work

This is the first study to infer stress from the computer mouse in the field (ie, at the workplace). In prior work, lab studies were conducted to investigate the association between stress and the use of the computer mouse [7-11]. In these lab studies, subjects performed artificial tasks (eg, point-and-click tasks) in a controlled environment. In contrast to that, our data were collected unobtrusively while subjects were performing office work in a real-world environment. On the one hand, this made data processing and analysis challenging. On the other hand, it provided us with the unique opportunity to present the first empirical evidence as to whether stress is associated with computer mouse movements in the field.

A drawback of our field study in comparison to the lab studies is that we are not able to estimate a causal link. The reason is that there are potentially unmeasured confounders. In particular, computer mouse movements as well as stress may depend on the difficulty of the task, with more difficult tasks resulting in higher levels of stress. In the lab, it is possible to control which task is performed, whereas this is not possible in the field without obtrusive monitoring of tasks. However, precisely because unobtrusive and continuous monitoring of tasks is not feasible in the field, computer mouse movements may be a good proxy for how stressful a task is perceived and may thus provide an indirect way to measure stress.

Benefits

Monitoring of computer mouse movements provide a number of benefits for stress management in the workplace. Most office work involves computer tasks; as such, computer mouse movement data are readily available. Unlike other forms of stress monitoring, computer mouse movements present a viable tool for monitoring stress at scale because they can be collected in an unobtrusive fashion and continuously over time [10]. The latter becomes important when offering on-demand stress management interventions by organizations and for monitoring their effectiveness [31]. It is also possible to monitor stress by monitoring physiological changes (eg, heart rate variability or skin conductivity) through wearable devices. However, when introduced by employers, the broad usage of physiological data in a corporate context raises issues regarding their acceptance and legitimacy [32]. When compared to such physiological stress measurements, many employees might consider the measurement of computer mouse movements as a clearly work-related behavior and as a less intrusive and more legitimate monitoring method at work. As computer mouse movements are bound to currently performed work, their measurement will trigger a more balanced action on the part of employees to mitigate work stress: both reducing their own receptivity to stress and improving the underlying working conditions, as it is also recommended by the European Union [33]. Thus, the measurement of computer mouse movements offers a valuable, complementary approach to physiological measurements.

Limitations

Our study also has limitations. First, our work constitutes an observational study with an explanatory analysis of the data. As a consequence, a causal interpretation of the estimated association is precluded. Second, computer mouse movements were only linked to the presence of stress, which was defined according to the circumplex model of affect [21]. The severity of stress could not be assessed due to the low prevalence of high levels of stress. Third, computer mouse movements were only linked to acute stress. The association of computer mouse movements with chronic stress is subject to future work. Fourth, the outcome of this study was psychological stress, which was measured based on self-reports. It is unclear if, and to what extent, psychological and physiological measures of stress are alternative or complementary by nature [34]. Thus, collecting physiological data from wearable devices to monitor stress [35,36] could be used to validate the association with computer mouse movements. Fifth, the sources of stress were not identified, which is important for managing stress. However, other work suggests that human-computer interactions also correlate with workplace stressors [37]. Sixth, the determinants for the directions of the speed-accuracy trade-off were not explored. This would probably require a different research setting, most likely a controlled lab experiment, in order to investigate what causes subjects to increase speed at the cost of accuracy, or vice versa.

Conclusions

To summarize, the findings of this study suggest that the computer mouse can be used to infer work stress. These findings could be combined with findings from other forms of human-computer interactions (eg, computer trackpads [38] or keyboard strokes [39]) in order to develop digital tools for detecting stress.

Acknowledgments

We would like to thank Andreas Filler for developing the software that allowed us to perform the computer mouse movement and self-report recordings. NB and SF acknowledge funding from the Swiss National Science Foundation outside of this study.

Conflicts of Interest

EF and TK are affiliated with the Center for Digital Health Interventions, a joint initiative of the Department of Management, Technology and Economics at ETH Zurich and the Institute of Technology Management at the University of St. Gallen, which is funded in part by the Swiss health insurer CSS. EF and TK are also cofounders of Pathmate Technologies, a university spin-off company that creates and delivers digital clinical pathways. However, Pathmate Technologies was not involved in the study described in this paper.

Abstract

Background: Exercise identity is an important predictor for regular physical activity (PA). There is a lack of research on the potential mechanisms or antecedents of identity development. Theories of exercise identity have proposed that investment, commitment and self-referential (eg, I am an exerciser) statements, and social activation (comparison, support) may be crucial to identity development. Social media may be a potential mechanism to shape identity.

Objective: The objectives of this study were to (1) explore whether participants were willing to share their Instagram data with researchers to predict their lifestyle behaviors; (2) examine whether PA-related Instagram uses (ie, the percentage of PA-related Instagram posts, fitness-related followings, and the number of likes received on PA-related posts) were positively associated with exercise identity; and (3) evaluate whether exercise identity mediates the relationship between PA-related Instagram use and weekly PA minutes.

Methods: Participants (18-30 years old) were asked to complete a questionnaire to evaluate their current levels of exercise identity and PA. Participants' Instagram data for the past 12 months before the completion of the questionnaire were extracted and analyzed with their permission. Instagram posts related to PA in the 12 months before their assessment, the number of likes received for each PA-related post, and verified fitness- or PA-related followings by the participants were extracted and analyzed. Pearson correlation analyses were used to evaluate the relationship among exercise identity, PA, and Instagram uses. We conducted mediation analyses using the PROCESS macro modeling tool to examine whether exercise identity mediated the relationship between Instagram use variables and PA. Descriptive statistical analyses were used to compare the number of willing participants versus those who were not willing to share their Instagram data.

Results: Of the 76 participants recruited to participate, 54% (n=41) shared their Instagram data. The percentage of PA-related Instagram posts (r=0.38; P=.01) and fitness-related Instagram followings (r=0.39; P=.01) were significantly associated with exercise identity. The average number of "likes" received (r=0.05, P=.75) was not significantly associated with exercise identity. Exercise identity significantly influenced the relationship between Instagram usage metrics (ie, the percentage of PA-related Instagram posts [P=.01] and verified fitness-related Instagram accounts [P=.01]) and PA level. Exercise identity did not significantly influence the relationship between the average number of "likes" received for the PA-related Instagram posts and PA level.

Conclusions: Our results suggest that an increase in PA-related Instagram posts and fitness-related followings were associated with a greater sense of exercise identity. Higher exercise identity led to higher PA levels. Exercise identity significantly influenced the relationship between PA-related Instagram posts (P=.01) and fitness-related followings on PA levels (P=.01). These results suggest that Instagram may influence a person's exercise identity and PA levels. Future intervention studies are warranted.

KEYWORDS

social media; exercise identity; physical activity; physical fitness

Introduction

Regular physical activity (PA) is critical to prevent chronic diseases and maintain overall well-being [1]. However, physical inactivity (ie, not meeting recommended guidelines) continues to be a major public health concern worldwide [2]. In Canada, approximately 79% of adults aged 18-39 did not meet the PA guidelines (150 minutes of moderate-to-vigorous PA per week) in 2015 [3]. Thus, there is an urgent need to find innovative solutions to better target and tailor PA interventions based on a person's needs to maximize public health impact [4]. Much of the PA promotion research literature has been based in the social cognitive tradition, which is focused on increasing expectations about the benefits of PA, improving perceptions of capability, and developing goals and self-regulation tactics to enable behavior change [5-8]. The social cognitive–based behavior change theories suggest that intentions are proximal antecedents of behavior; thus, supporting positive PA intentions can lead to subsequent behavioral enactment [9]. This approach has shown some effectiveness in terms of behavior change, albeit with modest effects [5]. There is clearly a need to continue to investigate additional mechanisms that can assist in PA continuance.

One of these mechanisms may be identity. Identity represents a person's self-categorization into a particular role [10]. This process assists in developing personal rules and standards of conduct with a particular behavior, such as PA [11]. As such, the central mechanism that sustains behavior becomes regulation around the identity standard [12]. Exercise identity refers to the degree to which an individual identifies himself/herself as an "exerciser" or someone who values and regularly engages in PA [13]. Discrepancies between the person's exercise identity and the present situation (eg, being physically inactive) can create negative emotions, which are proposed to motivate the individual to close the gap between the present behavior and the identity standard [12,14]. In essence, identity is a reflexive self-regulating system of behavioral continuance/stability [10]. Exercise identity has emerged as an important construct for PA promotion because of the reciprocal relationship between role identities and behavior [15]. Self-report surveys, such as the Exercise Identity Scale, have been developed and rigorously tested for assessing an individual's exercise identity, which has allowed for further investigation of the association between exercise identity and PA behavior [16].

Observational evidence has shown that PA behavior and identity have a reliable association in the medium to large effect size range [17]. Furthermore, the relationship is often independent of more traditional social–cognitive determinants (eg, intention) [17] and the mechanisms of identity dissonance and negative affect have been well-validated in hypothetical PA abstinence situations [18-20]. What has seen less attention, however, is the potential mechanisms or antecedents of identity development. Theories of exercise identity have proposed that investment, commitment and self-referential statements (eg, I am an exerciser), and social activation (comparison, support) may be crucial to identity development [13,21-23]. Another possible mechanism of identity is self-expression. Bem's self-perception theory [24], for example, suggests that identity may be formed largely by observing one's behavior and inferring self-categorization. This premise has some support in PA interventions from 2 small feasibility trials where participants who were encouraged to present PA-related imagery and self-expression (eg, a picture on the mantle) showed corresponding increases in identity [25,26]. However, the large focus on social media and self-expression across much of the population may be an even more effective mechanism of shaping identity.

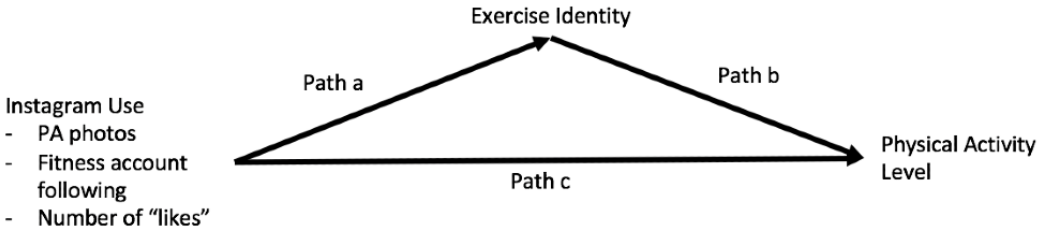
Social media websites, such as Instagram, allow users to easily and freely communicate and express themselves by posting photos, status messages, or links that become instantly available to the public [27]. Infodemiology is a new area of study where researchers examine ways to use data generated on social media to better understand and inform public health problems in real time [28]. Infoveillance has referred to applications where infodemiology methods are utilized, particularly for surveillance purposes [29]. PA promotion interventions can potentially extract useful information from user-generated social data for infoveillance and to tailor health promotion efforts to improve PA levels. In fact, recent studies have shown the possibility of using social media and digital interventions to promote PA [30-32].

Researchers have already shown that behavior characteristics extracted from social media sites, such as Twitter, can be used to model alongside other biomedical data sets to inform PA on a population level [30-34]. We believe that it is critical to explore the use of social data from other platforms, such as Instagram, to expand the field of infodemiology. Instagram is a highly unique and user-friendly platform that allows users to share photos and videos on their mobile devices anywhere at any time. This platform has evolved into a visual-oriented culture, promoting photos first and text second. Instagram enables users to express their personalities and lifestyles with others and form relationships with users that share similar interests and values. In contrast to Twitter and Facebook, Instagram's "photo-first" culture may contribute to different user behavior and motivation [35]. Approximately 71% of online adults in America have an Instagram account [36] compared with 38% of adults (18-29 years of age) that use Twitter [37]. In Canada, 37% of adults have a social networking account, and among adults aged 18-34, about 65% have an Instagram account [38]. An Instagram study suggested that analysis of the content of Instagram pictures, color analysis (amount of saturation brightness, photo filters), frequency of posts, patterns of followings, algorithmic face detection, and the number of likes are associated with symptoms of depression [39].

However, it remains unclear whether PA-related markers extracted from Instagram are associated with a person's exercise identity and subsequent PA level. Furthermore, Twitter data are designed to be publicly available, whereas Instagram data are

not publicly available by default [40]. Users may perceive their Instagram data as being more private and sensitive [41]. The percentage of participants who are willing to share their Instagram data for health behavior monitoring is currently unclear. Thus, the objectives of this study were to (1) explore whether participants were willing to share their Instagram data with researchers to predict their lifestyle behaviors; (2) examine whether PA-related Instagram uses (ie, the percentage of PA-related Instagram posts, fitness-related followings, and the number of likes received on PA-related posts) were positively associated with exercise identity; and (3) evaluate whether exercise identity mediates the relationship between PA-related Instagram use and weekly PA minutes. Commensurate with self-perception theory [24] and past research [25,26], we hypothesized (1) more than 50% of the participants would be willing to share their Instagram data for health infoveillance, (2) PA-related Instagram use was positively associated with exercise identity, and (3) exercise identity would mediate the relationship between PA-related Instagram use (ie, number of likes) and PA minutes. Figure 1 presents a visual representation of the hypothesized mediation model.

Figure 1. Hypothesized mediation model including Instagram use, exercise identity, and physical activity level.



Methods

Participants and Procedure

This cross-sectional study recruited university students (n=76) from the University of Victoria, British Columbia, Canada, using research posters and online advertisements. The rolling recruitment strategy took place between June 30, 2018, and July 1, 2019. Inclusion criteria required that participants be Instagram users, and between the ages of 18 and 29. Exclusion criteria included the inability to comprehend English. Interested participants were asked to contact the research team. The research team obtained consent from all eligible participants prior to data collection. During the consent process, participants were notified of the study objectives and that the sharing of their Instagram data was voluntary. All data obtained in connection with the study remained confidential. Confidentiality was maintained by means of encrypting on a secure server. All survey data and ID numbers were used on all databases. Researchers had access to participant Instagram data for up to 1 year from the start of the study.

Eligible participants who gave consent to participate in the study were asked to complete a questionnaire to record their demographic characteristics, daily Instagram use duration, and evaluate their current exercise identity and PA levels. Participants were also asked if they are willing to share their Instagram data. Participants that refused to share their Instagram data were given the option to write down reasons for not sharing. Those participants who agreed to share their Instagram data were asked to follow an Instagram research account in order for researchers to extract their Instagram data (photos, likes, followings). Researchers analyzed the previous 12 months of Instagram data from the completion date of the exercise identity and PA questionnaires. This study received research ethics approval from the research ethics board at the University of Victoria (protocol number: 17-294).

Measures

Demographic information (age, sex, and ethnicity) and daily Instagram usage time were collected using self-report instruments. PA levels were assessed using the Recent Physical Activity Questionnaire (RPAQ) [42]. Minutes of PA at low (metabolic equivalent of task [MET] < 6/week), moderate (MET 3-6/week), and high (MET > 6/week) intensities were calculated based on the RPAQ scoring instruction [42].

Exercise identity was assessed using the Exercise Identity Scale [16], which is a 9-item questionnaire on a 5-point Likert scale from 1 (strongly disagree) to 5 (strongly agree) (α=.92). Participants' exercise identities were determined by calculating a total score from the 9-item questionnaire; thus, scores ranged from 9 to 45 whereby a higher score represented a stronger exercise identity.

Participants' Instagram data were extracted using a customized program [43], which enabled the researchers to export users' posts, likes received for each post, and followings into separate Microsoft Excel files. Instagram posts extracted during the past 12 months before the completion of the study questionnaire were manually coded by 2 trained research assistants using standardized criteria to determine whether posts were PA related or not (eg, binary coded). PA-related posts were defined as those posts suggesting participants performed physical activities defined by the guidelines for exercise testing published by the American College of Sports Medicine [44]. Specifically, Instagram picture and video posts were identified as PA related if they included the person in sporting attire or the person in a location to perform PA (eg, kayaking, skiing, swimsuit, hiking) individually or in a group setting. Any discrepancies between the coders were resolved through discussion. The percentage of the number of PA-related posts relative to the total number of Instagram posts was calculated for each participant. The average number of likes for PA-related posts for each participant was also calculated.

An analysis of participants' Instagram "followings" was completed to identify the number of verified fitness or exercise-related Instagram accounts each participant followed. The verified fitness- or exercise-related Instagram accounts means Instagram has confirmed that an account is the authentic presence of the public figure, celebrity, or global brand it represents. A list of the most popular 300 verified fitness- or exercise-related Instagram accounts was compiled from publicly available Instagram rankings [45]. The percentage of exercise-related Instagram accounts following relative to the total number of Instagram followings was computed for each participant.

Statistical Analysis

All analyses were performed using the standard SPSS version 26.0 for Mac (SPSS, Inc./IBM), with a significance level set at $P<.05$. Descriptive statistical analyses were used to compare the number of willing participants with those who were not willing to share their Instagram data. Participants that were not willing to share their Instagram data were asked to provide reasons for not sharing in an open-ended question. Responses from these questions were grouped to create common themes. Independent *t* tests were used to compare differences between those groups (Instagram data shared versus Instagram data not shared) on demographics, PA, and exercise identity. A chi-square test was used to compare differences between categorical variables.

We examined normality (eg, skewness > 2 and kurtosis > 3) of all variables to determine whether any transformations were required by conversion to z-scores [46]. Pearson correlation analyses were used to evaluate the relationship among exercise identity, PA, and Instagram use metrics (percentage of PA-related Instagram post, percentage of fitness-related Instagram followings, and average number of "likes" on PA-related posts). Mediation analyses were based on 5000 bootstrapped samples using Hayes PROCESS Macro version 3.5 [47]. Multiple mediation analyses was used to examine whether exercise identity mediated the relationship between Instagram use variables and PA level [47]. This process involved examining path a, the association between Instagram use (independent variable) and exercise identity; path b, the impact of exercise identity (mediator variable) on PA level; and path c, the effect of Instagram use on PA levels (outcome variable). All analyses were controlled for age and sex. The 95% CIs must not cross 0 to satisfy the criteria for mediation.

Results

Participant Characteristics

A total of 76 participants were recruited and completed the study. Participant characteristics are presented in Table 1. The mean age was 19.7 (SD 0.31) years and the sample consisted of 72% female (55/76). Overall, 46% (35/76) of participants did not agree to share their Instagram data. Of these participants, 14 participants provided reasons for not sharing. Privacy was a major concern; specifically, there were concerns with (1) data oversight to prevent misusage of data and technology (n=9), (2) limitations to remain anonymous using Instagram photos (n=4), and (3) data ownership (n=1). Participants that were not willing to share their Instagram data reported significantly fewer weekly PA minutes at moderate to high intensity (MET ≥3/week) relative to participants that agreed to share their Instagram data ($P=.04$); however, there were no significant differences between groups for demographic characteristics, exercise identity, weekly PA minutes at low intensity (MET <3/week), and daily Instagram usage (Table 1).

A total of 41 participants agreed to share their Instagram data. The mean number of posts during the 12-month study period was 29.6 (SD 4.7). Examination of shared Instagram data revealed that, on average 7.3 (SD 1.1) or 25% of Instagram posts shared during the previous 12 months were related to PA. The mean number of Instagram following per person was 439.3 (SD 258) accounts. The mean number of verified PA- or fitness-related Instagram accounts following per user was 3 (SD 3.14). The mean number of "likes" received on all posts was 102.2 (SD 72.4) and the mean number of "likes" received on PA-related Instagram posts was 99 (SD 73).

Table 1. Baseline characteristics.

Characteristics	Instagram data shared (n=41)	Instagram data not shared (n=35)	*P* value
Age, mean (SD)	19.66 (2.08)	20.03 (1.81)	.42
Sex (female), n (%)	27 (66)	28 (80)	.20
Ethnicity, n (%)			.70
White	29 (71)	24 (69)	
East Asian	6 (15)	6 (17)	
Black	0 (0)	1 (3)	
Other (mixed, Spanish, South Asian)	6 (15)	4 (11)	
Exercise identity, mean (SD)	34.00 (8.20)	34.79 (7.16)	.67
Weekly PA[a] minutes at low intensity (MET[b] <3/week), mean (SD)	38.51 (135.94)	22.92 (59.94)	.50
Weekly PA min at moderate to high intensity (MET ≥3/week), mean (SD)	476.37 (542.40)	263.82 (238.27)	.04
Instagram usage (hours/day), mean (SD)	1.87 (1.04)	2.32 (1.91)	.29

[a]PA: physical activity.

[b]MET: metabolic equivalent of task.

The Relationship Among Exercise Identity, Physical Activity, and Instagram Use Metrics

Normality analysis revealed that weekly PA minutes at moderate to high intensity (MET ≥3/week) and fitness-related Instagram followings percentage were kurtotic (ie, values ≥3). These variables were transformed by conversion to z-scores. The Pearson correlation analyses are shown in Table 2. The results indicated that the percentage of PA-related Instagram posts (r=0.38; P=.01) and fitness-related Instagram (r=0.39; P=.01) followings were significantly associated with exercise identity. The strengths of the associates were moderate. We did not find that the average number of "likes" received (r=0.05, P=.75) to be significantly associated with exercise identity.

Table 2. Correlation analyses among exercise identity, physical activity, and Instagram use metrics.

Metrics	Variables				
	1	2	3	4	5
Pearson *r*					
Exercise identity	—				
Weekly PA[a] minutes at moderate to high intensity (MET[b] ≥3/week)	0.49	—			
Percentage of physical activity–related Instagram posts	0.38	0.03	—		
Percentage of verified fitness-related Instagram following	0.39	0.23	0.19	—	
Average number of "likes" received for the physical activity–related Instagram posts	0.05	0.01	–0.04	–0.13	—
***P* value**					
Exercise identity	—				
Weekly PA[a] minutes at moderate to high intensity (MET[b] ≥3/week)	.001	—			
Percentage of physical activity–related Instagram posts	.01	.86	—		
Percentage of verified fitness-related Instagram following	.01	.14	.23	—	
Average number of "likes" received for the physical activity–related Instagram posts	.75	.95	.78	.43	—

[a]PA: physical activity.

[b]MET: metabolic equivalent of task.

Mediation Analysis: Exercise Identity, Percentage of Physical Activity–Related Instagram Post, and Physical Activity

Exercise identity significantly influenced the relationship between the percentage of PA-related Instagram posts and PA levels (indirect effect: 3.28, 95% CI 0.54 to 8.11; direct effect: –3.65, 95% CI –9.70 to 2.39). As indicated in Table 3, a unit increase in percentage of PA-related Instagram posts was associated with a 0.10-unit increase in exercise identity; a unit increase in exercise identity was associated with 34 minutes of

PA (MET ≥3/week) increase. Approximately 29% of the variance was accounted for by the predictors (R^2=0.29).

Table 3. Mediation analyses of the effects of exercise identity on Instagram use and physical activity levels.[a]

Effects	B	95% CI	β	*P* value
Instagram PA[b]photos—PA levels (MET[c] ≥3/week)[d]				
Path a: Instagram PA photos—exercise identity	0.10	0.01 to 0.18	.33	.02
Path b: Exercise identity—PA levels	34.0	11.66 to 56.36	.51	<.01
Path c: Instagram PA photos—PA levels	–3.65	–9.70 to 2.39	–.18	.22
Instagram PA following—PA levels (MET ≥3/week)[e]				
Path a: Instagram PA following—exercise identity	3.18	1.02 to 5.33	.48	<.001
Path b: Exercise identity—PA levels	29.34	7.16 to 51.52	.44	.01
Path c: Instagram PA following—PA levels	32.75	–129.17 to 194.68	.06	.68
Instagram PA "likes"—PA levels (MET ≥3/week)[f]				
Path a: Instagram PA "likes"—exercise identity	0.02	–0.01 to 0.06	.21	.17
Path b: Exercise identity—PA levels	28.6	6.75 to 50.47	.43	.01
Path c: Instagram PA "likes"—PA levels	0.28	–2.06 to 2.61	.04	.81

[a]Model covariates include age, gender, B (unstandardized beta), and β (standardized beta).

[b]PA: physical activity.

[c]MET: metabolic equivalent of task.

[d]Indirect effect: 3.28 (95% CI 0.54 to 8.11); direct effect: –3.65 (95% CI –9.70 to 2.39).

[e]Indirect effect: 91.9 (95% CI 36.93 to 174.82); direct effect: 60.53 (95% CI –115.15 to 236.21).

[f]Indirect effect: 0.69 (95% CI –0.10 to 2.28); direct effect: 0.28 (95% CI –2.06 to 2.61).

Mediation Analysis: Exercise Identity, Fitness-Related Instagram Followings, and Physical Activity

Exercise identity significantly influenced the relationship between the percentage of verified fitness-related Instagram following and PA level (MET ≥3/week; indirect effect: 91.9, 95% CI 36.93 to 174.82; direct effect: 60.53, 95% CI –115.15 to 236.21). A unit increase in percentage of fitness-related Instagram following leads to a 3.18-unit increase in exercise identity; a unit increase in exercise identity was associated with an increase of 29.34 minutes of PA (MET ≥3/week; Table 3). Approximately 26% of the variance was accounted for by the predictors (R^2=0.26).

Mediation Analysis: Exercise Identity, Physical Activity–Related Instagram "Likes," and Physical Activity

Exercise identity did not significantly influence the relationship between the average number of "likes" received for the PA-related Instagram posts and PA level (MET ≥3/week; indirect effect: 0.69, 95% CI –0.10 to 2.28). We did not observe a significant direct effect between the number of "likes" received on PA-related Instagram posts and PA minutes (direct effect: 0.28, 95% CI –2.06 to 2.61; Table 3).

Discussion

Principal Findings

The objectives of this study were to explore whether participants were willing to share their Instagram data with researchers to predict their lifestyle behaviors and examine the relationship among PA-related Instagram metrics, exercise identity, and PA. We found that the majority of participants were willing to share their Instagram data for monitoring lifestyle behaviors. We also found that only PA-related Instagram posts and fitness-related followings were significantly associated with an increase in exercise identity. Furthermore, we found that exercise identity significantly influenced the relationship between certain Instagram use metrics (eg, PA-related Instagram posts and fitness-related followings) and PA level. To our knowledge, this is one of the first studies to examine the relationship among Instagram use, exercise identity, and PA levels. The methods and the findings from this study can be used to inform future infodemiology PA-related studies.

Our results suggest that over 50% (41/76, 54%) of the users were willing to share their Instagram data for monitoring their PA and health-related behaviors. This observation was supported by our hypothesis. It was worth noting that participants that agreed to share their data reported significantly higher weekly PA minutes at moderate to high intensity (MET ≥3/week) compared with participants who were not willing to share their data. A potential explanation is that those who were less active felt guilty for not showing consistent behavior with their social media posts. Individuals may not always portray their real selves on social media sites due to factors such as lower self-esteem, self-reflection, and self-concept clarity [48]. Alternatively, those participants may feel being monitored or judged for what they were posting, given the purpose of this study [27,49]. Concerns over privacy were the main reasons for not sharing their Instagram data. Unlike Twitter data, Instagram data are not

publicly available by default, and the users mainly share pictures instead of text. Thus, this poses a limitation to remain anonymous when analyzing Instagram photos. Our findings reinforced the ethical challenges faced in using social data for public health monitoring. There is a need to establish "best-practice" standards for analyzing social media data while simultaneously acknowledging peoples' individual rights and respecting their privacy [50,51]. Previous studies have shown that users are more likely to accept the use of social media data for research if there is an oversight body that protects user data to ensure that their data are not being used beyond the intended purpose and that user data can remain anonymous to protect the identity of the user [52,53]. Overall, these privacy considerations need to be addressed for the future development of social data monitoring technology.

Based on the self-perception theory [24] and past research [25,26], we hypothesized that PA-related Instagram use would be positively associated with exercise identity and that exercise identity would mediate the relationship between PA-related Instagram use and PA minutes. Interestingly, we observed that only the percentage of PA-related Instagram posts and fitness-related followings were positively associated with exercise identity. Exercise identity also significantly influenced the relationship between these Instagram usage metrics and PA level (MET ≥3/week). Exercise identity did not influence the relationship between the number of "likes" and PA level. Previous research has demonstrated that social media "likes" can contribute to PA engagement [54,55]. The Instagram "likes" metric is unlike the number of followings and posts metrics because users do not have direct control over the number of "likes" received. The lack of consistency of our findings compared with previous literature may be attributed to the way individuals are using their Instagram in our sample. "Surveillance users" (eg, users focused on monitoring other users) may post lesser often and have a lesser number of followers, leading to a lower number of "likes" compared with "cool-ness users" who are motivated to become popular [56,57]. Thus, the types of users need to be taken into consideration for future studies.

Findings from this study have several implications for PA promotion research. First, Instagram may have the potential to target identity antecedents through the reception of both inspirational and informative posts about exercise from respected verified fitness accounts (ie, enhancing self-efficacy and congruency with the self) [58-60]. Based on the self-perception theory [24] and self-definition model [21], future PA promotion interventions using Instagram may target personal investment, perceived commitment (ie, engaging with relevant fitness groups/users), social activation (ie, contributing and receiving support from fitness groups/users), and self-expression (ie, share photos of their PA or fitness-related experiences or write about these activities using social media), as these may play a role in strengthening an individual's exercise identity and subsequent PA behaviors [22,24]. However, it is worth noting that Instagram as a medium for expressing one's PA behavior with the end goal being to strengthen individuals' exercise identities may only be appealing to certain segments of the population. Second, results from this study extend previous Infodemiology research that Instagram data may be used to provide insights into health-related outcomes [39]. Future studies can build upon the methods used in this study and may also explore other Instagram metrics (eg, frequency of post) in PA infodemiology studies. Finally, PA researchers can leverage these social media analysis techniques to build prediction tools to monitor PA on a population level in real time. These tools may in the future aid public health agencies in identifying particular PA-related trends in various geographical areas on which to focus health and wellness initiatives.

There are potential negative aspects associated with using Instagram for the purpose of promoting PA and forming or strengthening one's exercise identity that must be considered. For example, recent movements known as "fitspiration" and "fitspro" have become popular on Instagram to inspire and motivate others to eat a healthy diet and exercise regularly. Fitspiration provides many positive attributes, such as accountability for exercising and education about fitness [61]. However, some women sharing fitspiration posts on Instagram may indicate disordered eating and exercise behaviors [62]. Despite the potential of using Instagram to motivate adherence to a healthy lifestyle, it is important for future interventions to consider the potential negative effect of social media on mental and physical health. Future studies need to examine ways to create a positive environment where participants feel comfortable posting pictures of their exercise experience and journey to fitness.

In terms of the limitations of the study, our sample only included university students which may limit the ability to generalize our findings beyond our sample. Future studies should examine the relationship between social media posts and PA-related behavior in middle-aged and older adults. Another limitation is that we used a list of verified fitness-related Instagram account in our analysis. It is possible that users may follow fitness-related Instagram accounts that are not verified and did not make it onto our list. Thus, this means that the observed relationship between exercise identity and the percentage of the fitness-related Instagram following needs to be interpreted with caution. Self-report questionnaires may result in confirmation bias. Moreover, it may be possible that some users' may have deleted photos, and thus affecting the number of PA-related photos in our analysis. Finally, the lack of longitudinal data for exercise identity and PA levels was another limitation when conducting mediation analysis. Thus, the mediation analysis result needs to be interpreted with caution. Future study with longitudinal data is needed to build more complex multivariate models to better examine mediation effects.

Conclusion

This study examined the relationships among Instagram use, exercise identity, and PA levels. Findings from this study demonstrated that over 50% (41/76, 54%) of participants were willing to share their Instagram data with researchers for the purpose of monitoring and predicting PA behaviors. Exercise identity significantly influenced the relationship between Instagram use (eg, PA-related Instagram posts and fitness-related followings) and PA level. Results from this study suggest that there is an association between Instagram posts and PA-related

outcomes (ie, exercise identity and PA levels). Future studies should examine whether Instagram may be used for a future intervention to help form or strengthen an individual's exercise identity, particularly if the individual can be supported by their "social world."

Acknowledgments

We acknowledge Henry La and Si Ning Yeo for their assistance in coding the physical activity–related posts. This study is supported by the Internal Research Project Grant at the University of Victoria.

Abstract

Background: Approximately 5%-10% of elementary school children show delayed development of fine motor skills. To address these problems, detection is required. Current assessment tools are time-consuming, require a trained supervisor, and are not motivating for children. Sensor-augmented toys and machine learning have been presented as possible solutions to address this problem.

Objective: This study examines whether sensor-augmented toys can be used to assess children's fine motor skills. The objectives were to (1) predict the outcome of the fine motor skill part of the Movement Assessment Battery for Children Second Edition (fine MABC-2) and (2) study the influence of the classification model, game, type of data, and level of difficulty of the game on the prediction.

Methods: Children in elementary school (n=95, age 7.8 [SD 0.7] years) performed the fine MABC-2 and played 2 games with a sensor-augmented toy called "Futuro Cube." The game "roadrunner" focused on speed while the game "maze" focused on precision. Each game had several levels of difficulty. While playing, both sensor and game data were collected. Four supervised machine learning classifiers were trained with these data to predict the fine MABC-2 outcome: k-nearest neighbor (KNN), logistic regression (LR), decision tree (DT), and support vector machine (SVM). First, we compared the performances of the games and classifiers. Subsequently, we compared the levels of difficulty and types of data for the classifier and game that performed best on accuracy and F1 score. For all statistical tests, we used α=.05.

Results: The highest achieved mean accuracy (0.76) was achieved with the DT classifier that was trained on both sensor and game data obtained from playing the easiest and the hardest level of the roadrunner game. Significant differences in performance were found in the accuracy scores between data obtained from the roadrunner and maze games (DT, *P*=.03; KNN, *P*=.01; LR, *P*=.02; SVM, *P*=.04). No significant differences in performance were found in the accuracy scores between the best performing classifier and the other 3 classifiers for both the roadrunner game (DT vs KNN, *P*=.42; DT vs LR, *P*=.35; DT vs SVM, *P*=.08) and the maze game (DT vs KNN, *P*=.15; DT vs LR, *P*=.62; DT vs SVM, *P*=.26). The accuracy of only the best performing level of difficulty (combination of the easiest and hardest level) achieved with the DT classifier trained with sensor and game data obtained from the roadrunner game was significantly better than the combination of the easiest and middle level (*P*=.046).

Conclusions: The results of our study show that sensor-augmented toys can efficiently predict the fine MABC-2 scores for children in elementary school. Selecting the game type (focusing on speed or precision) and data type (sensor or game data) is more important for determining the performance than selecting the machine learning classifier or level of difficulty.

Introduction

Background

Motor development is crucial in child development. Acquiring motor skills is not only essential for daily life functioning but also influences children's cognitive and social development [1]. Fine motor skills are a strong predictor of school results [2]. Motor skill development is not a fixed linear process. Every child has his/her unique learning curve and pace, and their motor skills develop by leaps and bounds [3]. Because of this unique and unpredictable motor development path, it is important to monitor children's motor development over time instead of assessing them once. That way, insight in the progress of their motor development can be given [3,4]. Children with fine motor development problems have difficulties with learning fine motor skills. They experience, for instance, problems with school tasks such as writing or cutting or daily life activities such as closing a zipper or tying shoelaces [4]. In total, 5%-10% of children in elementary school have developmental motor problems [5,6]. When monitoring children's motor development over time, these motor development problems can be recognized at an early stage. Consequently, appropriate diagnostic methods and required therapy could be started in time, which may diminish the effects of their motor development problems.

Both worldwide and in the Netherlands, the Movement Assessment Battery for Children Second Edition (MABC-2) is the major test for assessing children's motor development [5,7]. The MABC-2 consists of both tests for fine and gross motor skills. Finishing the fine motor skill part of the MABC-2 (fine MABC-2) takes approximately 15 minutes per child and requires a trained supervisor [7]. Elementary school would be a natural place to test children's motor skills since developmental motor problems affect cognitive development and school results and vice versa. Proficient fine motor skills are, for instance, essential for children to learn handwriting [8]. However, teachers in elementary school report that they do not have the required expertise and time to test all children, let alone to monitor them all over time.

Sensor-augmented toys and machine learning have been presented as possible solutions for the problems that teachers experience with the current assessment methods [9,10]. Both sensor data, regarding movements made with the toy, and game data, regarding events that occur in the game, can be collected while playing. Such a sensor-augmented toy can, for instance, measure the smoothness of movements made with the toy or how accurately a game was played. These data can be used to train machine learning algorithms in predicting children's motor skill levels. After training and testing those machine learning algorithms, they can be used to classify whether children have fine motor development problems or not. Thus, sensor-augmented toys can be used as an assessment tool for signaling fine motor development problems in children.

Using sensor-augmented toys for indicating fine motor development problems in children has many advantages. First, these toys do not require a trained supervisor and require less instruction time. Moreover, such toys provide more secure data collection compared to manually collected data. Furthermore, playing games can safely be considered to be more enjoyable for children than standard assessment methods. Last, since no trained supervisor is required and children can easily play with the toys in the classroom, the toys enable testing in a natural setting instead of a testing environment. By playing games in such a natural setting, the assessment can be kept implicit and, therefore, children are not aware of undergoing the assessment [11].

Related Work

Despite the advantages of evaluating children's fine motor skills with sensor-augmented toys and machine learning, limited research is done in this field. Gamification of assessment processes in other contexts such as cognitive assessments has been studied before [12]. The systematic review of Lumsden et al [12] shows that many gamified cognitive assessments have been validated successfully. Although gamification in the field of health and well-being is popular, most studies focus on promoting physical activity levels, mental health, and people with a chronic disease [13,14]. Only a few studied gamification in the context of motor skills and most of them involved training instead of assessment [15,16]. Moreover, most of those studies involved patients with motor problems that were primarily caused by medical conditions such as cerebral palsy or stroke. Those children are already seen by medical specialists who monitor their motor development. In contrast, our study involved children who may have a delay in their motor skill development but do not have such diseases.

To the best of our knowledge, only 3 studies involved smart toys for assessing children's fine motor skills [17-19]. Vega-Barbas et al [17] only performed a usability and feasibility test with smart toys that are potentially helpful for assessing motor skills, but they have not used it for assessment yet. The remaining 2 studies did use toys to evaluate children's fine motor skill levels, but both involved toddlers instead of elementary school children. Moreover, they did not build a classification model that might predict the outcome of current motor skill assessment tests. Rivera et al [18] studied the intraindividual variability. Guitiérrez García et al [19] did build a regression model, but this model has not been tested and used to classify the fine motor skill level based on the sensor data yet. In addition to the sensor data that both studies included, we will also include game data, that is, data about events that occur in the game, to study its additional value.

In preliminary research, we studied the possibilities to use sensor-augmented toys for fine motor skill assessment [9,10]. We studied whether a toy called the Futuro Cube could be used

to predict the outcome of the fine MABC-2 [9]. While a game was played with the toy, information regarding events occurring in the game was registered. In addition to these game data, sensor data were collected by measuring the movements of the toy with accelerometers inside the toy. These sensor data and game data were used as input for several supervised machine learning models, which then were used to classify the motor skill level of children. Our previous study showed that a machine learning model that uses sensor and game data of the Futuro Cube as input has the potential to classify the fine motor skill levels of children aged 7-8 years.

Objective of This Study

In this study, in which a larger number of children participated, we improved our toy and game compared to that used in our preliminary research. First, we explored whether additional sensor features would improve the results. Second, we studied a game in which children could choose their own pace in the game since such elements are also included in the fine MABC-2. Therefore, we added a gyroscope to the toy to collect rotational data in addition to acceleration data. Moreover, we designed an additional game that focusses on precision instead of speed. Based on these modifications, we will answer the following research question: *What is the influence of the classification model, game, type of data, and level of difficulty (LoD) on predicting the fine MABC-2 scores for children aged 6-9 years with playing games with the Futuro Cube?*

Methods

Recruitment

Children were recruited through their elementary school teachers. Since we required a sufficient number of participants having motor development problems for balanced class labels, we included 2 elementary schools in Amsterdam that were known for having a larger population of children with motor development problems. Children who were between the age of 6 and 9 years and who were in the 3rd or 4th year of elementary school were included. Fine motor development is important for handwriting education. In the Netherlands, handwriting education starts in the 3rd year of elementary school and is a very important part of the 4th year of elementary school. Teachers of those classes reported that they need to know whether children's fine motor development is proficient to start such education. Therefore, we chose not to include children in classes higher than the 4th year of elementary school. Pilot tests of our game showed that the explanation of the game was too hard for some children younger than 6 years. To make sure that all children understood how to play games with the toy, we chose not to include children younger than 6 years. Written informed consent was obtained from parents or legal guardians for participation of the child. A separate informed consent was acquired for publication of the pseudonymized raw data. In total, written informed consent for participation was given for 99 children and written informed consent for publication of the raw data was given for 49 children. A pseudonymized data set consisting of the sensor and game data of these children and their corresponding fine MABC-2 scores is available on request from the corresponding author. This study was performed according to the Declaration of Helsinki [20].

Procedures

Test Setup

Each child was tested for 25 minutes. The fine MABC-2 was taken in 15 minutes by a trained supervisor. Further, the child played 2 different games on the Futuro Cube. Each game started with a short instruction, followed by a warming-up phase in which the child was able to become familiar with the game. Half of the participants started with the fine MABC-2 and subsequently played with the toy. For the other half of the participants, the order was the other way around: first playing with the toy and subsequently performing the fine MABC-2.

Determining the Level of Fine Motor Skills

The subscale for the measurement of fine motor skills of the MABC-2 was used to determine the fine motor skill level of the children. The fine MABC-2 test consists of 3 subtests. In the first subtest, children had to place 12 pegs in a board with 12 holes. In the second subtest, children had to thread a lace back and forth through a lacing board with holes. Both the first and second subtests were time-sensitive. The child was told to perform the task as quickly as possible and the time to complete the task was denoted as the raw score of those subtests. In the last subtest, children had to draw a trail with a pencil. They had to draw a single line and were not allowed to cross the trail's boundaries. This subtest was not time-sensitive and the raw score consisted of the number of errors, that is, the number of times that the drawn line crossed the boundaries [7]. The raw scores of each subtest were summed to a raw total score. Based on the age of the participant, the raw total score was converted to a percentile score. This score, between 0 and 100, indicates the fine motor skill level of the participant compared to that of the children within the same age band. The higher the score, the better the fine motor performance of the participant compared to children of the same age. According to the MABC manual, a score in the 16th percentile or lower was defined as likely to have fine motor development problems. All scores in the 17th percentile or above were defined as not having fine motor development problems.

Toy and Games

The Futuro Cube, which is shown in Figure 1, is a commercial toy that was adapted for research [21]. The cube has 9 colored lights on each side. The accelerometer and gyroscope inside the cube track motion, sense rotation, and measure orientation. The cube is 52×52×52 cm with 9 colored light-emitting diodes (LEDs) on each side. Each square can be identified by a unique index number $i \in \{0, \ldots, 53\}$. This index number can be used to register the activation of an LED, including the color. The toy contains a tri-axial accelerometer with an acceleration sensitivity of ±8G and a tri-axial gyroscope with an angular rate sensitivity of 2000 dps. Based on these inertial measurement unit sensors, the orientation and the change of position can be recorded. Data collected with these sensors will be referred to as sensor data. The programming language PAWN2 was used for creating the games that are played with the toy. In the programmed script, we defined which information about events

that occur during a game should be saved, for example, the change of color of an LED during the game. Saved data about the game will from now on be referred to as game data. While playing, both the game data and the abovementioned sensor data were registered. Bluetooth low energy was used to wirelessly send all data in real time from the cube to a computer with a sample frequency of 110 Hz. In both games, a highlighted dot was moving on the cube's surface by activating the colored LEDs. In the first game, called the roadrunner game, the focus was on speed. The second game, called the maze game, focused on precision. In both games, no points were collected and neither visual nor auditory feedback was given about how well the game was played. In the roadrunner game, the velocity of the moving dot was predetermined and the child had to follow this speed. In the second game, however, the child was asked to move the dot as precisely as possible through the path without being tied to a certain pace.

Figure 1. Futuro cube.

In the roadrunner game, a green dot moved on the surface of the cube. The player was asked to rotate the cube in order to keep the spot on the top surface of the cube, which is shown in Figure 2. The dot moved with a certain velocity on the cube surface jumping from LED to LED. In case the spot was at the center LED of a side, it randomly turned left or right or kept moving forward. The velocity at which the spot moved was defined as the LoD. This game had 3 LoDs: LoD $\in$ {0,1,2}. The lower the level, the longer the spot remained at the same place. Thus, level 0 was the easiest level and level 2 was the hardest level. The time that the spot remained at the same index number was denoted as the delay in seconds. The LoDs correspond to a delay $d \in \{0.8, 0.6, 0.4\}$. Each level lasted for 30 seconds and occurred twice. Hereby, it has to be taken into account that each player started with the easiest level and 2 subsequent levels could not have the same LoD. The order of the LoDs was randomized and the game started with a warming up phase of 60 seconds to discover the game. Table 1 shows all 10 possible permutations along with their order of LoDs.

Figure 2. Schematic overview of the roadrunner game. A-D: show the way the cube should be rotated to keep the green dot in the correct position. E-H: show what happens in case the cube was not rotated at all.

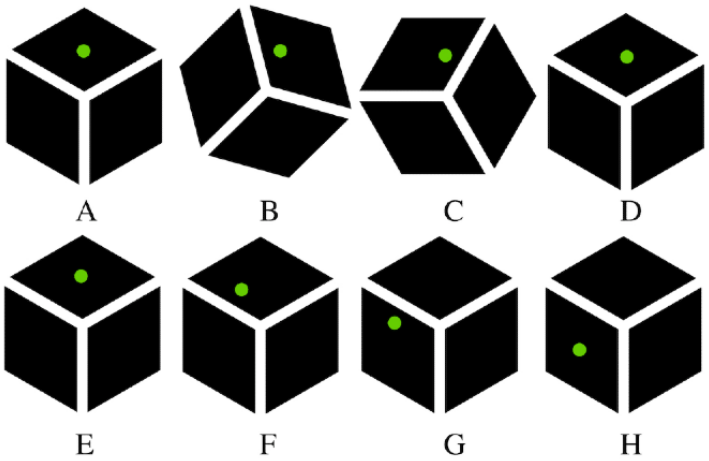

Table 1. All possible permutations for the roadrunner game.

Permutation	Order of levels of difficulty	Participants (n)
0	0, 1, 2, 0, 1, 2	10
1	0, 1, 2, 0, 2, 1	10
2	0, 1, 2, 1, 2, 0	10
3	0, 1, 2, 1, 0, 2	10
4	0, 2, 1, 0, 1, 2	10
5	0, 2, 1, 0, 2, 1	9
6	0, 2, 1, 2, 0, 1	10
7	0, 2, 1, 2, 1, 0	10
8	0, 1, 0, 2, 1, 2	7
9	0, 2, 0, 1, 2, 1	9

The goal of the maze game was to move a white dot through a maze of green dots, as is shown in Figure 3. The dot could be moved by rotating the cube. In case the player moved the white dot on a location that was green and thus not allowed to enter, the dot turned red. When the player moved the white dot back on the right track, the red dot returned green. The path that the players were asked to walk through with the white spot was created by displaying green LEDs on the cube at certain index numbers. The game had 2 different levels of difficulty, indicated by the index numbers that turned green and thus were not allowed to enter with the white dot: LoD $\in \{0, 1\}$. Level 0 was the easiest level. Here, the player only had to push the white dot around the corner of the toy in the middle of a side. In the hardest level, pushing around the corner of the toy could also have to take place at the edges of the cube. A schematic overview of both levels of the maze game is shown in Figure 4. The path in the maze was infinite and each level lasted for 60 seconds. Similar to the roadrunner game, each level occurred twice and the real levels were preceded to a warming up phase of 60 seconds. No permutations could be made to randomize the LoDs since there were only 2 LoDs; each game started with the easiest level and 2 subsequent levels could not have the same LoD.

Figure 3. Schematic overview of the maze game. A-C: show the way the cube should be rotated to correctly move the white dot through the maze. D: shows what happens in case the white dot was moved to a location wherein it was not allowed to enter.

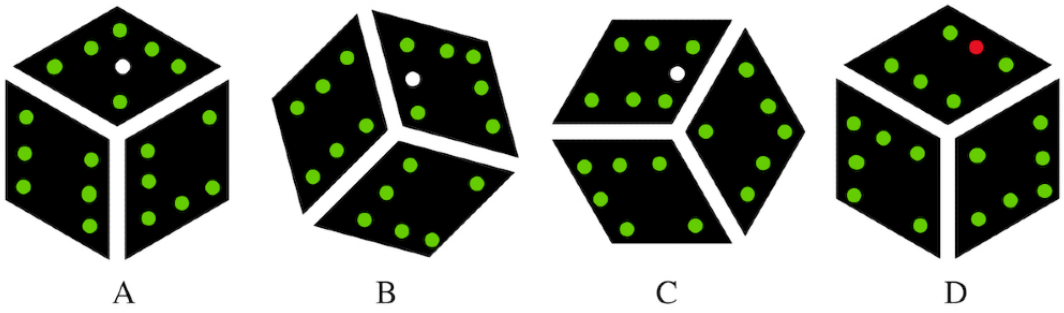

Figure 4. Schematic overview of the levels of the maze game. A: easiest level (level 0); B: hardest level (level 1).

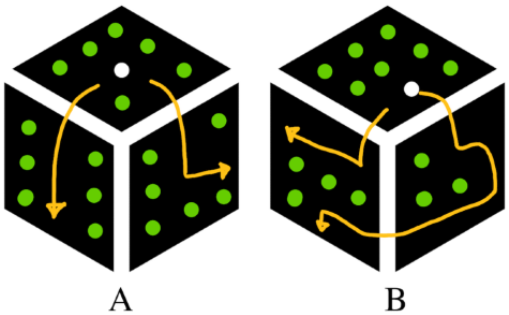

Features

Before constructing features from the sensor data, we filtered the raw sensor data. Both the acceleration data and gyroscope data were filtered with a low-pass filter with a cut-off frequency of 4 Hz. The so-called feature jerk was calculated as the derivative of the acceleration and indicates the smoothness of the translational movements. To indicate the smoothness of the rotational movements, the derivative of the angular velocity was calculated. For each game, we have built 1 game feature.

The game feature for the roadrunner game is the cosine similarity. This feature indicates how accurately a player kept the green moving dot on the top surface of the cube. The cosine similarity indicates the similarity between the location of the dot and the location of the top of the cube. The cosine similarity has a range of –1 to 1, with –1 meaning opposite orientations and 1 meaning identical orientations. Thus, for the roadrunner game, a cosine similarity value of 1 indicates that the player kept the cube exactly in the preferred position regarding the location of the green dot. For the maze game, the game state feature is the maze correctness. This feature indicates the time that the white dot was on the correct path.

We added gender and age of the participant as general features to the sensor and game features. Table 2 shows all the features together with its meaning in the context, which game the feature applies to, and what type of feature it is. For each game, the data of the warming-up phase (ie, the first 60 seconds of each game) were removed since the warming up was intended to familiarize the participant with the toy and was not part of the assessment. The mean value of a variable over time (eg, mean acceleration, mean jerk) and standard deviation were calculated for each sensor and game feature. Thus, we constructed 8 sensor features, 2 game features, and 2 general features per game.

Table 2. Overview of all the features.

Feature name	Meaning in context	Game	Type of feature
a	Total acceleration (m/s^2)	Both	Sensor
ω	Total angular velocity (rad/s)	Both	Sensor
Jerk	Smoothness of the translational movements, derivative of a	Both	Sensor
α	Smoothness of the rotational movements, derivative of ω	Both	Sensor
Cosine similarity	Accuracy of keeping the green dot at the preferred position	Roadrunner	Game
Maze correctness	Time being on the correct path	Maze	Game
Gender	Gender	Both	General
Age	Age in years	Both	General

Classification Models

Four different supervised machine learning algorithms were compared: k-nearest neighbor (KNN), logistic regression (LR), decision tree (DT), and support vector machine (SVM). LR and DT were selected because they provide interpretable models, which is important for teachers who will use the toy in their classrooms. KNN and SVM were chosen because they are known to have good performance with nontextual data, of which SVM often performs well with relatively little data [22]. The labels that were used for training and testing the classification model were the binary outcomes of the fine MABC-2. A child who was likely to have fine motor skill development problems according to the fine MABC-2 was denoted as 1, while a child not having fine motor skill development problems according to the fine MABC-2 was labeled as 0. The performance of the classification model was analyzed with stratified 49-fold cross validation [23]. Since our data set is relatively small, we chose to perform cross validation to prevent overfitting. Because the data set included 49 children with label 1, we performed 49-fold cross validation to maximize the use of the available data. Ideally, the distribution of class labels is almost equal in the training and test set. Stratified cross-validation enables this ideal distribution while performing cross validation [24]. Since our data set consisted of approximately as many children with label 1 as children with label 0, each test set of a fold consisted of one child with label 1 and one child with label 0. The label of each child was used as a test set in at least one fold because we performed 49-fold cross validation and the data set contained 49 children with label 1. Since the data set included 46 children with label 0, the data of 3 children were reused in the test set of another fold to enable stratified cross-validation.

Comparing Performances

In the first analysis, the games and classifiers were compared. We trained and tested 4 different machine learning algorithms on all features of the roadrunner game and all features of the maze game. We used accuracy to indicate the percentage of the correctly classified cases. As an additional performance metric, we used the F1 score since it considers both precision and recall and these are both important in an assessment tool. Precision indicates the proportion of cases labeled positive that were actually correct, whereas recall indicates the proportion of actual positive cases that were labeled correctly. Wilcoxon tests were performed to show whether the best performing classifier performed significantly better than the other 3 classifiers. Moreover, Wilcoxon tests were performed to show the differences between the roadrunner game and the maze game for each classifier. For all statistical tests, we used α=.05. The game and classifier that performed best were used in the second analysis. Here, we compared the LoDs and the type of input features. For each possible combination of LoDs of the roadrunner game, we trained and tested the best performing classifier on the sensor features, the game features, and both sensor and game features. The general features such as age and gender were always included as classifier input. Wilcoxon tests were performed to show whether the best performing combination of the levels performed significantly better than the other combinations of levels. Furthermore, Wilcoxon tests were performed to show whether there were differences between the type of features for the best performing combination of levels.

Results

Participant Characteristics

In total, 95 children (52 girls and 43 boys) participated. Their mean age was 7.8 (SD 0.7) years. Based on the fine MABC-2 scores, 49 children showed problems with their fine motor skills, while 46 children did not have fine motor skill problems. Thus, the group of children having fine motor skill problems according to the fine MABC-2 score and the group of children not having fine motor skill problems were almost equal in number. Since we deliberately included urban elementary schools having a larger population of children with motor skill problems, this ratio is higher than the typical percentage of 5%-10% of the children having motor skill problems [5,6].

Effects of the Games and Classifiers

The DT classifier with only features of the roadrunner game as input performed best with a mean accuracy score of 0.68 and a mean F1 score of 0.65. The corresponding mean recall score was 0.74. The DT classifier also performed best for the maze game with a mean accuracy score of 0.52, a mean F1 score of 0.44, and a mean recall score of 0.51. For all classifiers, the highest mean accuracy and mean F1 scores were achieved with features of the roadrunner game used as input. An overview of all mean accuracy and mean F1 scores per game and machine learning algorithm is shown in Figure 5.

Although the DT classifier achieved higher accuracy and F1 scores than the other 3 classifiers for both the roadrunner and the maze games, no significant differences were found. All results of the performed Wilcoxon tests to study differences between the DT and the other classifiers are shown in Table 3.

Figure 5. Mean accuracy and mean F1 scores for the comparison of the classifiers and games. DT: decision tree; KNN: k-nearest neighbor; LR: logistic regression; SVM: support vector machine.

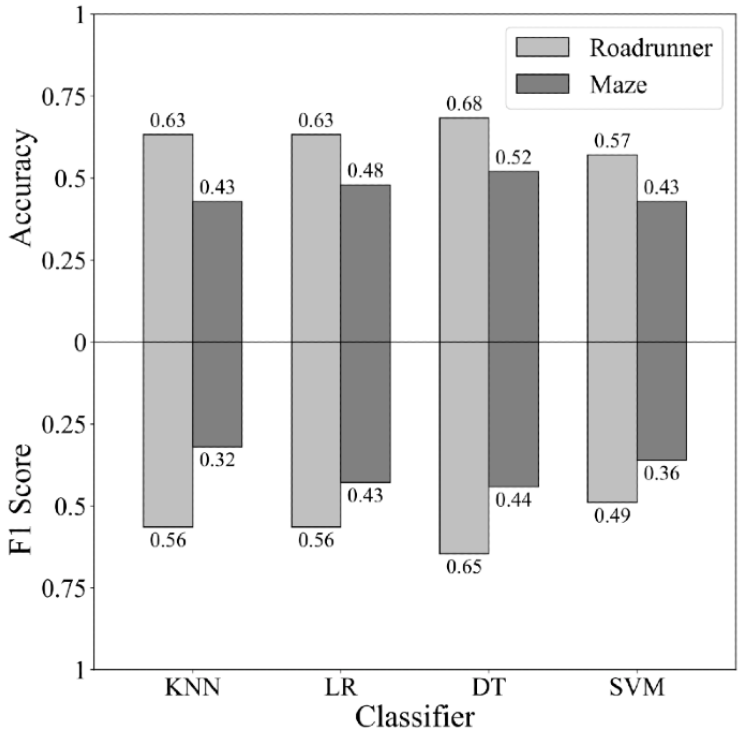

Table 3. Results of the Wilcoxon tests when the performance scores of the decision tree classifier were compared with those of the other classifiers.

Classifier	Accuracy (*P* value)		F1 score (*P* value)	
	Roadrunner game	Maze game	Roadrunner game	Maze game
k-nearest neighbor	.42	.15	.41	.14
Logistic regression	.35	.62	.18	.90
Support vector machine	.08	.26	.08	.23

Each classifier performed significantly better on accuracy with data obtained from playing the roadrunner game than with that obtained from playing the maze game (DT, *P*=.03; KNN, *P*=.01; LR, *P*=.02; SVM, *P*=.04). Except for the SVM classifier, each classifier also performed significantly better on the F1 score with data obtained from playing the roadrunner game than with data obtained from playing the maze game (DT, *P*=.02; KNN, *P*=.01; LR, *P*=.049). Table 4 shows all the results of the performed Wilcoxon tests to show differences between data obtained from playing the roadrunner game and the maze game.

Table 4. Results of the Wilcoxon tests when the performance scores of the roadrunner game were compared with those of the maze game for all classifiers.

Classifier	Accuracy (*P* value)	F1 score (*P* value)
Decision tree	.03[a]	.02[a]
k-nearest neighbor	.01[a]	.01[a]
Logistic regression	.02[a]	.049[a]
Support vector machine	.04[a]	.20

[a]Differences were statistically significant at $P<.05$.

Influence of the Game Levels and Features

The DT classifier with features of only the roadrunner game as input was used to compare the types of input features and combinations of levels since the combination of this classifier and game performed best in the first analysis. The highest mean accuracy, being 0.76, was achieved with a combination of data obtained from playing level 0 and level 2 and a combination of both sensor and game features. The corresponding mean F1 and recall scores were 0.67 and 0.71, respectively. The best mean F1 score, being 0.70, was achieved with the combination of level 1 and level 2 and only using game features. The corresponding mean accuracy and recall scores were 0.65 and 0.80, respectively. Figure 6 shows an overview of all mean accuracy and mean F1 scores per combination of levels and type of input features achieved with the DT classifier and data of the roadrunner game. Since the combination of data obtained from playing levels 0 and 2 with both sensor and game features achieved the highest mean accuracy, we compared levels 0 and 2 with the other combinations of levels. The combination of level 0 and level 2 only performed significantly better than the combination of level 0 and level 1 when both sensor and game features were used as input (P=.046). All results of the performed Wilcoxon tests to study differences between the combination of levels with both sensor and game features used as input are shown in Table 5.

Figure 6. Mean accuracy and F1 scores for the comparison of the levels and types of input features.

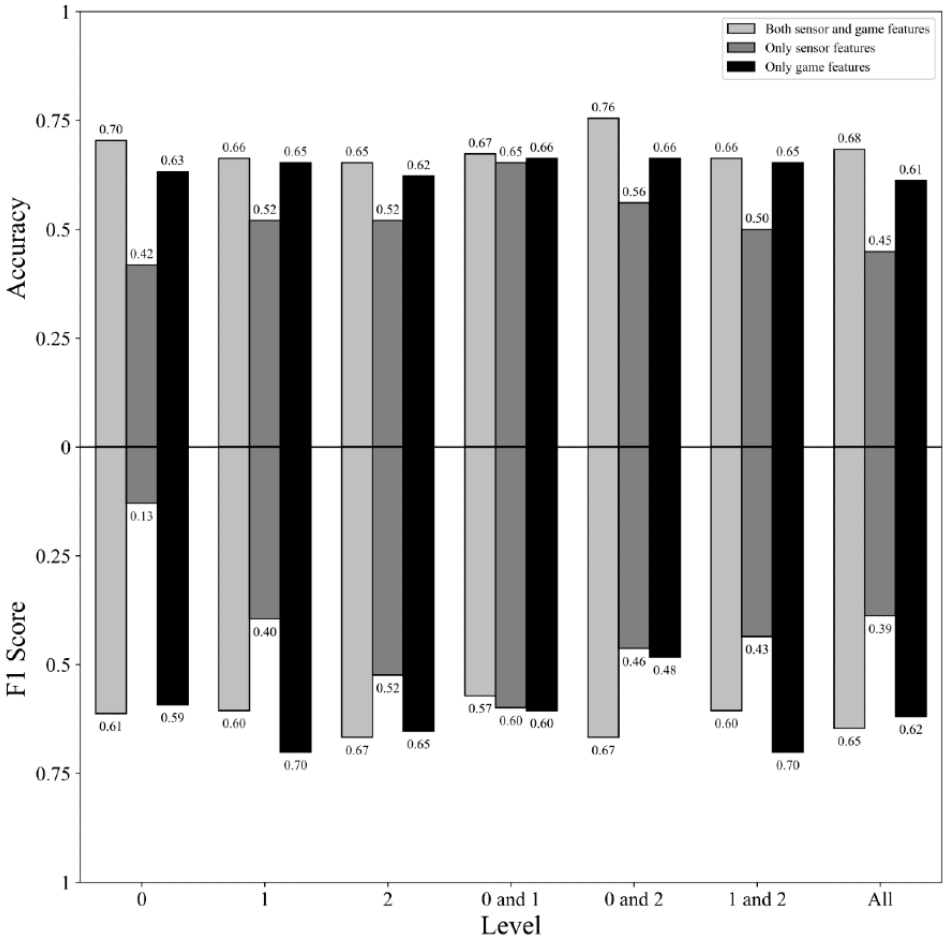

Table 5. Results of the Wilcoxon tests when the performance scores of game level 0 and level 2 were compared with those of the other levels.[a]

Game level	Accuracy (*P* value)	F1 score (*P* value)
Level 0	.38	.54
Level 1	.21	.52
Level 2	.11	.92
Level 0 + 1	.046[b]	.10
Level 1 + 2	.21	.52
Level 0 + 1 + 2	.20	.81

[a]In all cases, decision tree was used as the classifier and both sensor and game features of the roadrunner game were used as input.

[b]Differences were statistically significant at $P<.05$.

For all combinations of levels, the combination of both sensor and game features performed better regarding accuracy than only one of those features. When zooming in on the best performing combination of levels, that is, level 0 and level 2, we found a significant difference in the accuracy and F1 scores between using both types of features and using only sensor features (accuracy, $P=.001$; F1 score, $P=.01$). The results of the performed Wilcoxon tests to study differences between the type of input features for the combination of level 0 and level 2 are shown in Table 6.

Table 6. Results of the Wilcoxon tests when the performance scores of the types of input features were compared.[a]

Input feature	Accuracy (*P* value)	F1 score (*P* value)
Both features versus only sensor features	.001[b]	.01[b]
Both features versus only game features	.18	.06
Sensor versus game	.10	.91

[a]In all cases, decision tree was used as the classifier and both data from game level 0 and level 2 were used for the input features.

[b]Differences were statistically significant at $P<.05$.

Discussion

Principal Results

By comparing the classifiers and games, we learned that the game focusing on speed was more suitable for predicting the motor skill level than the game focusing on precision. Data obtained from playing the roadrunner game led to significantly better performances than data obtained from playing the maze game. Thus, adding the game focusing on precision did not improve our preliminary results. The important contribution of the roadrunner data to the classification performance may be explained by the fact that speed is an important component in the MABC-2 as well. Two out of 3 subtests of the fine MABC-2 are time-sensitive. These findings correspond to the results of Rivera et al [18], who showed that the time for completing a task was an important component for intraindividual variability with their tested sensor-augmented toy.

By comparing the types of data and the LoDs, we learned that the combination of both sensor and game features was the most suitable for predicting the motor skill level. For the combination of data obtained from playing level 0 and level 2, using both sensor and game features led to a significantly better performance than only using sensor features. Although the contribution of the sensor features to the performance was shown to be little, the addition of the gyroscope data led to improved results compared to our preliminary results [9]. The significant difference between using both sensor and game features and only using sensor features for the best performing combination of levels is interesting. This means that the game component of the assessment approach is not only beneficial for playfulness but it also plays an important role in the prediction of the motor skill level itself together with the sensor data. An interesting follow-up project could be to generate additional game features or design more speed-based games and study how they affect the prediction of the fine MABC-2 score. The fact that no significant differences were found between the DT classifier and the other 3 classifiers indicates that the selection of input features has more impact on the performance than the selection of the classifier. Although the DT classifier did not perform significantly better, it is preferred over the KNN and SVM algorithms since it gives insight into the classification process. This is an important characteristic for the teachers who will use the toy in their classrooms.

Strengths, Limitations, and Opportunities

The best achieved accuracy of 0.76 and F1 score of 0.70 on predicting the label of the fine MABC-2 are promising for assessing children's motor skills with sensor-augmented toys. Since the cube is easy to use in the classroom, it is relatively easy to collect data. Therefore, the current approach might not only be useful for one-time assessment but could also be used for monitoring. Although we predicted the outcome of the fine MABC-2 and this assessment indicates whether children have fine motor development problems or not, we cannot state that we can predict children's fine motor skill level with playing games with the Futuro Cube. To do so, we should repeat our research and replace the fine MABC-2 labels with expert view

labels of the motor skill level. Moreover, assessment with the Futuro Cube only indicates whether children might have fine motor development problems in general. However, fine motor development is complex and consists of several aspects. Important factors are, for instance, cognitive ability, anticipatory control, motor planning function, and spatial ability [4]. Since all of these factors are included in the tasks of the fine MABC-2, we included them in the games of the Futuro Cube as well. Thus, our toy only signals motor development problems in general but does not assess specific aspects of motor development. In case the assessment tool showed that a child was likely to have fine motor development problems, follow-up examination is required to investigate individual aspects or causes of fine motor development problems.

The current approach might not only be useful for assessment but might also be useful as a first screening tool. In that case, children who are not likely to have motor problems are already being filtered out with the results of the game. A valid and reliably fine motor skill assessment test such as the fine MABC-2 can be taken for the children who were likely to have fine motor skill problems based on the game results. That way, not all children have to take the fine MABC-2 test, and the false positives of the assessment with the toy can be filtered out afterwards.

Another promising opportunity of the Futuro Cube is using it for training instead of monitoring. Developing a valid and reliable assessment toy will take some time, but playing with the Futuro Cube might also be useful for training purposes. Children could train their fine motor skills while playing games with the toy. This could be valuable for both children with motor skill problems without having specific disorders as well as children with, for instance, cerebral palsy or fine motor problems after a stroke. For learning, fun is an important factor since it improves intrinsic motivation and focus [25]. It is shown that gamified training is highly engaging and boosts the motivation of players [12]. Therefore, such a playful way of training their motor skills would be a valuable addition to the current methods. When the toy is ready for assessment, it could also be used to monitor progress in therapy or rehabilitation of such children. Since data are wirelessly sent in real time to a computer, such training opportunities could be improved by making the game adaptive. The level could be fitted to the child's capacities, which improves the attention span and motivation. In this study, we focused on predicting the outcome of the fine MABC-2, but we did not include feasibility and usability in our approach. Although we did not study playfulness for children and usability for teachers in our approach, both children and teachers were very enthusiastic and their informal responses were, without exception, positive.

Conclusions

This study examined the possibilities of using sensor-augmented toys to assess children's fine motor skills. Such toys are less time-consuming and more playful and motivating than the current assessment methods. Compared to our preliminary research, we added the gyroscope for extra sensor data and an extra game that focused on precision instead of speed. With the best achieved accuracy of 0.76 and F1 score of 0.70, we showed that sensor-augmented toys can efficiently predict the outcome of the fine MABC-2 score. The selection of features is more important for the performance than the selection of the machine learning classifier. Classifiers that used input features obtained from playing the game focusing on speed performed significantly better that classifiers that used input features obtained from playing the game focusing on precision. Although our findings are a good start, further research is needed to develop a reliable and valid playful assessment tool. Possible improvements may be generating more game features, designing more speed-based games, and making the LoDs adaptive. Such adaptive games may also be valuable for training or rehabilitation purposes.

Acknowledgments

We thank all the children and teachers who participated in this study. Moreover, we thank Jan Krejsa for his valuable contribution to this study. This study is part of the research project Smart Play Sets, funded by COMMIT.

Abstract

Background: Outside of a clinical setting, oscillometric devices make remote monitoring of blood pressure and virtual care more convenient and feasible. HeartBeat Technologies Ltd developed a novel approach to measuring blood pressure remotely after an initial blood pressure reading by a nurse using the conventional measurement method. Using a finger pulse oximeter, a photoplethysmogram wave is transmitted by Bluetooth to a smartphone or tablet. A smartphone app (MediBeat) transmits the photoplethysmogram to a server for analysis by a proprietary algorithm—the person's current blood pressure is sent back to the smartphone and to the individual's health care provider.

Objective: This study sought to determine whether the HeartBeat algorithm calculates blood pressure as accurately as required by the European Society of Hypertension International Protocol revision 2010 (ESH-IP2) for validation of blood pressure measuring devices.

Methods: ESH-IP2 requirements, modified to conform to a more recent international consensus statement, were followed. The ESH-IP2 establishes strict guidelines for the conduct and reporting of any validation of any device to measure blood pressure, including using the standard manual blood pressure instrument as a comparator and specific required accuracy levels for low, medium, and high ranges of blood pressure readings. The consensus statement requires a greater number of study participants for each of the blood pressure ranges. The validation of the accuracy of the algorithm was conducted with a Contec CMS50EW pulse oximeter and a Samsung Galaxy XCover 4 smartphone.

Results: The differences between the HeartBeat-calculated and the manually measured blood pressures of 62 study participants did not meet the ESH-IP2 standards for accuracy for either systolic or diastolic blood pressure measurements. There was no discernible pattern in the inaccuracies of the HeartBeat-calculated measurements.

Conclusions: The October 4, 2019 version of the HeartBeat algorithm, implemented in combination with the MediBeat app, a pulse oximeter, and an Android smartphone, was not sufficiently accurate for use in a general adult population.

KEYWORDS

blood pressure measurement; remote monitoring; hypertension

Introduction

Accurately assessing blood pressure is necessary for the proper diagnosis of hypertension, implementing treatments and monitoring whether those treatments are working [1,2]. To measure blood pressure accurately, standardized measurement techniques, calibrated equipment, and valid interpretation of readings are necessary [2-4]. Aneroid sphygmomanometers that are properly calibrated and maintained are considered to be at

least as accurate as mercury-filled sphygmomanometers [5]. However, such instruments are not convenient for remote monitoring or virtual (remote) care because they can be difficult for a person to self-administer.

A novel approach to measuring blood pressure remotely has been developed (HeartBeat, HeartBeat Technologies Ltd). The measurement is taken after an initial blood pressure reading using the conventional measurement method, supplemented by specific characteristics of a person (age, gender, height, weight, and heart rate) to establish a baseline for the person. Unlike other devices [6-9], this approach uses a finger pulse oximeter that detects the changes in blood volume directly below the person's skin and indirectly measures oxygen saturation in the blood. The resulting photoplethysmogram (PPG) wave is transmitted by Bluetooth technology to a smartphone or tablet. The MediBeat (HeartBeat Technologies Ltd) smartphone or tablet app then transmits the PPG wave to a server where a proprietary algorithm analyzes the baseline measurement for the person and the PPG waveform to calculate the person's current blood pressure. The blood pressure measurement is then transmitted to the person's smartphone, and if applicable, to the person's health care provider's devices.

The purpose of this study was to test whether the accuracy of the HeartBeat algorithm, available as of October 4, 2019 and for a general adult population (ages 25 years and older), was sufficient to seek regulatory approval when compared with a standard aneroid sphygmomanometer with stethoscope for measuring blood pressure.

Methods

Protocol

The European Society of Hypertension International Protocol revision (ESH-IP2) for the validation of blood pressure measuring devices in adults [10] was followed, with modifications to account for additional guidance from an international consensus statement [11]. ESH-IP2 [10] requires strict adherence to its method and reporting requirements, which are reflected in this report: to "ensure a uniform distribution of test pressures across a representative range," 33 participants must be enrolled. Among the 33 participants, at least 10 must be male and 10 must be female; all should be at least 25 years of age; and between 10 and 12 participants must have blood pressure readings within each of the following recruitment ranges—systolic blood pressure: below 130 mmHg, between 130 and 180 mmHg, above 180 mmHg; diastolic blood pressure: below 80mmHg, between 80 and 130 mmHg, above 130 mmHg. All potential participants must be screened against these criteria and can be excluded if the gender criteria or age criteria are not met, or if including them in the study would exceed the maximum number of participants in any of the recruitment ranges.

An international consensus statement group [11] reviewed the adequacy of the number of participants in a variety of established protocols, including that of the ESH-IP2, and recommended that, to increase the power and accuracy of validation studies, at least 85 participants, rather than 33, should be included. To align with the consensus statement, the research team recalculated the ESH-IP2 requirement numbers to reflect the increased participant pool of 85. The recalculations are reflected in the tables and discussion in this report.

Devices

The pulse oximeter (Contec CMS50EW, Contec Medical Systems Co Ltd [12]) used to capture and transmit PPG is shown in Figure 1. The 8-bit Contec pulse oximeter is approved for use by Health Canada [13] and the US Food and Drug Administration [14]. The smartphone used in this study (upon which HeartBeat's MediBeat app was installed and used to transmit the data to HeartBeat servers and to receive and display the results) was a Samsung Galaxy XCover 4 (Figure 2).

Figure 1. Contec CMS50EW.

Figure 2. Samsung Galaxy XCover 4.

Recruitment

Potential participants were recruited by mass email and offline posters at a single-site multistory office building in Markham, Ontario, Canada, where they worked; participants provided informed consent (Multimedia Appendix 1) and were scheduled for a measurement appointment during their working day by a member of the research team.

Procedure

Three registered nurses who had training and expertise in blood pressure measurement carried out the measurements required for this study between October 4, 2019 to November 22, 2019. One nurse was the supervisor, and two nurses were the observers throughout the duration of the study. The nurses were trained as per ESH-IP2 directives and were instructed on how to follow the protocol guidelines for data collection. Blood pressure measurements were recorded to the nearest 2 mmHg.

Two new sphygmomanometers (Prosphyg 775 Model, American Diagnostics Corporation [15]), whose components were checked against one another and calibrated before the study, were used as the reference instruments by the observers. With respect to reliability and validity, the ESH-IP2 embeds an ongoing reliability mechanism requiring that any individual participants' blood pressure readings be excluded from the analysis if the difference in readings from the two observer nurses differ by 4 mmHg twice. The instruments were placed within one meter of the observers while they interacted with a participant, which allowed the observers to follow the instruments' dials at eye level from 40 mmHg to 180 mmHg. Multiple sizes of bladders (cuffs) were available for the sphygmomanometers to ensure that 80% to 100% of each participant's arm circumference could be encircled. The observers were also supplied with good quality nonelectronic stethoscopes with well-fitted earpieces.

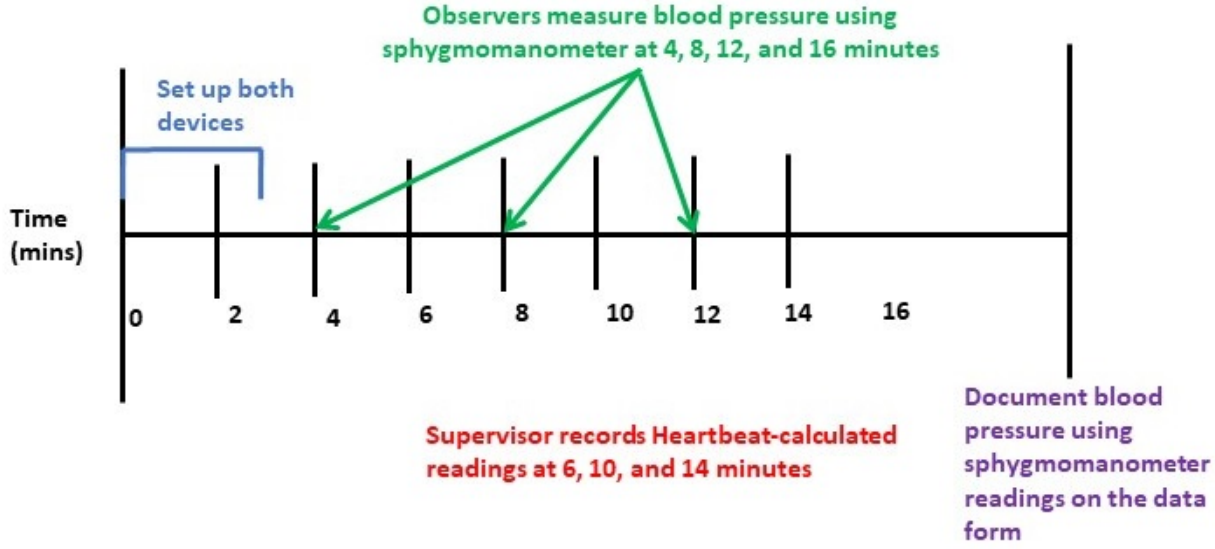
The observers were instructed that, in the event that an abnormal blood pressure reading was detected (for example, if the blood pressure was outside clinically normal range for a specific person), they were to remeasure the blood pressure using conventional means to determine if the abnormal reading was accurate. If the abnormal blood pressure measurement was accurate, the nurse supervisor was to act according professional standards. The abnormal blood pressure measurement should also be recorded on ESH-IP2 Form 2.

Participants' blood pressure measurements were taken in a room that was a comfortable temperature, without any noises or other influences that would have caused disturbances, such as telephones. The temperature in the room was the same as that throughout the building—20 °C to 24 °C. All participants participated in the study between the working hours of 9 AM and 4:30 PM. The pulse oximeter and the supervisor's smartphone were charged and tested each day prior to interactions with participants. The MediBeat app was calibrated for each participant as follows: (1) Reference data for the

individual (year of birth, height, weight, baseline manual blood pressure reading, and heart rate) were entered. (2) The participant rested for 10 minutes while seated comfortably with their legs uncrossed, back supported, and arm resting on the table at heart level. (3) The supervisor attached the finger pulse oximeter to the participant's index finger (on the opposite arm to the manual blood pressure cuff) and waited for a few seconds until a stable signal was received and the device displayed both the participant's pulse and SpO_2 (oxygen saturation) values. (4) Once the values were displayed, the supervisor initiated a new session on the smartphone to connect the phone to the Contec device via Bluetooth. This connection started the 1-minute calibration process, at which point each participant was asked to remain still until the calibration had been completed successfully.

Overseen by an independent supervisor, measurements were recorded by the two observers who were blinded from both the other observer's readings and from the reading calculated by the HeartBeat algorithm. Each participant's blood pressure was measured as illustrated in Figure 3. Each systolic blood pressure measurement and each diastolic blood pressure measurement calculated by the HeartBeat algorithm was compared with the nearest of the previous and next observer systolic and diastolic measurements, respectively, and the difference between each HeartBeat-calculated measurement and the nearest observer measurement was calculated. Every such difference was then classified in one of these error groups for each systolic and diastolic measurements: 0-5 mmHg, 6-10 mmHg, 11-15 mmHg, and >15 mmHg. The results were then compared with the number of tolerable differences allowed by the protocol at both the level of individual measurements (part 1) and at the level of the participants (part 2). The device gets an overall *pass* (an acceptable level of accuracy) if it meets 4 pass criteria.

Figure 3. Timeline of measurement of blood pressure for each participant.



Ethics

The study was reviewed and approved by the Southlake Regional Health Centre Research Ethics Board, Newmarket, Ontario, Canada (007-1920).

Results

A total of 105 individuals volunteered and were screened for the study, of whom 62 participants met the ESH-IP2 criteria, and 43 were excluded (Table 1; adapted version of the CONSORT flow diagram [16] in Figure 4). As required by the protocol, 5 participants out of the 105 were excluded because the differences in the measurements by the observer nurses exceeded 4 mmHg twice for the same participant, 34 were excluded participants were excluded because their blood pressure measurements fell within ranges for which the protocol quota had been fulfilled, and 4 participants were excluded because they were younger than 25 years of age. There was difficulty in recruiting hypertensive participants, that is, individuals with both systolic and diastolic blood pressures in the high ranges. This is reflected in the overall distribution (Figure 5 and Figure 6), in which most of the points fall below 125 mmHg and 90 mmHg, for systolic and diastolic blood pressures, respectively. By the time 105 participants had been recruited, only 2 met the criterion for high systolic blood pressure, and none met the criterion for diastolic blood pressure. The modified criteria would have required between 26 and 31 participants in the high blood pressure group to meet the protocol requirements. A calculation was performed to determine if it would be possible for the algorithm to achieve a pass if additional participants with high blood pressure were recruited, and there were a perfect match between their HeartBeat-calculated measurements and standard measurements. It was determined that such a result was not possible, and recruitment was discontinued. Therefore, the study concluded before the required number of participants was reached. The characteristics of participants are described in Tables 2 and 3.

Table 1. Participants screened, excluded, and recruited for the study.

Reason for exclusion	Excluded, n	Total, n
Participants screened		105
Participants excluded		43
Ranges complete[a]	34	
Range adjustment	0	
Arrhythmias	0	
Device failure	0	
Poor quality sounds	0	
Cuff size unavailable	0	
Observer disagreement[b]	5	
Distribution[c]	0	
Other reasons[c]	4	
Participants recruited		62

[a]Intake assessment placed them in ranges that had already been filled. The ESH-IP2 requires that the last participants to be recruited are the ones who are excluded.

[b]Discrepancy >4 mmHg twice for the same participant; therefore, these participants were, in accordance with the ESH-IP2, excluded from the study.

[c]Age <25 years or older, as required by the ESH-IP2.

Figure 4. Adapted version of the CONSORT flow diagram [16].

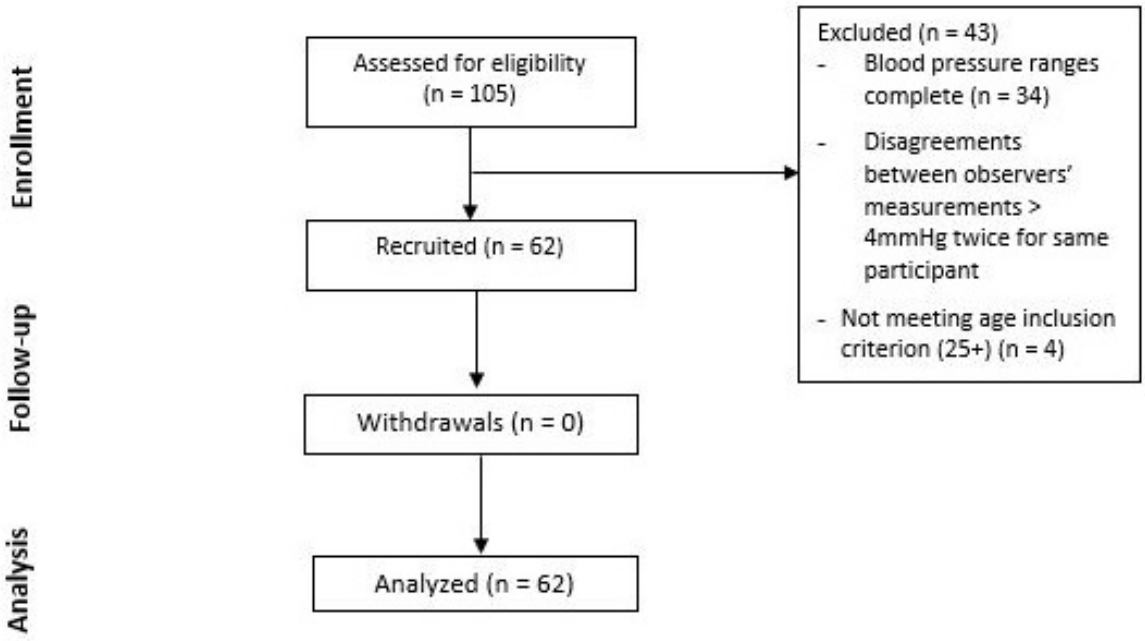


Figure 5. Bland-Altman plot of the differences between the Heartbeat-calculated measurements and the manual measurements of systolic blood pressure.

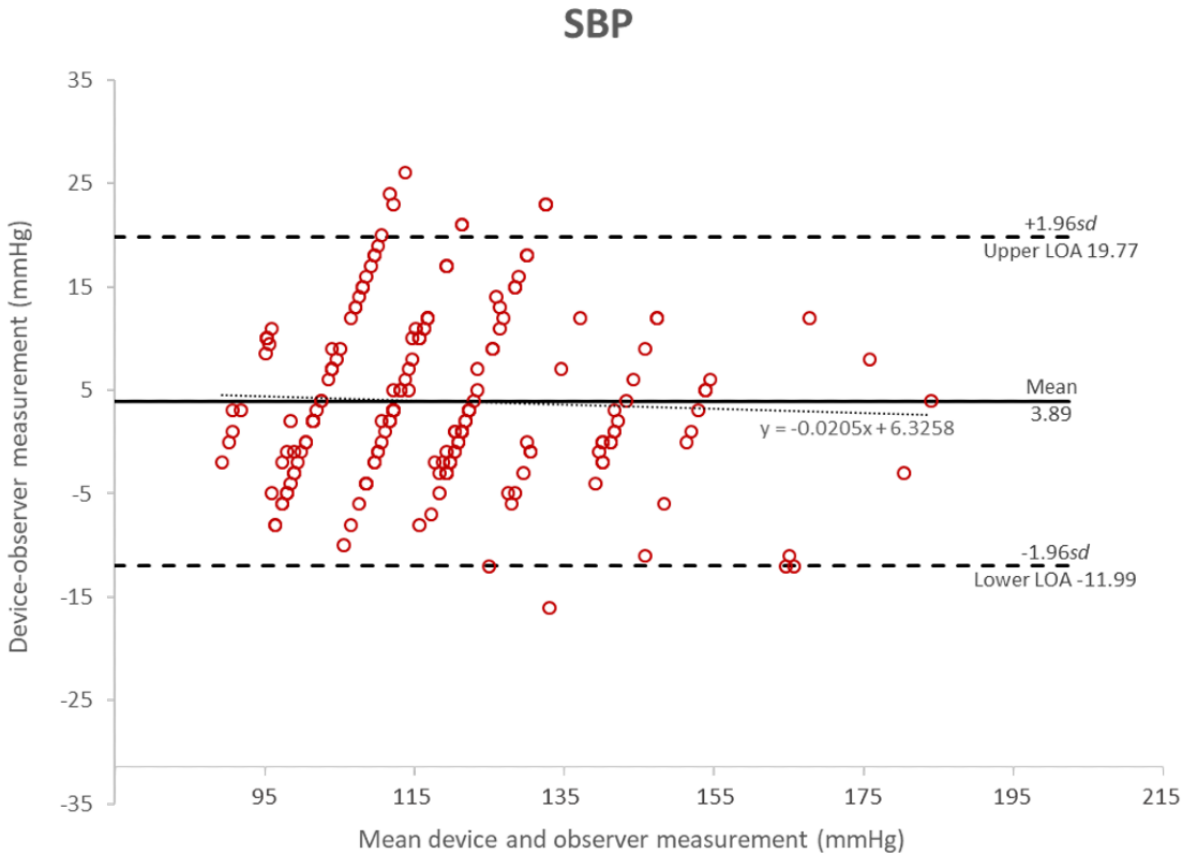

Figure 6. Bland-Altman plot of the differences between the Heartbeat-calculated measurements and the manual measurements of diastolic blood pressure.

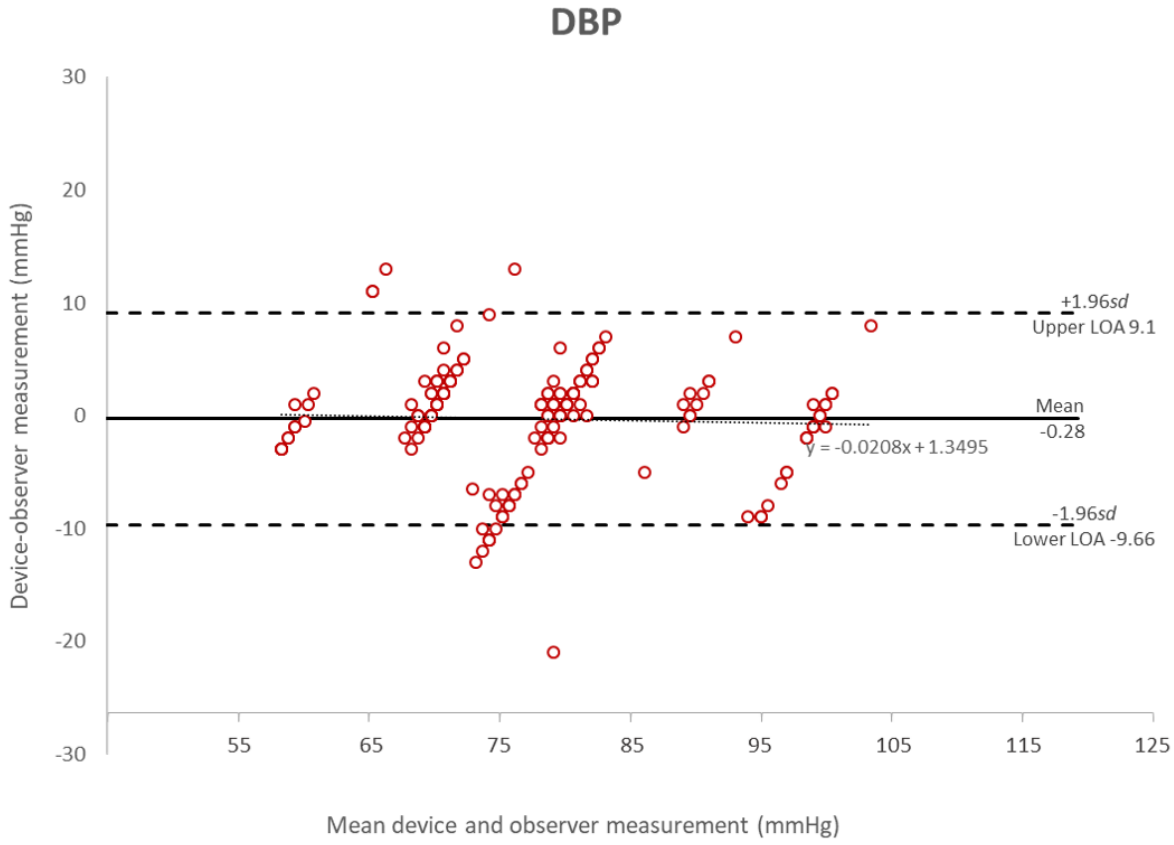

Table 2. Blood pressure and medication details for initially screened participants.

Category	Blood pressure (mmHg), range	Medication[a]	No medication	Total
Systolic blood pressure				
Low-low	<90	0	0	0
Low	90-129	5	40	45
Medium	130-160	7	9	15
High	161-180	1	1	2
High-high	>180	0	0	0
Diastolic blood pressure				
Low-low	<40	0	0	0
Low	40-79	3	30	33
Medium	80-100	10	19	29
High	101-130	0	0	0
High-high	>130	0	0	0

[a]Participants taking medication for hypertension.

Table 3. Participant details.

Category	Value
Sex, n	
Male	13
Female	49
Age (years)	
Mean (SD)	43.5 (11.2)
Range	25-66
Arm circumference (cm)	
Mean (SD)	29.5 (4.2)
Range	23-40
Cuff size used, n	
Small	0
Standard	61
Large	0
Missing data	1
Recruitment blood pressure (mmHg)	
Systolic blood pressure	
Mean (SD)	119.5 (18.9)
Range	90-180
Diastolic blood pressure	
Mean (SD)	77.6 (10.6)
Range	57-110

Table 4 and Table 5 present the blood pressure readings by the international consensus statement's predetermined levels. Table 4 shows the distribution of systolic and diastolic blood pressure readings across the recruited participants in the study. Table 5 shows the range of differences by observers 1 and 2.

Table 4. Blood pressure readings (3 per participant) after the initial screening measurement.

	Overall range (mmHg) (low-high)	Low[a], n	Medium[b], n	High[c], n	Maximum difference among highest and lowest totals in low, medium, and high ranges
Systolic blood pressure	90-180	150	30	6	144
Diastolic blood pressure	60-101	90	75	21	69

[a]Systolic ≤130 mmHg; diastolic ≤80 mmHg.

[b]Systolic 130 mmHg-160mmHg, diastolic 80 mmHg-100 mmHg.

[c]Systolic ≥160 mmHg, diastolic ≥100 mmHg.

Table 5. Observer differences.

	Range (low to high) (mmHg)	Mean (SD)	Repeated measurements
Systolic blood pressure[a]	–3 to 3	0.0081 (0.4)	—[b]
Diastolic blood pressure[a]	–4 to 3	0.0000 (0.6)	—[b]

[a]Measurements are calculated by subtracting observer 1 measurements from observer 2 measurements.

[b]There were no documented repeated measurements to calculate.

Table 6 shows the results in terms of each of the protocol requirements. According to the ESH-IP2 standards, for an acceptable level of accuracy, a device must pass all the protocol requirements in both parts 1 and 2. Note that in this study, the algorithm achieved a pass in only 1 category and a fail in 3 categories, for an overall fail.

Table 6. Validation results.

Protocol requirements	Range, n			Pass or fail
	<5 mmHg	<10 mmHg	<15 mmHg	
Part 1 (N=186[a])				
Required (2 of 3)	At least 137	At least 163	At least 180	
Achieved differences				
Systolic blood pressure[a]	120	147	169	Fail
Diastolic blood pressure[a]	159	180	186	Pass
Required (all)	At least 122	At least 152	At least 175	
Achieved differences				
Systolic blood pressure	120	147	169	
Diastolic blood pressure	159	180	186	
Part 2 (N=62[a])				
Required	At least 45			Fail
Achieved				
Systolic blood pressure	43	—[b]	—	
Diastolic blood pressure	10	—	—	
Allowed	At most 6			Fail
Achieved				
Systolic blood pressure	54	—	—	
Diastolic blood pressure	5	—	—	
Grade 3 (final result)—must pass all of parts 1 and 2				Fail

[a]These reflect the number of readings and participants included in the study when recruitment was stopped.

[b]Not applicable.

Figure 5 shows the Bland-Altman plots [17,18] of the differences in systolic blood pressure measurements between the MediBeat device and the manual observer measurements (*y*-axis) and the average of the 2 measurements (*x*-axis). Figure

6 shows the plots for the differences in diastolic measurements. In both cases, the averages of the 3 MediBeat measurements were plotted against their absolute differences from the manual measurements for both systolic blood pressure (bias 3.89, LOA –11.98 to 19.77) and diastolic blood pressure (bias –0.28, LOA –9.66 to 9.09). Although values fall within the 95% confidence interval for both Bland-Altman plots, there is no statistically significant correlation between the HeartBeat-calculated blood pressure measurements and the manual measurements (systolic blood pressure: r=0.04, P=.53; diastolic blood pressure: r=.04, P=.54). This indicates that the HeartBeat-calculated blood pressure measurements are not sufficiently accurate. There was no discernible pattern in the inaccuracies in the HeartBeat-calculated measures; therefore, the source of the inaccuracies is not known.

Discussion

The Bland-Altman plots show that the October 4, 2019 version of the HeartBeat algorithm, used in conjunction with a Contec CMS50EW pulse oximeter, MediBeat app, and a Samsung Galaxy XCover 4 smartphone, was not sufficiently accurate to meet ESH-IP2 standards for measuring the blood pressure of adults in the general population; therefore, as per the protocol, it is not recommended for personal or clinical use in this configuration.

Acknowledgments

We would like to acknowledge the nurses who conducted the measurements for this study: Favour Onyido, RN, Laura Agborchi, RN, and Valerie Mgbatogu, RN. We would also like to acknowledge the contributions of Brianna Croft, MMI, and Mary Lou Ackerman, MBA, who helped with the logistics of this study, and of Grace Lui, MSc, who helped with the early phase of this study.

Authors' Contributions

PH led the design of the study. KY and EK collected and analyzed the data. All authors contributed to the interpretation of the results and reviewed and edited the manuscript. All authors read and approved the final version of the manuscript.

Conflicts of Interest

Two Contec pulse oximeters were supplied for the purposes of the study by HeartBeat Technologies Ltd. None of the authors have any association with, or have received any personal benefit from, HeartBeat Technologies Ltd.

Abstract

Background: The successful completion of medical practices often relies on information collection and analysis. Government agencies and medical institutions have encouraged people to use medical information technology (MIT) to manage their conditions and promote personal health. In 2014, Taiwan established the first electronic personal health record (PHR) platform, My Health Bank (MHB), which allows people to access and manage their PHRs at any time. In the face of the COVID-19 pandemic in 2020, Taiwan has used MIT to effectively prevent the spread of COVID-19 and undertaken various prevention measures before the onset of the outbreak. Using MHB to purchase masks in an efficient and orderly way and thoroughly implementing personal protection efforts is highly important to contain disease spread.

Objective: This study aims to understand people's intention to use the electronic PHR platform MHB and to investigate the factors affecting their intention to use this platform.

Methods: From March 31 to April 9, 2014, in a promotion via email and Facebook, participants were asked to fill out a structured questionnaire after watching an introductory video about MHB on YouTube. The questionnaire included seven dimensions: perceived usefulness, perceived ease of use, health literacy, privacy and security, computer self-efficacy, attitude toward use, and behavioral intention to use. Each question was measured on a 5-point Likert scale ranging from "strongly disagree" (1 point) to

"strongly agree" (5 points). Descriptive statistics and structural equation analysis were performed using SPSS 21 and AMOS 21 software.

Results: A total of 350 valid questionnaire responses were collected (female: 219/350, 62.6%; age: 21-30 years: 238/350, 68.0%; university-level education: 228/350, 65.1%; occupation as student: 195/350, 56.6%; average monthly income <NT $30,000 [<US $1054.89]: 230/350, 65.7%; residence in northern Taiwan: 236/350, 67.4%; and health status perceived as "good": 171/350, 48.9%). Five indicators, including chi-square test (X^2_{310}=2.63), goodness-of-fit index (0.85), adjusted goodness-of-fit index (0.81), comparative fit index (0.91), and root mean square error of approximation (0.07), were calculated. The results indicated a good fit. Further analysis indicated that the most important factor affecting respondents' behavioral intention to use MHB was their attitude toward use (0.78), followed by perceived ease of use (0.65), perceived usefulness (0.41), health literacy (0.10), and privacy and security (0.07).

Conclusions: From the perspective of the populace, this study explored the factors affecting the use of MHB and constructed an interpretation model with a strong goodness of fit. The results of our analysis are consistent with the technology acceptance model. Through the diverse value-added services of MHB, Taiwan's experience in pandemic prevention with smart technology can facilitate future responses to unknown, emerging infectious diseases.

Introduction

Background

With the rapid development of various information and communication technologies (ICTs), medical institutions now use a variety of digital medical information tools to provide the information needed by patients and medical care providers and allow physicians and patients more time for communication and discussion to make correct medical decisions. Information tools are now regarded as the mainstream way to provide clinical care [1-3]. The digitization of personal health records (PHRs) is a particularly important tool for realizing the goal of patient-centered care [3-9]. PHRs can be collected in different forms for various health management purposes [10]. Compared with electronic medical records (EMRs), PHRs contain other health-related information in addition to medical records, such as social status, family history, and living environment [7,11-15]. Therefore, PHRs were built on the basis of EMRs. As the use of EMRs increases, the use of PHRs will also increase [11].

EMRs are mainly stored in hospital databases and can be accessed by different types of medical personnel but are not easily exchanged between hospitals. In 2004, Taiwan began to develop the basic format of EMRs to promote the digitization of health information. In 2007, Executive Yuan initiated the National Health Informatics Project to promote the development of a health care information infrastructure and create a development environment for health information [16]. In 2008, the Clinical Document Architecture was defined according to the Health Level 7 standard, and the localized EMR format—the Taiwan Electronic Medical Record Template—was created using 108 individual EMR templates, which provided an important foundation for the interhospital exchange of EMRs [7,17,18]. The Taiwanese governments have encouraged medical institutions to use EMRs through policies, regulations, and financial incentives for health care insurance.

Most studies on EMRs have been from the perspective of medical personnel. In a patient-centered paradigm, medical records would belong to the individual patient. Through EMRs, patients can have more control over their medical information. Zarcadoolas et al [5] used a focus group interview to explore the use of patient portals, which are health care–related web applications. Their results showed that most respondents were interested in accessing their own medical records and believed that such access was important in improving health literacy and promoting their own health and that of their family members. In a national study in the Netherlands, representatives of medical centers jointly discussed future medical information policies, among which "patient participation and empowerment" was given the highest score [19]. Therefore, for governments, the patients' acceptance of and intention to use electronic PHRs could influence subsequent policy formulation and must be considered. Owing to the advantages of EMRs, such as reducing medical costs, promoting care quality, and enhancing medical efficacy, many countries have begun to plan and develop EMRs with different formats and applications [20-24]. However, in most cases, patients cannot access and manage their PHR at any time. In view of this, the Ministry of Health and Welfare of Taiwan developed a web-based health information enquiry system, My Health Bank (MHB), in 2014 to allow people to access their personal health information from a computer or smartphone at any time or place [7,24-26].

The first edition of MHB could be used to check outpatient records, emergency records, inpatient records, dental records, traditional Chinese medicine records, disease diagnosis, drug usage, medical expenses, pathological reports, x-ray examinations, allergy histories, and vaccinations, but the interactivity and advanced query capabilities were limited. It also had no images. In other words, it only provided data, not information or knowledge [7,25,26]. Patient portals that present content in simple and easy-to-understand text or images are more in line with people's internet usage habits; in addition, a

user-friendly interface would help improve the utilization rate [5,26-28].

MHB was thus revised in July 2016 with the addition of functions for visualization of medical information, disease management service, and self-health management, as shown in Figures 1-3 [26]. These new functions greatly improved the functionality of MHB and provided diversified health management services. In response to the need for functions specific to COVID-19 prevention, new functions such as preordering masks, maps of masks, and assistance with getting masks were added to MHB in March 2020, as shown in Figure 4 [29]. When the COVID-19 pandemic became severe, people in Taiwan could purchase masks through the MHB app, which not only helped them effectively implement personal protective measures but also helped stabilize public sentiments.

Figure 1. Medical data visualization (screenshot from My Health Bank): People can query information about outpatients (emergency department and hospital) and medical diagnoses over the past 3 years. Statistical results are presented graphically.

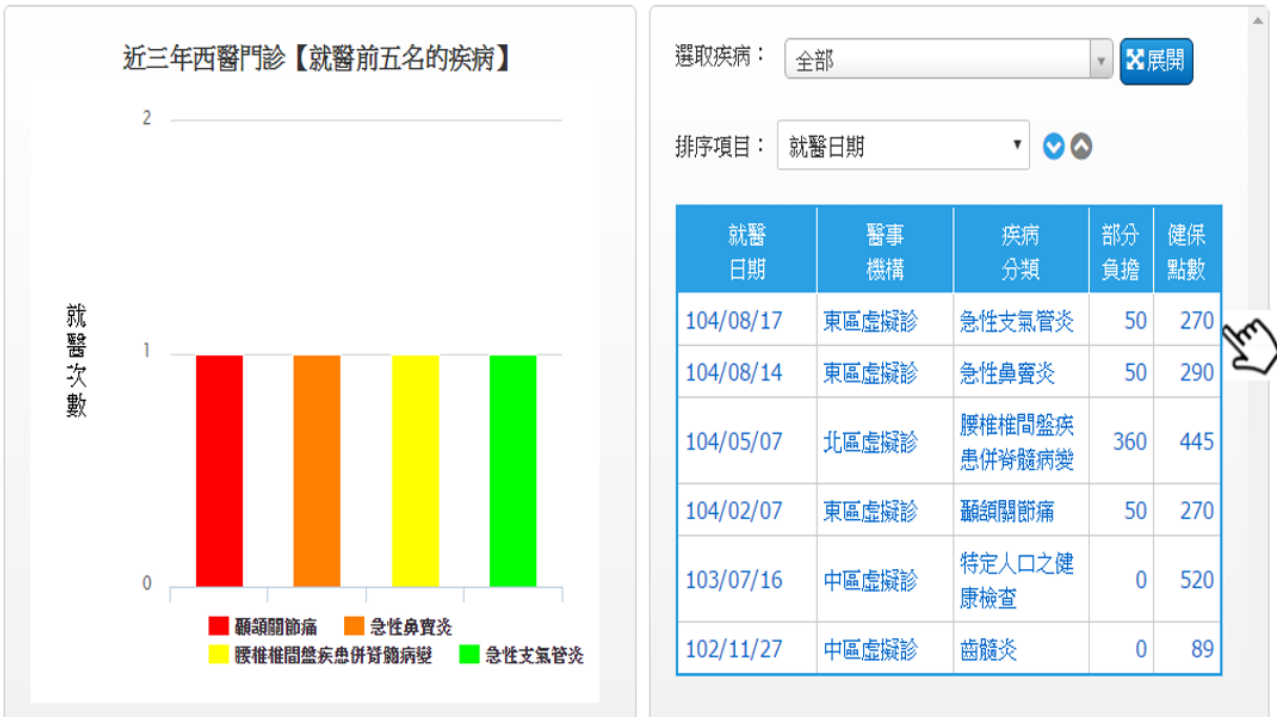

Figure 2. Disease management services (screenshot from My Health Bank): After the user enters their basic information, the system predict the risk of major diseases (eg, hepatic cancer and end-stage renal disease) and then provide links to external websites for further health information queries.

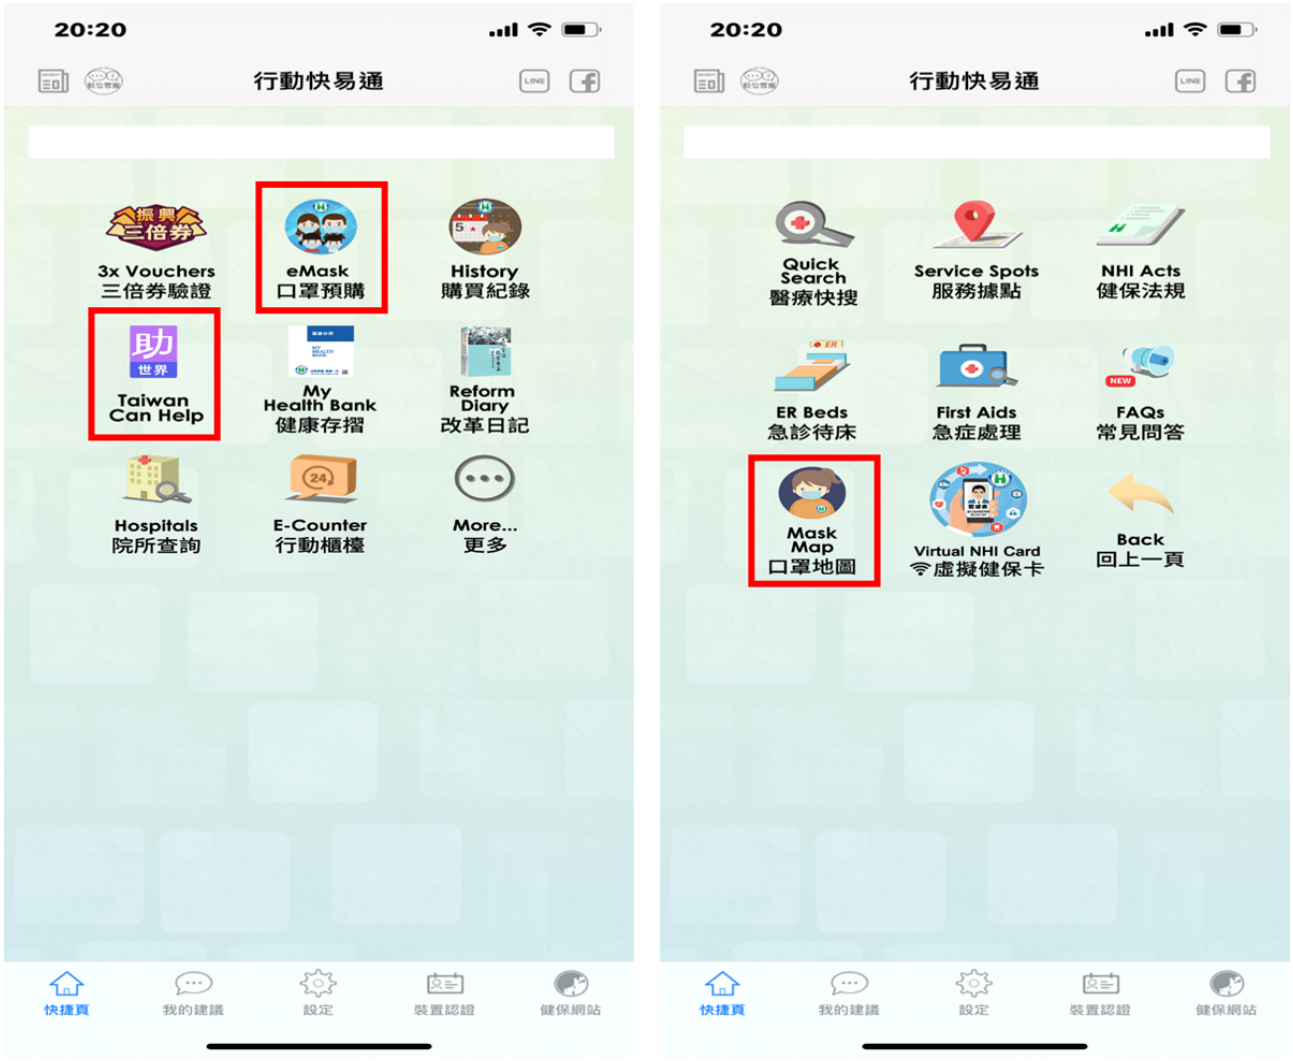
Figure 3. Self-health management (screenshot from My Health Bank): Physiological measurement data, such as height, weight, and blood pressure, are entered and historical trends are monitored. In addition, the system proactively reminds the user about dental cleaning, continuous prescription collection, and health check-ups.

Figure 4. Preordering masks (screenshot from My Health Bank mobile app): Users can log in with their ID or mobile phone number to buy masks, check the stock of masks in nearby drugstores, or even donate their mask quotas to other countries.



Theoretical Foundation

With the development of informatization of the medical industry, the acceptance and use of relevant information technology by clinical medical staff and patients have gradually received attention. The research model used by most researchers is the technology acceptance model (TAM). Although it was not initially developed for use in the medical industry [30,31], this model has become an important theoretical model for studying medical information usage behavior with the expansion of research on the medical industry in recent years [32-40]. In the original TAM, Davis et al [30,31] used three variables: "perceived usefulness," "perceived ease of use," and "attitude toward use" to explain and predict the behavioral intention of users. Because health behaviors are too complex to be explained by a single theory, many researchers use TAM as a foundation in combination with other theories or references to construct theoretical models with better explanatory capabilities in the form of added variables [31,33,36,37,40-46].

According to a literature review by Rahimi et al [45], the original TAM has been extended to suit the dynamic health service environment. TAM has been used to explore three categories of application areas of ICT in the medical service industry: "telemedicine," "electronic health records," and "mobile applications." Researchers have added different variables to the original TAM model according to different ICT application fields, thereby enhancing the explanatory power of the extended model. Health literacy is a predictive factor that has been widely studied in research on health-related behaviors and is also a key factor for the appropriate selection and use of health information [42,47]. Relevant studies have also found that the application of health literacy in TAM is related to perceived usefulness, perceived ease of use, and behavioral intention. A high level of health literacy can increase people's willingness to adopt new health information technology [12,42,48,49].

The health system is a complex social system composed of stakeholders with different backgrounds, experiences, and values [36]. ICT applications allow the system to run smoothly. The storage, retrieval, transmission, and sharing of medical information are closely related to the operation of computer software and hardware [31]. Compeau and Higgins defined "computer self-efficacy" as an individual's ability to use information technology, which plays an important role in shaping personal perception and usage behavior. Computer self-efficacy also affects an individual's perceived ease of use.

Individuals with high computer self-efficacy use computers more often and have less computer anxiety [44,46,50-52]. However, in the process of using medical information technology (MIT), new issues of security and privacy may arise [41]. To solve these security and privacy issues, many countries have not only enacted laws and regulations to protect their citizens' health data [53] but also studied and explored the impact of security and privacy on the use of mobile health (mHealth) systems [41,45,54,55].

This study explores the intention of the Taiwanese people to use MHB and the factors influencing this intention, thus providing a reference for governments to consult when promoting electronic PHRs in the future.

Methods

Study Design

This was a cross-sectional study. To investigate participants' intention to use MHB and the influencing factors, participants were asked to watch a brief introductory video about MHB on YouTube and then fill out a structured questionnaire on Google Forms. The content of the video was how to use MHB, as shown in Figure 5. After a patient goes to hospital A for medical treatment, he or she can log into MHB with their account number, password, or natural person certificate to access five items: basic personal information, hospital visit records, examination records, PHRs, and personal insurance status. This information can be shared with other medical personnel, family members, and insurance companies.

Based on the above study objectives and a literature review, we added three extended variables to the original technology acceptance model: "Health literacy," "Privacy and security," and "Computer self-efficacy." The research framework and hypotheses are illustrated in Figure 6 and described below:

- Hypothesis 1: Perceived ease of use has a positive effect on perceived usefulness.
- Hypothesis 2: Perceived usefulness has a positive effect on attitude toward use.
- Hypothesis 3: Perceived ease of use has a positive effect on attitude toward use.
- Hypothesis 4: Perceived usefulness has a positive effect on behavioral intention to use.
- Hypothesis 5: Health literacy has a positive effect on behavioral intention to use.
- Hypothesis 6: Privacy and security have a positive effect on behavioral intention to use.
- Hypothesis 7: Computer self-efficacy has a positive effect on behavioral intention to use.
- Hypothesis 8: Attitude toward use has a positive effect on behavioral intention to use.

Research Tools

Table 1 shows the questionnaire comprising 33 questions that covered seven dimensions: perceived usefulness, perceived ease of use, health literacy, privacy and security, computer self-efficacy, attitude toward use, and behavioral intention to use. Each question was answered on a 5-point Likert scale ("Strongly agree," 5 points; "Agree," 4 points; "Neutral," 3 points; "Disagree," 2 points; and "Strongly disagree," 1 point).

Before the formal survey, four experts in relevant fields were invited to assess the importance, applicability, and clarity of each question in the questionnaire to confirm that the questionnaire had good external validity. In addition, a pretest was conducted with 30 people to confirm that respondents could understand the questions and answer them clearly.

Table 1. Questionnaire design.

Dimension	Definition	Questions
Perceived usefulness	The usefulness of MHB[a] in managing the PHR[b]	5
Perceived ease of use	The ease of use of MHB in managing the PHR	5
Health literacy	When using MHB, the required ability to process and understand this information service in order to make appropriate medical and health decisions	3
Privacy and security	The awareness of privacy and security issues when using MHB	5
Computer self-efficacy	The basic computer skills required when using MHB	5
Attitude toward use	Public evaluation of MHB	4
Behavioral intention to use	The intention to use MHB	6

Sampling and Exclusion Criteria

From March 31 to April 9, 2014, in a promotion via email and Facebook, internet users were randomly selected to watch the introductory video about MHB and then complete the web-based questionnaire. The size of the valid sample was determined according to the sampling guidelines proposed by Magnani et al [56,57]. The calculated minimum number of valid samples needed for this study was 323. During the collection process, 614 people visited the website, 355 of whom completed the

questionnaire (response rate 57.8%). After excluding duplicate and invalid questionnaire responses, 350 questionnaire responses were collected, which exceeded the minimum number of valid samples needed for this study.

Data Analysis

The data in this study were sorted in Microsoft Excel and then analyzed with SPSS 21 (IBM Corp). The significance level for statistical analysis was set at 5%, that is, $P<.05$. Descriptive statistics, including the mean, SD, median, frequency distribution, and percentage, were used to observe the data distribution of the responses.

Inferential statistics were used to understand the correlations between the characteristics of the respondents and perceived usefulness, perceived ease of use, health literacy, privacy and security, computer self-efficacy, attitude toward use, and behavioral intention to use. AMOS 21 (IBM Corp) was used to test the validity of the dimensions and construct the research model.

Results

Respondent Characteristics

A total of 350 valid questionnaires were collected in this study, and the distribution of the respondents' characteristics is shown in Table 2. Most respondents were female (219/350, 62.6%). The age grouping interval was 10 years, and the majority of the respondents (238/350, 68%) were in the age group of 21-30 years. The majority of the respondents had a university education (228/350, 65.1%), were students (195/350, 55.7%), had an average monthly income lower than NT $30,000 (US $1054.89; 230/350, 65.7%), resided in northern Taiwan (236/350, 67.4%), and had a self-perception of *good* health (171/350, 48.9%).

Table 2. Characteristics of the respondents (N=350).

Characteristic	Value, n (%)
Sex	
Male	131 (37.4)
Female	219 (62.6)
Age (years)	
<20	46 (13.1)
21-30	238 (68)
31-40	56 (16.)
>40	10 (2.9)
Highest education level	
High school degree	8 (2.3)
University degree	228 (65.1)
Graduate school or above	114 (32.6)
Employment	
Student	195 (55.7)
Services	61 (17.4)
Manufacturing	29 (8.3)
Financial industry	7 (2)
Military and police education	47 (13.4)
Unemployed	11(3.1)
Monthly income in NT $ (US $)	
<30,000 (<1054.89)	230 (65.7)
30,001-50,000 (1054.92-1758.15)	94 (26.9)
50,001-70,000 (1758.18-2461.41)	21 (6)
>70, 001 (>2461.44)	5 (1.5)
Living area	
Northern Taiwan	236 (67.4)
Central Taiwan	49 (14)
Southern Taiwan	55 (15.7)
Eastern Taiwan	7 (2)
Offshore islands	3 (0.9)
Health status	
Excellent	28 (8)
Good	171 (48.9)
Normal	132 (37.7)
Poor	19 (5.4)

Measurement Model

This study evaluated the measurement model with internal reliability, convergent validity, and discriminant validity [58]. Internal reliability was evaluated by Cronbach alpha and composite reliability. A value higher than .70 can be regarded as an acceptable level of internal consistency [59]. If the “average variance extracted” (AVE) for a dimension is higher than 0.50, the model is deemed to have reached acceptable convergent validity. Table 3 shows the composite reliability, Cronbach α, and AVE obtained in this study.

Discriminant validity was evaluated by calculating the square root of AVE and cross-loading matrix. When the square root of the AVE is greater than the corresponding correlation, the discriminant validity of the data is confirmed. The calculated values are shown in Table 4.

Table 3. Cronbach alpha, composite reliability, and average variance extracted.

Dimension	Cronbach α	Composite reliability	Average variance extracted
PU[a]	.85	0.82	0.53
PE[b]	.83	0.81	0.52
HL[c]	.82	0.70	0.54

Structural Model

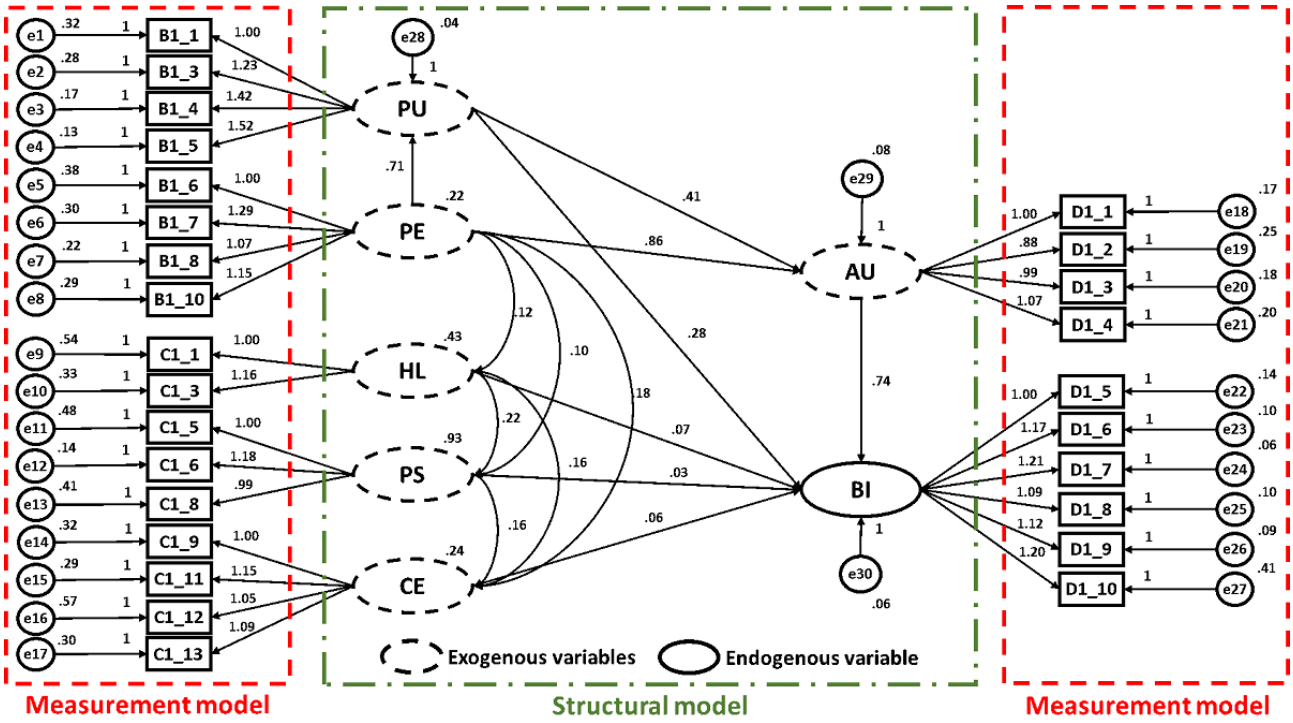
Structural equation modeling is a multivariate statistical technique combining factor analysis and path analysis [60]. In this study, we used structural equation modeling to investigate the relevant factors affecting participants' use of MHB and the importance of each factor [34]. Five indicators were used to assess the overall fit of the model: X^2 (*df*), goodness-of-fit index (GFI), adjusted goodness-of-fit index (AGFI), comparative fit index (CFI) and root mean square error of approximation (RMSEA). As shown in Table 5, X^2_{310}=2.63, which is less than the cutoff of 5 [61]; GFI=0.85 and AGFI=0.81, both of which are higher than the standard value of 0.8 [62,63]; CFI=0.91, which is close to 1 [64]; and RMSEA=0.07 [65]. The above results indicate that the overall fit and fitness of the model are good.

Table 5. Results of overall model fit.

Index	Criteria	Result	Mode fit
Chi-square (*df*)	<5	2.63 (310)	Fit
Goodness-of-fit index	>0.8	0.85	Fit
Adjusted goodness-of-fit index	>0.8	0.81	Fit
Comparative fit index	Close to 1	0.91	Fit
Root mean square error of approximation	• Acceptable: 0.08-0.10 • Good: 0.05-0.08 • Excellent: <0.05	0.07	Good

Structural equation modeling was used to evaluate whether the causal path relationships between the hypotheses proposed in this study were valid. The path diagram is shown in Figure 7, and the standardized estimation results are shown in Table 6. Perceived ease of use explained 74.7% of the variance in perceived usefulness. Perceived usefulness and perceived ease of use explained 67.4% of the variance in attitude toward use, and the other dimensions explained 72.6% of the variance in behavioral intention to use. The above results are the direct effects between the dimensions. To further understand the effects between dimensions other than direct effects, indirect effects were included in the analyses to calculate the total effects. Table 7 shows the standardized direct effects, indirect effects, and total effects of the dimensions.

Figure 7. Path diagram of the research framework. Measured items are illustrated in rectangles (eg, B1_1); latent variables are illustrated in ovals (eg, PU); smaller circles illustrate the error of measurement (eg, e1); associations are illustrated by arrows that indicate the direction of prediction. Factor loadings are noted next to the items. Coefficients are noted for each association (ie, directional arrow). AU: attitude toward use; BI: behavioral intention to use; CE: computer self-efficacy; HL: health literacy; PE: perceived ease of use; PS: privacy and security; PU: perceived usefulness.



In terms of behavioral intention to use, the direct effect of attitude toward use (0.78) was relatively large, whereas perceived ease of use (0.65) and perceived usefulness (0.13) had significant indirect effects on behavioral intention to use. Perceived ease of use had no direct effect on behavioral intention to use, and its indirect effect was much stronger than the direct effects of the other dimensions. Overall, the main factor affecting behavioral intention to use was the attitude toward use, followed by perceived ease of use, perceived usefulness, health literacy, and privacy and security. The test results of all hypotheses were statistically significant except for Hypothesis 5, Hypothesis 6, and Hypothesis 7.

Table 6. Results of path analysis.

Hypothesis	Path coefficient	*t* test (*df*)	*P* value	R^2
H1: Perceived ease of use has a positive effect on perceived usefulness.	0.71	8.24 (310)	<.001	0.747
H2: Perceived usefulness has a positive effect on attitude toward use.	0.41	3.12 (310)	<.001	0.674
H3: Perceived ease of use has a positive effect on attitude toward use.	0.86	5.01 (310)	<.001	__[a]
H4: Perceived usefulness has a positive effect on behavioral intention to use.	0.28	3.49 (310)	<.001	0.726
H5: Health literacy has a positive effect on behavioral intention to use.	0.07	1.83 (310)	.067	—
H6: Privacy and security has a positive effect on behavioral intention to use.	0.03	1.58 (310)	.115	—
H7: Computer self-efficacy has a positive effect on behavioral intention to use.	0.06	0.73 (310)	.468	—
H8: Attitude toward use has a positive effect on behavioral intention to use.	0.74	8.18 (310)	<.001	—

Discussion

Principal Findings

Taiwan has had no local cases of COVID-19 since April 12, 2020, and there has been no second wave of the pandemic in Taiwan, which is mainly due to the effective use of MIT to build a strong pandemic prevention network. For example, an integrated circuit card is used as an insurance certificate to give full play to the functions of smart medical cards. Physicians can log into the health care medical information cloud query system through a health insurance card to quickly obtain the medical information, travel history, and contact history of patients without revealing personal information. During the COVID-19 pandemic, assisting frontline medical personnel in assessing disease risk and taking corresponding infection control measures has been greatly helpful for prevention of disease spread [66]. In addition, in accordance with the policy of real-name mask purchasing, people who have completed identity authentication or mobile phone authentication can use MHB to prepurchase masks and know how many masks are still available to them from the mask purchase map, so they can purchase personal protective equipment more efficiently. The aforementioned innovative information technologies, together with the National Health Insurance and the Central Epidemic Command Center, which conducts daily live broadcasts to explain the pandemic situation and future pandemic prevention policies, has calmed

the unease and anxiety of the people and made pandemic control in Taiwan effective [67].

During the promotion of an innovative medical information service, users might experience the three stages of awareness, want, and adoption. Liang [2] found that there is a digital divide between these three stages. This digital divide differs significantly not only between demographic groups but also depending on personal computer ownership and internet use habits. Therefore, the acceptance of an innovative medical information service by users could play a key role in user attitude and experience [7].

This study found that perceived ease of use had a significant positive effect on perceived usefulness, indicating that the respondents believed that if MHB was easy to use, its effects could be significant. Perceived usefulness and perceived ease of use had significant positive impacts on the attitude toward use, indicating that the respondents believed that if MHB had practical benefits in managing personalized EMRs and was easy to use, they would have a positive attitude toward the use of MHB. Perceived usefulness had a significant positive impact on behavioral intention to use, which means that the respondents believed that if MHB helped them understand their own health conditions, their intention to use MHB would increase. Attitude toward use had a positive effect on behavioral intention to use, indicating that the better the functions of respondent's health records are managed, the higher their intention to use MHB.

Financial and resource constraints on the health care system are increasing due to the aging population and changing disease patterns [68]. To improve the service efficiency of medical institutions and the participation of patients, medical institutions are encouraging patients to make appropriate medical care decisions and undertake health promotion activities through electronic PHRs to control their own health status and achieve the goal of patient-centered care [9,27,69]. Therefore, increasing patients' intention to use electronic PHRs is particularly important. The TAM proposed by Davis et al [30] indicated that perceived ease of use affects perceived usefulness and, thus, intention to use. The results of this study showed that respondents strongly agreed (5="strongly agree," 1="strongly disagree) with the usefulness (mean score 4.42, SD 0.53) and ease of use of MHB (mean score 4.28, SD 0.57), and these two technical or cognitive factors had a significant positive effect on the respondents' attitude toward use and behavioral intention to use concerning MHB. Other studies have shown that both the general public and clinicians are more willing to use a medical information tool if the interface of the tool is designed to be easy to use and can fully realize the benefits of care [18,27,70-72]. MHB has become an extension of the medical treatment process and an important management tool to improve health knowledge and promote the health of people and their loved ones [5].

According to a web-based survey on health issues, 70% of people and 65% of physicians believe that patients can download and manage their personalized digital health information [73]. When people use digital health information tools, in addition to a certain ability to use information devices, they must also be able to understand the health information itself. In theory, with advances in information technology, the effectiveness of various health care services may also increase, but people with low computer self-efficacy and health literacy may not be able to make full use of the information technology, which could further deepen the digital divide [1,4,5,19,28,74]. Therefore, to effectively use personalized digital health information, people should have sufficient health literacy and computer self-efficacy. The World Health Organization defines health literacy as "the achievement of a level of knowledge, personal skills and confidence to take action to improve personal and community health by changing personal lifestyles and living conditions" [75]. In summary, health literacy refers to how people acquire, understand, use, and communicate health-related information [42,49]. Computer self-efficacy is self-judgment and self-confidence in the ability to use a computer and includes both computer operation skills (such as formatting hard disks) and the ability to combine these skills to perform different tasks [52]. In this study, health literacy and computer self-efficacy did not have a significant positive impact on behavioral intention to use MHB, indicating that the respondents' intention to use MHB would not be affected by their own health literacy and computer self-efficacy. Due to advances in information technology and higher education levels, the health literacy and computer self-efficacy of young people are higher than those of older people [5,76-78]. The respondents in this study were mostly young internet users who likely had confidence in understanding, acquiring, and applying relevant health information. Therefore, their levels of health literacy and computer self-efficacy did not affect their intention to use MHB. Nevertheless, the impact of health literacy and computer self-efficacy on the use of medical information tools cannot be ignored.

The promotion and use of various MITs are aimed at improving the quality of care and patient safety, enabling correct medical decision-making, reducing medical costs, improving the accessibility of medical services, and promoting service efficiency [1,2,7-9,18,27,69,74,79-81]. In the context of using these MITs, privacy and security are relatively important issues. Studies have shown that regardless of country or national conditions, people's views on the privacy and security of health information systems are consistent [23,24,73]. Since the discussion of medical privacy is a relatively abstract concept, this study evaluated privacy issues in PHRs from three aspects: information privacy, psychological privacy, and social privacy [82]. Privacy and security had no influence on the behavioral intention to use MHB. Due to the increasing popularity of social media (eg, Facebook, blogs, and Twitter), people care more about the speed of information transmission than about how to protect their privacy [83]; in addition, respondents who have not actually used MHB may have different views on privacy and security. Although our results on privacy and security did not reach statistical significance, the scores of the privacy and security dimension showed that most respondents chose the option "disagree" (mean score 2.45, SD 1.07), indicating that the respondents were still concerned about data privacy and security issues. In the future establishment and promotion of digital PHRs, privacy and security should be given continuous attention [4,6,23,84,85].

In addition, the results of this study show that attitude toward use was the main factor affecting behavioral intention to use (total effect: 0.78), and the Likert scores of the respondents on attitude toward use (mean 4.22, SD 0.56) and behavioral intention to use (mean 4.20, SD 0.56) were positive. The results of our path analysis showed that attitude toward use had a positive effect on behavioral intention to use. Therefore, our results confirm that when the attitude toward use is more positive, the intention to use is higher. To enhance the public's views on the ease of use and usefulness of MHB and to strengthen the positive assessment of MHB, the Ministry of Health and Welfare should continue to design diversified value-added services for MHB.

Since March 2020, with the policy of real-name mask purchases, MHB has combined the functions of mask preorders, mask purchase maps, and mask donation. The Taiwanese people can conveniently purchase masks during the COVID-19 pandemic to achieve effective COVID-19 prevention [29,86]. Combined with its excellent public health facilities, Taiwan took advantage of its advanced deployment of MIT to prevent and control the COVID-19 pandemic at the early stage. In contrast to the severe ongoing global COVID-19 pandemic, Taiwan has seen a respite from the impact of the disease [67,87]. In 2017, approximately 590,000 MHB accounts were registered and used, accounting for approximately 2.7% of the total Taiwanese population [24]. After adding a variety of diverse services in MHB, according to Apple, there were more than 7.3 million downloads of MHB in 2020, and the number of users significantly increased by 31.7% [88], which shows that as long as people are satisfied with the real benefits and value brought by an information tool, their intention to use it will increase, and the actual use of the tool will increase accordingly.

Limitations

The MHB discussed in this study is a newly promoted health information service in Taiwan, and relatively few people have used it before. Therefore, people might have a limited understanding of the service, content, and functions of MHB. To reduce possible errors in our study, before filling out the questionnaire, the respondents were asked to watch an introductory video about MHB to ensure that they had a certain level of knowledge about the service.

In this study, a structured web-based questionnaire was used to survey the people, so the results may not cover the entire parent population, and the sample representativeness may be limited. Most of the respondents were young female internet users and lived in northern Taiwan. Therefore, future studies should collect more samples to increase the representativeness of the results. In addition, respondents may be affected by the surrounding environment, emotions, and other uncertain factors, resulting in measurement errors, which can be corrected using appropriate statistical methods.

In this study, data were collected by means of a cross-sectional survey, a method that is fast, easy, and inexpensive to perform and the results of which are helpful for further complex research [89]. A study that used longitudinal methods to assess the 14-year use of clinical information systems found that the acceptance of clinical information systems increased over time. In addition, the factors affecting acceptance varied with time [38]. Accordingly, with the development of the life cycle of ICT applications, the relationship between variables in TAM may also change [45]. Therefore, future studies may also consider regularly collecting data to investigate the effect of time factors on the use of MHB. Although it is difficult to extrapolate the results, this pioneering study could still be used as a reference for the development of electronic PHR platforms in Taiwan.

Conclusions

This study used the TAM and a structured web-based questionnaire to investigate the Taiwanese people’s intention to use MHB. Validation by structural equation modeling was performed to obtain an interpretation model with good fitness, and the results showed that perceived ease of use has a significant positive impact on perceived usefulness; perceived ease of use and perceived usefulness both have a significant positive influence on attitude toward use; perceived usefulness has a significant positive impact on behavioral intention to use; and attitude toward use has a significant positive effect on behavioral intention to use. Health literacy, computer self-efficacy, and privacy and security have nonsignificant effects on behavioral intention to use. Further exploration of the effectiveness of each dimension indicates that attitude toward use is the most important dimension affecting respondents’ use of MHB. Even though health literacy, computer self-efficacy, and privacy and security have no significant impact on intention to use, they are still considered important influencing factors in relevant studies. In the future, different research designs can be used for further exploration.

The purpose of establishing MHB is to return the management of personal health information to patients so that they can check their past medical experience and health records at any time to strengthen their self-health care ability. In addition, MHB also allows patients to have autonomy over their personal digital health records, which truly realizes the idea of empowering the people. The planning of a nation's medical policy should be adjusted with the development of the latest ICTs and must be able to accommodate all kinds of complex scientific and humanity issues. Policy implementation not only enables disease management from the perspective of individuals but also promotes health value from the perspective of groups. Taiwan's successful experience in preventing the COVID-19 pandemic by using various MITs is conducive to the sustainable development of more diversified value-added services for MHB in the future and the creation of different medical service modes. The model developed in this study could not only be applied to the adoption of other similar PHR platforms but also be used as a reference for other countries to formulate medical information policies to provide management insights, thereby increasing the use of patients' PHRs.

Acknowledgments

The authors would like to thank Tang Feng, Minister without Portfolio of Taiwan, for using My Health Bank to strengthen the prevention of the COVID-19 epidemic and inspire this study.

Abstract

Background: The decision to use patient portals can be influenced by multiple factors, including individuals' perceptions of the tool, which are based on both their personal skills and experiences. Prior experience with one type of portal may make individuals more comfortable with using newer portal technologies. Experienced outpatient portal users in particular may have confidence in their ability to use inpatient portals that have similar functionality. In practice, the use of both outpatient and inpatient portal technologies can provide patients with continuity of access to their health information across care settings, but the influence of one type of portal use on the use of other portals has not been studied.

Objective: This study aims to understand how patients' use of an inpatient portal is influenced by outpatient portal use.

Methods: This study included patients from an academic medical center who were provided access to an inpatient portal during their hospital stays between 2016 and 2018 (N=1571). We analyzed inpatient portal log files to investigate how inpatient portal use varied by using 3 categories of outpatient portal users: prior users, new users, and nonusers.

Results: Compared with prior users (695/1571, 44.24%) of an outpatient portal, new users (214/1571, 13.62%) had higher use of a select set of inpatient portal functions (messaging function: incidence rate ratio [IRR] 1.33, 95% CI 1.06-1.67; function that provides access to the outpatient portal through the inpatient portal: IRR 1.34, 95% CI 1.13-1.58). Nonusers (662/1571, 42.14%), compared with prior users, had lower overall inpatient portal use (all active functions: IRR 0.68, 95% CI 0.60-0.78) and lower use of specific functions, which included the function to review vitals and laboratory results (IRR 0.51, 95% CI 0.36-0.73) and the function to access the outpatient portal (IRR 0.53, 95% CI 0.45-0.62). In comparison with prior users, nonusers also had lower odds of being comprehensive users (defined as using 8 or more unique portal functions; odds ratio [OR] 0.57, 95% CI 0.45-0.73) or composite users (defined as comprehensive users who initiated a 75th or greater percentile of portal sessions) of the inpatient portal (OR 0.42, 95% CI 0.29-0.60).

Conclusions: Patients' use of an inpatient portal during their hospital stay appeared to be influenced by a combination of factors, including prior outpatient portal use. For new users, hospitalization itself, a major event that can motivate behavioral changes, may have influenced portal use. In contrast, nonusers might have lower self-efficacy in their ability to use technology to manage their health, contributing to their lower portal use. Understanding the relationship between the use of outpatient and inpatient portals can help direct targeted implementation strategies that encourage individuals to use these tools to better manage their health across care settings.

Introduction

Background

Health information technologies (HITs) are increasingly being introduced and implemented to provide individuals with tools to help them manage their health. Patient portals are one such HIT tool that provides patients with the opportunity to learn about their health and participate in their health care [1]. These portals offer patients access to personal health information and educational materials, a means to manage their health and health care, and methods to communicate with their health care providers. There is evidence that links the use of patient portals to better patient-provider communication, clinical decision making, and patient satisfaction [2,3]. Furthermore, the use of patient portals has been associated with improved health outcomes such as controlled blood pressure and better glycemic and cholesterol control in patients with chronic diseases [4,5].

Despite the potential benefits of patient portals, there are still barriers to their adoption and use. First, individuals must have access to the internet to use outpatient portals [6]. In addition, individuals must have adequate eHealth literacy—defined as the ability to acquire, comprehend, and apply health information from electronic sources [7,8]—to understand the information that a patient portal can provide [9]. The decision to use patient portals also involves multiple factors related to an individual's perception of the tool in the context of their personal skills and experiences. For example, prior experience with technology may allow individuals to become more comfortable with new technologies compared with individuals who do not have technology experience [10]. Prior technology experience may be particularly valuable in supporting the adoption of technologies that are similar, as this experience may give individuals confidence in their abilities to use other technologies with similar functionalities [11].

Patient portals were first employed in outpatient settings but are now increasingly being implemented in inpatient settings, with functionality tailored to the hospital environment [12]. Inpatient portals have been suggested to have multiple benefits for patients, including the promotion of independence, reduction of anxiety, and increasing empowerment of patients during their hospitalization [13]. Their use has been shown to help uncover medical errors, improve medication adherence, and facilitate patient-provider communication [14]. Furthermore, there is evidence supporting the association between inpatient portal use and lower hospital readmission rates [15], medical errors, and adverse drug events [16]. In practice, the use of both outpatient and inpatient portals together can provide patients with continuity of access to their health information and their health care providers across care settings [17], but the influence of one type of portal use on the use of the other has not been studied.

Objectives

This study seeks to understand the relationship between the use of an outpatient portal and the use of an inpatient portal by examining the portal use of 3 groups of patients: patients who had used an outpatient portal before using an inpatient portal during hospitalization (*prior users*); patients who used an outpatient portal only after using an inpatient portal during a hospital stay (*new users*); and patients who did not use an outpatient portal, despite the fact that they used an inpatient portal during their hospitalization (*nonusers*). We hypothesized that prior users of the outpatient portal would have higher frequency of use and more comprehensive use of the inpatient portal compared with new users or nonusers of the outpatient portal and that these differences would persist after adjusting for demographic and clinical variables.

Methods

Study Setting and Design

A large-scale, pragmatic, randomized controlled trial (RCT) was conducted across 6 noncancer hospitals at a large academic medical center (AMC) between September 2016 and August 2019 [18]. The trial considered the use of 2 patient portals developed by Epic Systems (Epic Systems Corporation). The inpatient portal application, MyChart Bedside (MCB), available on tablet computers provisioned as part of the hospital admission, was introduced in 2013 in select units of the AMC and rolled out system wide in 2016. The outpatient portal, MyChart (MC), was a web-based patient portal that had been in use at the AMC since 2011 and was available as an app on a variety of personal devices, including computers and cell phones. The overall objective of the RCT was to examine how the introduction of MCB influenced patient experience. Briefly, the RCT was structured to examine the impact of 2 interventions, technology and training, using a factorial design. Individuals were provided with a tablet with either full-tech (full MCB) functionality or lite-tech (limited MCB) functionality and received either a high-touch (in-person training from a technology navigator to use the patient portal) or low-touch (instructional video) intervention. In the context of this larger study, we examined MCB use in relation to MC user status among participants in the arm of the RCT that was not impacted by study design considerations—that is, patients who were provisioned with the full-tech tablets and received the low-touch intervention.

MCB and MC Functions

The MCB app available to hospitalized patients included the following functions: Access MyChart (log in to or create an MC account), Dining on Demand (order food from a predefined menu), Happening Soon (view expected interactions with care team during the hospital stay), I Would Like (request ancillary services), Messages (communicate with the care team), My Health (review vitals and laboratory results), Notes (type notes), Taking Care of Me (view active members of the care team), To

Learn (access educational materials), and Tutorial (view a tutorial on how to use MCB). The Access MyChart function could be used by inpatients to create an MC account that was available in the outpatient environment. We refer to all these functions together as active functions in contrast to the administrative functions that were not part of our investigation. The methods for processing MCB log files have been previously described [19].

The MC functions included Messaging (links to messaging center, letters to the patient, and prescription refill option), Visits (list of past and upcoming visits), My Record (list of medications and allergies, medical history and immunizations, test results and health summary, preventive care, and a summary of plan of care), Medical Tools (share medical records with other services, participate in research studies, and connect tracking devices), Resources (terms and conditions, patient education, and frequently asked questions), Proxy (request or renew proxy), and Preferences (personal and security settings and notification preferences). Although MC is tailored for outpatient care, it also includes access to information from inpatient stays within 3 days of discharge. The methods for processing MC log files have also been described previously [20].

Study Data

We used audit log file data from September 2016 to August 2018, a period after MCB rollout that was considered stable with respect to MCB implementation, to test associations between MCB use by MC user status. Our analysis was restricted to a subsample who received access to the full suite of MCB functions and an instructional training video available on the tablet. This subsample provided an adequate sample size to test associations between MCB use by MC user status and avoided confounding effects that might have been related to the in-person technology navigation intervention. Our analytic sample comprised 1571 patients who met the study criteria for this focused analysis.

Our primary outcomes were based on the frequency of MCB function use. We defined MCB function use at 3 levels: the patient level, representing use aggregated over multiple admissions; the admission level, representing use during a single admission; and the sessions level, representing a single, defined instance of coherent MCB use. The definition of MCB use metrics has been previously described in detail [19]. In short, MCB use was defined as the number of times a function was used. We calculated the frequency of use of each of the 10 MCB functions as well as the total frequency of use of all 10 MCB functions.

First, we determined the number of MCB sessions for each patient. Next, we aggregated MCB function use from up to the first 3 admissions for all patients, where the first admission was when patients were enrolled into the RCT (ie, enrollment admission). We selected this cutoff for the number of admissions as most patients had admissions that fell within this range (number of admissions; median 1; 90th percentile=3). We excluded patients whose length of stay (LOS) during their enrollment admission was less than 3 days and those who had no recorded MCB use during their enrollment admission. We also calculated the comprehensiveness of MCB use, defined as the use of 8 or more unique MCB functions [19]. Finally, we defined composite use, a combination of comprehensive use and high-frequency use of MCB. High-frequency MCB use was defined as the total number of MCB sessions equal to or greater than the 75th percentile. We report the results at the patient level to present the aggregate perspective of patient use.

Our main predictor variable was MC user status at the time MCB use first occurred, which we defined as having occurred upon enrollment into the RCT. To define MC user status, we selected 90 days as the cutoff point based on the pattern of MC account activations among patients after their enrollment into the RCT. An MC account is activated when a user signs up to use the app. The number of MC account activations plateaued 3 months after enrollment, which was the basis for our decision that MC account activations occurring within 90 days of trial enrollment was a reasonable time frame during which portal activations could be considered. MC use was defined as any use of the MC functions. Using these definitions, patients were classified into 3 groups: (1) *prior users* (695/1571, 44.24%) were patients with any past recorded MC use before their enrollment admission, (2) *new users* (214/1571, 13.62%) were patients who first used MC during their enrollment admission or within 90 days of their enrollment into the RCT, and (3) *nonusers* (662/1571, 42.14%) were patients who did not use MC before, during, or within 90 days after enrollment. Other covariates included age at enrollment, sex, race, the length of time (days) the tablet with MCB was provisioned (ie, length of provisioning [LOP]) to the patient during their admission, and the Charlson Comorbidity Index (CCI). We did not include the LOS as a covariate because of variability in the length of time between admission and provisioning of the tablet to the patient; given this variability, the LOS does not reflect the duration of time that the patient had to use the inpatient tablet with MCB. Of note, this intersection between the LOS and LOP has been previously described in work pertaining to the processing of log files [19].

Data Analysis

For our analysis, we first examined the distributions of the outcome and predictor variables and assessed differences in the demographic characteristics of MC user groups via analysis of variance, Chi-square tests, and Kruskal-Wallis tests, as applicable. We then modeled the frequency of MCB use by using logistic and negative binomial regression and adjusting for demographic variables, the LOP, and CCIs.

We also performed several sensitivity analyses. First, we repeated the process of calculating MCB function use at the admission and sessions levels from up to 3 admissions. The purpose of examining MCB function use at different levels was to gain a better understanding of patient engagement with the app by considering both granular (sessions) and more aggregate (admission and patient) data. The 1571 patients in our sample had 2227 admissions and 53,823 sessions. Of the 2227 admissions, 1025 (46.02%) were prior users, 310 (13.92%) were new users, and 892 (40.05%) were nonusers. Of the 53,823 sessions, 25,810 (47.95%) were initiated by prior users, 9481 (17.62%) by new users, and 18,532 (34.43%) by nonusers. Our estimates for SEs were clustered by patient. We did not define

comprehensiveness and composite use at the sessions level, as the recording of function use may be influenced by system idiosyncrasies, such as automatically logging the patient out after 10 minutes of inactivity [19-21]. Second, we restricted the analysis to MCB function use to the first admission or the enrollment admission. Finally, we repeated the analyses by redefining MC user status as follows: (1) *prior users* (n=695) were patients with any past recorded MC use before their enrollment admission; (2) *new users* (n=240) were patients who first used MC during their enrollment admission or within 180 days of their enrollment into the trial; and (3) *nonusers* (n=636) were patients who did not use MC before, during, or within 180 days after their enrollment in to the RCT.

Results

Baseline Characteristics of the Participants

Table 1 summarizes the characteristics of the study participants for the analytic sample based on MC user status. The sample mostly consisted of female (899/1571, 57.22%) and White (1180/1571, 75.11%) participants, and participants had a mean age of 47 years (SD 15.09). The median CCI was 1 (range 0-15), and the median LOP was 7 (range 1-124) days. Across the different MC user groups, there were statistically significant differences in gender, race, age, and CCIs. Prior users were typically older, female, and White. New users were likely to have the portal provisioned to them for one more day than the other user groups.

The frequency of MCB use in relation to MC user status is summarized in Table 2. The prior users group had a median of 23 MCB sessions per patient, whereas new users and nonusers had 29 and 16 sessions per patient, respectively. Among prior users, 34.9% (243/695) were comprehensive users and 19.4% (135/695) were composite users. Among new users, 36.9% (79/214) were comprehensive users and 23.4% (50/214) were composite users. For nonusers, 23.1% (153/662) were classified as comprehensive and 9.8% (65/662) were classified as composite users.

Table 1. Baseline characteristics of the study population by MyChart user status.

Characteristics	Overall (N=1571)	Prior users (n=695)	New users (n=214)	Nonusers (n=662)	*P* value[a]
Gender (female), n (%)	899 (57.22)	433 (62.30)	127 (59.35)	339 (51.21)	<.001
Race, n (%)					.004
Black	326 (20.75)	119 (17.12)	42 (19.63)	165 (24.92)	
White	1180 (75.11)	541 (77.84)	162 (75.70)	477 (72.05)	
Other	65 (4.14)	35 (5.04)	10 (4.67)	20 (3.02)	
Age (years), mean (SD)	47 (15.09)	48 (14.95)	44 (14.75)	46 (15.15)	<.001
Charlson Comorbidity Index, median (range)	1 (0-15)	1 (0-15)	1 (0-11)	1 (0-13)	<.001
Length of provisioning (days), median (range)	7 (1-124)	7 (1-124)	8 (1-116)	7 (2-117)	.05

[a]Differences in gender and race were examined using the Chi-square test. Analysis of variance was used to assess differences in mean age. The Kruskal-Wallis test was used to assess differences in the Charlson Comorbidity Index and length of provisioning.

Table 2. Frequency of MyChart Bedside use by MyChart user status[a].

Characteristics	Overall (N=1571)	Prior users (n=695)	New users (n=214)	Nonusers (n=662)
Number of sessions, median (Q1[b], Q3[c])	20 (10, 41)	23 (12, 44)	29 (14, 51)	16 (8, 31)
Active functions, median (Q1, Q3)	93 (37, 198)	103 (44, 237)	136 (58, 259)	69 (26, 151)
Access MyChart, median (Q1, Q3)	2 (0, 4)	2 (1, 5)	4 (1, 7)	1 (0, 2)
Dining on Demand, median (Q1, Q3)	14 (4, 31)	15 (6, 33)	20 (6, 40)	9 (3, 26)
Happening Soon, median (Q1, Q3)	24 (6, 76)	27 (7, 82)	45 (14, 98)	17 (3, 61)
I Would Like, median (Q1, Q3)	0 (0, 0)	0 (0, 0)	0 (0, 0)	0 (0, 0)
Messages, median (Q1, Q3)	2 (0, 5)	2 (1, 6)	3 (1, 7)	1 (0, 3)
My Health, median (Q1, Q3)	1 (0, 16)	3 (0, 22)	5 (0, 27)	0 (0, 4)
Notes, median (Q1, Q3)	0 (0, 0)	0 (0, 0)	0 (0, 0)	0 (0, 0)
Taking Care of Me, median (Q1, Q3)	2 (1, 6)	3 (1, 8)	4 (1, 10)	2 (0, 5)
To Learn, median (Q1, Q3)	0 (0, 1)	0 (0, 1)	0 (0, 2)	0 (0, 1)
Tutorial, median (Q1, Q3)	6 (4, 11)	7 (4, 12)	7 (5, 13)	6 (3, 9)
Comprehensive user[d], n (%)	475 (30.24)	243 (34.96)	79 (36.92)	153 (23.11)
Composite user[e], n (%)	250 (15.91)	135 (19.42)	50 (23.36)	65 (9.81)

[a]MyChart (MC) user status was defined as follows: prior users (n=695) were patients with any past recorded MC use before their enrollment admission; new users (n=214) were patients who first used MC during their enrollment admission or within 90 days of their enrollment into the trial; and nonusers (n=662) were patients who did not use MC either before, during, or after their enrollment admission or those who first used MC 90 days after enrollment into the trial.

[b]Q1: 25th percentile.

[c]Q3: 75th percentile.

[d]A comprehensive user was defined as those who used 8 or more MyChart Bedside functions at both the patient and admission levels.

[e]A composite user was defined as a comprehensive user and high-frequency user of MyChart Bedside. High-frequency users were defined as users who had a total number of MyChart Bedside sessions greater than or equal to the 75th percentile (41 sessions).

Association Between MCB Use and MC User Status

The association between MCB use and MC user status is summarized in Table 3. In the unadjusted analysis, with the exception of the Notes and I Would Like functions, there were significant differences across the 3 MC user groups in the use of the remaining 8 MCB functions. Overall, compared with prior users, we found that new users had higher use of MCB, and nonusers had lower use of MCB. After adjustment, although the frequency of use of active MCB functions was not significantly different between new users and prior users, we found a significantly higher use of certain individual MCB functions among new users. For instance, new users had 33% higher use of the Messages function (incidence rate ratio [IRR] 1.33, 95% CI 1.06-1.67; *P*=.02) and 34% higher use of the Access MyChart function (IRR 1.34, 95% CI 1.13-1.58; *P*=.001), compared with prior users. Furthermore, new users had 12% higher use of the Tutorial function (IRR 1.12, 95% CI 0.99-1.26; *P*=.07), compared with prior users. In contrast, nonusers had a significantly lower frequency of MCB use compared with prior users for all but 2 functions (ie, I Would Like and Notes), even after adjusting for demographic factors, the LOP, and CCIs. The full model estimates are available in Multimedia Appendix 1.

Table 3. MyChart Bedside function use in relation to MyChart user status (in reference to prior users) at the patient level[a].

Functions	New users (unadjusted)	New users (adjusted[b])	Nonusers (unadjusted)	Nonusers (adjusted[b])
P value	.21	.50	<.001	<.001

[a]MyChart (MC) user status was defined as follows: prior users (n=695) were patients with any past recorded MC use before their enrollment admission; new users (n=214) were patients who first used MC during their enrollment admission or within 90 days of their enrollment into the trial; and nonusers (n=662) were patients who did not use MC either before, during, or after their enrollment admission or those who first used MC 90 days after enrollment into the trial.

[b]Adjusted for age at enrollment, female gender, race, Charlson Comorbidity Index, and the length of provisioning time of the inpatient tablet.

[c]IRR: incidence rate ratio.

[d]A comprehensive user was defined as those who used 8 or more MyChart Bedside functions at both the patient and admission levels.

[e]OR: odds ratio.

[f]A composite user was defined as a comprehensive user and high-frequency user of MyChart Bedside (MCB). High-frequency users were defined as users who had a total number of MCB sessions greater than or equal to the 75th percentile (41 sessions).

Association Between Comprehensive and Composite Use by MC User Status

Table 3 also summarizes the association between MCB comprehensive use and composite use by MC user status. Prior users and new users were similar in terms of comprehensive and composite MCB use. However, compared with prior users, nonusers had lower odds of being comprehensive users (odds ratio [OR] 0.57, 95% CI 0.45-0.73; *P*<.001) or composite users (OR 0.42, 95% CI 0.29-0.60; *P*<.001).

Sensitivity Analyses of the Association Between MCB Use and MC User Status

Multimedia Appendices 2 and 3 summarize the findings from our sensitivity analyses at the admission and sessions levels. These results were largely consistent with those from analyses conducted at the patient level. There were notable exceptions at the admission level: the Dining on Demand function was used 12% more among new users (patient level: IRR 1.10, 95% CI 0.96-1.27; *P*=.16; admission level: IRR 1.12, 95% CI 0.98-1.28, *P*=.10) compared with prior users and the use of the Tutorial function was not significantly different between nonusers and prior users (patient level: IRR 0.92, 95% CI 0.84-1.00; *P*=.05; admission level: IRR 0.99, 95% CI 0.91-1.08, *P*=.85). At the sessions level, the use of the Dining on Demand (IRR 1.02, 95% CI 0.98-1.06; *P*=.28) and Tutorial functions (IRR 1.04, 95% CI 0.97-1.12; *P*=.27) were similar between prior users and new users. For the Access MyChart (patient: IRR 1.34, 95% CI 1.13-1.58; *P*=.001; admission: IRR 1.37, 95% CI 1.16-1.61; *P*<.001; session: IRR 1.25, 95% CI 1.15-1.36; *P*<.001) and Messages (patient: IRR 1.33, 95% CI 1.06-1.67; *P*=.02; admission: IRR 1.37, 95% CI 1.09-1.71; *P*=.01; session: IRR 1.24, 95% CI 1.14-1.34; *P*<.001) functions, we found smaller differences between new and prior users than at the patient and admission levels.

Although nonusers had lower use of MCB compared with prior users, the difference between the 2 groups was smaller than that found at the patient and admission levels. At the sessions level, the frequency of use of the Happening Soon, Messages, and To Learn functions was not statistically different between nonusers and prior users. In contrast to the patient and admission levels, where nonusers had significantly lower use of most MCB functions compared with prior users, at the sessions level, the use of the Tutorial and Dining on Demand functions was with notable exceptions. Compared with prior users, nonusers had 27% higher use of the Tutorial function (IRR 1.27, 95% CI 1.20-1.32; *P*<.001) and 9% higher use of the Dining on Demand function (IRR 1.09, 95% CI 1.06-1.12; *P*<.001). Although the I Would Like function did not differ by MC user status at the other 2 levels, at the sessions level, nonusers had 38% higher use (IRR 1.38, 95% CI 0.99-1.91; *P*=.06) compared with prior users.

Multimedia Appendix 4 summarizes the results from our sensitivity analyses using information solely from the enrollment admission into the RCT (model 2) and those using information from up to 3 admissions but also using 180 days after enrollment as the cutoff to define MC user status (model 3). For comparison, we provide the results from the analysis of MCB use from up to 3 admissions and 90 days after enrollment (the cutoff to define MC user status; model 1). On restricting the analysis to the enrollment admission, the results were generally consistent with our main findings, with some exceptions. New users had 19% higher use (IRR 1.19, 95% CI 1.00-1.42; *P*=.048) of all active MCB functions compared with prior users. Furthermore, compared with prior users, new users had 15% (IRR 1.15, 95% CI 1.00-1.32; *P*=.05) and 30% (IRR 1.30, 95% CI 1.02-1.67; *P*=.04) higher use of the Dining on Demand and Happening Soon functions, respectively. Finally, compared with prior users, new users had 44% (OR 1.44, 95% CI 1.12-1.85; *P*=.01) greater odds of being comprehensive users of MCB. Using 180 days after enrollment in the trial as the cutoff to define MC user status did not affect the number of prior users (n=695), but there were more new users (n=240) and fewer nonusers (n=636). Our findings were consistent with the results of analyses using 90 days after enrollment in the trial as the cutoff to define MC user status.

Discussion

Principal Findings

In our study of inpatient portal use in relation to outpatient portal user status, we found that the use of specific portal functions as well as the frequency and comprehensiveness of inpatient portal use differed across user groups. Our analyses showed that Dining on Demand and Happening Soon were the most frequently used inpatient portal functions, whereas I Would Like and Notes were the least frequently used functions. These results align with previous findings from a cluster analysis, which also highlighted the variability in function use based on

distinct behaviors of subgroups [21]. Among new users in this study, we found more use of the Tutorial, Messages, and Access MyChart functions than those among prior users. Nonusers were found to use most MCB functions less than prior users. Nonusers were also less likely to be comprehensive or composite users of MCB than prior users.

Prior research has found that an individual's experience with technology may increase their adoption of new technologies by increasing their familiarity with technology and reducing their dependence on external resources for help [22]. Experience may thereby impact an individual's perceptions of the usefulness and ease of use of a new technology [23,24]. This may, in part, explain our finding of higher inpatient portal use by prior users compared with nonusers. At the same time, individuals with less technology experience may use technologies differently (ie, use fewer functions or use less frequently) than those with more technology experience [25], and this prior finding may explain the differences we observed in portal function use between prior users and nonusers. As previous studies have shown that individuals with less prior technology experience may benefit from supplemental education or ongoing support to help them use new technologies [10], it is possible that training patients without prior experience of portal functionality or the benefits of using the portal may increase portal use for nonusers.

Prior users in our sample were mostly older, female, and White. This is similar to the results of another recent study on portal usage from 3 iterations of the Health Information National Trends Survey, which showed that portal users were more likely to be female, White, and have higher education or income. Furthermore, this prior study also showed a widening gender gap and narrowing age gap in portal use among Americans over time [26].

Beyond experience with the outpatient portal, there are likely additional factors that influence both patients' use of the inpatient portal while hospitalized and their use of the outpatient portal post discharge. For instance, barriers to portal use such as low levels of patient activation or low health literacy may contribute to a patient's choice not to use patient portals; such factors may have been at play among the nonusers in our study. Low patient activation may diminish the patient's interest in using portals, as it has been shown that individuals with lower levels of activation have a lower likelihood of using the internet to access health information [27]. In addition, low health literacy has been recognized as a barrier to the use of patient portals, as this may prevent patients from effectively comprehending information found via the portal [28].

The abovementioned barriers to portal adoption and use are more likely to be experienced by vulnerable and underserved patients [29,30], and it is concerning that these patients may also be left behind in the use of portals and in leveraging the potential benefits these tools provide [2-5,14]. Notably, the digital divide may also explain some differences in MCB use among nonusers. Although the inpatient portal is offered on hospital-provided tablets with wireless internet connectivity, the use of the outpatient portal requires a patient to have access to both technology and the internet. Not all individuals have this access, contributing to the digital divide that has been found [31]. For instance, households with low incomes (<US $30,000 per year) are less likely to have home broadband internet access, computers, or smartphones [32]. In addition, enrollment to use an outpatient portal and use of its secure messaging function have been shown to be associated with whether individuals have internet access in their home neighborhoods [6]. Individuals may be less likely to adopt and use an inpatient portal when they do not have internet access at home to enable the use of an outpatient portal post discharge. It is also likely that nonusers include patients visiting the health system for a specific procedure but whose usual care is provided through a separate health system that has a different patient portal platform. These individuals may be less motivated to use either MCB or MC if they perceive their interaction with the AMC to be only temporary.

Interestingly, we found greater use of the inpatient portal for a specific set of MCB functions, such as the Messages function, among new users compared with prior users. As hospitalization may represent a major life event that may spark behavioral changes and increase an individual's engagement in their health care [33], this experience may have contributed to new users' high levels of MCB use during their hospital stay and their creation of MC accounts to manage their health after discharge. New users may also have used the Messages function more because of its novelty and the high expectations placed on it by this highly motivated group of users. In contrast, prior users may have viewed the Messages function as potentially less useful, and more research is needed to understand what factors may have contributed to this behavior.

However, we did not find differences between the new user and prior user groups in the odds of being a composite or comprehensive user. Although these findings contradict our study hypothesis, these results suggest that it is possible that prior users may have had a priori assumptions that they already completely understand portal functionality and perhaps overlooked unique functions that were available in the inpatient portal. Promoting awareness of patient portals and their varied functions may be important across settings, as it can support seamless care transitions and maintain patient engagement. Ultimately, knowing more about the relationship between the use of outpatient and inpatient portals can help inform implementation practices that encourage individuals to use these tools across care settings to better manage their health and participate in their health care.

The results at the patient level were generally consistent with those at the admission and sessions levels. However, there were some notable exceptions. New users had higher numbers of sessions compared with prior users when analyzed at the sessions level (Multimedia Appendices 2 and 3 provide detailed results at the admission and sessions levels). Nonusers had significantly higher use of the Dining on Demand, I Would Like, and Tutorial functions. Furthermore, at the sessions level, there were no significant differences in the use of the Messages and To Learn functions between nonusers and prior users. The results at the other levels, especially at the sessions level, could be highly sensitive to additional system artifacts in spite of our processing of the raw log file data, and more research is required

to explore how different data processing techniques and analytical models may account for these potential idiosyncrasies.

Finally, our findings were generally consistent when examined using information on MCB function use solely from the enrollment admission. It is notable that new users had significantly higher use of all active functions in the enrollment admission, but this association was no longer significant when examining MCB use from up to 3 admissions. This pattern was observed for the Happening Soon and Dining on Demand functions, suggesting a novelty effect. Similarly, the odds of being a comprehensive user were high when examining MCB use from enrollment admission alone.

Limitations

Limitations should be considered when interpreting our results. First, our analysis focused on a single health system and a single patient portal platform, potentially restricting the generalizability of our findings. However, our inclusion of multiple hospitals across this health system and the similarities in patient portal functionality across this and other vendor platforms does support the potential applicability of our findings to other settings. Second, we restricted our focus to the associations between outpatient portal use and inpatient portal use, without considering the alternative influence of inpatient portal use on outpatient portal use. Although we decided to examine this relationship because outpatient portals are more established than inpatient portals, giving patients more opportunity to have been introduced to outpatient portal technology, future studies can be designed to study the alternate relationship. Third, although experience with technology can be measured in multiple ways [34], we defined experience as having an active outpatient portal account. Additional work examining more granular measures such as length of experience with patient portals might provide greater insight into the impact of experience on patient portal use. Fourth, MC users can access the same set of MC functions using the inpatient tablet or personal devices. Therefore, the difference in MCB use (specifically, number of sessions, active functions, and Access MyChart function) by MC user status may be influenced by a patient's use of their mobile device to access their MC app during an inpatient stay. Finally, our study was not designed to explore the implications of portal use on health outcomes. Although functions such as My Health and To Learn have been previously noted to influence patients' health outcomes [21], studying such relationships within and among outpatient user groups was beyond the scope of this study.

Conclusions

Together, outpatient and inpatient portals can provide patients access to their health information and a means to communicate with their health care providers, including along the continuum of care. We found that in comparison with patients who had previously used the outpatient portal, new users of the outpatient portal had higher inpatient portal use for a select set of functions, whereas nonusers of the outpatient portal had lower use of the inpatient portal during their hospitalization. Understanding how the use of one type of patient portal affects the use of the other can help us better understand how these tools can be both implemented and promoted to increase patients' involvement in their health care across settings.

Abstract

Background: Digital technologies (DTs) for older adults focus mainly on health care and are considered to have the potential to improve the well-being of older adults. However, adoption rates of these DTs are considered low. Although previous research has investigated possible reasons for adoption and acceptance of DT, age-based stereotypes (eg, those held by health care professionals) toward the abilities of older adults to use DTs have yet to be considered as possible barriers to adoption.

Objective: The aim of this study was to investigate the influencing role of ageism in the context of health care professionals attitudes toward older adults' abilities to use health care DT. A further goal was to examine if social comparison and stereotype activation affect and moderate this association.

Methods: A new measurement to assess health care professionals' attitudes toward older adults using technology (ATOAUT-10) was developed and used in 2 studies. Study 1 involved the development of the ATOAUT-10 scale using a principal component analysis and further examined health care professionals' attitudes toward the use of health care DTs and correlations with ageism. Study 2 further explored the correlation between ageism and ATOAUT in an experimental design with health care professionals.

Results: In study 1, physiotherapists (N=97) rated older adults as young as 50 years as less able to use health care DT compared to younger adults (P<.001). A multiple regression analysis revealed that higher levels of ageism, beyond other predictors, were predictive of more negative ATOAUT, (β=.36; t=3.73; P<.001). In study 2, the salience of age was manipulated. Health care professionals (N=93) were randomly assigned to rate the abilities of a young or old person to use health care DT. Old age salience moderated the correlation between ageism and ATOAUT (R^2=0.19; $F_{6,85}$=3.35; P=.005), such that higher levels of ageism correlated with more negative ATOAUT in the old age salient condition, but not the young condition. Stereotype activation accounted for health care professionals' attitudes more than did the experience of working with older patients or the professionals' age.

Conclusions: Negative and ageist attitudes of health care professionals can potentially affect how older adults are viewed in relation to DT and consequently might influence actual use and adoption of technology-based treatment. Future studies should broaden the validation of the ATOAUT-10 scale on more diverse samples and focus on the discriminatory aspect of ageism and self-ageism of older adults. This study calls for a focus on ageism as a determinant of adoption of DT.

KEYWORDS

ageism; attitudes; stereotype activation; digital technology

Introduction

Digital technology (DT), hereby defined as technological devices, services or platforms that use, collect, and often process data and are connected to the internet, other devices, or apps [1], are thought by many to have the potential to improve quality of life and promote independent and active aging of older adults [2-4]. However, older adults are often discoursed as a homogenous group of "nonusers"[5], associated with illness, frailty, cognitive decline, and dependency [6]. This might be one of the reasons why DTs developed for the use of older adults primarily focus on health care [2], which positions health care professionals in the forefront of using DT with older adults. Substantive research has attempted to explain the factors for adoption of DT by older adults in general [7-9] and specifically for health care [10]. Yet, the specific influence of age-based stereotypes and ageism on the use and adoption of DT in care and health care, and the effect of social comparison and stereotype activation on health care professionals' attitudes toward older adults in relation to DT, have not been investigated.

Ageism comprises stereotypes, prejudice, and discrimination toward a person based on their age [11]. This definition reflects a cognitive component (eg, the belief that older adults are less able to use DTs), an emotional component (eg, the feeling that instructing older adults how to use DT is annoying), and a behavioral component (eg, not offering older adults treatments based on DT). The pervasiveness and social acceptability [12,13] of ageism is to some extent explained by its indirect and often implicit nature. Social behavior is often implicitly shaped by environmental cues and activation of stereotypical traits. Ageism is thus internalized throughout the life course and can operate implicitly [14] often without awareness as to how it influences our judgments [15]. Activation of age stereotypes and ageism, therefore, do not necessarily encompass explicit intention to do harm, as it is often expressed subtly in forms of benevolence [16], and older adults being disrespected, ignored, or patronized [17]. Therefore, it is important to measure both implicit and explicit attitudes [18]. Ageism can indeed be harmful and affect the opportunities of older adults for active aging, equal participation, and access to services such as health care [19] or DTs [20]. Furthermore, implicit attitudes and stereotypes are often embodied and self-directed [21] and may eventually lead to decreased physical and mental health [22].

Expressions of ageism manifest in different contexts and life domains, such as health care, leisure and employment, and different domains have different age thresholds as to when a person is considered "old" [23]. Ageism can also be context specific [24], meaning that negative attitudes toward older adults, (eg, use of DT) can vary in the context of family, work, or health care. A central stereotype about older adults that is very much apparent in relation to DT is that they are less competent [12], and simply presenting a question about "old" or "young" can lead to stronger associations with negative age traits [25].

Contrary to stereotypes that portray older adults as "laggards" [26], nonusers [5], and technophobic [27], accumulating evidence suggests that older adults find DT to be fascinating and empowering [28], and hold more positive than negative attitudes toward DT [29]. According to a recent report by the American Association of Retired Persons (AARP), use of various forms of DTs (eg, smartphones, tablets, smart home technologies) by adults aged 50 years and above has consistently increased since 2014, and for many devices, adoption rates are nearly similar to those of younger adults [30]. More importantly, reasons for which older adults use or do not use DT are complex and include social context, emotions, experience, support, and individual preferences [8,31], and perhaps also relate to social influence and attitudes of others [7], such as family members or health care professionals. Noticeably, there is often a mismatch between what is designed for the use of older adults (mainly in the context of health care) and what they actually want and need [32], which may be DT that is both enjoyable and empowering [33]. Older adults express high willingness to use certain care and health care DTs (eg, monitoring sensors), however, only if they perceive that their health status might severely decline [34]. Subsequently, this mismatch might lead to low adoption rates and abandonment of health care–related DT [10].

There is considerable evidence for ageism among health care providers, both self-reported and patient reported [35]. Negative age stereotypes, usually operating in indirect or implicit manners, were found to influence diagnosis, prognosis, and treatments provided. Ambady et al [36] found that implicit measures such as distancing and nonverbal communication of physiotherapists during treatment (eg, looking away from the person) were associated with short- and long-term physical decline of older patients. Patients with similar symptoms or complaints are often diagnosed differently or misdiagnosed because of their age. In a study by Linden and Kurtz [37], the same case description (differing only by age) led to a diagnosis of depression for younger patients and a diagnosis of dementia for older patients. Meanwhile, in a study by Gewirtz-Meydan and Ayalon [38], manipulating the age salient in a case description led to a different prognosis and treatment trajectory of a sexual function complaint. Unfortunately, use of chronological age in triage strategies (eg, in the Covid-19 pandemic) also raises ethical discussions about the influence of ageism on medical decisions [39]. As many aspects of health care are digitalizing, it remains unclear if these ageist manifestations might affect the use of DT with older adults.

There is contradicting evidence regarding characteristics of health care professionals that are associated with ageist outcomes [35]. Some studies indicate that negative attitudes are often associated with younger age of health care professionals [40], whereas positive attitudes are associated with older age, female professionals, and positive experience of working with older patients [41]. Other findings suggest that knowledge about aging and choosing to work with older adults might determine professionals' attitudes and reduce stereotypes and prejudice [42]. The latter might fit in with the idea of social contact theory [43].

In their daily work, health care professionals need to categorize patients in order to reach practical medical decisions. This type of categorization might be considered functional [44]. However, with a view of stereotypes as a process of internalizing and

learning [14], possible biases of health care professionals might be seen as consequence of increased exposure to older adults in situations of illness and dependency. This "clinician bias" might shape the general image health care professionals have of older patients, leading to "diagnostic overshadowing" [45] and pushing them to differentiate themselves from older patients, for example, because of existential fear of their own death [46]. It is therefore plausible that implicitly activated age stereotypes, created in situations of social comparison or categorization [47], determine health care professionals' attitudes toward older adults, more than characteristics of age, gender, or experience. This might lead to the disregarding of individuating information, perception of older adults as a homogeneous outgroup, and discriminatory behaviors.

The aim of this study was to investigate whether ageism plays a role in the perception of health care professionals toward older adults' abilities to use health care DT, or, in other words, whether people who reach a certain age are considered "too old" to use health care DT. Therefore, we first were interested in determining whether higher levels of ageism in health care professionals would be associated with negative attitudes regarding older adults' abilities to use DT. Second, we looked into whether social comparison and stereotype activation would affect this association. Generally, we hypothesized that health care professionals' attitudes of older adults' abilities to use DT would be negative and that higher levels of ageism would be associated with more negative attitudes. Furthermore, we hypothesized that social comparison and stereotype activation would moderate this association, leading to attitudes that are more negative. In study 1 we developed and tested new measurement tools and subsequently assessed the association between ageism and attitudes toward older adults' abilities to use DT. In study 2 we further tested how manipulating stereotype activation might moderate this association. Both studies received ethical approval from the Fontys University of Applied Science ethics research committee (approval file no. Mannheim22022019).

Methods

Study 1

The goal of study 1 was to initially assess the explicit and implicit attitudes of health care professionals toward older adults' abilities to use DT and the association between these attitudes and ageism. As specific measures are currently unavailable, an additional goal was to develop and test the use of new direct and indirect measurements of DT-related attitudes and ageism. We hypothesized that health care professionals would express negative attitudes toward the abilities of older adults (compared to younger adults) to use DT. We further hypothesized that higher levels of ageism would be correlated with more negative attitudes.

Participants

We recruited physiotherapists working in the Netherlands and fourth year physiotherapy students who had already gained professional experience during their internships using available mailing lists between April 2019 and May 2019. Out of the 155 who were contacted, 97 participants voluntarily completed the questionnaire. A statistical power analysis was performed for sample size estimation, using G*Power 3.1.9.4 (Heinrich Heine University Düsseldorf). We used the assumption of a minimal effect size of 0.2 (as no prior knowledge of this scale is available), with an α of .05 and a power of 0.9. The projected sample size needed for a multiple regression with 4 predictors was 82, 75% (73/97) of participants were female, M_{age} = 32.39 (SD 11.24), 23% (22/97) were fourth year students, 34% (33/97) had 1-5 years of work experience, 28% (27/97) had 6-20 years of experience, and the remaining 15% (15/97) exceeded 20 years of experience. Finally, 47% (46/97) indicated that most of their patients were 65 years or older.

Measures

Ageism

The Fraboni Scale of Ageism (FSA) was used as a direct measure of ageism [48]. The FSA assesses all 3 dimensions of ageism: stereotypes, prejudice, and discrimination [11]. As no available translation in Dutch was available, the questionnaire was forward translated from English to Dutch by 2 assessors (YVZ and another assessor), and back translated to English by 2 different assessors (EJMW and another assessor). Differences in interpretation and culturally sensitive aspects were then discussed with all 4 assessors and the corresponding author (IM). The scale consists of 29 items ranked on a 4-point ordinal scale (1, strongly disagree; 2, disagree; 3, agree; 4, strongly agree). Reversed items were recoded and a sum score of the scale was calculated (scale range 29-116). Higher scores represent higher levels of ageism. Missing values in 4 items (7 missing values in total) were replaced by the mean of the item as previously suggested in the use of the FSA by Helmes and Pachana [49]. The Cronbach α coefficient of the scale was .85, similar to the reliability levels found by Fraboni et al [48].

Attitudes Toward Older Adults Using Technology

As a direct measure, we developed the attitudes toward older adults using technology (ATOAUT) scale. Items were developed in accordance with known literature about stereotypes on older adults and technology, such as ease of use and perceived benefit [7,29], fear, anxiety, and self-efficacy [50,51]; our experience from interviewing technology designers and focus groups with older adults [52]; and feedback from experts. We eventually reached a group consensus regarding 15 items that potentially assess stereotypes (eg, "Using digital technology is harder for most older adults") and prejudice (eg, "One needs a lot of patience to explain to an older adult how to use digital technologies") toward older adults and DT (for the full list of items see Table 1). Participants rated their agreement with statements about older adults and DT on a Likert-type scale from 1 (totally disagree) to 6 (totally agree). Five reversed items were recoded, and a sum score of the scale was calculated (scale range 15-90). Higher scores represent attitudes that are more negative.

As an indirect measure, we modified a vignette technique previously used to assess health care–related ageism [37,38]. Participants were presented with 3 descriptions of health care–related DTs, namely a health care app, smartwatches, and rehabilitation videogames (see Multimedia Appendix 1).

Participants were then asked to rate (yes or no) if they believed different age groups (18-30 years, 31-50 years, 51-64 years, 65-79 years, and 80+ years) could use this DT. Positive answers were coded as 1 and negative answers as 0. Answers for each age category in all 3 vignettes were summed, creating a measure between 0-3 for each age group. The Cronbach α coefficient of all items was .82.

Additionally, we used a direct question to assess the belief that age might be a barrier to using DT. Participants rated (yes or no) if they believed that gender, age, culture, or financial situation can limit a person's ability to use technology.

Procedure

Participants received an invitation through email to participate in a study about how older adults use technology in health care and everyday life. Participants were directed to an online questionnaire on Qualtrics, where they gave consent to participate. Afterward, they answered questions about demographic information and to which age group most of their patients belonged. Following this, they answered the DT-related ageism measures (vignettes and ATOAUT scale) and the FSA.

Additionally, we inserted an unrelated validity item ("For this question only, mark the number 2") in the middle of the FSA and ATOAUT scales to check actual reading of the question.

Analysis

SPSS Statistics 26 (IBM Corp) was used to perform the analysis. In order to examine the ATOAUT scale, a principal component analysis was performed, and modifications were made to the scale. In order to examine our hypothesis on the attitudes of physiotherapists on the indirect measure of the vignettes, a repeated measures analysis of variance (ANOVA) was performed, with the sum of vignettes as the dependent variable, the age group assessed as the within-subject independent variable, primary age group of patients the physiotherapists work with as the between-subject independent variable, and the age of the physiotherapists as a covariate. Finally, to examine the correlation between ATOAUT and ageism (FSA scale) and other variables, we used a correlation matrix and a multiple regression.

Study 2

The goal of study 2 was to test how age salience and stereotype activation might moderate the correlation between ageism and ATOAUT. Specifically, we wanted to address the limitations of study 1: that by merely asking all participants to rank the abilities of every age group to use DT, we actually primed social categorization [47] and age-based stereotypes. Therefore, we sought to control the age group salient in the vignettes, so that participants would need to rate the ability of a young or contrastively an old person to use the DTs described in the vignettes. Additionally, we sought to broaden our findings to a more diverse group of health care professionals. We hypothesized that older adults would be assessed as less able than younger adults in using health care DTs. Furthermore, we hypothesized that the "old" salience condition would prime age stereotypes and the need to categorize and differentiate oneself from the older group, leading to attitudes that are more negative. In contrast, rating the "young" condition would allow participants to affirm their self-concept without categorizing and comparing themselves to the older group. Therefore, we hypothesized that the age salient manipulation would act as a moderator in the correlation between ageism and ATOAUT.

Participants

We recruited 93 health care professionals and fourth year health care students in the Netherlands between December 2019 and February 2020. A statistical power analysis was performed for sample size estimation, using G*Power 3.1.9.4 (Heinrich Heine University Düsseldorf). We used the assumption of a minimal effect size of 0.2, with an α of .05 and a power of 0.9. The projected sample size needed for a multiple regression with 6 predictors was 94. Participants were recruited among the students and staff at a university of applied science, and the questionnaire was further distributed within their networks of health care professionals. Of the respondents, 67% (62/93) of the participants were female, M_{age} = 37.01 (SD 11.89), 38% (35/93) were physiotherapists, 25% (23/93) were speech therapists, 17% (16/93) were medical doctors, and 20% (19/93) belonged to other health professions. Moreover, 18% (17/93) were students, 33% (31/93) had 1-5 years of experience, 29% (27/93) had 6-20 years, and the remaining 20% (18/93) had more than 20 years of experience. For patient age, 41% (38/92) of the professionals indicated that most of their patients are 65 or older.

Measures

Ageism

Due to the limitations of the FSA in study 1, we used the Expectations Regarding Aging (ERA-12) scale [53]. Consisting of 12 items, the ERA-12 is a shorter and more updated scale compared to other available ageism scales and is considered to have the most adequate psychometric properties [11]. The items reflect stereotypes about aging in general and toward one's own aging. As a Dutch translation to the ERA-12 was not available, we used the forward–backward translation method described in study 1. Items were ranked on a 4-point ordinal scale (1, definitely false; 2, somewhat false; 3, somewhat true; 4, definitely true). A summed score was calculated (scale range 12-48), with higher scores representing more negative expectations regarding aging. The Cronbach α coefficient of the scale was .78, which was slightly lower than that reported in Sarkisian et al [53].

Attitudes Toward Older Adults Using Technology

As a direct measure, we used the ATOAUT-10 scale developed in study 1 (for the factor analysis and description of how we reduced the scale from 15 to 10 items see the Results section). The Cronbach α coefficient was .73, which slightly lower than that in study 1.

For the indirect measure we used the vignettes developed in study 1 with certain modifications. We used 2 of the 3 vignettes from study 1 (health care app and smartwatch), and replaced the third (videogames in rehabilitation) as it was specific to the context of physiotherapists. Instead, we added a new vignette of using a voice-activated personal assistance, such as Siri,

google personal assistant, or Alexa (see Multimedia Appendix 1). Participants rated the probability that a person (25 or 75 years old) would be able to use the described DT on a Likert-type scale between 1 (not at all) to 6 (very much so). The scores of the 3 vignettes were summed to create the total measure (scale range 3-18). The Cronbach α coefficient was .86.

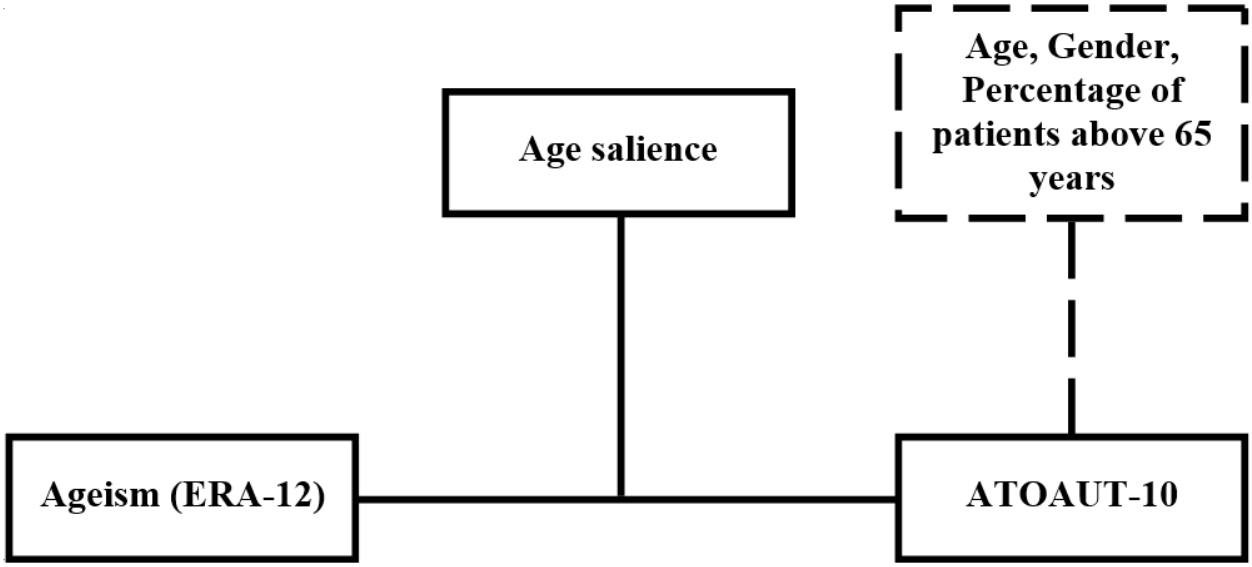
Procedure

Participants received an invitation through email to participate in a study about health care professionals' perspectives about using DT in everyday life and in health care. Participants were directed to an online questionnaire on Qualtrics, where they gave consent to participate and answered demographic questions. Participants were then randomly assigned to rate one of the contrastive age groups (young or old) in the 3 vignettes, and then completed the ATOAUT-10 and ERA-12 scales, and the question used in study 1 about the belief of age being a limiting factor. Finally, participants indicated the percentage of their patients who are above the age of 65 years. One validity check item was inserted in the middle of the ATOAUT-10 scale.

Analysis

SPSS 26 (IBM Corp.**)** was used to perform the analysis. In order to examine our hypothesis that older adults would be assessed as less able than younger adults to use health care DTs on the indirect measure, we used a correlation matrix and multiple regression. In order to examine our hypothesis that age salience would moderate the correlation between ATOAUT and ageism (ERA-12), we employed a regression procedure using the PROCESS bootstrapping macro [54] in SPSS (model 1: 5000 iterations). Figure 1 presents the assumed moderation model.

Figure 1. Assumed moderation model of age salience (young and old) on the correlation between ageism (measured by ERA-12) and attitudes towards older adults using technology (ATOAUT-10). Age, gender, and percentage of patients above 65 years were added to the model as covariates. ATOAUT: attitudes toward older adults using technology; ERA-12: Expectations Regarding Aging scale.



Results

Study 1

We found that 27 participants did not answer the validity items correctly. Consequently, concern regarding their attention in answering was raised. Analysis including and excluding these participants, revealed that the results would not be different. We therefore included all 97 participants in this study.

ATOAUT Scale

The initial Cronbach α coefficient of the 15-item scale was .77. We then used a principal component analysis in order to examine the latent components of the scale. Bartlett test confirmed no violation of sphericity (approximate $\chi^2 = 379.1$; $P<.001$). Five factors with eigenvalues larger than 1 were identified and accounted for 62.07% of the variance (see Table 1). Eight items loaded mainly on the first factor (all loadings above 0.43), representing stereotypes and prejudice toward older adults' abilities to use DT (eg, "Using digital technology is harder for most older adults"), with the exception of item 2, were also strongly loaded on the fourth factor. Two additional items (5 and 12), loaded on the second factor, represented attitudes toward older adults' access to DT and online digital services. Examining the remaining 5 items that did not load on the first and second factor revealed that the phrases used might have been ambiguous and interpreted variably. Consequently, answering them might not necessarily reflect stereotypes or prejudice toward older adults, but rather general attitudes toward the role of DT in improving well-being (item 8), matters of privacy (item 9), accessibility of the design (items 4 and 11), and how playful people of different ages are (item 3).

Item 10, which loaded on the first factor, seemed to have a weaker loading compared to the other items. This might have been related to confusion in the use of negation in this item. We therefore concluded to change the phrasing for future use to "Most older adults *can* give useful feedback about new digital technologies." Finally we formed the new ATOAUT-10 scale, comprising items 1, 2, 5, 6, 7, 10, 12, 13, 14, and 15. The Cronbach α coefficient of the new 10-item scale was higher

(.82), compared to the 15-item scale coefficient (.77), and explained 91.2% of the variance of the 15-item scale.

Table 1. Initial eigenvalues and explained variance and loadings after Varimax rotation of ATOAUT items as sorted by loading size (N=97).[a]

Items and factors	Rotated component matrix				
	1	2	3	4	5
Initial eigenvalues	4.28	1.55	1.28	1.19	1.01
Variance explained (%)	28.51	10.36	8.52	7.95	6.74
ATOAUT[b] item (loadings)					
15. One needs a lot of patience to explain to an older adult how to use digital technologies	.81	.01	–.12	–.02	–.20
7. Using digital technology is harder for most older adults	.76	.19	.04	.22	.08
1. It's hard to explain to older adults how to use digital technology	.71	.06	.01	.21	.08
6. Most older people do not see the benefits of using digital technology	.63	.38	.13	–.07	–.12
14. Most older adults are not interested in learning about using new digital technology	.58	.51	.10	.02	.02
13. Most older adults fear using digital technology because they believe they will break or ruin something	.47	.15	–.35	.11	.19
10. Most older adults cannot give useful feedback about new digital technologies	.43	.19	.21	–.12	.07
5. Most older people have less access to digital technology	.27	.80	–.03	–.02	.10
12. Online services can be used by adults of any age (for example online banking or government services)[c]	.08	.60	–.18	.53	–.05
4. When designing new digital technologies for older adults, older adults should take part in the design process[c]	.19	–.20	.83	–.03	.07
8. Using digital technology can improve older adults well–being and health[c]	.00	.34	.62	.30	–.05
9. Using digital technology can cause more harm to older adults' personal safety and privacy compared to younger adults	.01	.02	.07	.76	–.04
2. Most older adults can use digital technology just as well as younger adults[c]	.53	–.01	.07	.55	.07
11. Digital technology for older adults should be designed in a way that is accessible and easy to use[c]	–.30	.02	.34	–.19	.74
3. Video game devices are mainly for younger adults	.34	.05	–.34	.12	.69

[a]The final ATOAUT-10 scale comprised items 1, 2, 5, 6, 7, 10, 12, 13, 14, and 15.

[b]ATOAUT: attitudes toward older adults using technology.

[c]Reversed item.

Indirect Measure of Attitudes: Vignettes

Table 2 presents the means, SDs, and correlations of the sum of the 3 vignettes for each age category, ATOAUT-10, FSA, and other variables. Physiotherapists assessed older age groups as less able to use the health care DTs described in the vignettes (Figure 2). We further examined these differences using a repeated measures ANOVA, with the sum of vignettes as the dependent variable, age group assessed as the within-subject independent variable, primary age group of patients the physiotherapists work with as the between-subject independent variable, and age of the physiotherapists as a covariate. By interpreting the Greenhouse-Geisser test (due to violation of sphericity), we found a significant main effect of the age group assessed ($F_{2.33,\ 211.74}$=34.66; P<.001; ηp^2=0.28). Post hoc comparisons using the Bonferroni adjustment revealed that each age group above 31-50 years was assessed as significantly less able to use health care DT than the younger age group before it (all P values <.001). The interaction of age group assessed and age of the physiotherapists reached significance ($F_{2.33,211.74}$=5.79; P=.002; ηp^2=0.06), such that younger physiotherapists assessed the ability of older adults to use the DTs as lower than that of older physiotherapists. The interaction between age group assessed and the primary age group of patients the physiotherapists work with was not significant.

Table 2. Means, SDs, and correlations of the sum of the 3 vignettes for each age category, ATOAUT-10, FSA, and other variables (N= 95-97)[a].

Variable	Mean (SD)	1, *r*	2, *r*	3, *r*	4, *r*	5, *r*	6, *r*	7, *r*	8, *r*	9, *r*	10, *r*

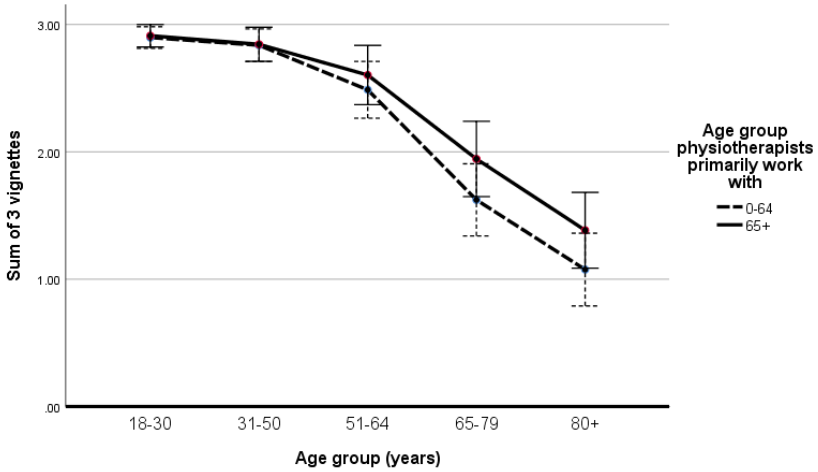
Figure 2. Assessed ability to use health care digital technologies by age group assessed and the primary age the physiotherapists work with (N=94). Error bars: 95% CI.



Correlation Between Ageism and ATOAUT

As seen in Table 2, a more negative ATOAUT score was significantly correlated with higher levels of ageism (FSA), a belief that age can be a barrier to using DT, and lower perceptions of older adults' abilities to use health care DTs (sum of vignettes for the 65-79 years and 80+ years age groups). Additionally, higher scores of ageism as measured by the FSA were correlated with lower perceptions of older adults' abilities to use health care DTs (80+ years age group). To further examine the correlation between ATOAUT and ageism, we performed a multiple regression with ATOAUT-10 as the dependent variable, and FSA, age, gender, and the primary age group physiotherapists work with as independent variables. A significant model was found (adjusted R^2=0.14; $F_{4,92}$=4.75; P=.002), indicating that beyond all predictors, FSA was the only significant predictor (β=.36; t=3.73; P<.001).

Study 2

One participant did not answer the validity item correctly. Analysis that included this participant revealed that the results would not be altered, and the participant was hence included in the analysis. Table 3 presents the means and SDs of the main variables by condition and correlations. No significant differences were found between participants in the different age salient conditions (young or old) regarding background variables of age, gender, health care profession, and percentage of patients over the age of 65 years that the professional works with. We then analyzed the indirect measure of assessing the ability in using actual health care DTs, using a multiple regression with the sum of the vignettes as the dependent variable and age salience condition and background variables (age, gender, and percentage of patients over the age of 65 years) as independent variables. As observed in Table 3, younger adults were perceived as more likely to use the described DTs compared to older adults. This was qualified by a significant regression model (adjusted R^2=0.59; $F_{4,87}$= 34.15; P<.001), with the age salience condition being the only significant predictor (β=–.78; t =–11.61; P<.001).

[g]n=92.

[h]This variable was dummy coded (0 = no, 1 = yes).

*P<.05.

**P<.01.

Examining the direct measure of the ATOAUT-10 scale revealed that negative ATOAUT scores correlated with the younger age of the health care professionals and belief that age is a barrier to using DT. Yet, the simple correlation with ageism (ERA-12) was insignificant. We then tested our hypothesis that age salience would moderate the correlation between ATOAUT and ageism. Table 4 and Figure 3 present the regression coefficients and interaction of age salience X ERA-12. A significant moderation model was found (R^2=0.19, $F_{6,85}$=3.35; P=.005) and the age salience X ERA-12 interaction qualified as a significant moderator, adding significant explanatory variance to the model (R^2 change=0.05; $F_{1,85}$=4.90; P=.03). For the conditional effect of the old age salience condition, negative ERA-12 (higher ageism) was (marginally) associated with a

more negative ATOAUT score (β=.34; *t*=0.82 *P*=.07; CI –0.03 to 0.72), whereas for the young age salience condition, it was not (β =–.22; *t*=–1.23; *P*=.22; CI –0.57 to 0.13). Moreover, the age of the professional was identified as a significant predictor of ATOAUT score, with the younger age of the professional being associated with a negative ATOAUT score.

Table 4. Regression coefficients of the moderation model between ERA-12 and attitudes toward older adults using technology (ATOAUT-10) by age salience, with controlling for age, gender, and professionals' percentage of patients above 65 (N=92).

Variable	Coefficient	SE	*t*	*P* value	LLCI[a]	ULCI[b]

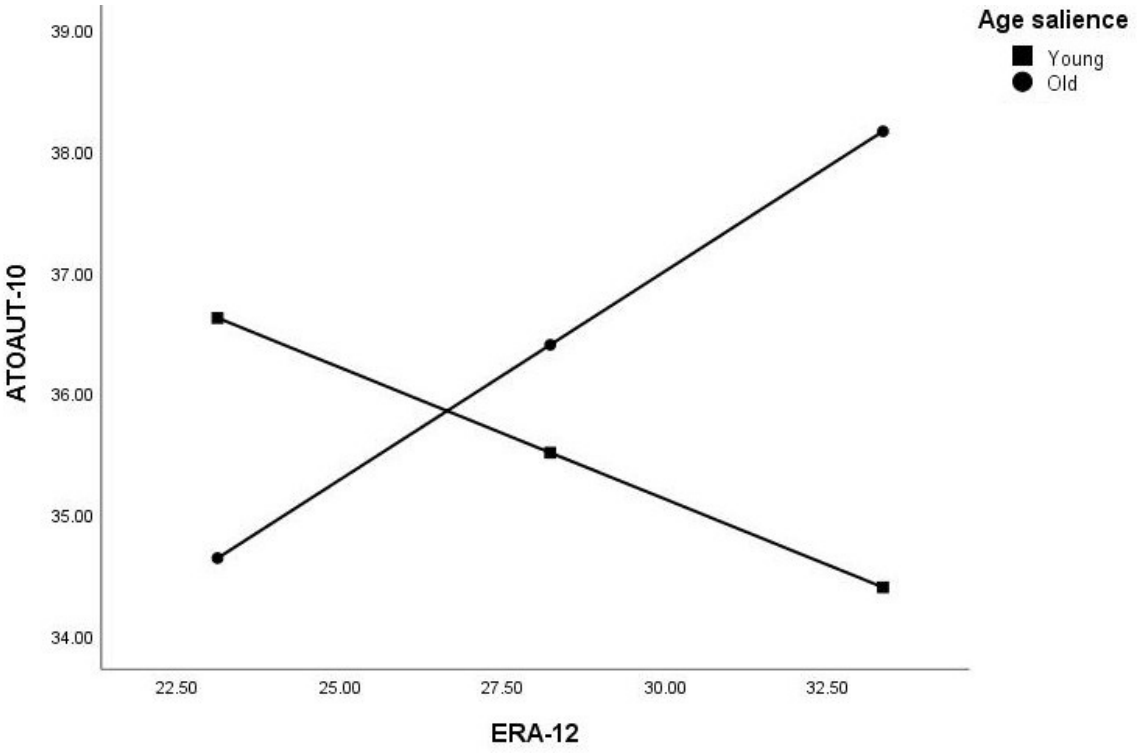
Figure 3. Moderation of the correlation between ATOAUT and ageism (ERA-12) by age salience (N=92). ATOAUT: attitudes toward older adults using technology; ERA-12: Expectations Regarding Aging.



Discussion

Principal Findings

The aim of these studies was to explore attitudes of health care professionals toward older adults' abilities to use DT, as a specific domain of ageism. In study 1 we developed the ATOAUT-10 scale, a direct measurement of stereotypes and prejudice toward use of DT by older adults, and an indirect measurement (vignettes), which were thereafter used in study 2. In the process of developing the ATOAUT-10, we identified ten items that represent stereotypes and prejudice toward older adults in the context of using DT. As hypothesized, significant correlations were found between negative ATOAUT and higher levels of ageism, measured by 2 different ageism scales (FSA in study 1 and ERA-12 in study 2). More so, negative ATOAUT correlated with lower perception of older adults' abilities to use actual health care DTs, measured by the vignettes; belief that

age is a barrier to using DT; and younger age of the health care professionals (in study 2). Thus, enhancing its construct validity. The correlation with ageism measured by the FSA in study 1 was significant and accounted for additional predictors in a multiple regression. Yet, this correlation was small to medium, suggesting that ageism alone does not fully explain physiotherapists' attitudes toward older adults' abilities to use DT.

By using an indirect measure of the vignettes, we were able to assess health care professionals' perceptions on how they believe older adults use health care DT. Our main finding in study 1, that individuals from older age categories are perceived as less able to use DTs is not surprising [10]. Yet still, the difference found between age groups was quite dramatic, with a significant difference between each age group above 31-50 years with the previous age group. Hence, a DT-specific age threshold [23] for negative assumptions about the ability to use health care DTs, might be as early as 50 years, which includes people in their working age who are considered to use DT on a daily basis, and not only people above 80 years. This finding alone might confirm an assessment that is based on stereotypes and not facts, as the majority of older adults in some countries use smartphones and the internet [30]. In study 1, rating all age groups by the participants might have activated age stereotypes by means of categorization and social comparison [47], but in study 2, the age group salient in the vignettes was manipulated (young or old). Once more, a significant difference was found in how the technological abilities of older adults were perceived by health care professionals. More importantly, as hypothesized, this subtle manipulation of age salience moderated the correlation between ageism and ATOAUT, such that higher levels of ageism were associated with a more negative ATOAUT score but only when old age was made salient beforehand. Although the moderator of age salience was significant, it should be noted that the effect size of the moderator's addition to the explained variance was small.

These results reveal perspectives that are quite ageist, considering the accumulating evidence on the increasing prevalence of using DT by older adults. Furthermore, they demonstrate how DT-specific ageism can operate implicitly by merely inducing social comparison or making the concept of age salient. Consequently, this raises the concern that older adults might be discriminated in how they receive (or do not receive) technology-based treatments, as found in other studies with nontechnological treatments [37,38]. This is worrying, considering the discussed benefits of DT in facilitating health care and reducing costs [2]. Notably, we did not explicitly ask health care professionals about their intentions to offer DT-based treatments; therefore, the behavioral and discriminatory aspect of ageism was not addressed in this study. However, it can be assumed that attitudes and beliefs might influence intentions to use and actual use, as is often emphasized by technology acceptance models [7,9,10]. Interestingly, the correlation between ageism and ATOAUT was not significant for participants in the young age salient condition. This could be explained by the matching of the age category (young vs old) and the specific attributes of the context (eg, competency of older adults in using DT) that occurs only in the old age salient condition and may activate specific age-based stereotypes [55]. Although people might be unaware of the underlying processes that influence their attitudes, there is still a matter of controllability of induced behavior and actual use of stereotypes [15]. Explicit and implicit stereotypical evaluations are both, to some extent, prone to belief-based learning processes [18]. Therefore, control over behavioral expressions (namely discrimination) is also a matter of social norms and social acceptability. As ageism is still relatively socially acceptable, expressions of discrimination, especially in domains where older adults are highly stereotyped, such as DT, might be prevalent.

Although previous studies reported gender and more experience of treating older patients [41] as possible predictors of attitudes of health care professionals, these effects on ATOAUT or ageism were not found in this study. Younger age of the professional was found to predict negative attitudes only to a limited extent. Unfortunately, these findings do not shed new light into the inconclusive findings in the literature [35] and do not strongly support the idea that increased social contact with older adults [43] can reduce negative attitudes in relation to health care DTs. This might be due to the higher exposure of health care professionals to older adults who are ill or suffer from chronic conditions [45]. Subsequently, these findings suggest that stereotype activation might be a stronger predictor of negative ATOAUT score. However, the effect sizes found were relatively low. Perhaps a stronger manipulation of stereotype activation, such as priming negative age stereotypes, could lead to stronger effects. Alternatively, other characteristics should be taken into account, such as professionals' desire to work with older adults, the valence of their professional and social contact with older adults, or previous experience of using DT in health care.

Knowledge and training are important aspects when trying to control or combat automatic stereotype activation. Gawronski et al [56] found that training people to acknowledge information that contradicts stereotypes may reduce automatic stereotype activation. Training might offer positive outcomes in reducing ageism in health care and enhance positive contact [57]. Nevertheless, formal training of health care professionals regarding ageing (more so stereotype activation) is still lacking in curricula, and the esteem of working with older patients is still low [58]. We therefore suggest that training should include modules to raise awareness on biases and how easily our behavior is affected by them.

This study focused mainly on the perspective of health care professionals. It is however important to consider that indirect expressions of ageism, including patronizing speech [17], "Elderspeak" [59] or other nonverbal communications [36], might in turn lead to stereotype activation within older patients. These stereotypes are often embodied [21] and directed toward oneself, further affecting participation [19] and actual use of DTs. Hence, attitudes of older adults, as well the reciprocal nature of the interaction between them and others, should be a focus of future research on DT-related ageism.

Limitations

The findings of this study provide a preliminary basis for future research and validation of the ATOAUT-10 scale. However, there were 3 main limitations regarding our measurements. First, our sample size in study 1, while sufficient for the regression analysis, can be considered to be on the lower boundary of minimal sample sizes for factor analysis [60]. Furthermore, the sample in study 1 consisted only of physiotherapists. The sample in study 2, therefore, was broadened to a wider range of health care professionals. However, in order to expand the scale's validity, future studies focusing solely on the validation of the scale with an appropriate sample size and including a diversity of health care professionals and other stakeholders, is needed. Second, it can be claimed that our sample was biased in gender and experience. Although early career and experienced professionals were represented in both studies, a better balanced and planned sampling might have enhanced the validation of the scale. Third, in study 1, a large number of participants missed the validity check item inserted in the FSA, which raised concerns they did not answer the FSA seriously enough. This could be due to the length of the FSA, and some outdated items which might be less suited to Dutch society. A recent review by Ayalon et al [11] found that the psychometric properties of the FSA are considered low compared to other ageism scales. This was the reason we used a different ageism scale in study 2 (ERA-12). Therefore, continued use of the ERA-12 in future studies aimed at replicating these findings is warranted. Finally, as mentioned, our study did not focus on the actual intentions of professionals to use health care DT, or, in other words, the behavioral aspect of discrimination and adoption of DT. This would also be a recommendation for future research with this scale, which could also be used to broaden theoretical models of technology adoption [7,9,10].

Conclusions

The highly negative attitudes of health care professionals toward older adults' abilities to use DTs raise the question of how DTs are used in treatment. Activation of age-based stereotypes seems to play a pivotal role in these attitudes, possibly suggesting that nonadoption of DT is not entirely attributable to chronological age or individual characteristics. Using health care DTs indeed presents an opportunity to improve treatment of chronic diseases and well-being. However, when categorizing the lower access of older adults to use DTs and discussing the digital divide as a purportedly well-established fact [28], we are often preserving a negative view that might hamper the successful implementation of DTs in health care. Instead, it is essential to acknowledge how the field of DT is constantly evolving and includes individuals from all ages with different wants and needs. It is suggested that in order to increase adoption of DT, the focus ought to shift toward how we can change stereotypes and their activation on the individual and societal level.

Acknowledgments

This work was supported by the European Union's Horizon 2020 research and innovation program under the Marie Skłodowska-Curie actions (grant agreement no. 764632; "Euroageism").

We would like to thank Anne van Tintelen and Snædís Guðmundsdóttir for assisting in the data collection as well as the colleagues from the Fontys University of Applied Science, Madelon Pijnenburg, Thom Rutten, and Jaron Schnitzer, for participating in the translation process of the FSA and ERA-12. Lastly, we would like to thank Maria Varlamova from the "Euroageism" Innovative Training Network for providing useful statistical and methodological advice. The corresponding author may be contacted for additional information regarding the methods, data analysis, and study material. This study was not preregistered.

Authors' Contributions

All authors were involved in the conceptualization of the study, development of the measurements and scales, data collection, and analysis. IM prepared the first draft of the paper. All authors contributed by reviewing and editing the final draft.

Abstract

Background: The delivery of physiotherapy via telehealth could provide more equitable access to services for patients. Videoconference-based telehealth has been shown to be an effective and acceptable mode of service delivery for exercise-based interventions for chronic knee pain; however, specific training in telehealth is required for physiotherapists to effectively and consistently deliver care using telehealth. The development and evaluation of training programs to upskill health care professionals in the management of osteoarthritis (OA) has also been identified as an important priority to improve OA care delivery.

Objective: This study aims to explore physiotherapists' experiences with and perceptions of an e-learning program about best practice knee OA management (focused on a structured program of education, exercise, and physical activity) that includes telehealth delivery via videoconferencing.

Methods: We conducted a qualitative study using individual semistructured telephone interviews, nested within the *Physiotherapy Exercise and Physical Activity for Knee Osteoarthritis* randomized controlled trial, referred to as the *PEAK* trial. A total of 15 Australian physiotherapists from metropolitan and regional private practices were interviewed following the completion of an e-learning program. The *PEAK* trial e-learning program involved self-directed learning modules, a mock video consultation with a researcher (simulated patient), and 4 audited practice video consultations with pilot patients with chronic knee pain. Interviews were audio recorded and transcribed verbatim. Data were thematically analyzed.

Results: A total of five themes (with associated subthemes) were identified: the experience of self-directed e-learning (physiotherapists were more familiar with in-person learning; however, they valued the comprehensive, self-paced web-based modules. Unwieldy technological features could be frustrating); practice makes perfect (physiotherapists benefited from the mock consultation with the researcher and practice sessions with pilot patients alongside individualized performance feedback, resulting in confidence and preparedness to implement new skills); the telehealth journey (although inexperienced with telehealth before training, physiotherapists were confident and able to deliver remote care following training; however, they still experienced some technological challenges); the *whole package* (the combination of self-directed learning modules, mock consultation, and practice consultations with pilot patients was felt to be an effective learning approach, and patient information booklets supported the

training package); and impact on broader clinical practice (training consolidated and refined existing OA management skills and enabled a switch to telehealth when the COVID-19 pandemic affected in-person clinical care).

Conclusions: Findings provide evidence for the perceived effectiveness and acceptability of an e-learning program to train physiotherapists (in the context of a clinical trial) on best practice knee OA management, including telehealth delivery via videoconferencing. The implementation of e-learning programs to upskill physiotherapists in telehealth appears to be warranted, given the increasing adoption of telehealth service models for the delivery of clinical care.

Introduction

Background

Physiotherapy care is traditionally delivered via in-person consultations. However, for many people, access to physiotherapy is limited by geographical isolation, or limited local services, or both [1]. To this end, experts in Australia [2] and the United Kingdom National Health Service [3] have identified the need to make full use of digital technologies to facilitate patient convenience and access to care. Such services have become even more critical during the COVID-19 pandemic. Social distancing requirements and *lockdown* restrictions have affected the delivery of in-person health care worldwide, including for noncommunicable diseases, where rehabilitation services have been among the hardest hit [4]. The COVID-19 pandemic has accelerated the drive toward telehealth service delivery as a safe and viable model for physiotherapy services [5,6].

Telehealth is defined by the World Health Organization as the "delivery of health care services, where patients and providers are separated by distance. Telehealth uses information communication technology for the exchange of information for the diagnosis and treatment of diseases and injuries, research and evaluation, and for the continuing education of health professionals" [7]. Data suggest that only a minority of physiotherapists were providing telehealth services prepandemic [8,9], highlighting the lack of telehealth experience within the profession. Delivering physiotherapy via telehealth requires new technical skills and new clinical skills to adapt clinical practice to treating a patient located remotely from the clinician [10,11]. Although generally computer literate, clinicians delivering rehabilitation services for chronic pain typically have limited confidence and knowledge in the use of telehealth [12]. Furthermore, clinician acceptance and confidence in telehealth increases with both training and repeated exposure to telehealth practice [10,12,13]. Thus, specific training in telehealth is required for physiotherapists to effectively and consistently deliver care via this medium [14].

Advancing technologies allow education and training for medical and allied health students and professionals to overcome learning barriers such as distance and the limited availability of specialist training staff while also providing a standardized experience for learners [15]. e-Learning broadly relates to the delivery of educational material through information and communication technology (ICT) [16,17], using the internet to wholly or partially replace the need for a human instructor [18,19]. e-Learning can be synchronous (mediated in real time, eg, videoconference), asynchronous (self-directed, self-paced learning), or a combination of both. A systematic review of studies in practicing or trainee doctors and other health professionals compared e-learning interventions with noninternet learning or no learning interventions. Findings revealed that e-learning was associated with large positive effects on education outcomes (knowledge and skills) compared with no learning, whereas only small, inconsistent effects were seen between e-learning and noninternet learning [18], suggesting that e-learning may be similarly effective to more traditional teaching methods.

Osteoarthritis (OA) is a common and often debilitating chronic joint disease and is one of the leading causes of pain and disability in Australia [20] and worldwide [21]. Symptoms can become increasingly debilitating over time and can greatly affect quality of life, contributing to feelings of dependence and loss of autonomy in older people [22]. As a result of an aging population, combined with increasing obesity rates, the disease burden associated with knee OA is forecast to increase substantially over the coming decade [23]. There is no cure for OA. However, improvements in pain, physical function, and quality of life have been demonstrated with exercise-based interventions [24,25]. Thus, clinical guidelines consistently emphasize education, exercise, weight loss (if required), and support for self-management to alleviate knee OA symptoms before using surgical or pharmacological interventions [26-30].

Given the central role of exercise in disease management, physiotherapists in primary care settings play an important role in providing care to people with knee OA. However, physiotherapists often feel underprepared to manage OA, lacking knowledge about evidence-based practice and confidence in implementing recommendations into routine care [31-34]. The development and evaluation of training programs to upskill health care professionals in OA management has thus been identified as an important priority for improving OA care [35-37]. Telephone- and videoconference-based telehealth interventions have been shown to be effective and acceptable [14,38-40] modes of service delivery for exercise-based interventions aimed at relieving chronic knee pain and improving physical dysfunction and are as effective as in-person care for adults with musculoskeletal pain [41]. Australia's National Osteoarthritis Strategy [20] has also called for the increased implementation of remotely delivered evidence-based OA services.

Objectives

In this study, we explore the experiences of physiotherapists with and their perceptions of an e-learning program aimed at educating physiotherapists about best practice knee OA management, including the implementation of a protocolized management program focused on education, exercise, and physical activity, and how to deliver such care remotely using a videoconferencing platform.

Methods

Design

A qualitative study nested within an ongoing randomized controlled trial (RCT; Australian New Zealand Clinical Trials Registry: ACTRN12619001240134) [42] was conducted. The Physiotherapy Exercise and Physical Activity for Knee OA RCT (known and referred to as the *PEAK* trial) is a noninferiority trial comparing physiotherapist-delivered in-person consultations with physiotherapist-delivered video consultations for people with knee OA. For the RCT, 15 physiotherapists were provided with a structured program of e-learning in best practice knee OA management, including the implementation of a protocolized management program focused on education, exercise, and physical activity as well as how to deliver such care remotely using a videoconferencing platform. In this study, a qualitative approach was chosen to explore the physiotherapist's experience of e-learning as well as its impact and perceived effectiveness. The research design was centered around a constructivist paradigm, which asserts that people generate their own understanding and knowledge subjectively through experience and reflection [43]. The Standards for Reporting Qualitative Research checklist guided the reporting [44].

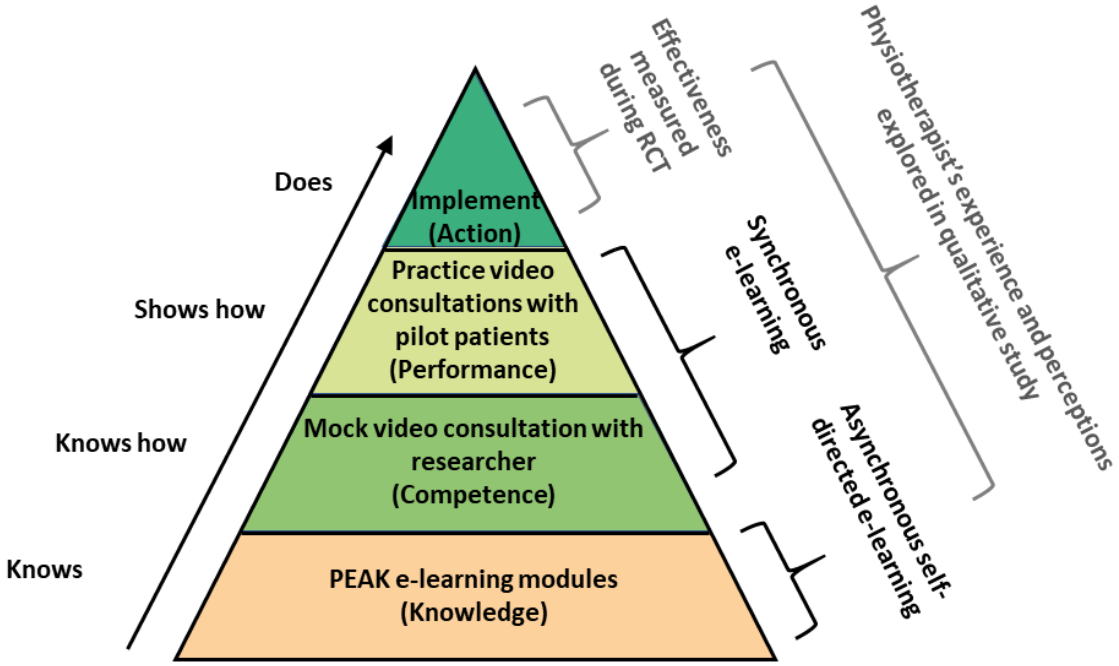
Participants

All 15 physiotherapists recruited to deliver trial interventions for the PEAK RCT participated in this qualitative study. Eligibility criteria for physiotherapist participation in the RCT included current registration to practice as a physiotherapist, private practice located in metropolitan or regional Victoria or Queensland (Australia), access to a computer with internet connection, suitable workspace for confidential video consultations, and some previous experience with videoconferencing software, for example, Skype, Zoom, or Facetime (not necessarily for delivering clinical care). Physiotherapists who met the eligibility criteria were considered for the study, and participating physiotherapists were selected based on their availability and location to ensure geographical spread across metropolitan and regional areas of Victoria and Queensland. All participants provided written informed consent, and the qualitative study was approved by the Institutional Human Research Ethics Committee, separate from the RCT.

Training Program

The PEAK trial training program was developed by the research team, using an e-learning approach featuring both asynchronous and synchronous learning, developed in line with the Miller Pyramid (Figure 1), a learning model designed for use in health education [45]. The model proposes that the foundation of the pyramid is knowledge (*knows*), with learners understanding the relevant facts and theories. The next level is competence (*knows how*), with learners developing skills necessary to apply knowledge, demonstrated via a mock video consultation with a researcher (simulated patient). Next is performance (*shows how*), with learners demonstrating, via practice video consultations with pilot patients, that they can apply knowledge and skills in a realistic clinical context. The final stage represents action (*does*)—the stage at which the learner has integrated their knowledge, skills, and attitudes and is prepared to integrate the competency into their clinical practice. Results from the linked RCT will provide data on the effectiveness of the implementation.

Figure 1. Schematic representation of the PEAK (Physiotherapy Exercise and Physical Activity for Knee Osteoarthritis) training components mapped to the Miller Pyramid learning model. PEAK: Physiotherapy Exercise and Physical Activity for Knee Osteoarthritis. RCT: randomized controlled trial.



Physiotherapists first completed approximately 5 hours of self-directed e-learning modules delivered at the University of Melbourne Learning Management System (LMS; Canvas LMS by Instructure, 2019) covering OA management best practices (including a structured physiotherapy treatment protocol), telehealth (the delivery of care via Zoom videoconferencing), and trial procedures. Each module included a quiz to help reinforce user's knowledge and learning. e-Learning was completed at the user's own self-selected pace (ideally within 4 weeks) and delivered knowledge as the foundation of the physiotherapist's learning. The PEAK training program e-learning modules have since been released for use by clinicians more widely [46].

The e-learning then moved to *practical* synchronous components, whereby physiotherapists participated in a mock initial consultation via videoconferencing with a physiotherapist researcher (AJK; simulated patient), who provided immediate verbal feedback on consultation quality and performance and evaluated the physiotherapist's competency according to a standardized competency checklist (Multimedia Appendix 1). The next stage of *practical* synchronous e-learning required physiotherapists to complete 4 practice video consultations, with 2 pilot patients with chronic (>3 months) knee pain (recruited by research staff) to practice their video consultation skills and apply the education, exercise, and physical activity management program taught in the e-learning modules in a realistic scenario. The research staff conducted spot-checks of consultation recordings to assess the fidelity of the practice consultations to the protocolized treatment plan. Written feedback on common mistakes was provided to participants, and personalized feedback was provided verbally to individual physiotherapists after all pilot patient consultations had been completed. Physiotherapists were financially compensated for the time away from private practice that was dedicated to all elements of participating in the training program and the time taken to complete the interviews.

Semistructured Interviews

Semistructured interviews were conducted after physiotherapists completed all components of the training program and commenced treating participants in the PEAK RCT. The interview schedule (Table 1) was developed based on a constructivist schema whereby physiotherapist expectations, training experience, and perceptions of effectiveness of the e-learning program in changing confidence, imparting knowledge, and addressing learning needs were explored. Questions were loosely aligned with the theoretical framework of acceptability [47], focusing on the framework's five most relevant constructs to the e-learning program (affective attitude, burden, perceived effectiveness, intervention coherence, and self-efficacy). All interviews were conducted over the telephone by SEJ (a researcher who is not a physiotherapist but is trained in qualitative research) who was not involved in the RCT or in developing the training program and was otherwise unknown to the participants. Interviews lasted approximately 30 minutes and were audio recorded and then transcribed verbatim by a third party. Audio recordings and transcripts were deidentified, with transcripts assigned gender-matched pseudonyms to ensure participant confidentiality. All data were stored in digital format on a password-protected university server.

Table 1. Semistructured interview schedule (loosely aligned with the theoretical framework of acceptability).

Topic and construct	Questions (prompts)
Expectations	
Affective attitude; self-efficacy	
	1. Can you tell me how confident you were in your ability to deliver an OA[a] management program before the PEAK[b] trial training? Previous OA management training? *Usual* management of knee OA before training?
	2. Can you tell me about how confident you were in your ability to deliver physiotherapy to OA patients via videoconferencing, before you started the PEAK training? Training or professional development or experience in telehealth?
	3. What were your overall impressions and experience of the training program? Expectations? Comparison with previous professional development?
Training experience	
Burden	
	4. What did you like and dislike about the training program? Consider both the web-based modules and the *practical* aspects of training (ie, the *competency* video consultation and 4 practice patient video consultations)? Time taken for web-based modules? Volume of material?
Intervention coherence	
	5. To what extent did you feel your learning needs were met (or not) through the PEAK training program? Was there anything else you felt need to be covered or a required a greater focus in the training? Was there anything included that you felt was unnecessary?
	6. What were your thoughts on the content and presentation of the content in the PEAK web-based modules? How did you feel about the volume of text presented? How would you prefer to see the content delivered? If you were to change the content or its presentation, what would you suggest?
	7. What were your impressions about the usability of the web-based training platform? Like/dislikes/changes?
	8. How did you find the *competency video consultation* with the research staff member? Was it useful?
	9. Can you tell me a little bit about what you thought about the practice video consultation sessions with the pilot patients with knee pain? Were these consultations useful?
Perceived effectiveness	
	10. Can you tell me overall how useful you found the PEAK trial training program? Intent to implement changes to usual clinical practice?
	11. How confident do you feel in delivering OA management to patients now, after completing the PEAK trial training? What elements do you feel most/least confident with?
	12. How confident do you feel in delivering physiotherapy to your OA patients over videoconference, now that you have completed the PEAK training? What elements do you feel most/least confident with?
Concluding remarks	
	13. Given the restrictions on clinical practice imposed by the current COVID-19 pandemic, has the PEAK training program enabled you to make any changes to your own current clinical practice?
	14. Thank you very much for all your time today and all your time and efforts with this study. Is there anything else you would like to add about your experiences with the PEAK training program?

[a]OA: osteoarthritis.

[b]PEAK: Physiotherapy Exercise and Physical Activity for Knee Osteoarthritis.

Data Analysis

Data analysis was conducted using a thematic approach [48]. Shortly after transcription, interview transcripts were read by SEJ to familiarize with the data. Transcripts were then reread and coded, with text indexed into topics, each identified with a short descriptor. To demonstrate the credibility and confirmability of the emergent topics and patterns, coding was also performed by a second researcher PKC (not a physiotherapist but assisted with developing the training program and recruited physiotherapists into the RCT, and trained in qualitative research). Topics identified by both SEJ and PKC were reviewed, and in collaboration, closely related topics were collated to generate emergent themes within the data. All transcripts were also read by RSH (a physiotherapist who led the development of the training program and an experienced qualitative researcher) who confirmed the relevance of emergent themes across transcripts. Emergent themes were then further refined, ensuring clear and encompassing definitions were generated when naming final themes and subthemes. Themes and subthemes were presented with exemplary quotes from interviews to demonstrate the transferability of the results [49].

Results

Physiotherapist Characteristics

All 15 physiotherapists recruited to deliver care as part of the PEAK RCT were invited to participate in the qualitative interviews. The sample comprised physiotherapists who worked in private practices across 2 Australian states. Physiotherapist characteristics are summarized in Table 2, including the number of PEAK RCT participant consultations conducted by each physiotherapist at the time of the interview. Participating physiotherapists were more often male (11/15, 73%). There was an even divide between those who worked in major cities (8/15, 53%) and those who worked in regional areas (7/15, 47%). Of the 14 physiotherapists, 8 of them (60%) had no previous experience with telehealth. The mean (SD) of years of clinical experience was 11 years (SD 4), and the mean numbers of PEAK RCT participants who physiotherapists had already treated at the time of the interview were 2 (SD 1) via videoconferencing and 2 (SD 2) in-person.

Table 2. Physiotherapists' characteristics (n=15).

[c]RCT: randomized controlled trial.

Emergent Themes

A total of five themes, with associated subthemes, emerged and are described in Multimedia Appendix 2.

Theme 1: The Experience of Self-Directed e-Learning

Physiotherapists found the self-directed e-learning modules to be of high quality, comprehensive, and user-friendly and that they would "benefit the least experienced physiotherapist and the most experienced physiotherapist". Although physiotherapists were more familiar with "hands-on" in-person

professional development training for furthering their knowledge and clinical skills, they highly valued the web-based structure. In particular, the self-paced nature of the program was highly regarded and enabled the physiotherapists to fit the training into their busy daily lives and complete it as time allowed. However, the physiotherapists spoke of feeling annoyed and frustrated by some unwieldy features of the delivery platform (including log-in and navigation). Although most physiotherapists spoke highly of the web-based modules, 3 physiotherapists with divergent views spoke of the e-learning modules being "slow going", "tedious", or "fatiguing". The telehealth learning module content, in particular, was felt to be "dry" and "overtly obvious".

Theme 2: Practice Makes Perfect

Physiotherapists frequently referenced the benefit gained from individualized performance feedback from the research team during or after the practical components of the training. They spoke of "learning from applying" and that feedback was helpful ahead of implementing their new skills in a true clinical scenario. Physiotherapists found the mock consultation with the researcher (simulated patient) facilitated the transition from theory to implementation, commenting it "gave us a feel of what to expect for the upcoming pilots" and that it prevented them having to "worry about looking silly with the patients." Similarly, the practice consultations with the pilot patients with chronic knee pain were valued, with physiotherapists reporting that this stage of practical e-learning was "hugely beneficial" and "consolidated everything" ahead of consulting with actual patients. Upon completion of the practical components of the e-learning program, physiotherapists expressed a high level of confidence and readiness to go into their first patient consultations using their new skills and knowledge. Two physiotherapists with divergent views felt that the mock consultation with the researcher was "daunting" or "confronting", with one feeling that it was not necessary. The same physiotherapist also felt that the practice consultations with pilot patients were "surplus to needs".

Theme 3: The Telehealth Journey

For the most part, physiotherapists were inexperienced in telehealth before training. Experience was largely constrained to videoconferencing for social purposes rather than for health care delivery. Physiotherapists in general were nervous or uncertain about providing care to patients via telehealth before undertaking the training program. However, 3 physiotherapists felt that they were moderately confident in telehealth before training, with one stating that "it didn't seem like too much of a leap to deliver these services [exercise prescription via telehealth] to people." After completing the training, most physiotherapists were much more confident and reported that they felt ready to deliver OA care via telehealth using videoconferencing. Despite improved confidence and feelings of preparedness, physiotherapists still felt that telehealth posed some challenges, particularly in supporting patients with OA to be able to navigate videoconferencing technology effectively.

Theme 4: The Whole Package

Physiotherapists highlighted the benefits of the structured approach of the e-learning program. They found that the combination of self-directed e-learning modules, followed by practical components (mock consultation and pilot patient consultations), was very effective as a "whole package" to develop the knowledge and skills required for best practice OA care via telehealth. Physiotherapists valued the resources and patient information booklets that accompanied the training program, stating that the resources "made it really easy" to navigate the consultations and supported the implementation of their knowledge and skills into practice. One physiotherapist with a divergent view appreciated the package but felt that they would get more out of in-person training because of their learning style.

Theme 5: Implementation in Broader Clinical Practice

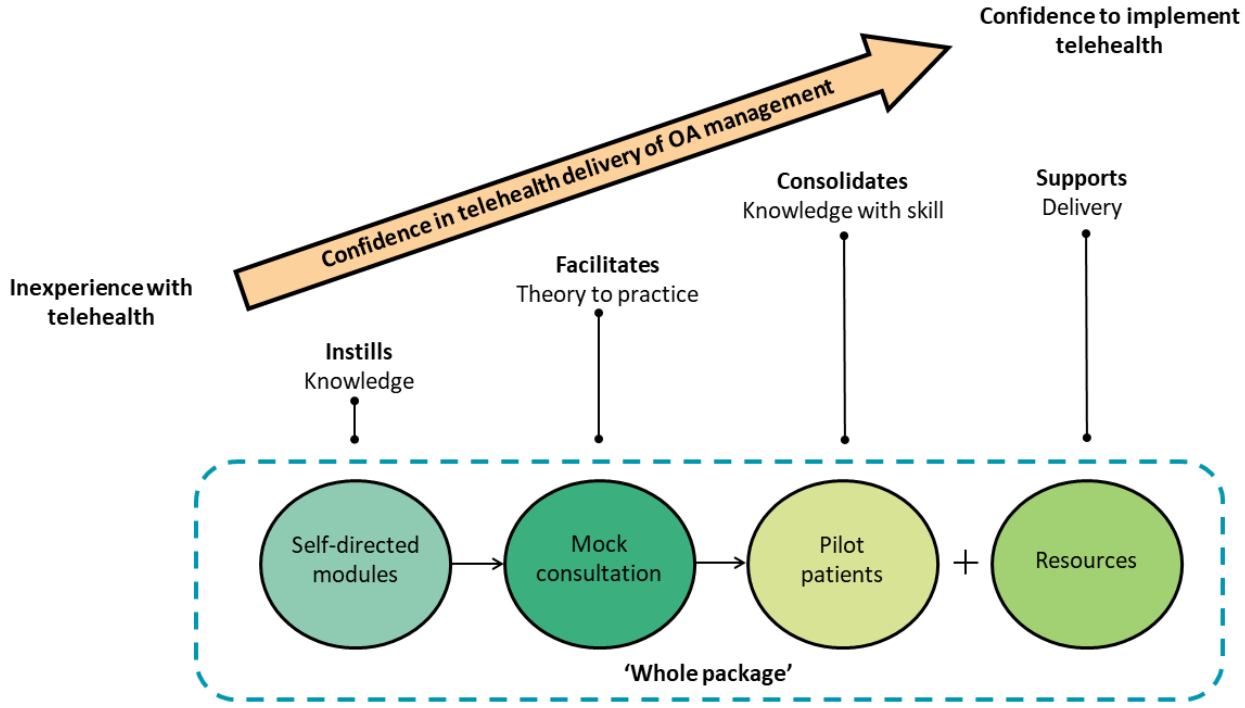
Although the greatest knowledge gains from the training program were regarding the practical implementation of telehealth for the PEAK randomized trial, physiotherapists also described their intent to apply new knowledge and skills in OA management more broadly to their own private practice. They spoke of how the training program filled "knowledge gaps", particularly regarding patient education, and provided them with a more structured approach to OA management that could be used when treating their own clients. Given that the training was completed before the COVID-19 pandemic, physiotherapists felt they were "well equipped for this COVID situation" and expressed feeling "ahead of the curve" when it came to implementing telehealth physiotherapy services more broadly, given social distancing and lockdown restrictions. They felt that the skills they had learned allowed them to confidently switch their private practice service delivery to telehealth as well as teach their colleagues about telehealth. Overall, 4 physiotherapists commented that despite the COVID-19 pandemic, they had not ramped up telehealth services or experienced demand for telehealth in their clinical practice.

Discussion

Principal Findings

Our study shows that physiotherapists accepted e-learning despite their lack of familiarity with professional development delivered entirely via the internet. Physiotherapists valued both the theoretical and practical components of training, which together formed the *whole package*. Most physiotherapists described increasing confidence in providing OA management via telehealth as they progressed through the elements of the e-learning program (Figure 2). The e-learning approach first built a foundation based on new knowledge, before facilitating a transition from theory to practice, then consolidating knowledge in a clinical scenario, and ultimately resulting in the implementation of telehealth into their broader clinical practice.

Figure 2. Schematic representation of emergent themes and their contribution to the development of confidence in delivering osteoarthritis care via telehealth. OA: osteoarthritis.



Physiotherapists perceived the asynchronous aspect of the self-directed e-learning modules to be generally user-friendly; however, the unwieldy technological features of the delivery platform could be frustrating. A previous systematic review of enablers and barriers affecting e-learning in health science education found that 33% (8/24) of the studies identified the lack of user-friendly ICT as a barrier to successful e-learning [50]. This highlights the importance of a delivery platform that is simple and user-friendly when developing e-learning resources to maximize user engagement. Similarly, a previous qualitative study identified user-friendly training and technology as key factors in the successful implementation of telehealth in diabetic foot care [51]. Physiotherapists valued the comprehensive and self-paced nature of the web-based modules, which is consistent with other research. A previous study evaluated the perceptions of physiotherapy students on asynchronous e-learning for the management of chronic health conditions [52]. Students consistently highlighted the flexibility to work at their own pace and time and access to comprehensive information as advantages of e-learning. Collectively, these findings suggest that the ability to self-pace a person's learning should be prioritized when creating adult e-learning materials.

Telehealth practical components of our e-learning program were valued by physiotherapists, which supports previous research highlighting the importance of practical components in health care education, given the need to develop *clinical or hands-on skills* alongside knowledge [53-56]. In a study evaluating e-learning for physiotherapy students on intensive care work placements [57], students perceived the e-learning modules to be helpful in preparing them for their clinical rotation and reducing their anxiety. However, e-learning modules could only sufficiently prepare students when integrated with an in-person clinical placement, where practical experience was considered necessary to build clinical reasoning skills. Similarly, other studies have noted that supervised practice and clinical simulations are valuable for building confidence and preparedness for physiotherapy students to provide care in clinical situations [58,59]. A qualitative study showed that physiotherapy students felt that clinically oriented learning, focusing on knowledge, skills, and *learning through doing*, was an important feature to include in an e-learning program about the management of chronic health conditions [52]. It is likely that the benefit of and amount of practical training required might differ depending on the level of the learner's previous relevant clinical experience as well as the nature of the clinical skill being taught, and therefore, all of these factors should be considered when developing e-learning programs. From a pedagogical perspective, learning approaches incorporating both knowledge and skills practice are consistent with adult learning theories centered around the concept of competency being developed in sequential stages of learning, grounded in theory with proficiency built through experience [45,60,61]. Our ongoing PEAK RCT will provide additional insights into the fidelity and clinical effectiveness of the structured physiotherapy treatment plan delivered using telehealth compared with the same treatment plan delivered in person.

Although most physiotherapists described increased confidence in the delivery of telehealth after training, we do not have quantitative measures in this study documenting changes in telehealth proficiency over time. Thus, we cannot draw strong conclusions about how clinical skills in telehealth changed as a result of the training. A previous study of e-learning in physiotherapists showed that asynchronous e-learning was effective in increasing quantitatively measured confidence and

knowledge in delivering self-management interventions for OA and lower back pain to patients and that the intervention was delivered with high fidelity despite a lack of supervised practical training [62]. Future research incorporating quantitative measures of intervention confidence, knowledge, and fidelity may be warranted to compare outcomes between e-learning approaches with and without synchronous practical elements of training. Future research may also aim to explore innovative alternatives to synchronous practice consultations. Such examples might include encouraging the learner to practice skills with friends or family, including completion of self-audit and self-reflection exercises.

Our sample of Australian physiotherapists was inexperienced with telehealth before training and lacked confidence in delivering care remotely. This is unsurprising given that the uptake of telehealth across Australian health services before 2020 was minimal [63,64], despite recognition of its potential to facilitate efficient health service delivery [65-67]. The COVID-19 pandemic has driven a step change in health care delivery, with rapid adoption of telehealth services by health care providers [4], coupled with increased funding for telehealth services (including physiotherapy) in several countries, including Australia [6,68] and the United Kingdom [69]. Our findings showed that the e-learning program facilitated most physiotherapists to make a rapid switch to telehealth with the sudden onset of the COVID-19 pandemic. This suggests that e-learning courses may be an effective means to train physiotherapists in best practice telehealth delivery. Education providers may also wish to incorporate e-learning telehealth training into the entry-to-practice curriculum to prepare emerging practitioners for the evolving digital health landscape.

Strengths and Limitations

Strengths of our study include the evaluation of an e-learning program for which the e-learning modules are now freely accessible to clinicians globally. Our qualitative evaluation allowed for a thorough understanding of participants' experiences and perceptions of participating in the e-learning program. Our interviews were conducted and the analysis was led by a person who was unknown to the participants and who was not a physiotherapist, minimizing the chances of personal or professional bias influencing findings. Limitations include that our sample was of limited size and comprised solely of physiotherapists who had applied and been selected to deliver the intervention as part of the PEAK RCT. Participants were bound by their clinical trial agreement to complete the training, and they were financially compensated for their time. Therefore, we cannot generalize our findings to the general population of physiotherapists who may be unwilling or unmotivated to complete training in their own time. As the training program is also only available in English, we cannot generalize the findings to non-English speakers nor to countries that may have a different scope of physiotherapy practice to that of Australia.

Conclusions

In conclusion, this study provides evidence for the perceived effectiveness and acceptability of an e-learning program to train physiotherapists (in the context of a clinical trial) on best practice knee OA management, including telehealth delivery via videoconferencing. The implementation of e-learning programs to upskill physiotherapists in telehealth appears to be warranted, given the increasing adoption of telehealth service models for the delivery of clinical care.

Abstract

Background: Sedentary behavior (SB) and lack of physical activity (PA) have been associated with poorer health outcomes and are increasingly prevalent in individuals working in sedentary occupations such as office jobs. Gamification and nudges have attracted attention as promising strategies to promote changes in health behavior. However, most effectiveness studies thus far lacked active controls, and few studies have tested interventions combining these strategies.

Objective: This study investigates the effectiveness of combining a gamified digital app with physical nudges to increase PA and reduce SB in Dutch office workers.

Methods: Employees in the municipality of Rotterdam (N=298) from two office locations were randomized at the location level to either a 10-week intervention, combining a 5-week gamification phase encompassing a gamified digital app with social support features and a 5-week physical nudges phase, or to an active control (ie, basic digital app with self-monitoring and goal setting). The primary outcome was the daily step count, objectively measured via accelerometers. Secondary outcomes were self-reported PA and SB measured at baseline and at 5, 10, and 14 weeks. Mixed effects models were used to analyze the effects of the intervention on the outcome measures.

Results: A total of 78.5% (234/298) of participants completed the study and provided accelerometer data, whereas 36.9% (110/298) participants completed the self-report measures at 14 weeks. In the gamification phase, step count data were missing for 13.5% (473/3492) of observations in the control and 11.4% (445/3888) in the intervention condition; however, these percentages increased to 39.6% (1154/2910) and 59.6% (1932/3492) at follow-up, respectively. During the gamification phase, intervention participants increased their number of daily steps by 634 (95% CI 154.2-1113.8; *P*=.01) more than participants in the control group, after controlling for relevant factors. Improvements were not sustained during the physical nudges phase (*P*=.76) or follow-up (*P*=.88).

Conclusions: A digital intervention with gamification and social support features significantly increased the step count of office workers compared with an active control. Physical nudges in the workplace were insufficient to promote the maintenance of behavioral changes achieved in the gamification phase. Future research should explore the long-term effectiveness of similar gamified digital interventions.

Introduction

Background

Ample evidence has demonstrated that moderate-to-vigorous physical activity (PA) is associated with improved health outcomes [1]. However, increasing evidence has demonstrated that light forms of PA are associated with decreased risks of cardiovascular disease and all-cause mortality, even after adjusting for levels of moderate-to-vigorous PA [2]. A systematic review has shown that light PA, such as walking (ie, objectively measured step count), is associated with lower risk of obesity and diabetes type 2 [3], and studies have found associations between light PA and lower levels of depression [4,5], stress, and burnout [6]. Moreover, sedentary behavior (SB) has been linked to higher risks of all-cause mortality [7] and reduced life expectancy [7]. SB can be defined as any waking behavior with an energy expenditure ≤1.5 metabolic equivalent of task while in a sitting or reclining posture [8]. SB can be reduced by frequently interrupting the sitting time with light PA, such as walking breaks, which have been shown to reduce the health risks related to SB [9]. Thus, even for individuals meeting guidelines for moderate-to-vigorous PA, regular engagement in light PA is recommended to further reduce all-cause mortality and improve mental and physical health.

Despite these findings, a sedentary lifestyle is an escalating epidemic. Most common occupations have become increasingly sedentary because of technological advancements, and particularly for office workers, workplace sitting patterns are largely responsible for decreases in light PA and increases in SB [10,11]. One study showed that highly educated office workers in the Netherlands spend less time in light PA and more time in SB than workers in other occupations [12], and a recent report found that Dutch workers sit on average for 10 hours per week day [13]. Given that workplace sitting is the largest contributor to decreases in light PA [12] and increases in SB [14], behavior change interventions in this setting can bring considerable benefits at both the individual and societal levels, for instance, through the prevention of health care costs associated with noncommunicable diseases [15].

Influencing Health Behaviors: Behavior Change Theory and Nudging

Noncompliance with health behaviors can be largely attributed to lack of motivation, insufficient capacity to self-regulate toward one's goals [16-18], or environmental and policy factors that may limit opportunities for healthy behavior [19-21]. According to the Social Cognitive Theory by Bandura [22], several factors influence motivation for health behavior change, such as whether people are confident in their capacity to change (ie, self-efficacy), which depends on goal characteristics (eg, difficulty), or whether people have social support to change. Social support may involve modeling by family and friends; feedback and support from peers; or social incentives enhancing accountability, competition, and cooperation. People's capacity to self-regulate can also be influenced by social support and self-efficacy and their ability to self-monitor and their use of planning strategies and reminders [17,18,23]. Socioecological models emphasize the importance of environmental and policy factors for PA, such as walkability and esthetics of the environment, and social norms. Several behavioral change techniques (BCTs) can be used to influence motivational, self-regulatory, or environmental factors to promote behavior change.

Nudging in the Environment to Promote Motivation and Self-Regulation for Light PA

Certain BCTs attempt to motivate individuals to change by providing information on the risks of their current behavior or on the future benefits of behavior change. However, although these strategies can influence people's self-reported intention to change, they have, at best, a modest effect on behavior change [24]. Recently, increased attention has been paid to using insights from behavior change theory to help people make better choices by modifying their physical and social environment [25,26] (ie, *nudging*). Nudges are typically BCTs that exploit behavioral and cognitive tendencies to promote a desired behavior, and various interventions have successfully used nudges to stimulate healthy choices in a workplace setting. Motivational nudges can increase motivation for light PA by conveying information on the benefits of walking through an authority figure (eg, a doctor). Nudges can also enhance motivation for PA by influencing the social environment related to PA; for instance, by describing the social norms regarding that behavior or through role models [27,28]. A systematic review found that motivational sign nudges were effective in promoting stair climbing in various settings, including the workplace [29].

Other nudges can help promote the self-regulation of PA goals. For instance, point-of-choice prompts are cues that function by interrupting maladaptive habitual behaviors, such as prolonged sitting, and by highlighting opportunities in the environment to engage in alternative health-enhancing behaviors, such as walking breaks. Point-of-choice prompts have been shown to be effective in promoting stair climbing instead of escalator use [30] and walking, thereby reducing SB in the workplace [31]. Workplace nudges typically involve modifications in the physical environment, ranging from changes in the default positions of desks to reduce sitting to the use of motivational or point-of-choice prompt signs incorporating various BCTs to promote walking. However, although nudges are increasingly popular, partially because of their promising cost-effectiveness [32], the effect sizes of nudging interventions tend to be modest [33], and evidence for their effectiveness is still mixed [34,35]. One way to increase the effectiveness of nudges is innovation in intervention delivery, for instance, by including nudges in interactive digital apps [31,36] or by combining it with physical

nudges in the work environment, an approach that has been largely overlooked [37].

Gamification: Improving Digital Interventions to Promote Health Behavior Change

Given the growing use of technology, digital apps are promising avenues for delivering behavior change interventions. Digital interventions provide an empirically supported, convenient, and potentially more cost-effective alternative for reaching large proportions of the public over long periods [38,39]. However, digital interventions still depend on active user engagement to promote behavior change, which is challenging to maintain. Recently, gamification has emerged as a promising persuasive strategy to increase users' engagement, motivation, and social interaction in digital behavior change interventions [40]. Gamification is an *umbrella term* that refers to the use of game design elements in a nongaming context [41,42]. Gamified digital intervention can flexibly implement a wide range of BCTs, including nudges, such as educational strategies, social support, social comparison, self-monitoring, goal setting, rewards (eg, badges), and personalized feedback, all of which have been associated with greater behavioral change [23,43,44]. Besides promoting self-regulation and motivation for the initiation and maintenance of PA [38,45], gamification can enhance social support and social comparison through competition, cooperation, and salient visualization of others' behavior (eg, leaderboards) [45,46]. Two recent studies found that digital interventions with elements such as gamification, social support, and social comparison increased light PA in office workers and promoted adequate engagement and adherence with the digital app [46,47].

Despite the promising potential of gamification, recent reviews of gamified digital interventions have highlighted lack of empirical studies comparing gamified digital interventions with active controls (ie, nongamified digital interventions) [45,48]. Although multiple BCTs and nudges can be flexibly incorporated in gamified digital interventions, the effectiveness of such interventions could still be further enhanced through complementary strategies that engage participants outside of the virtual environment. For instance, physical nudges in the workplace, such as *motivational* and *point-of-choice prompts* sign *nudges*, are easy to implement and could serve as a cost-effective way to improve maintenance of the initial behavior change promoted through gamified digital interventions. However, research is needed to explore whether these types of physical nudges could complement and increase the effectiveness of gamification to promote behavior change.

This Study: MoveMore

We conducted a cluster randomized controlled trial (RCT) to evaluate the effects of *MoveMore*, a 10-week multicomponent intervention, on the PA and SB of office workers. The MoveMore intervention consisted of a 5-week gamification phase that included a commercially available gamified digital app incorporating several BCTs and nudges, such as social support and social comparison, followed by a physical nudges phase for the last 5 weeks, in which physical *motivational* and *point-of-choice prompt nudges* were introduced in the workplace. Intervention effects were compared with an active control encompassing a basic version of the digital app. We hypothesized that during the gamification phase, participants in the intervention condition would increase their levels of objectively measured light PA (ie, daily step count), compared with the control. Similarly, we hypothesized that during the gamification phase, we would observe increases in self-reported light PA, increases in self-reported moderate-to-vigorous PA, and reductions in SB in participants in the intervention condition compared with the control. We expected that improvements achieved during the gamification phase would be maintained during the physical nudges phase and at a 1-month follow-up.

Methods

Study Design

To evaluate the effects of the MoveMore intervention, a 2-arm cluster RCT was conducted at 2 office locations in the municipality of Rotterdam, the second largest city in the Netherlands. Each office location was randomly allocated to either the control or the intervention condition to minimize treatment contamination. The study protocol was approved by the Ethics Review Committee of the Department of Psychology, Education and Child Studies, Erasmus University Rotterdam (application number 18-039). The study was registered in the International Standard Randomized Controlled Trial Number Register (ISRCTN 49129401). This study is conducted and described according to the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist (Multimedia Appendix 1) [49].

Study Setting and Population

Participants were office workers (N=298) from 2 government workplaces in the city center of Rotterdam (office locations A and B). Office location A consisted of a tall office building, with 44 floors accommodating city management and urban development departments, whereas office B consisted of a wide office building, with 5 floors accommodating social development departments. In both locations, government employees belonged to several different occupational groups, including managers, administrative workers, and blue-collar workers. In this field study, it was only possible to recruit departments located in 2 office buildings in the municipality of Rotterdam. Given the limited number of departments involved in this study, our sample size was limited by the number of employees in these departments who were willing and eligible to participate in the research. Considering that the feasible sample size of this field study was larger than that of multiple other PA intervention trials in office workers with similar methodologies [46,50,51], our feasible sample size was considered sufficiently adequate to investigate the effects of this intervention.

Eligibility Criteria

Given that several components of the intervention were in Dutch, only individuals fluent in the Dutch language were eligible to participate. Additional eligibility criteria included working in a department that was not involved in another PA-related intervention, access to a smartphone capable of

running the required digital app, and provision of written informed consent for participation.

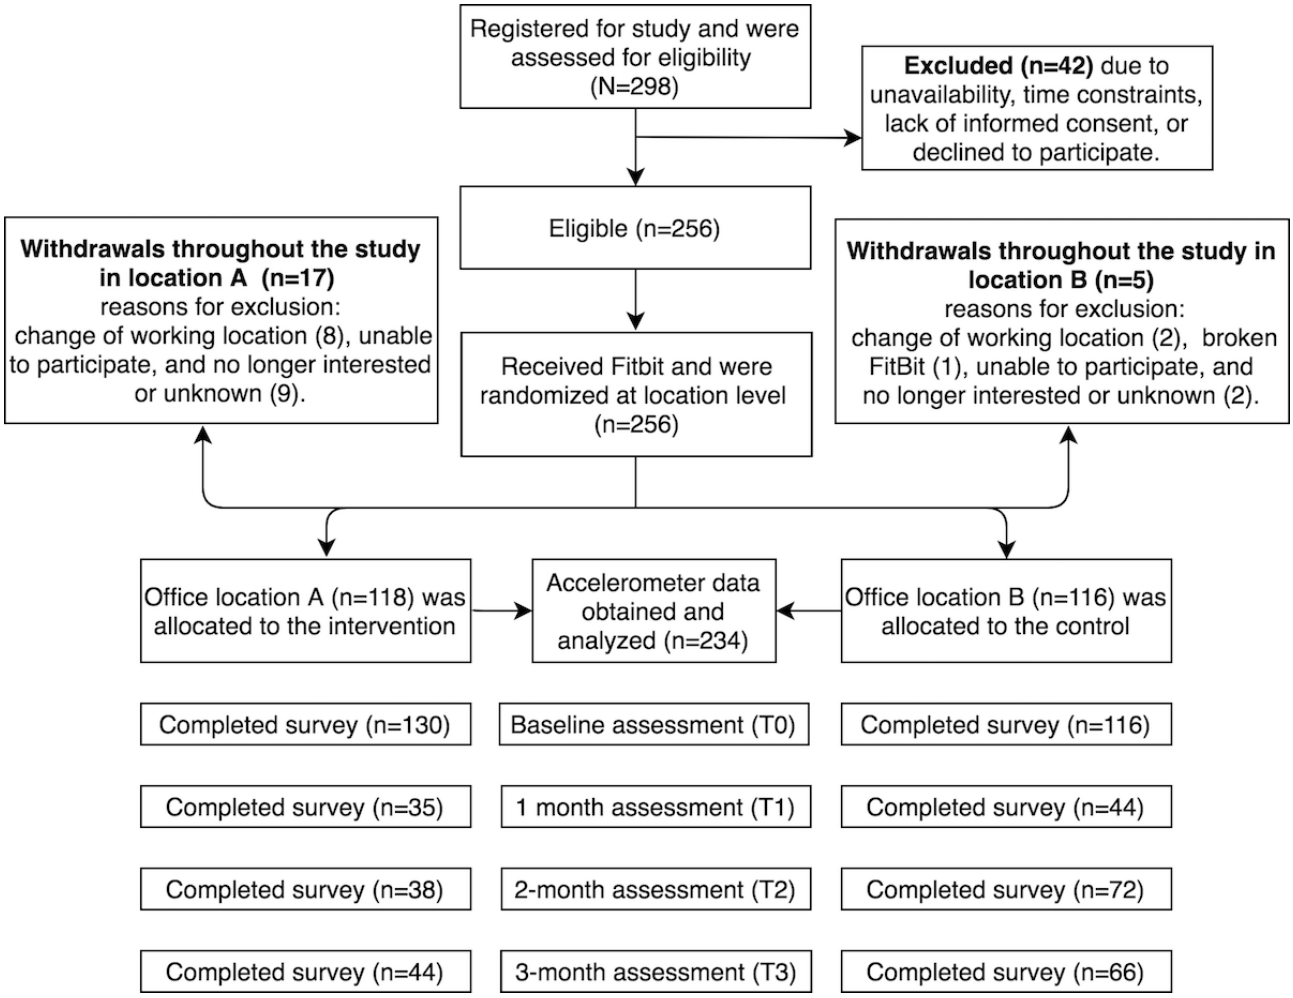
Recruitment

Potential participants were invited via email and social media and through their department team leaders to participate in a study on PA in office workers. Once approximately 150 office workers from each location responded, the invitation was closed. In total, 125 office workers from location A were included in the intervention arm, and 131 office workers from location B were included in the control arm. Participants were enrolled in October 2018 and were followed until February 2019.

Procedure

Participants were invited to attend an information session held by a study representative from the municipality, during which potential participants were screened for eligibility criteria, and participants' baseline measurements and informed consent were collected. Participants received written and verbal explanations of the intervention requirements before providing their consent. Subsequently, participants received a wrist-worn, triaxial accelerometer device (Fitbit Flex) to monitor step count [52] and were shown how to use it in combination with a digital app installed on their mobile phones during the session. The app was available for both iOS and Android operating system and was accessible through a website. Participants authorized their data to be captured for the study. Participants were told that the digital app was intended to support them in becoming more active and that they should use it throughout the day to help them increase their PA. Participants received subsequent questionnaires (Figure 1) via email during the interventions, at 5 weeks after baseline (T1), at 10 weeks after baseline (T2; postintervention), and at 14 weeks after baseline (T3; follow-up). Figure 1 illustrates the flow of participants throughout the study.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram displaying the flow of participants throughout the study.



Intervention and Control

Participants in the control location were given a basic version of the app (Figure 2), whereas those in the location receiving the MoveMore intervention were given the full version of the digital app, which included additional features (Figure 3). Both versions of the app were linked to the accelerometer and provided users with a default daily step count goal. Participants were instructed on how to monitor their own daily step count and how to set more challenging daily step goals for themselves (Figure 2). The basic features available in both apps also included weekly personalized feedback to participants via email. In the first 5 weeks of the MoveMore intervention condition (ie, gamification phase), office workers were invited to participate in PA challenges through the digital app, which incorporated elements of gamification and social support and social comparison features. After the gamification phase, physical nudges were introduced to the workplace of participants

in the MoveMore intervention for another 5 weeks (ie, physical nudges phase). As one of this study's aims is to investigate whether physical nudges could promote maintenance of improvements in light PA achieved through the gamification phase, the order of the different study phases was not randomized. An overview of the study and intervention design is shown in Figure 4. The exact BCTs used in the MoveMore intervention and in the active control are described in the subsequent sections and in Table 1 according to the BCT version 1 taxonomy developed by Michie et al [53].

[a]Behavior change techniques applied through the gamified digital app, physical nudges, or basic digital app.

[b]N/A: not applicable.

Control Condition

The basic app used in the control condition allowed participants to self-monitor and to set their own daily step goal (Figure 2). The basic app gave participants a default daily step goal of 10,000 steps, which remained the same throughout the study. The basic app also provided participants with weekly personalized feedback on their step count progress via email (Multimedia Appendix 2). This basic app served as an active control because it allowed for an objective assessment of light PA, and its components (ie, self-monitoring, goal setting, and personalized feedback) are effective in promoting PA [54]. The same features provided in the basic apps were available to participants in the MoveMore intervention using the full version of the digital app. The gamified challenges provided to those in the MoveMore intervention were disabled in the basic app provided to those in the control condition (Figure 2).

Gamification Phase

In addition to the features included in the basic digital app, the full digital app allowed participants in the MoveMore intervention to participate in team walking challenges (Figure 3). During the first 5 weeks, office workers were invited to participate in 2 challenges, each lasting 2 weeks, with 1 week

in between them. To increase participants' light PA, the challenges incorporated elements of gamification and several BCTs to promote motivation and self-regulation for walking. During the challenge, participants in the MoveMore intervention were allocated to different teams (20-30 subjects), according to the department they worked in. The challenges consisted of a *virtual walking tour* (eg, a roundtrip across Rotterdam) representing a large goal that participants could achieve by attaining their daily goal for 2 weeks. In addition to progressing toward their daily step goals, participants' daily steps contributed toward their team step goal (ie, set as the number of participants in the team multiplied by their default daily step goal). A leaderboard served to enhance intrateam cooperation and individual accountability while promoting competition between teams (Figure 4). To enhance team identity and motivation, each team was allocated as a representative of a different charity. By earning points and climbing the leaderboard ranks, teams could win gradually bigger prizes for their charity, sponsored by the municipality. The first team earned €100 (US $120), the second team earned €90 (US $108), and so on, with the sixth and last team earning €50 (US $60). These components (ie, teams, leaderboards, and charity representations) were included to restructure the social environment regarding PA, thereby promoting social support and social comparison for walking in the workplace.

In addition to changes in social factors, the game elements of the app were also supposed to motivate participants to walk while increasing their ability to self-regulate their behavior. Similarly, in a game, the challenges started easy and became increasingly more difficult (ie, graded task) to enhance self-efficacy and, therefore, motivation for PA. The default goal for the first challenge was set at 8500 steps, which is easier than the default goal used in the basic version of the app provided to those in the control (ie, 10,000 steps), whereas for the second challenge, participants in the MoveMore intervention were encouraged to reach this more difficult default goal of 10,000 daily steps. Participants could also set more challenging daily step goals. The app rewarded participants with virtual awards for certain individual- (eg, "Daily step goal achieved!") and team-based achievements (eg, "Your team completed a challenge!"). On the website, participants could access detailed information on their achievements and on their progress with the team challenge, which was illustrated by their virtual avatars crossing the virtual tour scenarios (Figure 3). To promote self-regulation during the challenges, in addition to the weekly feedback on their personal step goals that is provided by the basic digital app, participants in the MoveMore intervention received biweekly newsletters during the challenges via email with updates on the competition and their team's progress (Multimedia Appendix 2).

Physical Nudges

After the gamification phase, physical nudges were introduced in the office workspace of participants in the intervention condition for 5 weeks to promote maintenance of behavior change. These nudges consisted of table signs aiming to (1) further motivate participants to engage in PA and reduce SB and (2) remind participants of the opportunities for PA in their work environment and routine. To achieve the former, motivational nudges incorporating several different behavioral insights were implemented. For example, 2 table sign posters portrayed an interaction between the office physician and an employee and presented the following messages from the physician: "walking breaks are healthy and increase work productivity!" or "My advice: Stand up every half an hour and move a little!" Another type of motivational nudge used social comparison to increase motivation for PA, with the following message: "Half of your colleagues try to move at least 10000 steps per day. What about you?" Motivational nudges were placed in visible locations (eg, on top of tables and eye-level closets) in office spaces and open areas of the intervention location. Complementarily, another type of nudge, namely, point-of-choice prompts, reminded participants of their PA goals, highlighting opportunities for PA in a timely manner and prompting cognitive and behavioral rehearsal. For instance, 2 point-of-choice prompt nudges were placed in the coffee and lunch areas of the workspace with the messages "Grabbing a drink? Perfect moment to be healthy and go for a walking break!" and "Lunch time? Perfect moment to move!" The messages reported have been translated from Dutch (Multimedia Appendix 3). The office workers participating in the intervention were spread across 22 floors. Approximately 5 table sign nudges, including at least one point-of-choice prompt, were placed on every floor in which participants of the intervention worked, for a total of over 110 nudges spread throughout the office building.

Measures

Demographics and Other Variables

The demographic information collected during baseline included participants' age, gender, weight, length, BMI (ie, calculated from self-reported length and weight), nationality, migrant background (ie, parental nationality), highest educational attainment, occupation in the municipality, weekly number of working days, and working hours.

Primary Outcome Measure

The primary outcome measure of walking behavior was the number of daily steps objectively measured using Fitbit Flex accelerometers (objective light PA). Previous studies have determined that the Fitbit Flex accelerometer has acceptable reliability and validity for step count measurements [52].

Secondary Outcome Measures

Secondary outcome measures included self-report measures of work time light PA, moderate-to-vigorous PA, and SB. SB at work was assessed using 2-item self-report measures of workplace sitting time and breaks in the sitting time. The self-report measures for assessing the duration of SB (Pearson r=0.44, 95% CI 0.24-0.60) and the frequency of breaks from sitting (Spearman r=0.26, 95% CI 0.11-0.44) were positively correlated with accelerometer measurements in a sample of desk workers [55]. The item on frequency of breaks, "During a typical work day how many breaks from sitting (such as standing up, or stretching or taking a short walk) during one hour of sitting would you take at work?," and the item on duration of SB at work, "Please estimate the total time during the last week that you spent sitting down as part of your job while at work or

working from home," were translated into Dutch and assessed for face validity. In our sample, the intraclass correlation coefficients (ICCs) for different measurements of SB duration and SB break frequency during work were 0.44 and 0.60, respectively, indicating poor to moderate test-retest reliability. To assess the intensity and levels of PA in various settings (ie, at work, at home, during active transport), the validated Dutch version of the Short Questionnaire for Assessing Health enhancing physical activity (SQUASH) was used [56,57]. The test-retest reliability of the SQUASH items was poor for assessing hours per week spent in light PA (ICC=0.35) and moderate for items assessing moderate-to-vigorous PA at work (ICC=0.60) and number of days or weeks engaging in at least 30 minutes of moderate-to-vigorous PA (ICC=0.55). Thus, the suboptimal test-retest reliability of some of our self-report measures may have hindered the assessment of intervention effects on secondary outcomes.

Data Management, Monitoring, and Safety

Except for the baseline, questionnaires were all administered electronically using the web survey platform Qualtrics [58]. Fitbit Flex accelerometer data were obtained through the company responsible for the gamified digital intervention [59] via the Fitbit app and were downloaded at the completion of the follow-up period. Data were exported into R statistical software version 3.5.2 and analyzed using the R package *lmer* [60]. Hardcopy consent forms were stored in locked filing cabinets, and electronic data were stored on password-protected drives accessible by study investigators.

Data Analysis

In this study, following a period of 2 weeks of baseline measurement, participants' daily number of steps (ie, primary outcome) was measured continuously for 14 consecutive weeks, resulting in a hierarchical data structure. Daily step count observations (level 1) were nested within participants (level 2), who, in turn, were nested within the departments (level 3). Recent statistical studies simulating variance in longitudinal data have shown that misspecification of the number of levels can lead to biased findings [61]. Therefore, we used a mixed effects model to account for the nested hierarchical structure of the data by including random intercepts for the different levels when the variance at that level was significantly different from zero [62]. As recommended by Haan-Rietdijk et al [61], we used autoregressive models (in combination with Akaike Information Criteria scores) to assess the variance at different levels and determine the levels needed to be included in the model. Given that the variance at the department level was not significant (χ^2_1=0; P=.99), models were only adjusted for the clustering of observations within participants (ie, level 2; χ^2_1=4934.5; P<.001). As we were interested in comparing daily step counts during the different study phases (ie, gamification, physical nudges, and follow-up) with baseline and in investigating potential interactions between intervention conditions and different phases, the study phase was not considered a level but rather included as a predictor in our models.

Considering that multilevel models can handle data missing at random, no missing data imputation was performed, and partially completed records were included in the model to avoid biases associated with a completer-only analysis [63]. In the primary analysis, the first 5 days of data were ignored when estimating the baseline step count to diminish the potential upward bias from estimating higher activity during initial accelerometer use. Observations with less than 1000 steps and more than 60,000 steps were considered missing because evidence indicates that these values are unlikely to represent actual activity [64-66]. Such observations were considered either extreme outliers or the result of forgetting to wear the accelerometer.

To assess the interaction between intervention condition and time and study phases, a repeated measures mixed effects model was employed following the intention-to-treat principles. Models were initially fit with a random intercept for participants, fixed effects of time, study phase (ie, baseline, gamification, nudging, and follow-up), and covariates. When the relationship between our outcome variable and time was quadratic or cubic, quadratic and cubic parameters of time were included in the model as fixed effects. To avoid convergence issues in the primary analysis, time was rescaled to represent 2-week intervals. Covariates initially included in the model were age, sex, parental nationality, work occupation, number of weekly working hours, education, and BMI (ie, calculated from self-reported weight and length). Covariates that were not significant predictors of outcome variables were excluded from the model. Next, the level 2 variable intervention condition (ie, intervention vs control) was included as a fixed effect. Random slopes of the study phase and time per participant were added to the model. When the random slope of the study phase per participant was significant, a 2-way cross-level interaction between the study phase and the intervention condition was included in the final model to investigate the effects of the intervention during each phase. In addition, in an exploratory analysis, we investigated whether intervention effects were influenced by individual differences by examining interactions between intervention effects and relevant covariates. The model used in the primary analysis was refit using secondary outcome measures: (1) the mean number of hours spent in light PA and moderate-to-vigorous PA during work and the number of days engaging in sufficient amount of moderate-to-vigorous PA, as assessed by the SQUASH questionnaire, and (2) 2 self-reported items assessing SB: the average number of sitting breaks taken per hour during work and the mean daily sitting time during work.

Results

Demographic Statistics

Table 2 presents baseline descriptive statistics of the study sample per intervention condition. Relative to the control condition, the intervention condition had a significantly higher proportion of male participants and participants of lower educational backgrounds. In addition, participants in the intervention condition weighted significantly more and had significantly higher BMI than participants in the control

condition. Participants in the intervention group also logged a lower number of daily steps at baseline, although this difference did not reach statistical significance.

Table 2. Sociodemographic and behavioral characteristics of participants at baseline.

Variable	Intervention (n=118)	Control (n=116)	*P* value
Behavioral characteristics			
Number of daily steps, mean (SD)	10,138 (4643.5)	10,403 (4191.6)	.22
Meeting physical activity guidelines (days per week)[a], mean (SD)	5.1 (2.0)	5.4 (1.0)	.20
Hour sitting per week[b], mean (SD)	30.1 (9.5)	29.2 (10.2)	.45
Breaks per hour[b], mean (SD)	1.8 (1.2)	1.9 (1.3)	.49
Demographic characteristics			
Age (years), mean (SD)	47.5 (9.6)	45.9 (10.2)	.25
Gender (female), n (%)	63 (55.3)	83 (72.8)	*.02* [c]
Weight (kg), mean (SD)	82 (17.8)	75.7 (13.9)	*.003*
BMI[d], mean (SD)	26.9 (5.0)	25.6 (4.5)	*.04*
Nationality (Dutch), n (%)	101 (89.4)	104 (92.0)	.57
Parental nationality (Dutch), n (%)	88 (77.9)	89 (78.1)	.63
Education (higher education), n (%)	78 (69.6)	99 (86.1)	*.005*
Work position (highly skilled)[e], n (%)	105 (97.2)	110 (96.5)	.99
Number of weekly working days, mean (SD)	4.4 (0.6)	4.3 (0.5)	.16

[a]Meeting daily physical activity guidelines was defined as self-reported engagement in at least 30 minutes of moderate-to-vigorous physical activity per day.

[b]The number of hours sitting per week and the number of sitting breaks per hour refer specifically to sedentary behavior during work time.

[c]Italics indicates statistical significance ($P<.05$).

[d]Calculated from self-reported height and weight.

[e]Nonmanual labor occupations, such as managers and administrative positions, were coded as highly skilled.

Primary Analysis: Daily Step Count

After controlling for relevant covariates and subject-specific differences, our mixed effects model investigated the effects of the intervention condition, time, study phase, and the interaction between study phase and intervention condition on the objectively measured step count of participants. The step count data included in the model were recorded for 109 days from baseline to follow-up. Participants, on average, wore their accelerometers and recorded at least 1000 daily steps for approximately 75 (68.8%; SD 27.8) days throughout the study. During the gamification phase, step data that were missing or had values less than 1000 steps per day represented 13.5% (473/3492) of observations for the control arm and 11.4% (445/3888) for the intervention arm. During the follow-up period, these percentages increased to 39.6% (1154/2910) in the control arm and 59.6% (1932/3240) in the intervention arm, indicating substantial missing data in our sample during the later study phases.

The mean number of daily steps of participants in each condition across the study phases is shown in Table 3 and Figure 5. The first repeated measures mixed model analysis (model 1; Table 3) included the effects of relevant covariates, study phase, time, intervention, and random slopes of time and study phase per participant. Model 1 revealed that the daily number of steps was negatively associated with BMI ($B=-178.03$; SE 38.94; $t_{168.61}=-4.57$; $P<.001$) and positively associated with age ($B=35.85$; SE 18.89; $t_{172.50}=1.90$; $P=.06$) in two-tailed t tests. These 2 predictors explained 12.6% of the variance at the participant level ($R^2=0.126$), with larger BMI and younger age being associated with lower daily step counts overall. The fixed effects of gender, work occupation, number of working hours, education, and nationality (both individual and parental) were removed from the model, as they were not significantly related to step count.

Table 3. Means of primary and secondary outcome variables across study phases.

Variable	Baseline (intervention: n=130; control: n=116)	Gamification (intervention: n=35; control: n=44)	Physical nudges (intervention: n=38; control: n=72)	Follow-up (intervention: n=44; control: n=66)
Intervention location, mean (SD)				
Number of daily steps[a]	10,138.3 (4643.5)	10,901.8 (5068.3)	9873.5 (5020.8)	10,481.1 (5035.9)
Meeting PA[b] guidelines[c]	5.2 (2.0)	5.8 (1.6)	5.8 (1.4)	5.6 (1.7)
Hours in light PA	26.1 (13.9)	28.4 (12.2)	22.7 (14.4)	20.7 (14.3)
Hours in moderate-to-vigorous PA	0.35 (2.2)	0.05 (0.23)	0.08 (0.41)	0.71 (2.24)
Hours sitting per week[d]	30.9 (10.7)	32.6 (10.6)	30.4 (9.8)	30.0 (6.8)
Number of breaks per hour[d]	1.7 (1.2)	1.5 (0.8)	1.6 (0.9)	1.4 (0.7)
Control location, mean (SD)				
Number of daily steps[a]	10,403.0 (4191.6)	10,618.6 (4377.3)	10,138.5 (4820.7)	10,279.3 (4387.8)
Meeting PA guidelines (days per week)[c]	5.4 (1.9)	5.7 (1.6)	5.8 (1.6)	5.7 (1.7)
Hours in light PA	26.4 (13.1)	23.2 (14.1)	23.1 (14.3)	24.7 (13.25)
Hours in moderate-to-vigorous PA	0.16 (0.75)	0.22 (0.71)	0.17 (0.81)	0.73 (2.66)
Hours sitting per week[d]	29.1 (10.2)	28.9 (8.2)	31.6 (10.7)	29.9 (10.7)
Number of breaks per hour[d]	2.0 (1.3)	1.6 (1.0)	1.6 (0.8)	1.6 (0.8)

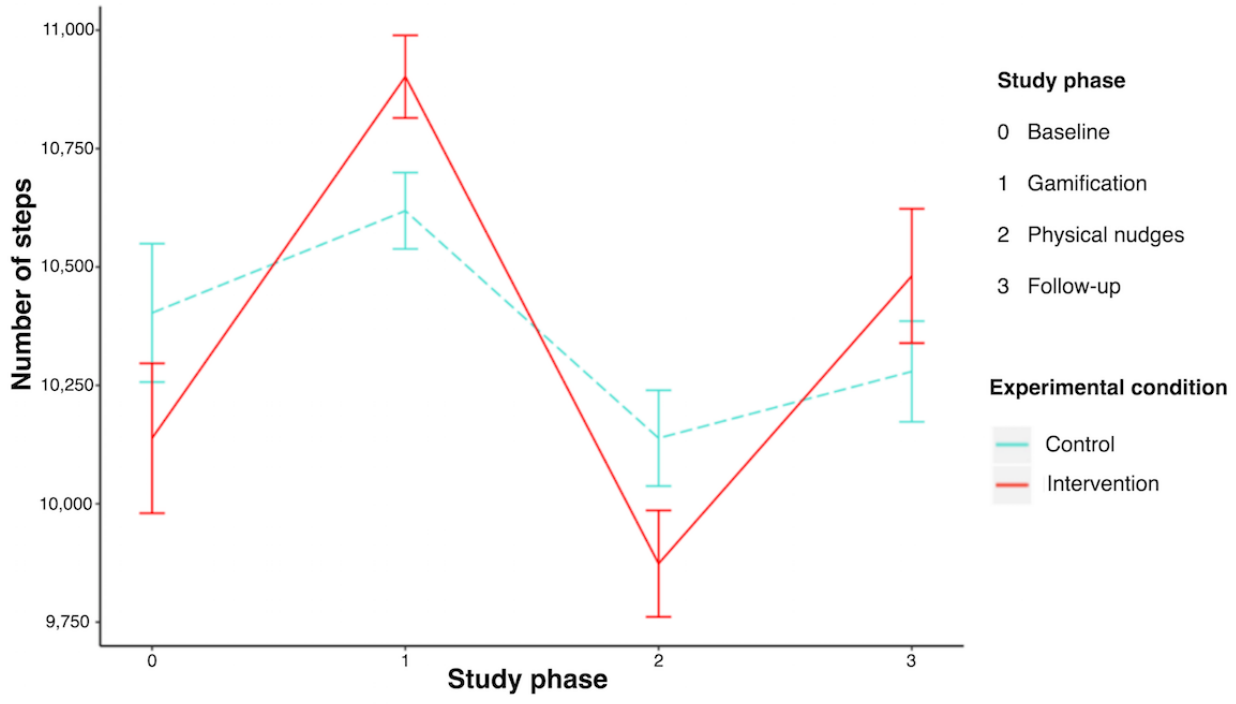
[a]The sample size shown refers to questionnaire assessments and does not apply to the number of daily steps measured using accelerometers. In total, 234 participants completed the accelerometer measurements, and on average, the accelerometer was worn on 68.8% of the days.

[b]PA: physical activity.

[c]Meeting daily physical activity guidelines was defined as self-reported engagement in at least 30 minutes of moderate-to-vigorous physical activity per day.

[d]The number of hours sitting per week and number of sitting breaks per hour refers specifically to sedentary behavior during work time.

Figure 5. Unadjusted differences in average daily step counts between intervention and control conditions across study phases.



Given the initial novelty of the gamification and physical nudges phase, which potentially wears off toward the end of each phase, it is plausible that daily step counts oscillated significantly within each study phase. In support of this interpretation, our

analysis revealed that linear, quadratic, and cubic effects of time were significant, suggesting that changes in step count within a study phase oscillated across time. Within-subject variability was partially modeled by the fixed effects of time and study phase, whereas the remaining unexplained variance was accounted for by the level 1 error term ε_{ij}. Model 1 revealed significant effects of the study phases on step count; however, the main effect of the intervention condition was not significant (model 1; Table 4). These effects of study phases reflect that, after controlling for the effects of time and other covariates, participants from both groups increased their number of daily steps during the novel gamification phase and decreased their number of daily steps during the nudging and follow-up phases, compared with baseline.

Table 4. Results of models with and without cross-level interactions predicting number of daily steps.

[a]Model 1: $\gamma_{ij}=\beta 0_j + \beta 1\text{BMI}_j + \beta 2\text{Age}_j + \beta 3\text{Time}_{ij} + \beta 4\text{Time}_{ij}^2 + \beta 5\text{Time}_{ij}^3 + \beta 6\text{Gamification}_{ij} + \beta 7\text{Nudging}_{ij} + \beta 8\text{Follow-up}_{ij} + \beta 9\text{Intervention}_j + \varepsilon_{ij} + \mu_{ij}$. Model 1 (Akaike Information Criteria: 269682) refers to the model without cross-level interactions between the intervention and study phases.

[b]Model 2: $\gamma_{ij}=\beta 0_j + \beta 1\text{BMI}_j + \beta 2\text{Age}_j + \beta 3\text{Time}_{ij} + \beta 4\text{Time}_{ij}^2 + \beta 5\text{Time}_{ij}^3 + \beta 6\text{Gamification}_{ij} + \beta 7\text{Nudging}_{ij} + \beta 8\text{Follow-up}_{ij} + \beta 9\text{Intervention}_j + \beta 10\text{Intervention}_j\text{Gamification}_{ij} + \beta 11\text{Intervention}_j\text{Nudging}_{ij} + \beta 12\text{Intervention}_j\text{Follow-up}_{ij} + \varepsilon_{ij} + \mu_{0j} + \mu_{1j}\,\text{Gamification}_{ij} + \mu_{2j}\,\text{Nudging}_{ij} + \mu_{3j}\,\text{Follow-up}_{ij}$. Model 2 (Akaike Information Criteria: 269679) refers to the model with cross-level interactions between the intervention and study phases. Model 2 significantly improved the model fit (χ^2_3=8.6; *P*=.04).

[c]N/A: not applicable.

[d]Calculated from self-reported height and weight.

[e]Italics indicates statistical significance (*P*<.05).

[f]Time is rescaled to represent 2-week intervals.

[g]Represents the quadratic function of time.

[h]Represents the cubic function of time.

The changes in daily step count across study phases and time were different between participants, as evidenced by the significant random slopes of the study phase and time per participant detected in model 1. Adding cross-level interactions between the study phase and intervention phase (model 2; Table 4) significantly improved the model fit, indicating that differences between participants in changes in daily step counts across study phases could be explained by intervention effects. Findings from model 2 suggest that differences between participants in changes in daily steps are partially explained by significantly greater increases in daily steps during the gamification phase for participants in the intervention condition than in the control. This was evidenced by a significant interaction between the intervention condition and gamification phase (*B*=634.00; SE 244.81; $t_{167.52}$=2.59; *P*=.005) in a one-sided test, which explained 20.3% of the variance between participants in changes during the gamification phase (R^2=0.203). There were no differences in changes in daily steps between participants in the intervention and control conditions during the nudging phase (*B*=98.23; SE 325.52; $t_{163.28}$=0.30; *P*=.76) or follow-up (*B*=53.49; SE 381.67; $t_{143.61}$=0.14; *P*=.89) in a two-tailed test. Exploratory analysis showed that differences in changes in daily steps between participants could not be explained by individual differences, such as BMI, education, or gender. In essence, our findings indicate that the gamification phase of our intervention was effective in increasing the daily step count of office workers, compared with an active control.

However, improvements were not maintained during the physical nudges or during the follow-up phase.

Secondary Analysis: Self-Reported PA and SB

The sample size and mean values for the secondary measurements at each assessment point are listed in Table 3. Model 1 used in the primary analysis was refitted using secondary outcome measures. Higher BMI was associated with less time spent in SB (B=−0.21; SE 0.07; $t_{115.66}$=−2.96; P=.003) in a two-tailed test; however, no association was found between the intervention condition or study phase and the time spent in SB. The two-tailed tests revealed that participants in the intervention condition took fewer breaks from sitting than those in the control (B=−0.22; SE 0.11; $t_{229.12}$=−2.00; P=.046), and participants in both conditions took fewer breaks during follow-up compared with baseline (B=−0.34; SE 0.11; $t_{363.08}$=−3.01; P=.003). The two-tailed tests also showed that there was no effect of the intervention on hours spent in light PA in the workplace while controlling for parental nationality and age; however, overall, participants engaged in less light PA at the end of the nudging phase (B=−4.39; SE 1.45; $t_{333.73}$=−3.03; P=.002) and at follow-up (B=−3.47; SE 1.40; $t_{333.98}$=−2.48; P=.01), compared with baseline. After controlling for BMI, there was no main effect of the intervention for self-reported engagement (hours and days) in moderate-to-vigorous PA (ie, 150 minutes per week). However, a two-tailed test revealed a significant effect of study phase, with participants engaging in more hours of moderate-to-vigorous PA (B=0.55; SE 0.19; $t_{178.83}$=2.82; P=.005) and more days with sufficient moderate-to-vigorous PA (B=0.33; SE 0.16; $t_{304.05}$=2.14; P=.03) during follow-up, compared with baseline. Owing to low response rates for web-based questionnaires, it was not possible to refit model 2 with secondary outcomes to examine interactions between the intervention and study phases.

Discussion

Principal Findings

This study tested the effects of MoveMore, a multicomponent intervention designed to promote walking behavior (ie, light PA) and reduce SB in office workers. The MoveMore intervention consisted of an initial 5-week gamification phase encompassing a gamified digital app with social support features, followed by a 5-week physical nudges phase, including motivational and point-of-choice prompt nudges. By offering the gamification and physical nudges components separately, we could gain insights into their independent effects and explore whether physical nudges could promote maintenance of behavior change achieved during the gamification phase.

In line with our main hypothesis, significant increases in daily step counts were observed for participants in the intervention condition during the gamification phase compared with participants in the control group. However, contrary to our expectations, improvements in the daily step count for participants in the MoveMore intervention were not maintained during the physical nudges phase or at follow-up. We also hypothesized that similar improvements in secondary outcomes would be observed during the gamification phase for participants in the intervention. Although questionnaires administered in-person at baseline yielded high response rates, we could not investigate differences between intervention and control in changes of secondary outcome measures because of the low response rate in subsequent assessments via email. Nonetheless, overall, participants reported higher engagement in moderate-to-vigorous PA during work at follow-up compared with baseline. Unexpectedly, participants in both conditions reported engaging in less light PA during the physical nudges and follow-up phases than at baseline. Participants in the MoveMore intervention reported taking fewer breaks from sitting than those in the control, and participants in both groups reported taking fewer breaks during later study phases relative to baseline. However, given the poor reliability of the self-report measures in our sample, the validity and generalizability of these findings are limited. Future studies could address these limitations by using more sophisticated accelerometers that measure SB and by using more frequent and less time-consuming measurements that can be integrated in digital apps, such as ecological momentary assessments.

Nevertheless, our main findings suggest that adding gamification components with social support and social comparison features to a digital intervention seems to be an effective strategy for promoting PA in office workers, as evidenced by a significant interaction detected between the gamification phase and intervention condition. Exploratory analysis revealed that intervention effects were not influenced by individual differences, for example, BMI, education, or gender. The short-term effects of the gamification phase on step count were modest (ie, 763.5 increase in average number of daily steps for the participants in the intervention condition compared with 215.6 increase for those in the control) but comparable with previous RCTs evaluating this type of gamified digital intervention [46,67]. Similarly, these studies observed small but clinically significant effects on PA and/or SB. However, systematic reviews of pedometer-based interventions have found that these interventions typically increase PA by approximately 2000 steps per day [68]. Although the gamification phase of the MoveMore intervention resulted in considerable increases in step count, considering the increases reported in other RCTs assessing similar gamified interventions [46,69], these effects may seem underwhelming.

Several factors may explain the smaller effect sizes reported in this study, such as high daily step counts at baseline. Most similar intervention studies recruited inactive adults moving approximately 7000-7500 steps, which is far below the fairly disputed yet often recommended guideline of 10,000 steps per day [46,69,70]. Consequently, larger increases in step counts (ie, approximately 2000 steps) may have been observed in these samples precisely because low levels of PA at baseline allowed for and motivated participants to achieve greater improvements during the intervention period. Comparably, participants in this study walked on average 10,270 steps per day at baseline. Although increasing one's daily number of steps beyond the recommended guidelines is still beneficial [71], high rates of functioning at baseline may have hindered motivation and limited how many participants in our sample could improve (ie, ceiling effect). Given this ceiling effect, it is comprehensible

that increases in the step count of the highly active participants in our sample are lower and more difficult to maintain than those of interventions with inactive participants. Meta-analysis of PA interventions with healthy adults reported that studies with active adults reported lower effect sizes than those with sedentary adults [72]. Given that our sample was already highly active at baseline, the significant improvements in step count observed in participants in the intervention location during the gamification phase highlight the potential of gamified digital interventions to promote light PA.

In addition to the high rate of functioning at baseline, several other factors may partially explain our findings. For example, the use of an active control. Most studies exploring the effects of gamified digital interventions for PA and SB use either nonintervention controls [73] or self-monitoring controls [46,74]. To our knowledge, only a few studies investigating similar gamified digital interventions have used active controls with self-monitoring, goal setting, and personalized feedback [69]. In this study, implementing an active control allowed us to make stronger causal inferences about the effects of gamification and social support features on PA and SB. However, it is well established that the combination of self-monitoring and goal setting alone leads to the initiation of behavior change [54,71]. A meta-analysis of worksite PA interventions found that studies implementing active controls unsurprisingly reported lower effect sizes than those with no intervention controls [75]; thus, the use of active rather than no intervention control is another possible explanation for the relatively smaller effect sizes detected in this study. Another factor that may have influenced our results was the short duration of the gamification phase (5 weeks). A systematic review suggests that PA interventions with longer durations (ie, >24 weeks) are more likely to promote the maintenance of behavior change [76]. Thus, although behavior change was initiated during the gamification phase, 5 weeks may have been too short to form the habit of walking. Due to operational constraints, it was not possible to offer the gamification phase for longer durations in this study; however, future research should explore the effects of gamified digital interventions for longer durations to help establish habit formation.

We anticipated that physical nudges in the workplace could promote the maintenance of the behavior change achieved during the gamification phase. When designing the social norms nudges and point-of-choice prompts, fellow office workers from the intervention location served as role models, which could act as motivators and goal reinforcement [22,77]. Studies have found that combining motivational and point-of-choice prompt nudges was more effective than a control or either strategy alone in increasing stair climbing behavior [78]. However, in this study, combining motivational nudges based on social norms and authority with point-of-choice prompts for walking behavior resulted neither in increases in step count nor in maintenance of improvements achieved through the gamified digital intervention.

A possible explanation for these results may be the differences between the 2 locations. The effectiveness of certain BCTs, particularly nudges, is largely influenced by the context of implementation [33]. The 2 offices randomly allocated to the intervention and control groups differed considerably in terms of location and design. The control location was a wide building located in the city center, with large floor spaces and easy access to stairs and outside areas. Conversely, the intervention location was a tall building, with less surface area per floor and difficult access to outside areas. Participants in the control location had more space to walk indoors, whereas participants in the intervention location worked on multiple floors and may instead have had more opportunities to climb the stairs. Owing to operational constraints, no nudges for stair use could be implemented. Furthermore, weather conditions worsened (ie, lower temperature and more precipitation) throughout the course of the study, which may have discouraged participants from walking outside, maximizing the influence of the physical differences between the 2 locations. In addition, because of the collaborative nature of the study, the nudges used the colors and logos of the municipality of Rotterdam, which are used in other promotional materials found throughout the offices. This may have hindered the attractiveness of the nudges because they easily blended with other unrelated promotional materials.

The ineffectiveness of the nudges may also stem from the possibility that the physical nudges in the workplace in the form of table signs were not sufficiently engaging and motivating, especially when compared with the gamified digital intervention encompassing several BCTs. These findings, however, add support to the emerging evidence indicating that multicomponent interventions incorporating several nudges and BCTs, such as the gamified digital intervention used, are more effective at changing complex behaviors such as PA than interventions relying on only one or a few BCTs, such as the physical nudges used [23]. Most importantly, our findings suggest that gamification can be a useful complementary tool that can be flexibly incorporated to improve intervention effectiveness.

Strengths and Limitations

Given that reviews of gamified interventions have called for stronger empirical evaluations isolating the impacts of gamification [45], we consider the presence of an active control one of the strengths of this study. This study is the first to combine a gamified digital intervention with physical nudges to promote behavior change. An advantage of this study's design was the possibility to gain insight into the effects of gamification and physical nudges on initiation and maintenance of behavior change, respectively, although lack of randomization of the order of these components and order effects were the possible drawbacks. The use of objective measurements (ie, accelerometers) was another strength of this study, as self-reported measures of PA are often biased compared with objective measures, leading to false-positive findings [79]. In addition, the MoveMore intervention was implemented in the actual working environment of a large sample of Dutch office workers rather than in a controlled setting, which adds to the ecological and internal validity of our findings. As teams for the gamified challenges were formed according to office departments, a collective motivation for winning may have played a role. However, research has found that gamification is also effective in fostering motivation and promoting PA in adults when applied in individual settings [80]. Our findings, on the other hand, suggest that combining gamification with

changes in the social environment that promote social support and social comparison can effectively increase walking in office workers. As shown in a few previous studies, leveraging existing social structures through gamification by, for instance, allocating departments to different teams and stimulating cooperation and competition seems to be an effective strategy for promoting motivation and self-regulation for PA [46,47,81]. Although we recognize that the effects of gamification and social elements of the intervention could not be disentangled, the primary aim of this study is to design an effective intervention rather than isolating these effects.

Nevertheless, this study had several limitations inherent to field experiments, such as the inability to control for extraneous variables and operational constraints with regard to the physical nudges and the time frame of the study phases. Despite the large sample size, given that only 2 worksites were randomized to intervention or control, the limited number of clusters hindered the effectiveness of randomization and comparability between groups. Although we controlled for baseline differences between groups, differences between locations were possible confounders. However, given that the physical attributes of the control location facilitated PA, whereas the attributes of the intervention location hindered PA, it is highly unlikely that increases in step count of participants in the intervention location during the gamification phase can be attributed to physical differences between locations. Due to financial constraints, we could not opt for accelerometers that objectively measured SB. We relied on self-report measures of SB, which had poor reliability in our sample and have been shown to underestimate SB in adults [82,83], possibly explaining why the hypothesized intervention effects on SB were not observed even though they were supported by accelerometer step count data.

With regard to our statistical analysis, although we justified the quadratic and cubic effects of time in our model, we recognize that these higher-order effects are less stable and may be specific to our sample. In addition, dropout during physical nudges and follow-up phases resulted in a considerable amount of missing data, which hindered the assessment and interpretation of intervention effects during those phases. This dropout could simply be a result of timing, as physical nudges and follow-up phases occurred during the holiday season (ie, from December to February). Another possible explanation is that, as research has suggested, although gamification could be effective in enhancing engagement in the short term, users' motivations are unlikely to be sustained in the long term [48]. Another likely explanation for the high dropout rate in subsequent phases is that, as participants knew that the challenges were only available for a limited time, the gamification phase created a limited-time interest in the intervention, which then diminished once the gamified challenges ended. Owing to privacy agreements, it was not possible to collect data on user experience, functionality, and engagement with the app, which is a limitation of this study. Future research should investigate the long-term effects of gamified interventions while measuring user experience, engagement, and other possible mediators of intervention effectiveness.

Although our findings support the effectiveness of integrating gamification and social support features in digital interventions to promote light PA in active office workers, further research is needed to confirm the generalizability of our findings in more at-risk populations, such as inactive adults and adolescents from disadvantaged backgrounds. Given the unexpected effects of physical nudges, future studies should carefully consider the design and context of nudges. Nudges have gained attention because they are cost-effective in influencing people's behavior momentarily. However, further research is needed to explore how physical nudges can be more effectively combined with other interventions to promote the maintenance of complex behaviors, such as PA, in the short and long term. For example, offering gamified digital interventions and physical nudges simultaneously, rather than sequentially, may increase the intervention effectiveness. Research on gamification and nudging is still in its infancy. Future research with gamified digital interventions should continue innovating with the design of digital interventions by, for instance, testing different forms of social support and gamification components. Finally, future research on digital interventions should investigate complementary strategies to promote long-term maintenance of behavioral change, such as increasing engagement by tailoring the interventions to the participants' needs or using guided approaches in incorporating personal coaches or peer support.

Conclusions

Compared with an active control consisting of a digital app, including self-monitoring and goal setting, a gamified social support–based digital intervention was effective at promoting light PA (ie, objectively measured number of daily steps) in a sample of active office workers. Given the high prevalence of sedentary lifestyles and the associated health problems, both of which are costly to health care systems, even small improvements in light PA can have considerable effects at the population level. This study was one of the first to compare the effects of gamification with an active control and to test its effects on PA and SB of office workers. Our findings demonstrate that gamification can effectively complement the BCTs (eg, social support and social comparison) and nudges used in digital interventions to promote clinically significant improvements in PA, even beyond the recommended guidelines of 10,000 steps. Although more research is needed to establish its long-term effectiveness, policy makers should explore the use of gamified digital interventions with social support features as a promising strategy to promote behavior change and improve the health of the population. Physical nudges in the workplace were insufficient to promote the maintenance of behavior changes achieved during the gamification phase. Further research should explore how gamified digital interventions can be better leveraged to promote long-term behavior change, for instance, by investigating how to optimally tailor digital interventions to users' needs.

Acknowledgments

The authors would like to thank Ruth Plaggenborg and the team at SelfCare for designing and providing the MySelfCare and SelfCarePro apps used in the control and intervention locations, respectively, and for their contributions to the design and implementation of the study. The authors would also like to thank Berdi Christiaansen and other staff and participants from the municipality of Rotterdam for their involvement and contributions to the MoveMore study. Finally, the authors would like to thank Healthy'R [1], the expertise center on health behavior of the municipality of Rotterdam and Erasmus University Rotterdam. Healthy'R combines scientific knowledge in the field of behavior and health with practical knowledge and experiences to develop and investigate measures that lead to healthier choices of people in Rotterdam. The costs of the accelerometers, physical nudges, and digital apps used in this study were funded by the municipality of Rotterdam. The content is solely the responsibility of the authors and does not necessarily represent the official views and interests of the funders or authors' affiliated academic institutions. The funders had no role in the design of the study and were not involved in data analysis, decision to publish, or preparation of the manuscript.

Editorial Notice

This randomized study was only retrospectively registered; this is because, as explained by authors, at the time of data collection they did not believe that this study met the criteria for a clinical trial, due to the fact that the study only included behavioural outcomes, and did not involve any health outcomes. The editor granted an exception from ICMJE rules mandating prospective registration of randomized trials because the risk of bias appears low and the study was considered formative, guiding the development of the application. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Authors' Contributions

AM designed the study, developed the intervention, implemented the intervention, managed data collection, conducted statistical analyses and interpretation, and wrote the manuscript. MS helped develop the intervention material, recruit participants, implement the intervention, and manage the data collection. JJ helped with the statistical analysis and interpretation and provided feedback on the manuscript. AS, GN, and SD contributed to the study design and provided guidance and consultation throughout the study and feedback on the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Effectively and efficiently diagnosing patients who have COVID-19 with the accurate clinical type of the disease is essential to achieve optimal outcomes for the patients as well as to reduce the risk of overloading the health care system. Currently, severe and nonsevere COVID-19 types are differentiated by only a few features, which do not comprehensively characterize the complicated pathological, physiological, and immunological responses to SARS-CoV-2 infection in the different disease types. In addition, these type-defining features may not be readily testable at the time of diagnosis.

Objective: In this study, we aimed to use a machine learning approach to understand COVID-19 more comprehensively, accurately differentiate severe and nonsevere COVID-19 clinical types based on multiple medical features, and provide reliable predictions of the clinical type of the disease.

Methods: For this study, we recruited 214 confirmed patients with nonsevere COVID-19 and 148 patients with severe COVID-19. The clinical characteristics (26 features) and laboratory test results (26 features) upon admission were acquired as two input modalities. Exploratory analyses demonstrated that these features differed substantially between two clinical types. Machine learning random forest models based on all the features in each modality as well as on the top 5 features in each modality combined were developed and validated to differentiate COVID-19 clinical types.

Results: Using clinical and laboratory results independently as input, the random forest models achieved >90% and >95% predictive accuracy, respectively. The importance scores of the input features were further evaluated, and the top 5 features from each modality were identified (age, hypertension, cardiovascular disease, gender, and diabetes for the clinical features modality, and dimerized plasmin fragment D, high sensitivity troponin I, absolute neutrophil count, interleukin 6, and lactate dehydrogenase

for the laboratory testing modality, in descending order). Using these top 10 multimodal features as the only input instead of all 52 features combined, the random forest model was able to achieve 97% predictive accuracy.

Conclusions: Our findings shed light on how the human body reacts to SARS-CoV-2 infection as a unit and provide insights on effectively evaluating the disease severity of patients with COVID-19 based on more common medical features when gold standard features are not available. We suggest that clinical information can be used as an initial screening tool for self-evaluation and triage, while laboratory test results should be applied when accuracy is the priority.

Introduction

COVID-19 is a pandemic disease caused by the novel SARS-CoV-2 virus. As of January 12, 2021, COVID-19 had spread through at least 220 countries and regions, resulting in more than 88 million cases and almost 2 million deaths [1]. It has become the single most severe pandemic in the 21st century, dwarfing other coronavirus-caused epidemics, such as severe acute respiratory syndrome (SARS) in 2003 and Middle East respiratory syndrome (MERS) in 2012. COVID-19 is especially challenging to health professionals and the general population. Unlike in the preceding SARS and MERS epidemics, patients with COVID-19 can be either asymptomatic or symptomatic, and the virus has been demonstrated to be transmissible in both states to varying degrees [2-5]. In addition, the distinct clinical types of COVID-19, nonsevere and severe, require different treatment and care plans [6]. In current studies, patients with COVID-19 can be differentiated from patients who do not have the disease; however, further detection of nonsevere or severe types of COVID-19 has not been comprehensively explored. Patients with nonsevere COVID-19 can be accommodated with less intensive clinical monitoring and intervention, including treating pre-existing conditions and preventing health care–associated infections and other comorbidities [7]. In contrast, patients with severe disease require close monitoring, usually in the intensive care unit (ICU), by more clinicians [6]. Therefore, effectively and efficiently classifying clinical types of COVID-19 is essential for triage, resource optimization, and care planning for frontline clinicians and health care systems as well as for the patients [6,8].

Currently, nonsevere and severe COVID-19 types are classified based on only a few clinical features in China, including shortness of breath, O_2 saturation, and PaO_2 [9]. Because of the complexity of the pathological, physiological, and immunological response of COVID-19, these three features do not sufficiently characterize the difference between nonsevere and severe types in patients with COVID-19 [9-11]. Although shortness of breath can be self-monitored, O_2 saturation and PaO_2 cannot be accurately self-evaluated and may not be readily assessed in clinical settings, especially for socioeconomically disadvantaged patients. In addition, some patients with severe disease may not present shortness of breath initially. However, without proper medical intervention, their clinical course will worsen abruptly, often resulting in respiratory failure with high mortality [6]. Therefore, these gold standard features bear the risk of misclassification and misdiagnosis. Misclassification of COVID-19 clinical types can result in inappropriate early treatment decisions; this can place patients at risk of progression due to insufficiently aggressive supportive therapy or expose other patients to overly invasive treatment, both of which have negative clinical consequences. In addition, the three defining features may not be readily available during initial diagnosis when resources are inadequate.

It is therefore critical to provide a rapid, accurate, and efficient method to determine the severity of COVID-19 infection and identify the clinical type using alternative features. This determination will enable optimization of treatment plans for patient care and improve utilization of health care resources and staff. We suggest that additional readily available medical features, including the patient's comorbidities (eg, hypertension and diabetes) and symptoms (eg, fever and chest pain), as well as laboratory test results, can be used to develop an effective method to determine the clinical type and severity of COVID-19 [12,13]. Angiotensin-converting enzyme 2 (ACE-2) receptors, which facilitate SARS-CoV-2 infiltration, are distributed across multiple organs and systems in the human body [14]. More recent discoveries have found that in addition to the respiratory system, SARS-CoV-2 can invade digestive, reproductive, and even neural systems [15-18]. In other words, all clinical and laboratory test information of patients with COVID-19 could be consequences or risk factors of SARS-CoV-2 infection. In clinical practice to treat COVID-19, clinicians not from respiratory units or ICUs may rely only on the referenced features [9] while neglecting diverse and important clinical features of COVID-19, and they may miss critical signs leading to undesirable prognosis.

The potential power of clinical and laboratory testing features, as well as their combinations, to determine COVID-19 clinical type is currently being explored [19-24]. To use such diverse multimodality information as alternative evidence to facilitate accurate classifications, we propose a data mining and machine learning (ML) framework as an alternative to commonly used hypothesis-driven parametric models. The goal of this study is to provide reliable data-driven support for clinicians, even those who do not have comprehensive experience in diagnosing the emerging disease COVID-19. We aim to explore and contrast the distributions of clinical and laboratory testing features between nonsevere and severe COVID-19 types. We will identify key features that differ substantially between the two clinical types. Next, we will investigate whether a single

modality or specific combination of features across modalities are able to provide accurate classification models via ML techniques. Specifically, we aim to identify a small and practical set of input features that can accurately differentiate COVID-19 clinical types. The insights gained from this study, as well as the developed end-to-end multimodal data analysis and ML framework, will enable us to better understand the comprehensive pathology of COVID-19, further distinguish COVID-19 from other respiratory infections, and apply the framework to other diseases with multimodal medical data in the future.

Methods

Data Source and Clinical Feature Extraction

In this study, we recruited 362 patients with COVID-19 from January to March 2020, including 148 patients presenting with severe disease and 214 patients lacking criteria for severe disease during admission, from Wuhan Union Hospital, China. The definitions of nonsevere and severe cases were mainly adopted from the official COVID-19 Diagnosis and Treatment Plan from the National Health Commission of China, and we also consulted guidelines from the American Thoracic Society [9-11]. Patients with severe COVID-19 should present any one of the following features: (1) respiratory rate >30 breaths per minute; (2) oxygen saturation <93% at rest; or (3) PaO_2/fraction of inspired oxygen <300 mm Hg (40 kPa). Each patient with COVID-19 was confirmed by two independent quantitative reverse transcriptase–polymerase chain reaction tests before being included in this study. All patients or their responsible surrogates signed informed consent forms prior to study inclusion. The patients' symptoms were evaluated and blood samples were drawn upon admission to perform laboratory testing. No pediatric patients aged less than 18 years were included.

The patients' deidentified medical information include two major modalities of features, both of which were assessed at the time of admission. The first modality was a total of 26 pre-existing comorbidities and symptoms, referred to as "clinical features" hereinafter. These features included gender, age, hypertension, coughing, and different types of fever. A detailed description of these 26 features is provided in Table S1 in Multimedia Appendix 1. All clinical features were coded as 0-1 binary variables (age was dichotomized using 50 years as the threshold).

In addition, we collected the patients' laboratory test results. The laboratory tests were plasma, serum, or whole blood assays for commonly obtained biochemistry tests, complete blood counts with differential counts and percentages, immunologic markers, such as interleukin 6 (IL-6), dimerized plasmin fragment D (D-dimer) and high-sensitivity C-reactive protein (hsCRP). After initial screening, several features with too many missing data, such as calcitonin, were excluded. In addition, respiratory rate, oxygen saturation, and PaO_2 without supplemental oxygen were excluded because they are type-defining features according to the official National Diagnosis and Treatment Plan of China [9]. We used 26 laboratory test features in this study. Detailed descriptions and units of these features are provided in Table S2 in Multimedia Appendix 1. All these laboratory testing features were continuous features, in contrast to the binary features used in the clinical feature modality.

Patient-specific identifying information (eg, name and address of residence) was removed from the data collected for this study. This study was evaluated and approved by the IRB committee of Union Hospital, Wuhan, China (approval number: 2020-IEC-J-345).

Data Mining on Multimodal Features

Initial data mining on the multimodal COVID-19 data was conducted. The patients' clinical data were complete. Approximately 5% of the laboratory testing data were missing. Predictive mean matching (PMM) was applied to impute the missing data. To evaluate the effectiveness of PMM, we used a subset of the original data set with no data missing, randomly dropped 5% data to simulate potential data loss, re-extrapolated the data with PMM, and evaluated the root mean square error (RMSE) between the original and imputed data sets. The RMSE was less than 0.05, indicating that the extrapolation was feasible and reliable. The imputed data were then passed on to successive data mining and ML steps.

The prevalence of each clinical feature was calculated as the number of positive test results divided by the number of patients in the nonsevere and severe groups as defined by the Diagnosis and Treatment Plan [9]. The *z* test was applied to detect any statistically significant differences in the features between the two types. In addition, a forest plot of the odds ratios (ORs) and 95% confidence intervals of the clinical features between severe and nonsevere COVID-19 types was graphed.

For the continuous laboratory testing features, we characterized and contrasted the distribution of each feature between the two types. Because the values of most features were not normally distributed, we applied a 2-sided Kolmogorov-Smirnov test instead of the Student *t* test to determine whether distributions of the feature values differed significantly between the two clinical types.

COVID-19 Clinical Type Classification via ML

Commonly used hypothesis-driven parametric models rely heavily on human decisions of how features interact with each other (eg, interaction terms in the logistic regression model), which may not reflect the underlying medical reality. In addition, these models have strict prerequisites to perform correctly, including normality of residuals, homoscedasticity, and independence of input features. Our initial exploratory analyses showed the that input features in both the clinical and laboratory testing modalities had nonnormality and high collinearity among the features. Another technical challenge to logistic regression in this study was the mixture of binary clinical and continuous laboratory testing input features.

Due to these problems, logistic regression would not be a preferred modeling approach to accurately classify and predict COVID-19 clinical types. Our exploratory analysis showed that logistic regression could only achieve average predictive accuracies of 68% and 77% on an 80-20 training-testing split

using clinical and laboratory testing feature data sets, respectively (Table S3, Multimedia Appendix 1). Thus, logistic regression is less feasible in clinical settings, where high accuracy, sensitivity, and specificity are required to differentiate COVID-19 clinical types.

On the other hand, state-of-the-art ML classification models work directly with data to avoid possible human bias. In addition, ML models do not have restrictions on how input data should be distributed or related. Therefore, in this study, we determined that ML classification would be a more appropriate modeling approach to predict COVID-19 clinical type with a complicated data structure. We developed an end-to-end ML analytical framework to accurately predict the clinical type of patients with COVID-19 based on clinical and laboratory testing modality features. We built random forest (RF) classification models, as RF enables excellent interpretability of the relative importance of an input variable to provide a more comprehensive understanding of the pathobiology of COVID-19. RF is a widely used ML model based on decision theory and the decision tree approach. Due to the internal validation process with out-of-bag error measurement, RF is especially accurate and reliable. Unlike other commonly used ML models (eg, support vector machine or k-nearest neighbor), which usually require a separate cross-validation set, the RF model performs internal validation and is especially suitable when the data set is not large. In addition, RF is robust against data loss and data unbalancing (eg, there are more patients with nonsevere than severe disease in our study [25-29]). Because the major goal of this study was not to compare the performance of different ML models, we focused on RF to deliver the most accurate classification possible.

For the single modality RF model, we used 50% randomly selected data for both clinical and laboratory testing blood biochemistry features. In this step, 107 patients with nonsevere COVID-19 and 74 patients with severe COVID-19 were randomly chosen, while the other patients' information was held to build the multimodal RF model. We assigned severe cases as "positive" and nonsevere cases as "negative" in the classification. The goal of ML classification through RF was to accurately predict the patient's COVID-19 type, either positive (severe) or negative (nonsevere), based on features from different clinical modalities. In this part of the study, we first used a single modality of features, either clinical or laboratory testing, as the input. The detailed RF modeling and validation processes are provided in Multimedia Appendix 2. We trained the model with 100 independent runs; in each run, a different set of 80% of the data was randomly selected for training, while the remaining 20% of the data were held for testing only. This step was performed to explore whether the RF model was robust against different input data and to assess the generalizability of the model. Hyperparameters in this RF model include using Gini impurity to determine the decision tree split, a minimum of 2 samples for tree spit, a minimum of 1 sample at any leaf node, and a total of 8 trees for the model ensemble [26]. Important ML performance metrics, including accuracy, sensitivity, specificity, F1 score, and area under the curve (AUC) value based on the receiver operating characteristic (ROC) curve, were computed for the testing set only.

In addition, RF can evaluate the relative importance of the input variables based on their Gini importance scores [28]. We further quantified the Gini impurity importance scores of the input features in each RF run during the model development stage on the training set (80% randomly selected data). We then identified the top contributing features based on the Gini importance scores in each of the 100 runs, aggregated over 100 runs; identified the overall top contributing features; and explored the clinical relevance and interpretability of these features for COVID-19. Note that the Gini impurity importance was calculated from the RF model based on the training set only and not on the testing set. In addition, each run of the RF model was based on a completely different, randomly sampled, and independent set of 80% training data, from which the Gini importance was calculated. Therefore, this approach avoided potential issues of overfitting and inflated performance [30]. If an RF model is robust, important input features should be consistent with the different 80% portions of the data used as the training set to develop the model. The most important features to differentiate COVID-19 clinical types were also cross-checked with our results from exploratory data mining, including the prevalence of the clinical features and the distribution of the laboratory testing features.

COVID-19 Clinical Type Classification With Multimodal ML

More importantly, we explored whether and how combining features across feature modalities improved classification performance. We developed another RF model with the same hyperparameter setting that incorporated features from both modalities. The modeling process using a single modality was similar. Instead of putting all 52 features into the model, we selected only the top 5 features from each of the two modalities as new inputs to reduce the increase model feasibility in case certain features in the total 52-feature pool would not be readily available. These top features were identified from the Gini importance of the single modality RF models (highlighted in Table S1 and Table S2 in Multimedia Appendix 1). The data set for developing the multimodal RF model was a completely new data set, as in, the other 50% of the original data was based on 107 additional patients with nonsevere COVID-19 and 74 additional patients with severe COVID-19 whose data were not used in the development of the single modality RF model.

We explored whether only 10 important features from different modalities could perform sufficiently well to address the clinical challenge of differentiating COVID-19 clinical types. This study can serve as alternative and supplemental tool to the gold standard features, which may not be readily available at the time of diagnosis.

All statistical analyses and ML models were built in R 4.0.2 (R Project) and Python 3.7 with additional supporting packages. The complete codes and fully deidentified data are freely available on GitHub [31].

Results

Clinical Findings in Nonsevere and Severe COVID-19

The prevalence of clinical features in patients with nonsevere and severe COVID-19 at the time of entry into the study were calculated and compared (Figure 1). A more detailed comparison of the clinical features between the two COVID-19 clinical types is provided in Table S1 in Multimedia Appendix 1, which shows the ORs, confidence intervals, and associated *P* values. For patients with the two clinical types of COVID-19, the prevalence was distinct for a number of different features. Patients with severe COVID-19 were statistically much more likely to be older (aged ≥50 years, OR 13.77, 95% CI 7.33-25.86, *P*<.001) and male (OR 1.89, 95% CI 1.24-2.90, *P*=.003) and to have renal diseases (OR 8.51, 95% CI 1.86-38.99, *P*<.001), cardiovascular diseases (OR 5.61, 95% CI 2.81-11.20, *P*<.001), hypertension (OR 5.37, 95% CI 3.36-8.56, *P*<.001), diabetes (OR 4.61, 95% CI 2.53-8.38, *P*<.001), loss of appetite and taste (OR 3.20, 95% CI 1.70-6.01, *P*<.001), chills (OR 2.21, 95% CI 1.16-4.22, *P*=.01), and chest congestion (OR 1.88, 95% CI 1.22-2.89, *P*=.003) than their counterparts with nonsevere COVID-19. The only exception was sore throat, which patients with severe COVID-19 were significantly much less likely to develop (OR 0.30, 95% CI 0.14-0.61, *P*<.001). These discoveries are further demonstrated in the forest plot of the ORs and confidence intervals in Figure 2, which shows the differences between the two clinical types. Therefore, these relatively easily measured and acquired clinical features could be used to clinically evaluate the disease severity of patients with COVID-19. Our findings, especially for patients with severe COVID-19, echoed the US Centers for Disease Control and Prevention's recently updated list of symptoms of COVID-19 [32] and more recent characterizations of patients with COVID-19 in the United States [33]. Our findings showed that older male patients with COVID-19 who had cardiovascular disease, respiratory disease, renal disease, and diabetes were at much higher risk of developing serious complications of COVID-19, such as acute respiratory distress syndrome (ARDS) and even death [20,21]. In addition, we discovered that Chinese patients with renal diseases were significantly more likely to develop severe COVID-19, which has not been widely reported. Clinical evidence has shown that ACE-2 expression is associated with kidney diseases; thus, kidney disease is a potential complication of SARS-CoV-2 infection [34,35]. This finding would inform clinicians that they should also monitor kidney dysfunction, such as acute kidney injury, as a clinical sign or consequence of severe COVID-19 complications.

Figure 1. Comparison of clinical features of patients with nonsevere and severe COVID-19. Note that because these features were binary, the y-axis indicates the prevalence of a positive result. CAR: cardiovascular disease; CHL: chills and shaking; CNC: cancer; CON: contact with patients with COVID-19; COU: coughing; CPD: chronic obstructive pulmonary disease; DIA: diabetes; DIR: diarrhea; FAM: family members with COVID-19; FEV: fever; FTG: fatigue; HED: headache; HIF: high fever; HYP: hypertension; KID: renal disease; LOF: low fever; MOF: medium fever; MSA: muscle ache; MUC: phlegm; NAP: loss of appetite; OLD: older age; PREV: prevalence; SEX: male sex; SHB: chest congestion; SMK: history of smoking; SOR: sore throat; VOM: vomiting.

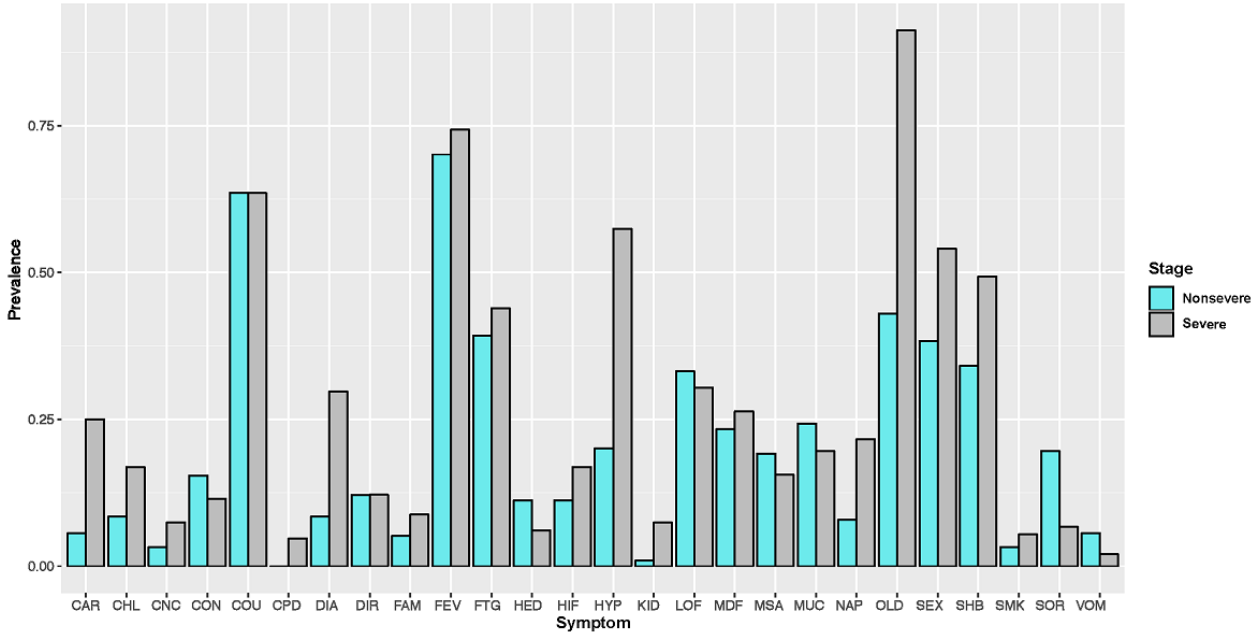

Figure 2. Forest plot of the importance of clinical features of patients with nonsevere and severe clinical types of COVID-19. Chronic obstructive pulmonary disease is not included because only patients with severe COVID-19 showed it as a comorbidity. The threshold for a feature to be positively or negatively associated with severe COVID-19 was 1 (dashed line), not 0. CAR: cardiovascular disease; CHL: chills and shaking; CNC: cancer; CON: contact with patients with COVID-19; COU: coughing; CPD: chronic obstructive pulmonary disease; DIA: diabetes; DIR: diarrhea; FAM: family members with COVID-19; FEV: fever; FTG: fatigue; HED: headache; HIF: high fever; HYP: hypertension; KID: renal disease; LOF: low fever; MOF: medium fever; MSA: muscle ache; MUC: phlegm; NAP: loss of appetite; OLD: older age; SEX: male sex; SHB: chest congestion; SMK: history of smoking; SOR: sore throat; VOM: vomiting. *P<.05, **P<.01; ***P<.001 from the 2×2 contingency table for each feature.

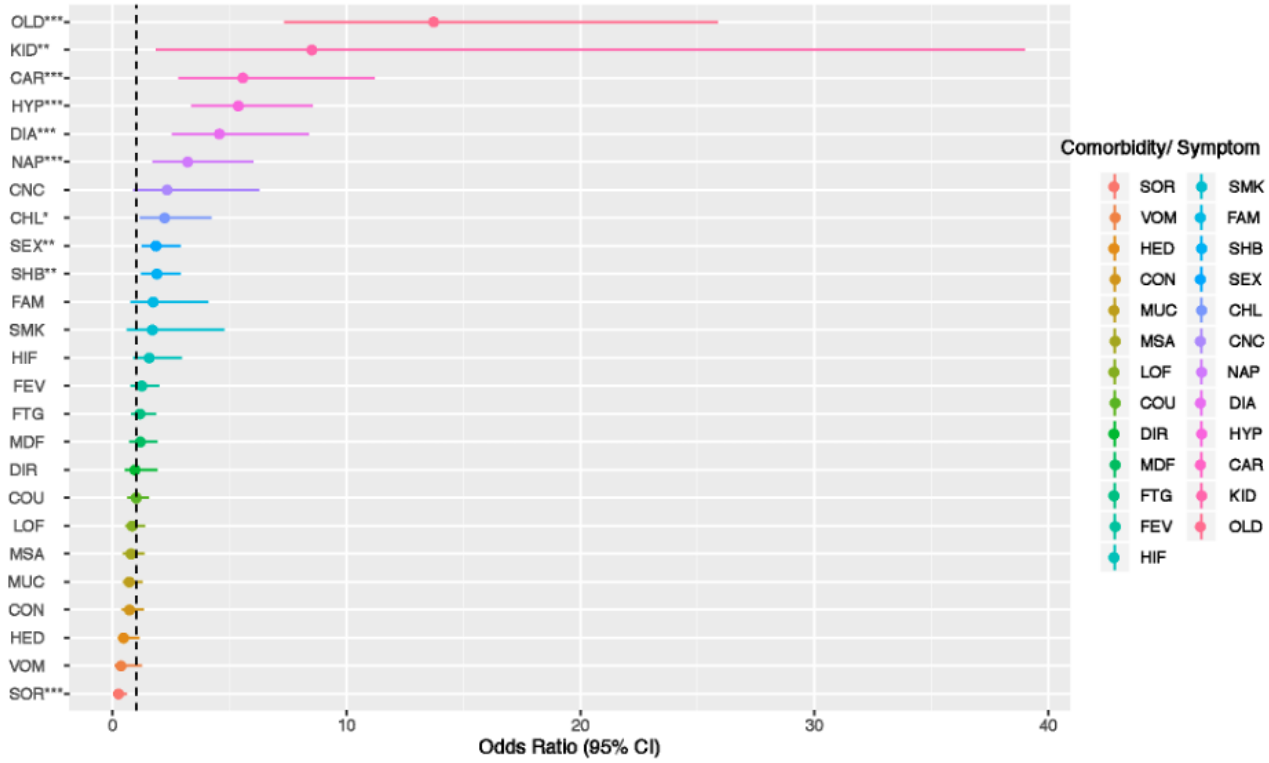
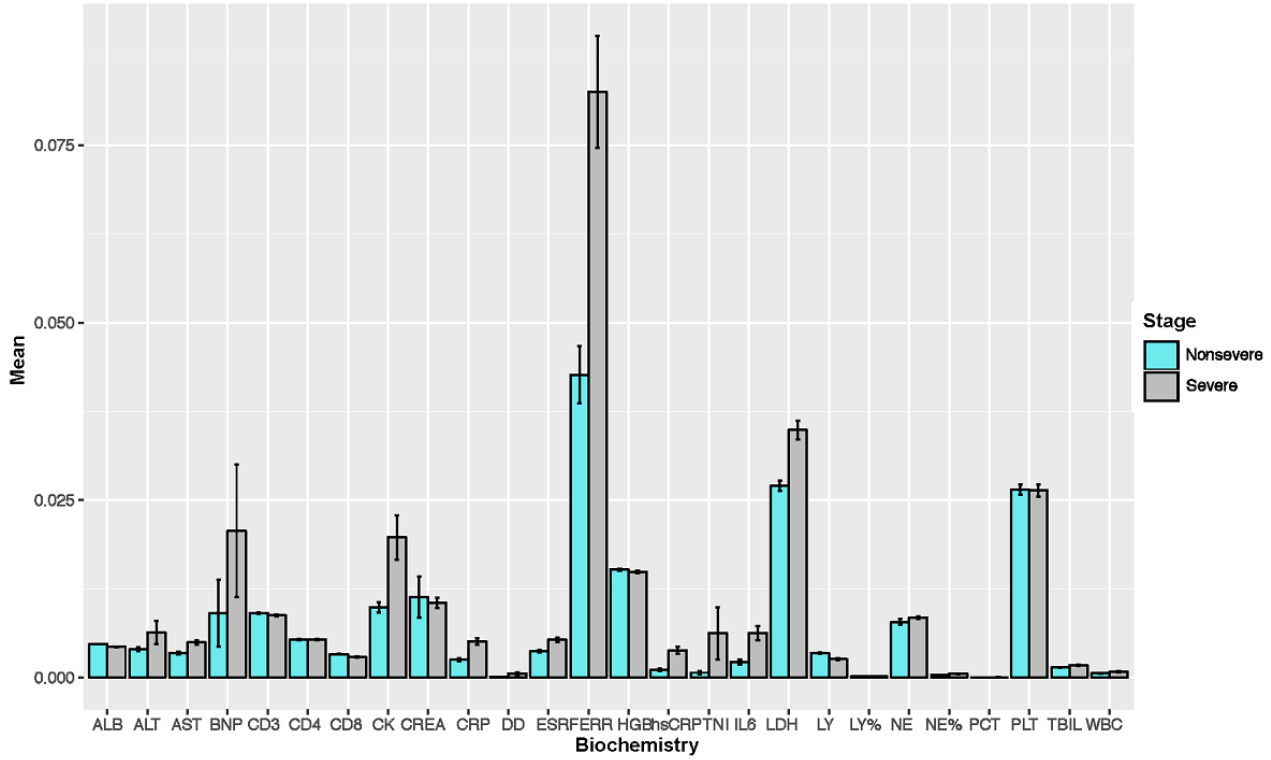


For the laboratory testing modality features, we compared the distributions of the continuous features between nonsevere and severe COVID-19. The results are demonstrated in Figure 3. A more detailed comparison of these 26 laboratory testing features between the two clinical types is provided in Table S2 in Multimedia Appendix 1, which shows the *P* values from the Kolmogorov-Smirnov tests. Based on the 2-sided Kolmogorov-Smirnov test, severe and nonsevere COVID-19 types differed significantly in most laboratory features, except for platelet (PLT), hemoglobin (HGB), CD3, and CD4. Among all laboratory features, IL-6, high-sensitivity troponin I (hsTNI), and D-dimer had the most significant differences between nonsevere and severe COVID-19 types.

Figure 3. Comparison of laboratory testing features of patients with nonsevere and severe COVID-19. Values shown on the y-axis were obtained after feature scaling and are between 0 and 1. The error bars represent the standard error of each laboratory testing feature. ALB: albumin; ALT: alanine transaminase; AST: aspartate aminotransferase; BNP: Brain natriuretic peptide; CK: creatine kinase; CREA: creatinine; CRP: C-reactive protein; DD: dimerized plasmin fragment D; ESR: erythrocyte sedimentation rate; FERR: ferritin; HGB: hemoglobin; hsCRP: high-sensitivity C-reactive protein; TNI: troponin I; IL6: interleukin 6; LDH: lactate dehydrogenase; LY: lymphocyte; LY%: percent of lymphocytes; NE: neutrophil; NE% percent of neutrophils; PCT: procalcitonin; PLT: platelet; TBIL: total bilirubin; WBC: white blood cell.



In conclusion, after extensive clinical feature extraction and data mining, we obtained strong qualitative and quantitative evidence that nonsevere and severe COVID-19 types differ substantially with regard to clinical features and laboratory test results. These findings pave the way toward creating an effective ML classifier to accurately differentiate these two COVID-19 types in clinical practice.

Clinical Type Classification via ML

Comorbidity and Symptom (Clinical) Modality

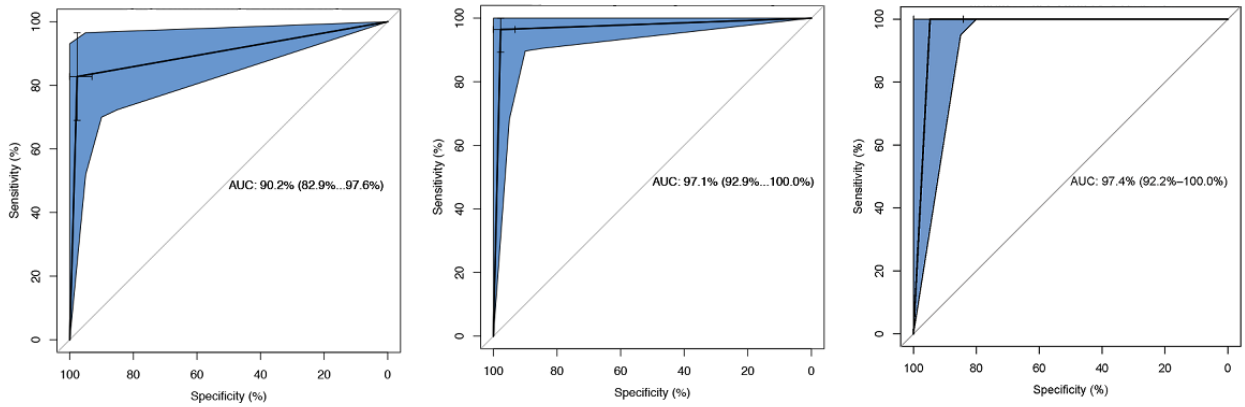
We first explored whether relatively simple binary features could provide accurate insights in identifying COVID-19 disease severity. The performance of this model is summarized in the upper section of Table 1. Based on 100 independent runs, the RF model reached a median of >99% and 94% accuracy for the training and testing sets, respectively (Table 1). Median is reported instead of mean value because the performance metrics were not normally distributed. The AUC was 90.2% (range 82.9%-97.6%) based on the ROC curve (Figure 4, left panel). The model performed better in detecting true positives (ie, severe clinical type) than true negatives (ie, nonsevere type). In other words, clinical features alone in the RF models were very unlikely to misclassify a severe case as a nonsevere case but had a higher likelihood of predicting a nonsevere case to be a severe case. In clinical practice, this would be a lesser concern, as a false positive (failure to detect nonsevere type) would be more tolerable than a false negative (failure to detect severe type).

Table 1. Performance of the random forest model with multimodal features. The results are based on 100 runs. In each run, 80% of the data was randomly selected as the training set and 20% as the testing set. The table shows the model performance on the testing set only.

Feature and performance metric	Median	Minimum	Maximum
Clinical (%)			
Accuracy	94.59	81.08	>99
Sensitivity	>99	80.95	>99
Specificity	93.75	75.00	>99
F1 score	97.30	82.93	>99
AUC[a]	90.20	82.90	97.60
Laboratory testing (%)			
Accuracy	97.22	93.06	>99
Sensitivity	>99	94.59	>99
Specificity	96.97	83.33	>99
F1 score	97.89	94.74	>99
AUC	97.10	92.90	>99
Multimodal (%)			
Accuracy	97.22	91.67	>99
Sensitivity	>99	90.00	>99
Specificity	94.44	75.00	>99
F1 score	97.78	97.22	>99
AUC	97.40	92.20	>99

[a]AUC: area under the curve

Figure 4. ROC curves from the random forest models based on clinical, laboratory testing, and multimodal features. Left: the symptom feature as the sole input; middle: the laboratory testing feature as the sole input; right: both features combined as the input. AUC: area under the curve; ROC: receiving operator characteristic.



Our RF model also identified the major influential features to differentiate COVID-19 types based on their contributions to the Gini importance in the training set. The top influential clinical features, in descending order, were age, gender, hypertension, diabetes, and cardiovascular diseases, in accordance with existing literature reports [36]. Other important clinical features included fatigue, chest congestion, sore throat, phlegm, and fever. Most of these findings aligned well with our parametric data mining with OR comparison (Figure 2, Table S1 in Multimedia Appendix 1) but showed much higher accuracy (94% accuracy on the testing set of the RF model compared to 68% accuracy from logistic regression). The only exception was renal disease, which was not considered to be a major differentiating factor based on its Gini importance (Table S1, Multimedia Appendix 1).

Clinically, older male patients with pre-existing comorbidities, especially hypertension, diabetes, and cardiovascular diseases, are much more vulnerable to COVID-19 and have a much higher risk of developing severe disease [19,21]. Therefore, we suggested using the comorbidity and symptom features of patients with COVID-19 as the first round of evaluation of severity with reasonable accuracy.

Laboratory Testing Modality

The RF model with 26 laboratory testing features was highly effective in differentiating nonsevere and severe COVID-19. The RF model achieved >99% and >95% accuracy for the training and testing data sets, respectively. The sensitivity, specificity, and F1 scores were all >95% when using only 8 trees in the RF model (Table 1, middle section). The AUC was 97% based on the ROC curve (Figure 4, middle panel). Although this study focused on ML methods, we evaluated the model performance of non-ML logistic regression in Table S3 (Multimedia Appendix 1) as a reference point to show the improvement that state-of-the-art ML models could achieve.

The top differentiating features in the laboratory testing modality were D-dimer, hsTNI, neutrophil, IL-6, lactate dehydrogenase (LDH), and hsCRP, in descending order. The clinical interpretation of their important roles was that patients with severe COVID-19 experience more intense immune responses and hyperinflammation, such as cytokine storm syndrome, with substantially increased IL-6 [37]. Research has also shown that SARS-CoV-2 can infect many organs other than the lungs, including the heart, and induce dysfunction of these organs [38,39]. Increasing hsTNI was found to be a sign of heart tissue damage from SARS-CoV-2 infection [40]. In addition, patients with severe COVID-19 may have microthrombosis, which induces higher D-dimer levels [19,21,41-43]. Abnormal levels of neutrophils may be responsible for cytokine storms and ARDS in patients with severe COVID-19 [13,44]. hsCRP, a biomarker of acute inflammation, cardiovascular disease, and ischemic events, was also confirmed to be a major contributing factor of COVID-19 mortality [19]. LDH is a biomarker of tissue damage and has been used to predict the clinical course of patients with COVID-19 [45]. These findings add further clinical insights to how multiple organs and systems, not just the lungs, respond to SARS-CoV-2 infection in different clinical types [14,46,47].

Multimodal Features

We further developed a multimodal RF model that incorporated both clinical and laboratory testing modalities with a completely new data set that was not used for the single modality model development. We used only the 5 most important features from the clinical and laboratory testing modalities, based on their Gini importance scores. The results showed that the top 10 of a total of 52 features from both modalities achieved almost >95% in every model performance metric, including accuracy, sensitivity, specificity, and F1 score (Table 1). The AUC was >97% as well (Figure 4, right panel). Therefore, we concluded that a two-step evaluation and triaging process would be feasible to differentiate the clinical types of patients with COVID-19 when the gold standard type-defining features were not readily available.

These findings reflect our clinical understanding that SARS-CoV-2 attacks multiple organs and systems, and the human body reacts in a unity against infection. Different features (eg, comorbidity, symptom, and laboratory testing results) complemented each other to provide a more comprehensive characterization of how the human body as a united entity, not only the respiratory system, reacted to SARS-CoV-2 infection [14]. In addition, the decent model performance supports the feasibility of multimodal data mining in detecting and differentiating patients with nonsevere COVID-19 from patients with severe disease.

Comparing the original 52 features in both modalities, which may not be all available at the same time during COVID-19 diagnosis, the top 10 most differentiating multimodal features provided a more practical input combined with the highly accurate ML model. Therefore, we concluded that our work would help effectively optimize health care operations during the pandemic and avoid overloading of the health care system [8].

Discussion

Principal Findings

This study provides a novel analytical framework that combines the power of multiple clinical features from different modalities to differentiate COVID-19 clinical types via ML techniques. Practically, it enables the delivery of a more comprehensive understanding of the pathobiology of COVID-19. It can aid the development of optimal treatment plans for individual patients, such as sending them to a mobile cabin hospital or admitting to a hospital with an ICU [7]. In addition, it will enable more effective triaging and optimization of health care system resources and personnel. This will substantially reduce the risk of overloading the health care system by admitting all patients with COVID-19 to hospital, decrease potential health care–associated infections, and improve clinical outcomes for the patients, especially during the COVID-19 pandemic [8].

In addition to accurately detecting vulnerable patients with COVID-19 who are likely to have severe disease, this study also provides insights on why these patients may have severe disease. ML models work directly with data and therefore are generally not good at providing clear interpretations. In this study, we combined the power of both hypothesis-driven and data-driven ML models. The highest-contributing comorbidities, symptoms, and biochemical features help predict and explain potential COVID-19 clinical courses and prognoses. Our research echoes recent studies that characterize and predict the clinical course, critical illness, and mortality of patients with COVID-19 [13,19,21]. In particular, another decision tree–based algorithm, extreme gradient boosting (XGBoost), showed promising performance in predicting the mortality of patients with COVID-19 [19]. RF is technically similar to XGBoost, and our results were consistent in identifying the key differentiating features, including LDH and hsCRP.

A continuous-valued risk score calculator for predicting risk of transitioning to critical-type COVID-19 (an even more severe type that requires ICU hospitalization, an invasive ventilator, or extracorporeal membrane oxygenation, and has a mortality rate as high as 50%) has been developed for patients with COVID-19 [21]. As a comparison, although our RF model predicts a 0-1 binary outcome for nonsevere and severe type disease, the internal RF modeling process through decision tree approach actually calculates an intermediate score between 0 and 1. By using a cutoff threshold, the RF model reports a final

dichotomized 0-1 outcome. Therefore, our analytical framework can also be readily adjusted to provide a continuous risk score for clinical evaluation and triaging of patients with COVID-19, if needed.

Many patients with severe COVID-19 present symptoms in lungs, especially ground-glass opacity (GGO), which can be detected by biomedical imaging techniques such as computed tomography (CT). However, a major clinical challenge of COVID-19 lies in the asymptomatic patient problem, which creates far worse difficulties than other coronavirus epidemics, including the original SARS and MERS epidemics. These patients show few or no classic symptoms related to viral pneumonia, and they present no GGO; however, they are almost as capable of transmitting the virus as symptomatic patients [4-6]. We suggest that the term "asymptomatic" is used due to lack of a comprehensive characterization and understanding of this novel pathogen and the pathophysiology of the host; we also suggest that these patients are not truly "asymptomatic," as in, without any clinical symptoms or signs. Approximately 10% of the patients with mild COVID-19 in our study cohort did not show typical respiratory symptoms, including fever, coughing, and chest pain, upon admission. However, they showed other symptoms from the more comprehensive modality of 26 clinical features.

Future Work

The next step of this study is to further include a biomedical imaging modality. A technical barrier is that a CT scan is a high-dimensional feature set, while clinical and laboratory test data have relatively low dimensionality. Therefore, the CT scan, in its original form of imaging, cannot be effectively combined with other modalities. We will evaluate the feasibility of using a convolution neural network (CNN, another ML technique) first to reduce the feature space in CT scans and extract a fully connected layer in the CNN as a representation of the CT scan feature. A fully connected layer is a 1D vector and has the same dimensionality as the other two modalities. Therefore, in theory, we would be able to further combine CT scans with other clinical features and investigate the association between these features with regard to COVID-19.

COVID-19 is a complex disease in which the pathogen not only attacks the respiratory system but other organs and systems that possess ACE-2 receptors as well [14,33]. Our findings reveal the complicated pathological, physiological, and immunological responses to SARS-CoV-2 infection and shed light in understanding the complex interactions between the virus and the human body. Although our multimodal data mining and ML framework was developed with data from patients with severe and nonsevere COVID-19, we suggest that the end-to-end framework is applicable to many disease systems in which multimodal inputs are common, including demographic information, comorbidity, laboratory testing, imaging, and -omics data. Having a more holistic viewpoint and approach will enable us to understand and respond to these emerging diseases, especially the unprecedented COVID-19, more readily in the field. Another feasible analytical solution is ensembling. Each input feature modality can be used independently to train a specific model, and the final prediction of COVID-19 clinical type can be made through ensembling. We will further explore this analytical framework and transfer our insights to future clinical studies, such as differentiating healthy patients from patients with non–COVID-19 viral pneumonia, nonsevere COVID-19, and severe COVID-19.

Limitations

In this study, we recruited participants from a single hospital in Wuhan, the first epicenter of COVID-19. There will inevitably be selection bias, as the ethnic group is currently limited to Chinese participants who are mostly of Han ethnicity. It is possible that ethnicity and race and their confounding risk factors (eg, socioeconomic status, nutrition conditions, accessibility of care, and other social determinants of health) are different in various studies. Therefore, we wish to share our findings with our colleagues worldwide and determine whether different demographic backgrounds influence feature distributions between nonsevere and severe COVID-19 in patients. Some of our findings of the top contributing clinical and laboratory testing features were supported in other COVID-19 studies across different ethnic groups, while others were not [32,40]. For example, while we found male gender to be a strong influencing factor of severe COVID-19, other studies did not reach a similar conclusion [36]. The findings in this study on Chinese ethnicity could actually complement other existing studies on other ethnic groups and reveal the clinical and epidemiological complexity of this unprecedented ongoing pandemic.

Another limitation of this study is that the patients were evaluated at the time of admission; therefore, the study was a cross-sectional instead of a longitudinal study. Future studies could examine both diagnosis and prognosis and further explore how and why some patients with nonsevere COVID-19 may transition to a severe disease state and whether ML techniques are able to identify critical predictive features to undesirable prognoses such as death.

Additionally, different subtypes of SARS-CoV-2, their specific pathogenicity and virulence, and their host-pathogen interactions should be taken into consideration when conducting and comparing studies across different regions of the world. The other factors that this study did not include are behavioral and societal aspects, such as whether and how using mobile cabin hospitals to treat patients with nonsevere COVID-19 reduces the rate of transition to severe type. The COVID-19 epidemic, like all infectious disease epidemics, has individual clinical, epidemiological, behavioral and societal factors. Therefore, we will also explore cross-scale individual clinical course and population-level epidemics in future studies.

Conclusion

We trained and validated ML RF models to predict COVID-19 severity based on 26 comorbidity and symptom features and 26 laboratory testing features from a cohort of 214 patients with nonsevere COVID-19 and 148 patients with severe COVID-19. We identified the top features from both feature modalities to differentiate the clinical types, and we achieved predictive accuracies of >90%, >95%, and >99% when clinical features, laboratory test data, and the top 5 features from each modality

combined were used as inputs, respectively. The results will help patients with COVID-19 self-evaluate their condition, help clinicians to evaluate disease severity and triage patients, and optimize health care resource utilization during the COVID-19 pandemic.

Abstract

Background: Clinical decision support (CDS) is a valuable feature of electronic health records (EHRs) designed to improve quality and safety. However, due to the complexities of system design and inconsistent results, CDS tools may inadvertently increase alert fatigue and contribute to physician burnout. A/B testing, or rapid-cycle randomized tests, is a useful method that can be applied to the EHR in order to rapidly understand and iteratively improve design choices embedded within CDS tools.

Objective: This paper describes how rapid randomized controlled trials (RCTs) embedded within EHRs can be used to quickly ascertain the superiority of potential CDS design changes to improve their usability, reduce alert fatigue, and promote quality of care.

Methods: A multistep process combining tools from user-centered design, A/B testing, and implementation science was used to understand, ideate, prototype, test, analyze, and improve each candidate CDS. CDS engagement metrics (alert views, acceptance rates) were used to evaluate which CDS version is superior.

Results: To demonstrate the impact of the process, 2 experiments are highlighted. First, after multiple rounds of usability testing, a revised CDS influenza alert was tested against usual care CDS in a rapid (~6 weeks) RCT. The new alert text resulted in minimal impact on reducing firings per patients per day, but this failure triggered another round of review that identified key technical improvements (ie, removal of dismissal button and firings in procedural areas) that led to a dramatic decrease in firings per patient per day (23.1 to 7.3). In the second experiment, the process was used to test 3 versions (financial, quality, regulatory) of text supporting tobacco cessation alerts as well as 3 supporting images. Based on 3 rounds of RCTs, there was no significant difference in acceptance rates based on the framing of the messages or addition of images.

Conclusions: These experiments support the potential for this new process to rapidly develop, deploy, and rigorously evaluate CDS within an EHR. We also identified important considerations in applying these methods. This approach may be an important tool for improving the impact of and experience with CDS.

KEYWORDS

AB testing; randomized controlled trials; clinical decision support; clinical informatics; usability; alert fatigue

Introduction

Clinical decision support (CDS) is a valuable feature of electronic health records (EHRs). CDS can generate several forms of decision support that have been extensively studied, including alerts, calculators, reminders, and order sets [1-3]. Successful examples of CDS have led to reductions in prescribing brand-name antibiotics [4], improved lipid management in renal transplant patients [5], improved compliance with guidelines for treating HIV [6-8], reduced ordering of tests when costs were displayed [9], and age-specific alerts that reduced inappropriate prescribing in the elderly [10-15]. Although conceptually straightforward, successful CDS alerts must deliver accurate information, in clinical context and at the point of care, and must be well-integrated into the clinical workflow. These complexities have contributed to inconsistent results [16,17] that reflect the enormous heterogeneity in system design, workflow integration, usability, simplicity, and content [18,19].

Despite the complexity of designing effective CDS and the inconsistent results, the sheer volume of CDS in modern EHRs has increased dramatically. In the past 5 years, the number of alerts released in our institution's EHR increased from 13 to 117. This volume has amplified the underlying challenges of clunky user interfaces, poor usability, and workflow integration and has fueled the rapid escalation of alert fatigue [20-22]. Alert fatigue has yielded an environment in which providers ignore clinical alerts at rates as high as 70% of the time or more [23].

Consequently, while many CDS have been effective in promoting better care, they do so with generally poor efficiency. Moreover, EHRs burden providers with tedious, cognitively draining documentation requirements, leaving little time or energy to engage with CDS tools that have the potential to improve care but are not necessary requirements to complete a visit [24]. Alert fatigue contributes to provider burnout, a highly publicized phenomenon that is a major threat to patient safety and physician satisfaction.

CDS designers' capabilities are often constrained by the limitations of commercial EHR systems and the operational challenges inherent to local customizations; new CDS tools are frequently released with minimal modification of the standard tools. Similarly, traditional randomized controlled trials (RCTs) require a long, static experimental design to determine the potential statistical advantage of the intervention. These approaches stand in contrast to how other industries launch new products and determine their value. Software development and other industries leverage rapid experimentation processes, often termed "A/B trials," to efficiently evaluate multiple design choices using live environments and users [25]. In this paradigm, there is an a priori acknowledgement that the "best" version of the product is unknown until it is empirically tested. This approach is applied to big and small design choices, from what features to include in a new smartphone app to where to place icons on a web page. To enable this process, agile procedures have been developed to quickly implement versions, assess the relative impact, and then modify the product for the next round of A/B testing. Highly agile companies like Amazon use this rapid experimentation to deliver the optimal customer experience and release code modifications every 11.7 seconds to accommodate their rapid learning [26]. We believe CDS developers can deploy A/B testing methods to evaluate many aspects of evaluation including promotion of positive outcomes, minimizing unintended consequences on safety, and poor user experience.

The inpatient influenza alert was intended to promote vaccination for eligible patients. The interruptive alert triggered at the time the nurse documented responses to the influenza screening question flowsheets. Acceptance was defined as placing the order for the influenza vaccine. The alert continued to trigger from flowsheet documentation until the patient was ordered for the vaccine or the patient no longer met eligibility criteria.

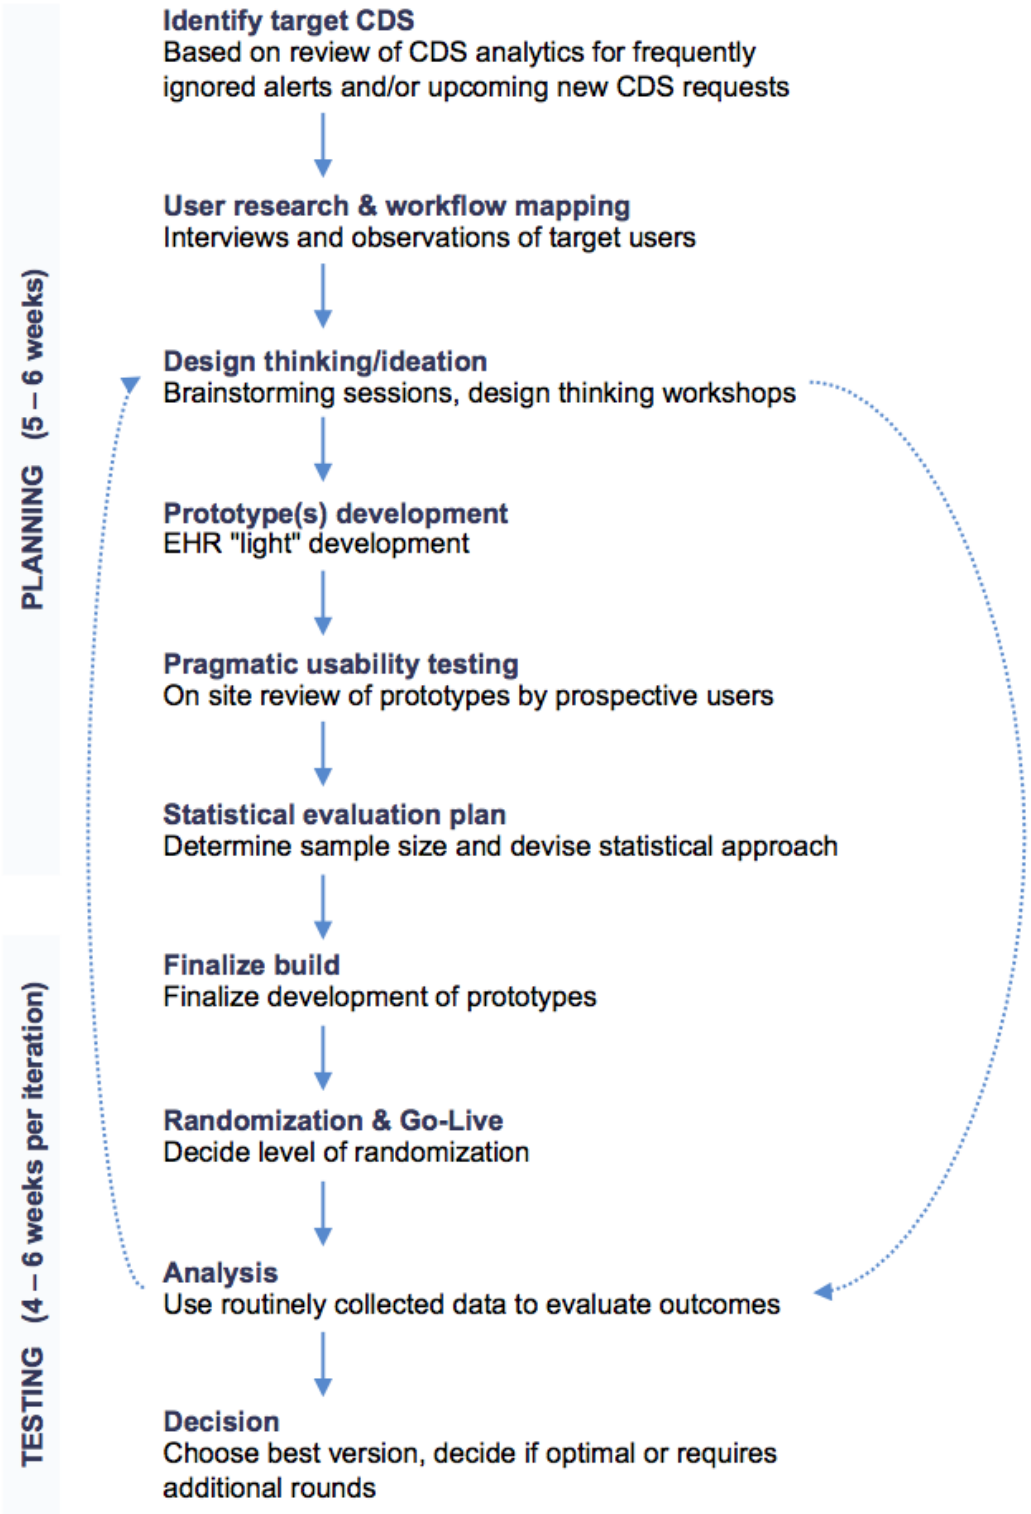
The outpatient tobacco cessation alert was designed to promote counseling and treatment for patients using tobacco products. The noninterruptive alert displayed in an alert section for outpatient providers at chart opening when active smokers had not received counseling within the previous 3 months. Acceptance was defined as documentation of counseling, prescription of therapy, or referral to the state tobacco quit line. We hypothesized that A/B testing methods would enable our CDS development teams to quickly evaluate CDS designs and iteratively modify them to maximize their acceptance rates and impact on clinical outcomes while minimizing their firing rates.

Methods

Creating an A/B Testing Framework

The CDS optimization initiative was a partnership between our CDS team and the Rapid RCT lab at NYU Langone Health [27]. The Rapid RCT lab uses elements of the traditional RCT methodology in a series of rapid cycle experiments to test and optimize systems interventions at our institution. Together, the CDS and Rapid RCT lab teams collaboratively defined a new process combining A/B methods with traditional RCTs to optimize our CDS alerts. To achieve this synergy, a multidisciplinary team was assembled including physician and nurse informaticists, implementation scientists, EHR analysts, data analyst, statistician, project manager, and project associate. A multistep process was developed that combined tools from user-centered design, A/B testing, and implementation science (Figure 1).

Figure 1. Clinical decision support (CDS)/randomized controlled trial (RCT) process map. EHR: electronic health record.



This process was supported by 3 key "enablers." One was the work done by the Rapid RCT lab to engage the local institutional review board (IRB) and create sufficient understanding of how A/B testing works so that these projects would typically be self-certified as quality improvement research and not require IRB review. This enabled our team to develop and test each iteration of a CDS alert at a rapid pace. Second, our CDS team engaged the relevant health system leadership early in the process for each alert so that there was sufficient buy-in for this novel approach to CDS development and optimization. This required multiple presentations on our process to develop trust in how it would improve the clinician experience with CDS and acceptance that there would be multiple versions of each CDS, creating heterogeneity in the user experience. This effort has been ongoing and critical to educating clinicians and administrators about this highly novel work that touches many important clinical processes. Third, our CDS team developed its technical ability to randomize experiences in the EHR at the

patient level (Multimedia Appendix 1). This work leveraged native EHR functionality. However, this logic did not provide for automated randomization at the practice level. To overcome this limitation, our team developed a process for manual randomization of clinical practices and then created logic to assign the appropriate CDS version to the appropriate target group. Fourth, we created a robust ability to report on CDS tool engagement that gave us near real-time access to the impact of each new version. Our team developed reporting capabilities beyond the standard EHR tools to drill down on what parts of each CDS tool were being "clicked" versus "ignored," what orders were being placed from what exact location, and trends in utilization. These tools allowed the team to quickly ascertain if new trends were emerging. Last, we prespecified safety metrics before each go-live. Along with our CDS outcomes, balancing clinical outcomes were evaluated to track performance and ensure patient quality and safety after each iteration. These capabilities unlocked our team's ability to scale rapid, randomized CDS experiments.

Application of the Framework

Based on the A/B testing process described in the previous section, our team was now positioned to implement our CDS A/B testing process more widely across our enterprise. We use 2 examples, our inpatient, nurse-facing influenza vaccine alert and our ambulatory, provider-facing tobacco cessation counseling alert, to detail the experimental methods involved in implementing our CDS A/B testing process.

The first step involved rapid user research. Both of these alerts were already active, with low rates of acceptance by the relevant users: 2% for the influenza vaccine alert and 31% for the tobacco cessation alert. Our process involved conducting interviews and observations (usually by our clinician informaticists and a research team member) of users interacting with the alerts using our pragmatic usability testing method to quickly summarize field notes that could be reviewed by the design team [28]. With these data in hand, the team conducted ideation sessions to develop potential alternatives to the current CDS that could enable higher adoption rates. These included modifications based on CDS best practices to reduce cognitive load (embedding images, simplifying text, consistency of formatting) [29-31] and other motivational tools ("nudges," such as highlighting financial incentives [eg, relative value units] or using more authoritative messaging) [32].

Once the team identified the versions of interest, the EHR development team created lightweight (eg, paper-based illustrations) prototypes of each version for further review by stakeholders. After iterative rounds of refinement, the prototypes were fully built within our EHR testing environment for additional usability testing and feedback from target users. With these data, the multiple CDS versions were then built and randomized to control for unmeasured confounders (eg, changes in patient volumes, staffing changes, seasonal changes), and deployed into the live environment. The inpatient influenza alert and the tobacco alert were randomized at the patient and practice level, respectively.

Statistical Analysis

Once deployed, our team used relevant CDS metrics (alert views and follow-up actions such as placing a suggested order) and the predetermined statistical approach to evaluate which CDS version was superior. Initially, we used only simple statistics (*t* tests or Chi square tests) to compare outcomes between versions. Once the testing cycle was completed, the team reconvened and evaluated if the improvement (or lack thereof) was sufficient or if additional rounds of A/B testing were warranted.

Post-hoc analysis initiated based on result irregularities in the cluster randomization tobacco experiment revealed unanticipated behaviors in the 3 groups that resulted in different baseline rates by randomization group. To control for these underlying irregularities, we modified our methods to employ a more sophisticated analysis. A multilevel logistic regression model was developed to predict alert acceptance, using the lme4 library from R [33]. Ambulatory practice was included as a random effect, and randomization group and study rounds were included as fixed effects. This method produced odds ratios that compared acceptance rates of different alert modification groups to a reference group. We obtained odds ratios from the models and profiled confidence intervals for the odds ratios using the approach of Venables and Ripley [34].

Results

Flu Alert Experiment

Our week-long user feedback sessions highlighted several issues, including confusion about the need for the ordering nurse to obtain a physician cosignature and difficulty of appropriately documenting patient refusal to prevent future triggering of the alert. This feedback was used to tailor the alert to the appropriate setting and user. We first conducted a 5-week RCT to address the most frequently mentioned nursing barrier: a misconception that ordering the influenza vaccine was outside of the nurse's scope of practice. We tested whether explicitly stating nurses were empowered to order the vaccine with no cosignature requirement would improve alert acceptance. We randomized patients into 2 arms: the existing alert (Figure 2) and the new alert that stated that nurses can order the vaccine without cosignature (Figure 3). The new message resulted in a negligible reduction in firings per patient per day.

Figure 2. Original version of the flu alert tested in the randomized controlled trial (RCT). Copyright 2020, Epic Systems Corporation.

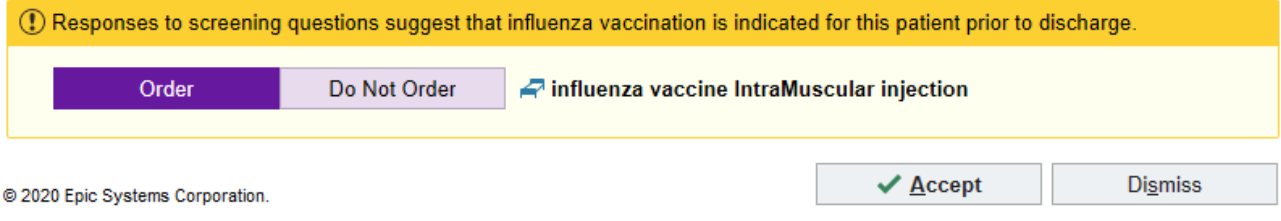


Figure 3. New version of the flu alert tested in the randomized controlled trial (RCT), with a simpler header and more directed verbiage that states "RN to order. Per Protocol; no cosign required". Copyright 2020, Epic Systems Corporation.

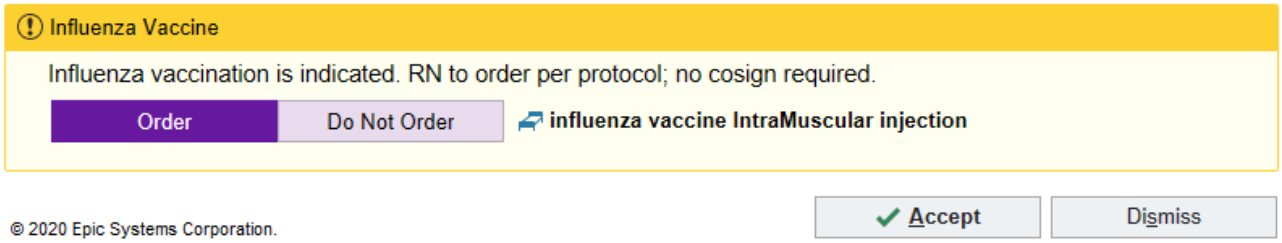

This limited impact encouraged the team to conduct a more intensive review of the triggering logic and user response options. This review had surfaced fundamental flaws inherent in both versions of the alert. These enhancements were prioritized, and the change most likely to succeed was implemented in version 3. Specifically, the team identified that nurses did not appreciate that when they dismissed the alert with no action, the alert would appear automatically again at next flowsheet filing. Consequently, for version 3, we eliminated the ability to "dismiss" the alert without ordering the vaccine or selecting the acknowledgment reason. When nurses attempted to rapidly satisfy the alert with "accept," the influenza order would automatically be placed, satisfying the alert and suppressing future firings (Figure 4). The CDS design team concluded that testing a new alert against an original version in a rapid RCT was no longer justifiable as we did not believe the 2 options had equipoise and did not want to delay enhancements that had high likelihood of reducing nurse fatigue. Version 3 resulted in a 64% reduction in firings per patient per day (Table 1).

Figure 4. Version 3 of the flu alert, in which an acknowledgement reason button was added and the "dismiss" button was removed. Copyright 2020, Epic Systems Corporation.

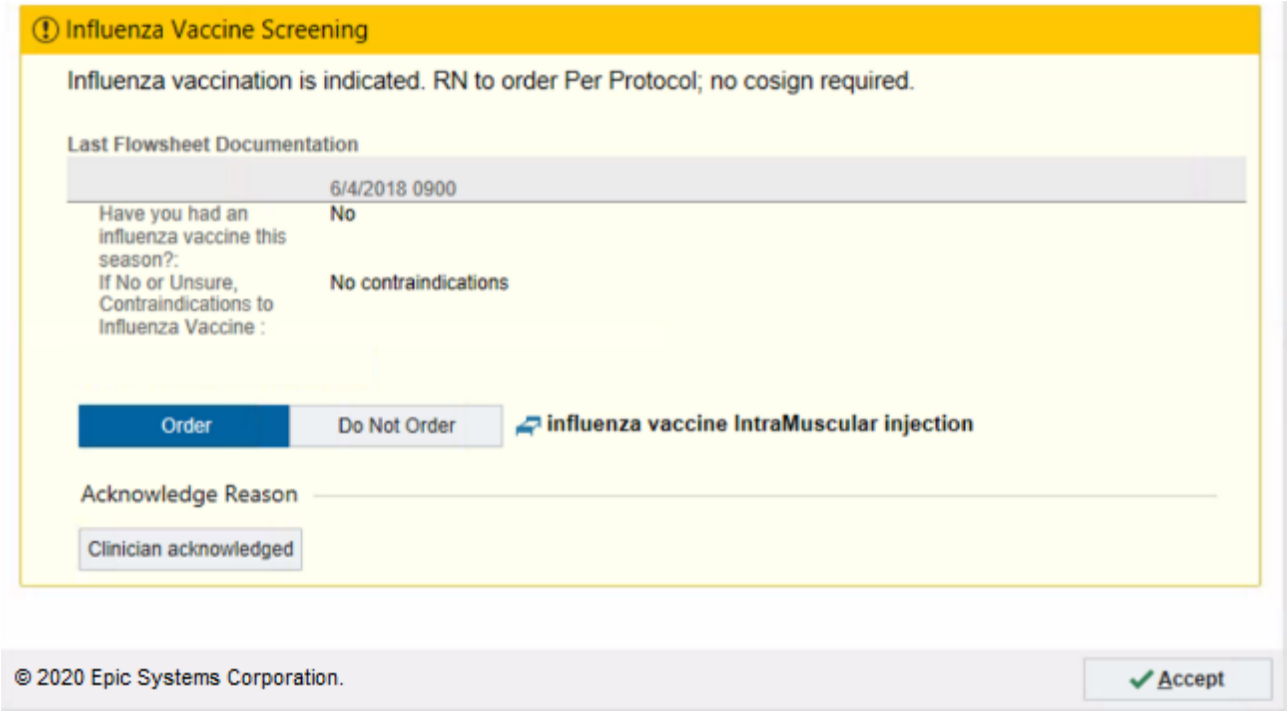

Table 1. Flu alert results.

Round	Alert version	Firings per patient per day	*P* value	Vaccination compliance rate at discharge, %
Baseline (Nov 2018 - Jan 2018)	1 (n=8296)	23.0	N/A[a]	N/A
1 (Feb 2018 - Apr 2018)	1 (n=2025)	23.6	.521[b]	90.8
1 (Feb 2018 - Apr 2018)	2 (n=2039)	23.1		
2 (Sep 2018 - Dec 2018)	3 (n=8777)	8.4	<.001[c]	87.7
3 (Jan 2019 - Feb 2019)	4 (n=1952)	7.3	<.001[c]	89.0

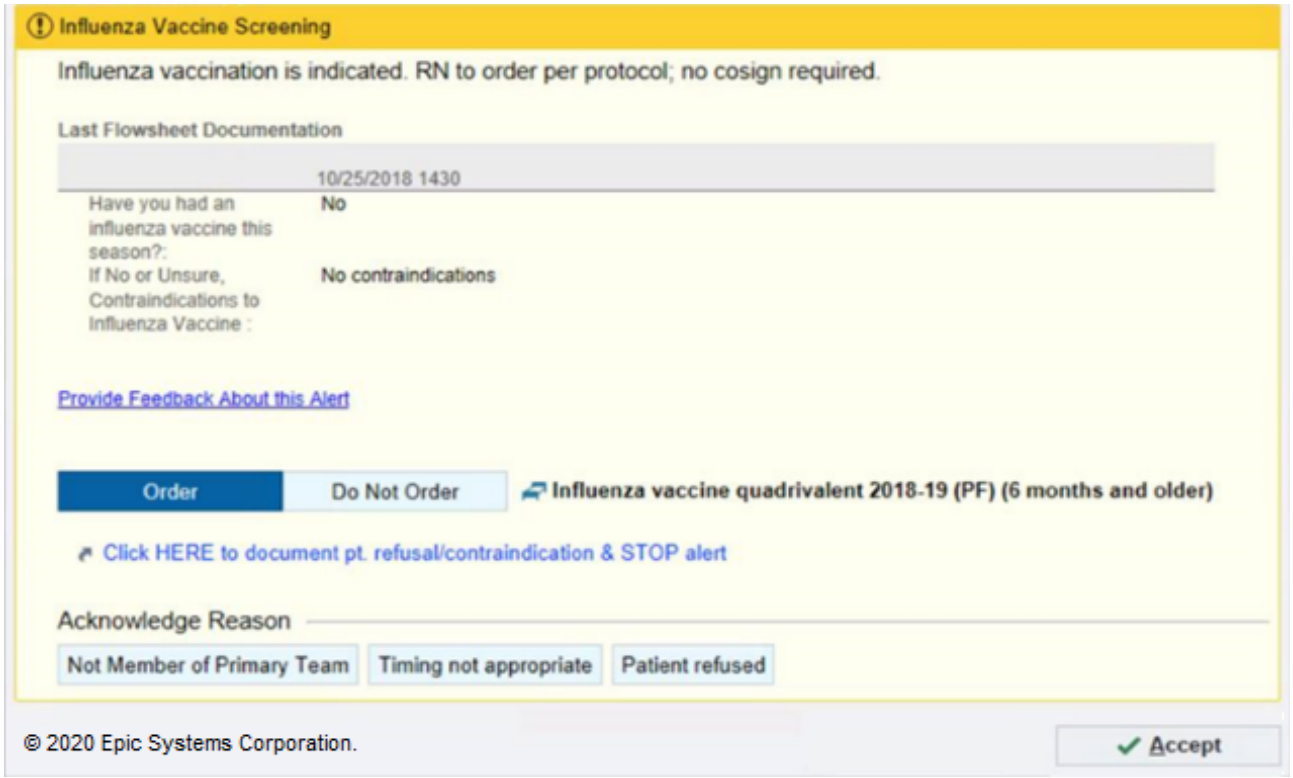
[a]N/A: not applicable.

[b]Comparing 1 vs 2 in the randomized controlled trial.

[c]Compared to baseline.

The CDS design team implemented the next prioritized enhancements in version 4. For the fourth cycle, the team identified that nurses disproportionally dismissed alerts in specific hospital units, including the Post-Anesthesia Care Unit. Upon learning about this finding, nursing leadership determined that these units were not appropriate locations to trigger the alert. Furthermore, our usability testing identified that the alert did not offer nurses sufficient locus of control. Specifically, nurses could not suppress the alert for a period of time when they felt the timing or recipient of the alert was inappropriate without placing the order. Consequently, we added targeted acknowledgement buttons to the alert based on these reasons that prevented the alert from firing for an acceptable period of time (Figure 5). This improvement resulted in a 13% reduction in alert firings per patient per day compared to version 3 (Table 1). These mixed methods served as a reminder that while A/B testing is a helpful tool, employing A/B testing in all situations is not the goal.

Figure 5. Version 4 of the flu alert, in which new acknowledgement reason buttons with lockout periods and a jumplink to update flowsheet documentation was added, and inappropriate units were excluded. Copyright 2020, Epic Systems Corporation.



Tobacco Alert Experiment

In the tobacco alert experiment, our week-long design thinking exercises produced 3 potential improvements with varying message framing (financial, evidence-based, regulatory) and complementary images (Figures 6-12). A financial framing indicated the additional revenue that a physician could generate by performing tobacco cessation counseling and gave them tools to document appropriately and create the relevant billing charge. The evidence framing highlighted that tobacco cessation was a part of providing high-quality care, and the regulatory framing indicated that tobacco cessation counseling was integral to the institution's expectations and policies. Additionally, in Round 2, images were added to reinforce the message framing.

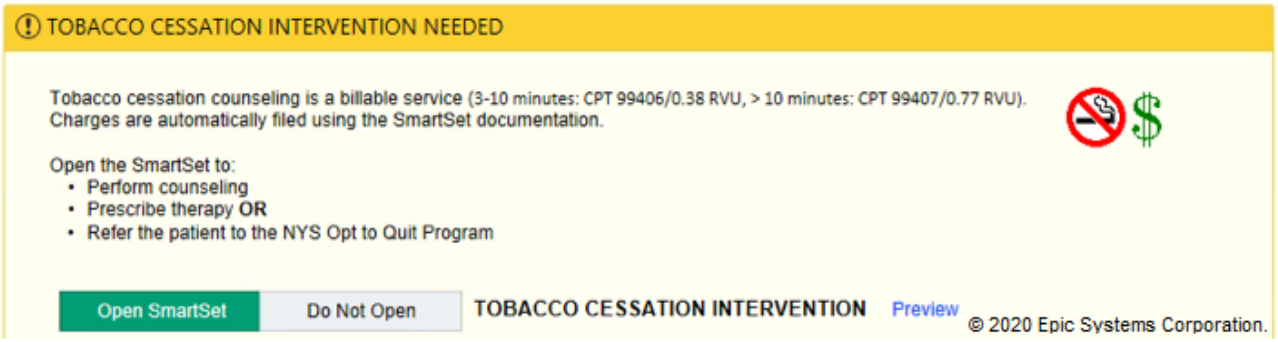

Figure 8. Tobacco evidence-based messaging alert with images tested in Round 2 of the randomized controlled trial. Copyright 2020, Epic Systems Corporation.

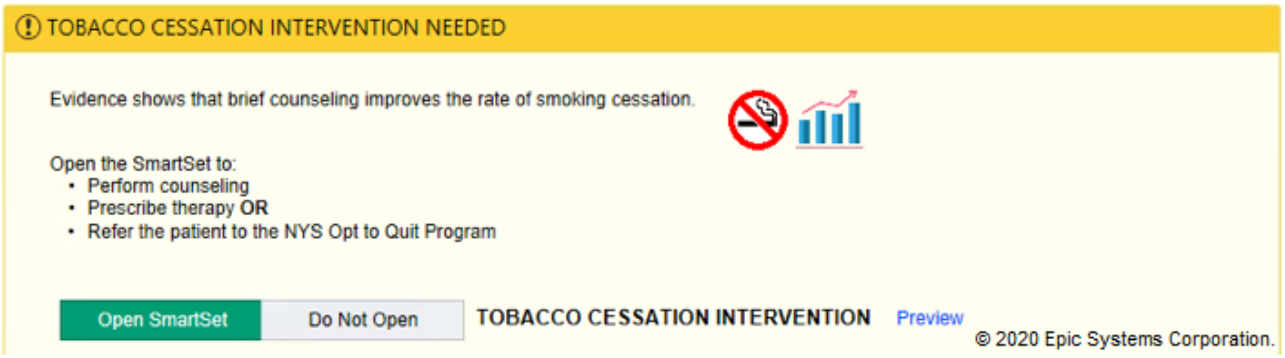

Figure 9. Tobacco regulatory messaging alert with images tested in Round 2 of the randomized controlled trial. Copyright 2020, Epic Systems Corporation.

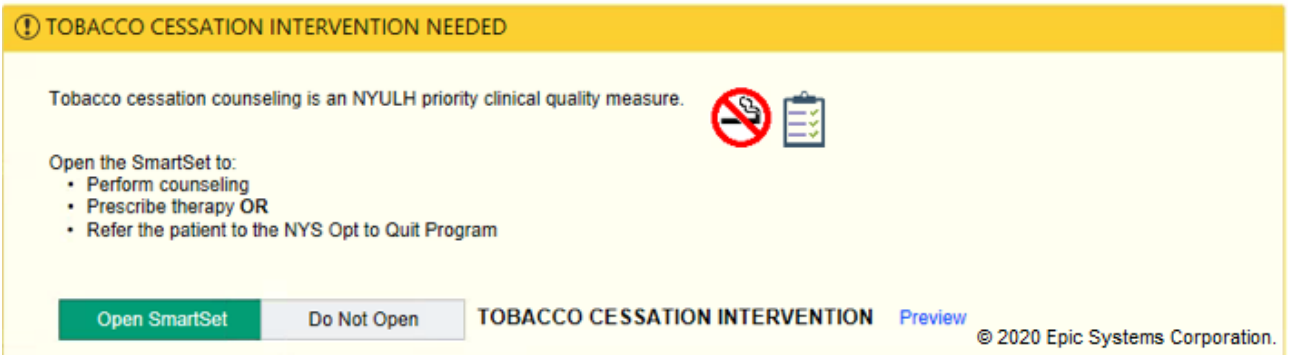

Figure 10. Tobacco financial messaging alert with no images tested in Round 3 of the randomized controlled trial. Copyright 2020, Epic Systems Corporation.

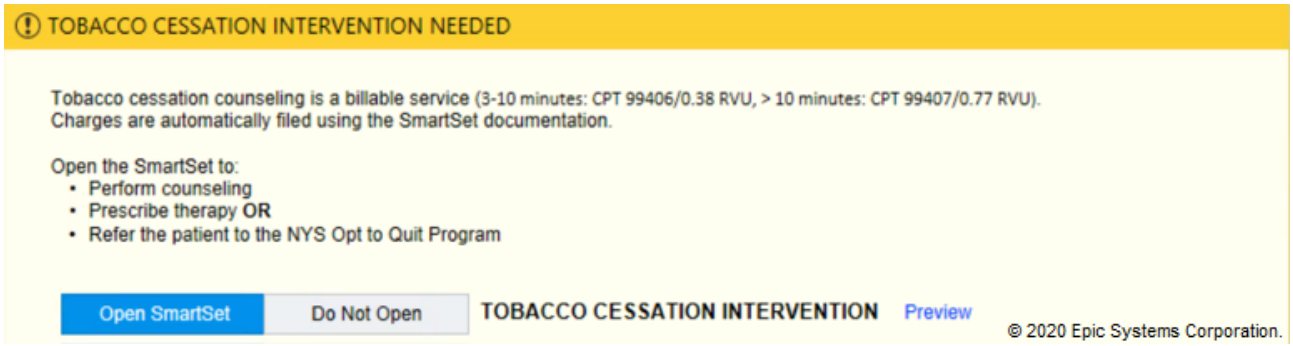

Figure 11. Tobacco financial messaging alert with both images (no smoking sign and dollar sign) tested in Round 3 of the randomized controlled trial. Copyright 2020, Epic Systems Corporation.

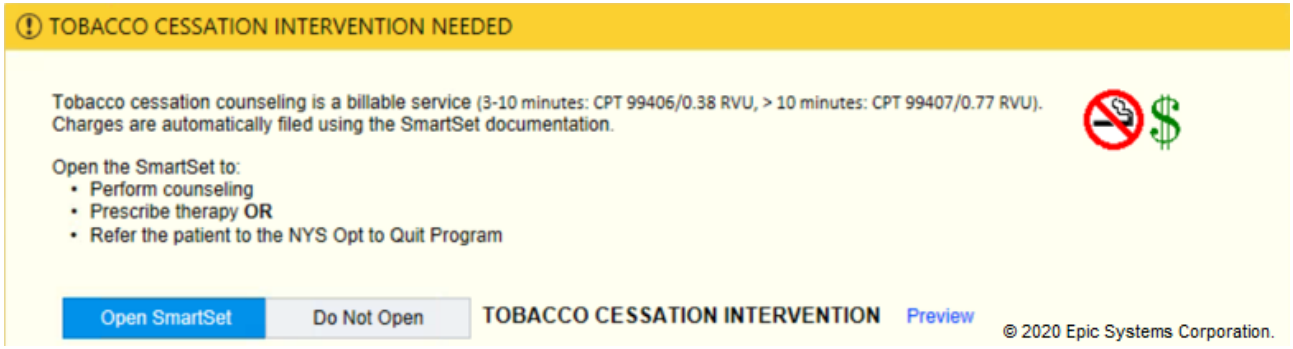

Figure 12. Tobacco financial messaging alert with image of no smoking sign tested in Round 3 of the randomized controlled trial. Copyright 2020, Epic Systems Corporation.

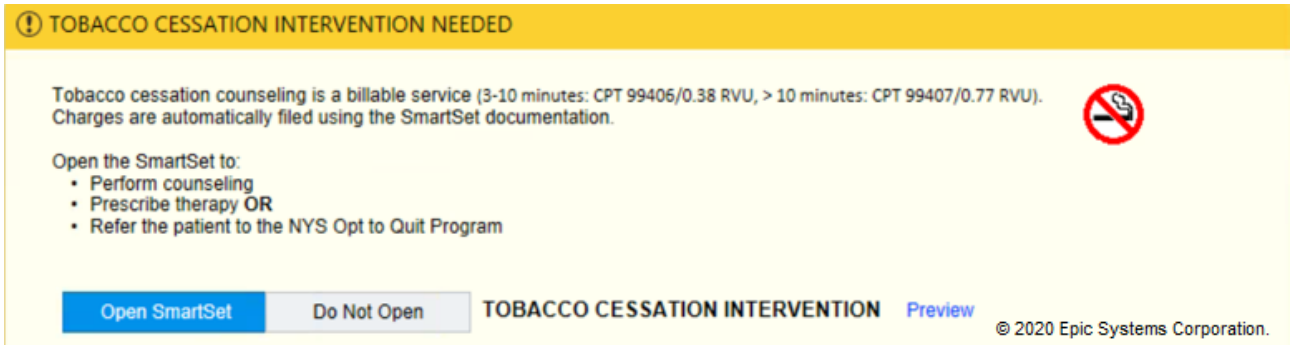

Each version was randomized at the ambulatory practice level for 4-5 weeks. In a series of 3 A/B testing experiments over a period of 8 months, our team observed that neither the framing method nor the addition of multiple or single images resulted in significant differences in acceptance rates for the tobacco alert (Table 2).

Table 2. Acceptance rates by alert type (encounter level acceptance rates; acceptance includes any positive action — perform counseling, prescribe therapy, or refer to state tobacco quit line).

Discussion

Our experience and results provide significant insights into the opportunities and challenges in transitioning to a strategy of optimization that has worked so successfully in other areas of information technology.

By creating an infrastructure to support this approach, we successfully tested multiple versions of alerts in a short period of time with outcomes that are supported by rigorous methods. This capability stands in contrast to the common approach of releasing single versions of CDS alerts with no empiric data supporting the relative efficacy of their design and then relying on weaker pre-post statistical methods for assessment.

This success is predicated on having assembled a multidisciplinary team, institutional support, and a repeatable process that can be applied to the rapid improvement of any CDS tool. It draws heavily on both the user-centered, agile approach from software and other quality improvement philosophies and traditional RCT methodologies. In our experience, standing up this approach is the most challenging phase. It requires effort to foster buy-in from the IRB, operational leadership, enhanced EHR randomization capabilities, and reporting to rapidly test CDS variations. The creation of the process drew heavily on our prior experience in usability and user-centered design [35] and a flexible randomization schema that could be tailored to the dynamic research methodology.

While we were successful at developing this infrastructure, the outcomes from our initial experiments offer guidance to other institutions embarking on a similar approach. For our first A/B testing experiment in influenza, we intentionally chose a less invasive design change (verbiage and mild display modifications) that would not be controversial to operational leaders and minimized risk of unintended consequences in our deployment. We recommend this approach as it allowed the information technology team members and clinical members to focus their efforts on creating the robust testing infrastructure without the distraction of complex intervention changes. The first experiment confirmed that a simple solution would not result in a dramatic improvement in alert acceptance. While strategizing the next experiment, the team uncovered more fundamental design flaws with clear remedies. Rather than subjecting these remedies to a round of RCTs, we opted to follow a traditional pre-post evaluation given the extremely high likelihood of success. This approach proved successful as we had dramatic increases in alert acceptance rates. All nurses benefited from this enhancement rather than having to wait for the result of a second RCT. Consequently, CDS teams have to consider the appropriate use cases in deploying randomized A/B testing vs more traditional heuristics-based approaches to improving CDS [21,36]. In the future, A/B testing could be more beneficial after these basic heuristic constructs have been satisfied.

In addition to the right use case, there are outstanding questions related to the right volume of usability testing vs rapid A/B testing to deploy when refining the CDS. Usability testing is significantly more resource and time intensive as compared to rapid A/B testing. Consequently, we will continue to explore how to balance a priori usability testing versus empiric A/B tests.

Similarly, despite repeated cycles, no intervention improved the acceptance rate of the tobacco alert. This result is likely because clinical practice behaviors are challenging to modify and changes to CDS presentation displays might not be sufficiently impactful. While small tests of change could be helpful to large internet sites with millions of users per day, these changes might not translate as well to CDS with a smaller, highly trained population. With our growing confidence in our underlying framework and approach, we will begin to experiment with larger structural changes to our CDS that are more likely to have impact.

Despite the successes in our implementation strategy, there are several constraints to this approach. Randomizing at the clinician level continues to be a challenge as our EHR does not easily support it and manual randomization of thousands of providers is suboptimal. Moreover, due to the pragmatic nature of the research, contamination is always a risk since clinicians and clinical workflows are not static. For instance, the flu alert was randomized at the patient level, which meant that nurses likely

interacted with both versions of the alert even on the same day, possibly reducing the potential effect size.

Our cluster randomization, while minimizing contamination bias, was challenging given underlying unanticipated irregularities in the practice sites. Specifically, operational reorganization of the ambulatory network during the trials distorted the original randomization. Furthermore, we assumed that randomization had successfully distributed key characteristics across arms and initially did not check baseline rates in randomized groups. We corrected for this using statistical procedures and now examine baseline rates of all key variables prior to randomization. We also did not include a baseline control arm, which made interpretation of our results more challenging. In the future, to mitigate inevitable changes in organization structures, cluster randomization should be stratified by practice groups in addition to by individual practices. Nonetheless, organizational changes may disrupt pragmatic experiments reinforcing the importance of a rapid, iterative evaluation framework.

Finally, post-hoc analysis revealed that our statistical team had misinterpreted data retrieved from the EHR. Data from each round were captured at the EHR department level. However, our analysis was conducted at the clinical practice level. This disconnect required our team to manually map EHR departments to clinical practices, which were not always in a 1:1 relationship. This allocation was further complicated by operational changes where practices were removed and combined. For the future, we would recommend randomizing at the level data will be reported (ie, at the EHR department level for cluster randomization).

These experiences highlight the importance of having the capability to make quick, data-driven decisions and a process to rapidly remediate mistakes and apply these learnings to future A/B cycles.

Fundamental differences between health care organizations and software companies provide additional challenges to prioritizing A/B experiments. Unlike large software companies whose primary key performance indicators are dependent on user acceptance of decision support (eg, clicking on an advertisement), alert burden is not yet the major priority of clinical institutions, though it is gaining importance given the rising appreciation of physician burnout [37].

Rapid A/B testing of CDS alerts in combination with RCT methods is a promising approach to efficiently, rapidly, and rigorously evaluating the impact of the tools and the clinicians' experience using them. Our experience also highlights the evaluative challenges associated with cluster randomization and the outstanding need for collaboration with EHR vendors to design scalable randomization approaches at various levels. Applied broadly, this approach could also help reduce the amount of CDS "noise" in the system, by both reducing the number of alerts and making each more impactful. If this proves true, the application of rapid A/B testing and RCT methods to CDS alerts could be a potential intervention for alert fatigue and improve the EHR experience.

Acknowledgments

Funding for the Rapid RCT Lab program was provided by Allen Thorpe. The authors thank Allen Thorpe for funding the Rapid RCT Lab program and Mark Samia RN, Christopher Mahoney, Lani Albania RN, Dawn Feldthouse RN, Rose Ann Alfaro RN, and Catherine Snapp at NYU Langone Medical Center Information Technology who worked on project implementation.

Authors' Contributions

All authors made substantial contributions to (1) conception and design, acquisition of data, or analysis or interpretation of data and (2) drafting or critical revisions of the manuscript. All listed authors approved the final version of the manuscript to be published.

Abstract

Background: Asthma exerts a substantial burden on patients and health care systems. To facilitate preventive care for asthma management and improve patient outcomes, we recently developed two machine learning models, one on Intermountain Healthcare data and the other on Kaiser Permanente Southern California (KPSC) data, to forecast asthma-related hospital visits, including emergency department visits and hospitalizations, in the succeeding 12 months among patients with asthma. As is typical for machine learning approaches, these two models do not explain their forecasting results. To address the interpretability issue of black-box models, we designed an automatic method to offer rule format explanations for the forecasting results of any machine learning model on imbalanced tabular data and to suggest customized interventions with no accuracy loss. Our method worked well for explaining the forecasting results of our Intermountain Healthcare model, but its generalizability to other health care systems remains unknown.

Objective: The objective of this study is to evaluate the generalizability of our automatic explanation method to KPSC for forecasting asthma-related hospital visits.

Methods: Through a secondary analysis of 987,506 data instances from 2012 to 2017 at KPSC, we used our method to explain the forecasting results of our KPSC model and to suggest customized interventions. The patient cohort covered a random sample of 70% of patients with asthma who had a KPSC health plan for any period between 2015 and 2018.

Results: Our method explained the forecasting results for 97.57% (2204/2259) of the patients with asthma who were correctly forecasted to undergo asthma-related hospital visits in the succeeding 12 months.

Conclusions: For forecasting asthma-related hospital visits, our automatic explanation method exhibited an acceptable generalizability to KPSC.

asthma; forecasting; patient care management; machine learning

Introduction

Background

Asthma affects 8.4% of the US population [1], resulting in over 3000 deaths, almost 500,000 hospitalizations, and over 2,000,000 emergency department (ED) visits every year [1,2]. The state-of-the-art method for reducing asthma-related hospital visits, including ED visits and hospitalizations, is to use a model to forecast which of the patients with asthma are prone to future poor outcomes. We then enroll these patients in care management, ensuring care managers call them periodically to help them schedule health and related services. As used by health care systems like University of Washington Medicine, Intermountain Healthcare, and Kaiser Permanente Northern California [3] and by health plans in 9 of 12 metropolitan communities [4], this method, if implemented properly, can cut up to 40% of patients' future hospital visits [5-8].

Having a limited capacity, a care management program can enroll only a small portion of patients [9], and its effectiveness is upper bounded by the accuracy of the predictive model. Because they are missing certain important features, the existing models for forecasting asthma-related hospital visits among patients with asthma [3,10-22] are inaccurate, with each model missing over half of patients who will undergo future asthma-related hospital visits and mislabeling many others as making such visits. As a result, care management programs continue to be used inefficiently because they are unable to focus on the highest-risk patients. In addition, patient outcomes deteriorate, whereas health care costs increase. To address this problem, we recently considered many candidate features and developed two extreme gradient boosting (XGBoost) [23] machine learning models, one on Intermountain Healthcare data [24] and the other on Kaiser Permanente Southern California (KPSC) data [25], to forecast asthma-related hospital visits in the succeeding 12 months among patients with asthma with a higher accuracy. As is typical for machine learning approaches, these two models do not explain their forecasting results. Clinicians would know that a patient is considered to be at a high risk by the model, but the model offers no reason why this is the case. This makes it difficult for clinicians to understand and trust the model's prediction result, determine whether the patient should be put into care management, and pinpoint interventions suitable for the patient. To address the interpretability issue of black-box models, we designed an automatic method to offer rule format explanations for any machine learning model's forecasting results on imbalanced tabular data and to suggest customized interventions with no accuracy loss [26]. Our method worked well for explaining our Intermountain Healthcare model's forecasting results [26], but its generalizability to other health care systems remains unknown.

Objectives

The objective of this study is to evaluate the generalizability of our automatic explanation method to KPSC in forecasting asthma-related hospital visits. In the following sections, we describe our evaluation approach and results.

Methods

Ethics Approval and Study Design

After receiving approval from the institutional review boards of KPSC and University of Washington Medicine, in this study, we conducted a secondary analysis of retrospective data.

Patient Population

We adopted the same patient cohort from our previous KPSC predictive model paper [25]: a random sample of 70% of patients with asthma who had a KPSC health plan for any period between 2015 and 2018. This sample size is the largest one permitted by KPSC for sharing its data with another non-Kaiser Permanente institution for research. KPSC has 227 clinics and 15 hospitals. It is the largest integrated health care system in Southern California, offering care to approximately 19% of residents there [27]. A patient was deemed asthmatic in a specific year if during that year, at least one asthma diagnosis code (*International Classification of Diseases, Tenth Revision* [*ICD-10*]: J45.x; *International Classification of Diseases, Ninth Revision* [*ICD-9*]: 493.0x, 493.1x, 493.8x, and 493.9x) was recorded on the patient in the encounter billing database [11,28,29]. Patient death during that year served as the exclusion criterion.

Prediction Target (Dependent Variable)

We adopted the same prediction target as our prior KPSC predictive model paper [25]. For every patient deemed to have asthma in a specific year, the indicator of any asthma-related hospital visit in the succeeding year is the outcome. An asthma-related hospital visit is a hospitalization or ED visit with asthma as its principal diagnosis (*ICD-10*: J45.x; *ICD-9*: 493.0x, 493.1x, 493.8x, and 493.9x). When training and testing our automatic explanation method and our KPSC XGBoost model, for each patient who had a KPSC health plan on a year's last day and was also deemed asthmatic in the year, we used the patient's data up to the year's last day to forecast the patient's outcome in the succeeding year.

Data Set

We adopted the same administrative and clinical data set from our prior KPSC predictive model paper [25]. Obtained from KPSC's research data warehouse, this structured data set covered our patient cohort's visits at KPSC between 2010 and 2018.

Features (Independent Variables), Predictive Models, and Data Preprocessing

Our KPSC model [25] uses the XGBoost classification algorithm [23] and 221 features to forecast asthma-related hospital visits in the succeeding year in patients with asthma. These features are listed in our previous KPSC predictive model paper [25], were computed on the structured attributes in our data set, and cover various characteristics such as patient demographics, medications, visits, diagnoses, vital signs, procedures, and laboratory tests. An example feature is the total number of asthma relievers that the patient filled in the previous 12 months. Every input data instance to our KPSC model aims at a (patient, index year) pair, includes these 221 features, and is used to forecast the succeeding year's outcome of the patient. As in our

prior KPSC predictive model paper [25], the top 10% of patients with asthma projected at the highest risk were used as the cutoff point for binary classification. We used the same data preprocessing approach adopted in our prior KPSC predictive model paper [25] to clean, normalize, and prepare the data.

Review of Our Automatic Explanation Method

Previously, we designed an automatic method to offer rule format explanations for the forecasting results of any machine learning model on tabular data and to suggest customized interventions with no accuracy loss. The original method [30] was designed for relatively balanced data. Recently, we extended the method to handle imbalanced data [26], where one value of the outcome variable has a much lower prevalence rate than another. This fits the case of forecasting asthma-related hospital visits in patients with asthma. At KPSC, the prevalence rate of having asthma-related hospital visits in the succeeding year was approximately 2%. In the remainder of this paper, we focus on the extended automatic explanation method.

Main Idea

The central idea of our automatic explanation method is to use two models side by side to separate the forecasting and offering explanations. Each model serves a different purpose. The first model was used for the forecasting. Typically chosen to be the most accurate one, this model can be any model built on continuous and categorical features. The second model contains class-based association rules [31,32] mined from past data. It is used not to forecast but to explain the forecasting results of the first model. After using an automatic discretization method [31,33] to convert continuous features to categorical features, we use a standard approach such as Apriori to mine the association rules [32]. Each rule presents a feature pattern linking to a value u of the outcome variable and has the form:

r_1 AND r_2 AND ... AND $r_s \rightarrow u$.

The values of s and u can differ across the rules. For the binary classification of poor versus good outcomes, u is typically a poor outcome value. Each item r_i ($1 \leq i \leq s$) is a feature-value pair (g, v). When v is a value, r_i shows that feature g has a value v. When v is a range, r_i indicates that the value of g is within v. The rule signifies that a patient's outcome is apt to be u if r_1, r_2, ..., and r_s are all satisfied by the patient. An exemplar rule is:

> The patient had 8 or 9 primary or principal asthma diagnoses in the previous 12 months
>
> AND the patient had ≥6 no shows in the prior 12 months
>
> → The patient will undergo ≥1 asthma-related hospital visit in the subsequent 12 months.

The Rule Mining and Pruning Process

Our automatic explanation method uses 5 parameters: the minimum commonality threshold, the minimum confidence threshold, the largest number of items permitted on an association rule's left-hand side, the confidence difference threshold, and the number of top features used to construct rules. For a given rule

r_1 AND r_2 AND ... AND $r_s \rightarrow u$,

its commonality reflects its coverage in the context of u and refers to the fraction of data instances fulfilling r_1, r_2, ..., and r_s among all the data instances connected to u. Its confidence reflects its precision and refers to the fraction of data instances connecting to u among all the data instances fulfilling r_1, r_2, ..., and r_s. Our method uses those rules whose commonality is no less than the minimum commonality threshold, whose confidence is no less than the minimum confidence threshold, and each containing no more than the maximum permitted number of items on its left-hand side.

We use 3 techniques to reduce the number of association rules and prevent it from being excessively large. First, we remove every more specific rule q_1 in the presence of a more general rule q_2 satisfying q_2's confidence ≥ q_1's confidence−the confidence difference threshold. Second, certain machine learning algorithms, such as XGBoost [23], can automatically compute every feature's importance value. When handling a large data set with many features, only the top few features having the largest importance values and used in the first model are adopted to construct rules. Third, a clinician in the design team of the automatic explanation function examines all possible values and value ranges of the features adopted to construct rules and labels those values and value ranges that could have a positive correlation with the poor outcome value. Only the labeled feature values and value ranges are adopted to form rules.

For each feature-value pair item that is adopted to construct association rules, a clinician in the design team of the automatic explanation function compiles zero or more interventions. We tag an item actionable if it links to at least one intervention. Each rule passing the rule pruning process is automatically linked to the interventions related to the actionable items on the left-hand side of the rule. We tag a rule actionable if it contains at least one actionable item on its left-hand side; that is, it links to at least one intervention.

The Explanation Approach

For every patient whom the first model forecasts to take a poor outcome value, we explain the forecasting result by showing the association rules in the second model having this value on their right-hand sides and whose left-hand sides are satisfied by the patient. Each rule provides a reason why the patient is forecasted to take this value. For each actionable rule that is shown, the interventions connected to it are listed next to it. The automatic explanation function's user can find customized interventions that fit the patient from the listed interventions. Usually, the rules in the second model present common reasons for having poor outcomes. Some patients will experience poor outcomes for other reasons. Thus, the second model can explain most, but not all, of the poor outcomes correctly forecasted by the first model.

Parameter Setting

In our experiments, we used the same parameter setting approach used in our previous automatic explanation paper [26]. Each association rule had no more than 5 items on its left-hand

side. Our KPSC XGBoost model [25] used 221 features to forecast asthma-related hospital visits. We used the top 50 features that our KPSC model ranked with the largest importance values to construct association rules. Our KPSC model gained an area under the receiver operating characteristic curve (AUC) of 0.820 using all 221 features and an AUC of 0.815 using the top 50 features.

For forecasting asthma-related hospital visits, our KPSC model [25] obtained a lower AUC for KPSC data than our Intermountain Healthcare model on Intermountain Healthcare data [24]. As mentioned in our previous automatic explanation paper [26], the harder it is to forecast the outcome, the smaller the minimum commonality and confidence thresholds need to be to ensure that our automatic explanation method can provide explanations for a large percentage of the patients whom the first model correctly forecasts to take a poor outcome value. Following this guideline on KPSC data, we set the minimum commonality threshold to 0.08%, which is lower than the corresponding value of 0.2% we used on Intermountain Healthcare data [26]. We set the minimum confidence threshold to 25%, which is lower than the corresponding value of 50% used for the Intermountain Healthcare data [26]. Despite not looking large, 25% is much greater than 2%, which is the percentage of KPSC data instances associated with asthma-related hospital visits in the succeeding year, as well as our KPSC model's positive predictive value of 11.03% [25].

To set the value of the confidence difference threshold τ, we calculated the number of association rules passing the rule pruning process versus τ. Our previous paper [26] shows that this number of rules first drops quickly as τ rises and then drops slowly when τ becomes sufficiently large. The value of τ was set at the transition point.

Data Analysis

Partitioning of the Training and Test Sets

We used the same method adopted in our prior KPSC predictive model paper [25] to divide the entire data set into training and test sets. As several features were computed on the data from up to 2 years before the index year and the outcomes came from the succeeding year, our data set included 6 years of effective data (2012-2017) over the 9-year period of 2010-2018. To match the use of our KPSC model and our automatic explanation method in clinical practice, we used the 2012-2016 data as the training set to train our KPSC model and mine the association rules adopted by our automatic explanation method. We used the 2017 data as the test set to gauge the performance of our KPSC model and the automatic explanation method.

Performance Metrics

We used the same performance metrics from our previous automatic explanation paper [26] to assess the performance of our automatic explanation method. A performance metric on our method's explanation power is the fraction of patients with asthma whom our method could offer explanations for among the patients whom our KPSC model correctly forecasted to undergo asthma-related hospital visits in the succeeding year. We computed the average number of rules and the average number of actionable rules that suit such a patient. A rule suits a patient if all items on its left-hand side are satisfied for the patient.

As our previous automatic explanation paper [26] showed, several rules suiting a patient often differ by a single item on their left-hand sides. When multiple rules suit a patient, the amount of nonredundant information included in them is usually much less than the number of rules in them. To plot a full picture of the amount of information included in the automatic explanations given to the patients, we computed 3 distributions of the patients with asthma whom our KPSC model correctly forecasted to undergo asthma-related hospital visits in the succeeding year: (1) by the number of actionable rules suiting a patient, (2) by the number of different actionable items included in all the rules suiting a patient, and (3) by the number of rules suiting a patient.

Results

Demographic and Clinical Characteristics of Our Patient Cohort

Remember that each data instance aims at a different (patient, index year) pair. Tables 1 and 2 present the demographic and clinical characteristics of our KPSC patient cohort during 2012-2016 and 2017, respectively. The two sets of characteristics are sufficiently similar to each other. During 2012-2016, 2.42% (18,925/782,762) of data instances were linked to asthma-related hospital visits in the succeeding year. During 2017, this fraction was 2.13% (4353/204,744). Our previous KPSC predictive model paper [25] provides a detailed comparison of the two sets of characteristics.

Table 1. Demographic and clinical characteristics of our Kaiser Permanente Southern California patient cohort during 2012-2016.

Characteristics	Data instances associated with no asthma-related hospital visit in the succeeding year (n=763,837), n (%)	Data instances associated with asthma-related hospital visits in the succeeding year (n=18,925), n (%)	Data instances (n=782,762), n (%)

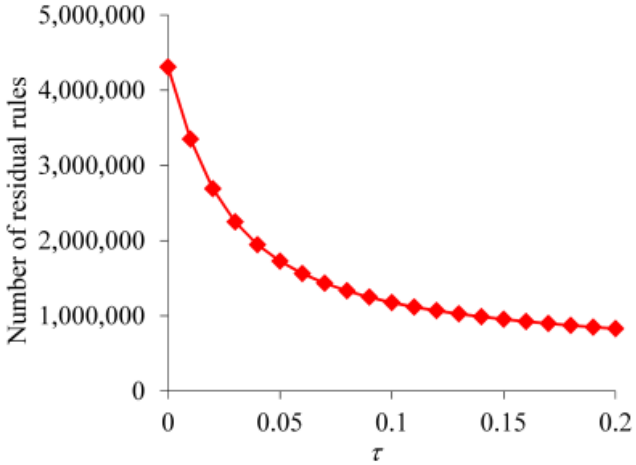
The Number of Residual Association Rules

Taking the top 50 features that our KPSC model ranked with the largest importance values, we mined 11,628,850 association rules from the training set. Figure 1 displays the number of residual rules versus the confidence difference threshold τ. This number first drops quickly as τ rises and then drops slowly when τ becomes ≥0.15. Accordingly, the value of τ was set to 0.15, resulting in 954,493 residual rules.

An asthma clinical expert in our team labeled the values and value ranges of the top 50 features that could have a positive correlation with asthma-related hospital visits in the succeeding year. After we removed those rules involving any other value or value range, 725,632 association rules remained. Each rule provides a reason why a patient is forecasted to undergo future asthma-related hospital visits. Almost all (725,623) of these rules were actionable. Thus, our automatic explanation method's performance numbers are almost the same regardless of whether all these rules or only the actionable rules were used. In the remainder of this section, we present only the performance numbers when only the actionable rules were used.

Figure 1. The number of residual rules versus the confidence difference threshold τ.



Example Association Rules Adopted by the Second Model

To allow the reader to gain a sense of the association rules the second model adopted, we present 5 example rules:

- Rule 1: The patient filled ≥89 asthma relievers in total in the previous 12 months

  → The patient will undergo ≥1 asthma-related hospital visits in the subsequent 12 months.

The use of many asthma relievers indicates poor asthma control. An intervention tied to the item *the patient filled ≥89 asthma*

relievers in total in the prior 12 months is to tailor prescribed medications and to suggest the patient to maximize adherence to asthma control medications or to improve avoidance of asthma triggers.

- Rule 2: The patient had ≥25 nebulizer medication orders in the previous 12 months

  AND the patient incurred ≥16 major visits for asthma in the previous 12 months

  → The patient will undergo ≥1 asthma-related hospital visits in the subsequent 12 months.

The use of many nebulizer medications indicates a poor asthma control. An intervention tied to the item *the patient had ≥25 nebulizer medication orders in the prior 12 months* is to tailor prescribed medications and to suggest the patient to maximize adherence to asthma control medications or to improve the avoidance of asthma triggers.

As defined in our previous paper [24], major visits for asthma cover outpatient visits linked to a primary diagnosis of asthma, and ED visits and hospitalizations linked to an asthma diagnosis code. Outpatient visits linked to a secondary, but not a primary, diagnosis of asthma are deemed minor visits for asthma. Having many major visits for asthma indicates a poor asthma control. An intervention tied to the item *the patient incurred ≥16 major visits for asthma in the prior 12 months* is to adopt control strategies for the patient to avoid needing emergency care.

- Rule 3: The patient had 8 or 9 primary or principal asthma diagnoses in the previous 12 months

  AND the patient had ≥6 no shows in the previous 12 months

  → The patient will undergo ≥1 asthma-related hospital visits in the subsequent 12 months.

Having many primary or principal asthma diagnoses indicates a poor asthma control. An intervention tied to the item *the patient had 8 or 9 primary or principal asthma diagnoses in the prior 12 months* is to offer the patient suggestions on how to improve asthma control.

Having many no shows correlates with poor outcomes. An intervention tied to the item *the patient had ≥6 no shows in the prior 12 months* is to give the patient social resources to handle socioeconomic challenges to keep appointments.

- Rule 4: The patient incurred ≥8 ED visits in the previous 12 months

  AND the patient was prescribed ≥28 short-acting beta-2 agonist medications in total in the previous 12 months

  AND the patient is Black or African American

  → The patient will undergo ≥1 asthma-related hospital visits in the subsequent 12 months.

In the United States, Black and African American people tend to have poorer asthma outcomes than others. Frequent ED visits indicated a poor asthma control. An intervention tied to the item *the patient incurred ≥8 ED visits in the prior 12 months* is to adopt control strategies for the patient to avoid needing emergency care.

Short-acting beta-2 agonists are rescue medications for the quick relief of asthma symptoms. The use of many short-acting beta-2 agonists indicates a poor asthma control. An intervention tied to the item *the patient was ordered ≥28 short-acting beta-2 agonist medications in total in the prior 12 months* is to tailor prescribed medications and to suggest the patient to maximize adherence to asthma control medications or to improve the avoidance of asthma triggers.

- Rule 5: The highest exacerbation severity of all asthma diagnoses recorded on the patient in the previous 12 months is status asthmaticus

  AND the patient incurred ≥11 and ≤17 visits with same-day appointments in the previous 12 months

  AND the admission type of the patient's last visit in the previous 12 months is nonelective

  → The patient will undergo ≥1 asthma-related hospital visits in the subsequent 12 months.

Status asthmaticus is the most severe form of asthma exacerbation. An intervention tied to the item *the highest exacerbation severity of all of the asthma diagnoses recorded on the patient in the prior 12 months is status asthmaticus* is to offer the patient suggestions on how to improve asthma control.

Having many visits with same-day appointments indicates a poor asthma control. An intervention tied to the item *the patient incurred ≥11 and ≤17 visits with same day appointments in the prior 12 months* is to improve support offered to the patient between visits to enhance medication adherence, address asthma triggers, and maximize the value of each visit.

A patient incurs a nonelective visit when the patient's condition requires an immediate medical attention, for example, when the patient experiences severe asthma exacerbation. An intervention tied to the item *the admission type of the patient's last visit in the prior 12 months is nonelective* is to adopt control strategies for the patient to avoid needing emergency care.

The Performance of Our Automatic Explanation Method

We evaluated our automatic explanation method on the test set. Our method explained the forecasting results for 97.9% (599/612) of the children (age <18 years) with asthma and 97.45% (1605/1647) of the adults (age ≥18 years) with asthma our KPSC model correctly forecasted to undergo asthma-related hospital visits in the succeeding year. Put together, our method explained the forecasting results for 97.57% (2204/2259) of the patients with asthma who were correctly forecasted to undergo asthma-related hospital visits in the succeeding year. For every such patient, on average, our method provided 1516.25 (SD 2161.30) explanations, each from one rule, and found 24.04 (SD 8.68) actionable items.

For the patients with asthma whom our KPSC model correctly forecasted to undergo asthma-related hospital visits in the succeeding year, Figures 2 and 3 display the patient distribution according to the number of actionable rules suiting a patient.

Having a long tail, this distribution is significantly skewed toward the left. As the number of rules suiting a patient increases, the number of patients each covered by this number of rules tends to decline nonmonotonically. The biggest number of rules suiting a patient is fairly large (15,252). However, only one patient matched this number of rules.

For the patients with asthma whom our KPSC model correctly forecasted to undergo asthma-related hospital visits in the succeeding year, Figure 4 displays the patient distribution according to the number of different actionable items included in all the rules suiting a patient. The largest number of different actionable items included in all the rules suiting a patient is 42, much less than the largest number of actionable rules suiting a patient. As noted in our previous automatic explanation paper [26], 2 or more actionable items included in the rules that suit a patient often connect to the same intervention.

Our automatic explanation method provided explanations for 67.61% (2943/4353) of patients with asthma who would undergo asthma-related hospital visits in the succeeding year.

Figure 2. The patient distribution by the number of actionable rules suiting a patient for the patients with asthma whom our Kaiser Permanente Southern California model correctly forecasted to undergo asthma-related hospital visits in the succeeding year.

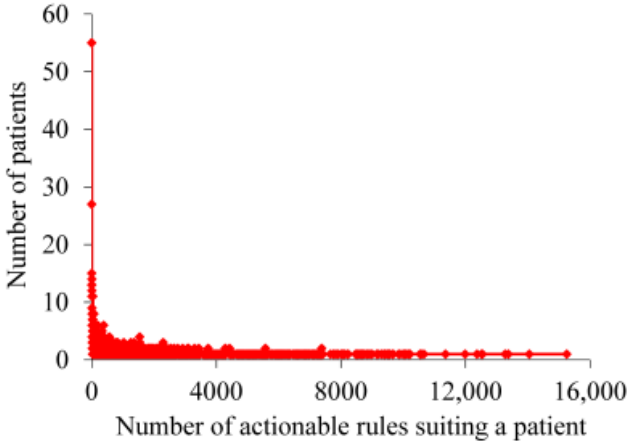


Figure 3. The patient distribution by the number of actionable rules suiting a patient when this number is ≤250 for the patients with asthma whom our Kaiser Permanente Southern California model correctly forecasted to undergo asthma-related hospital visits in the succeeding year.

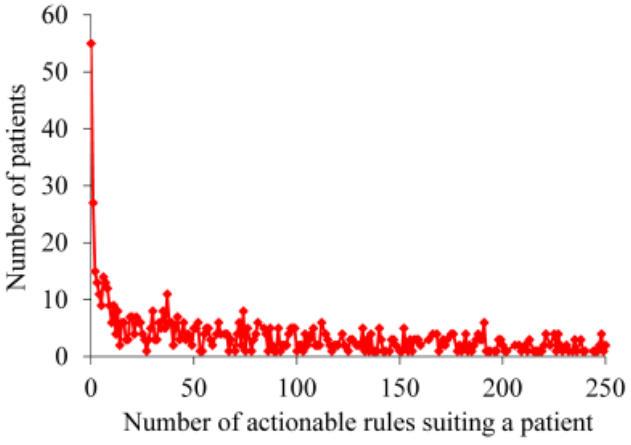

Figure 4. The patient distribution by the number of different actionable items included in all the rules suiting a patient for the patients with asthma whom our Kaiser Permanente Southern California model correctly forecasted to undergo asthma-related hospital visits in the succeeding year.

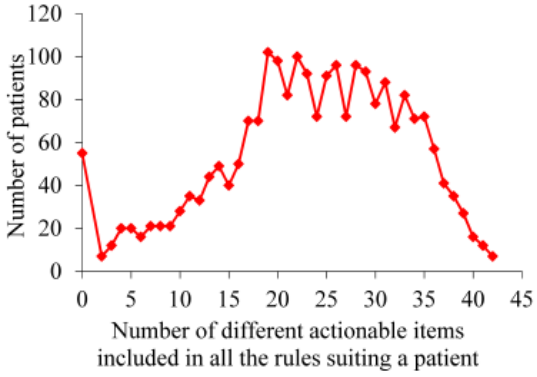

Discussion

Principal Findings

The results presented in this paper are similar to those presented in our previous automatic explanation paper [26]. For forecasting asthma-related hospital visits, our automatic explanation method exhibited an acceptable generalizability to KPSC. In particular, our method explained the forecasting results for 97.57% (2204/2259) of the patients with asthma who were correctly forecasted to undergo asthma-related hospital visits in the succeeding year. This fraction is comparable with that (89.68%) on Intermountain Healthcare data in our previous automatic explanation paper [26] and is large enough to put our automatic explanation method into daily clinical use. After further development to boost its accuracy, our KPSC model combined with our automatic explanation method could be used to guide asthma care management's use to help enhance patient outcomes and reduce health care costs.

Our automatic explanation method provided explanations for 67.61% (2943/4353) of patients with asthma who would undergo asthma-related hospital visits in the succeeding year. This fraction is less than the 97.57% (2204/2259) success rate, at which our method explained the forecasting results for the patients with asthma our KPSC model correctly forecasted to undergo asthma-related hospital visits in the succeeding year. This is possibly due to the correlation between the association rules' and our KPSC model's forecasting results. Among the patients with asthma whom our KPSC model correctly forecasted to undergo asthma-related hospital visits in the succeeding year, many are easy cases for us to explain their outcomes using association rules. Among the patients with asthma who would undergo asthma-related hospital visits in the succeeding year and whose outcomes were incorrectly forecasted by our KPSC model, many are difficult cases for any model to correctly explain or forecast their outcomes.

Displaying the Automatic Explanations

Many rules could suit a patient. In this case, it is undesirable to list all of them simultaneously and overwhelm the user of the automatic explanation function. Instead, we should rank these rules and display the top few (eg, 3) of them by default. If desired, the user can ask an automatic explanation function to show more rules. In ranking the rules suiting a patient and the items on the left-hand side of a rule, we consider the following factors and strike a balance among them:

1. All else being equal, rules with fewer items on their left-hand sides are easier to understand and should be ranked higher.
2. All else being equal, rules with higher confidence are more precise and should be ranked higher.
3. All else being equal, rules with a higher commonality cover more patients with poor outcomes and should be ranked higher.
4. The automatic explanation function's user tends to read the rules one by one in the display order. All else being equal, the more items on the left-hand side of a rule appear in higher-ranked rules, the less new information that the user has not seen so far is contained in the rule and the lower the rule should be ranked.
5. Consider the items on the left-hand side of a rule. The automatic explanation function's user tends to read the items one by one in the display order. All else being equal, the items that have appeared in higher-ranked rules contain repeated information and should be put after the other items that have not appeared in any of the higher-ranked rules.
6. The automatic explanation function's user cares about finding suitable interventions for the patient. Consider the items on the left-hand side of a rule. All else being equal, the actionable items should be placed before the nonactionable items.
7. Actionable rules should be ranked higher than nonactionable rules.

We are in the process of preparing a paper describing our rule-ranking method in detail.

Related Work

As described in the book [34] and the survey paper [35], many other researchers have proposed miscellaneous methods for automatically offering explanations for the forecasting results of machine learning models. Such explanations are typically not in a rule format. Many such methods sacrifice a part of the forecasting accuracy and/or are designed for a particular machine learning algorithm. In addition, none of these methods can automatically suggest customized interventions. In comparison, our automatic explanation method supplies rule format explanations for any machine learning model's forecasting results on tabular data and suggests customized interventions with no accuracy loss. Rule format explanations are easier to comprehend and can suggest customized interventions more directly than other forms of explanations.

To the best of our knowledge, we were the first to use association rules to automatically offer rule format explanations for any machine learning model's forecasting results on tabular data and to suggest customized interventions with no accuracy loss [30]. Our original method [30] was designed for relatively balanced data and was initially tested in the case of forecasting type 2 diabetes diagnoses. Subsequently, Alaa et al [36,37] applied the original method to multiple medical prediction tasks. So far, no researcher outside of our group has applied our extended automatic explanation method [26], which can handle imbalanced data, to any prediction task. Rudin et al [38] and Ribeiro et al [39] used rules to automatically offer explanations for the forecasting results of any machine learning model. These rules are not association rules and are unknown before the prediction time; hence, they cannot be used to automatically suggest customized interventions at the prediction time. In comparison, the association rules used in our automatic explanation method are mined before the prediction time and used to automatically suggest customized interventions at the prediction time.

Limitations

This study has three limitations, all of which can be fine areas for future work:

1. For forecasting asthma-related hospital visits, our study evaluated the generalizability of our automatic explanation method to a single health care system. It would be nice to assess our automatic explanation method's generalizability to other health care systems, such as academic ones, which have different properties from Intermountain Healthcare and KPSC. In comparison with nonacademic systems, academic health care systems tend to handle more complex and sicker patients [40]. To prepare for such an evaluation, we are currently retrieving a data set of patients with asthma from the enterprise data warehouse of the University of Washington Medicine [41].
2. Our study evaluated the generalizability of our automatic explanation method only for forecasting asthma-related hospital visits. It would be nice to assess the generalizability of our automatic explanation method for other diseases and outcomes [41].
3. Our current automatic explanation method is designed for structured data and traditional machine learning algorithms that are not deep learning algorithms. It would be nice to extend our method so it can also handle deep learning models built directly on longitudinal data [41,42].

Conclusions

In its first generalizability assessment, our automatic explanation method for imbalanced tabular data exhibited a decent generalizability to KPSC for forecasting asthma-related hospital visits. After further development to boost its accuracy, our KPSC model combined with our automatic explanation method could be used to guide asthma care management's use to help enhance patient outcomes and reduce health care costs.

Acknowledgments

The authors thank Lee J Barton, Don McCarthy, Emily Rozema, Amanda I Messinger, and Michael D Johnson for useful discussions and helping retrieve the KPSC data set. GL, CLN, MS, RSZ, and CK were partially supported by the National Heart, Lung, and Blood Institute of the National Institutes of Health under award number R01HL142503. The funders had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Authors' Contributions

GL was mainly responsible for this study. He conceptualized and designed the study, performed a literature review and data analysis, and wrote the paper. CK, CLN, WWC, MS, and RSZ provided feedback on various medical issues, contributed to conceptualizing the presentation, and revised the paper. CK and CLN took part in retrieving the KPSC data set and interpreting its detected peculiarities.

Conflicts of Interest

None declared.

Abstract

Background: Obtaining accurate clinical information about recent acute care visits is extremely important for outpatient providers. However, documents used to communicate this information are often difficult to use. This puts patients at risk of adverse events. Elderly patients who are seen by more providers and have more care transitions are especially vulnerable.

Objective: This study aimed to (1) identify the information about elderly patients' recent acute care visits needed to coordinate their care, (2) use this information to assess discharge summaries, and (3) provide recommendations to help improve the quality of electronic health record (EHR)–generated discharge summaries, thereby increasing patient safety.

Methods: A literature review, clinician interviews, and a survey of outpatient providers were used to identify and categorize data needed to coordinate care for recently discharged elderly patients. Based upon those data, 2 guidelines for creating useful discharge summaries were created. The new guidelines, along with 17 previously developed medical documentation usability heuristics, were applied to assess 4 simulated elderly patient discharge summaries.

Results: The initial research effort yielded a list of 29 items that should always be included in elderly patient discharge summaries and a list of 7 "helpful, but not always necessary" items. Evaluation of 4 deidentified elderly patient discharge summaries revealed that none of the documents contained all 36 necessary items; between 14 and 18 were missing. The documents each had several other issues, and they differed significantly in organization, layout, and formatting.

Conclusions: Variations in content and structure of discharge summaries in the United States make them unnecessarily difficult to use. Standardization would benefit both patients, by lowering the risk of care transition–related adverse events, and outpatient providers, by helping reduce frustration that can contribute to burnout. In the short term, acute care providers can help improve the quality of their discharge summaries by working with EHR vendors to follow recommendations based upon this study. Meanwhile, additional human factors work should determine the most effective way to organize and present information in discharge summaries, to facilitate effective standardization.

Introduction

Rising rates of burnout among outpatient clinicians have been linked to the adoption of electronic health records (EHRs) [1,2], which are known to have poor usability [3,4]. Other work has shown that updating EHRs is a burden for many outpatient providers [5,6]. However, few researchers have explored how inpatient providers' adoption of EHRs impacted outpatient clinicians' ability to assimilate information about recently discharged patients [7,8].

Most acute care facilities in the United States currently use EHRs to generate documents intended to communicate important information about patients and their recent acute care visits to outpatient providers, including skilled nursing facilities (SNFs), and long-term care facilities. These may be called transition of care documents, clinical handover documents, end-of-visit summaries, or, most commonly, discharge summaries (DSs). Since each acute care organization's EHR system is "customized" during implementation, outpatient providers who treat patients that utilize different acute care facilities must extract information from DSs that can vary greatly in content, format, and organization. Moreover, EHR customization is performed by information technology professionals who work for EHR vendors or inpatient providers. These professionals do not possess a complete understanding of the data needs, priorities, and information presentation preferences of outpatient providers. Not surprisingly, acute care and outpatient providers have different impressions about how useful EHR-generated DSs are [9].

DSs that either make it difficult for outpatient providers to find, or do not include, all of the information needed to coordinate care put patients at risk of adverse events [10]. Elderly patients (65 years old or older) are especially vulnerable: They tend to have more comorbidities and thus are often followed by multiple outpatient specialists, and they are more likely to have multiple postacute care transitions than younger, less complex patients. One study found discrepancies between medication lists from a referring hospital and a home health care agency for *all* 770 elderly patient participants [11], putting them at risk of medication errors. Other care transition–related adverse events include treatment delays and unnecessary tests [12-14]. However, a literature search yielded only 1 study, conducted in Canada nearly a decade ago, that suggests creating specialized DSs for elderly patients [15].

A standard method of presenting information in US discharge summaries could boost patient safety by (1) facilitating information transfer, by making it easier for outpatient clinicians to find the data needed to coordinate care for their patients and (2) reducing risk of burnout-related adverse events, by decreasing frustration associated with trying to extract information from poorly organized documents [16]. A first step towards standardizing all US DSs is identifying the data that US outpatient providers need to coordinate care for recently discharged patients who are transitioning to SNFs. We focused on this scenario because we judged that medically complex elderly patients would be more likely to transition from acute care to a SNF setting than to other outpatient care settings. Moreover, the data needed to coordinate care for adults transitioning to SNFs should be a superset of the data needed to coordinate care for other elderly patients and younger adults.

This study addresses 2 gaps in knowledge: (1) Through qualitative methods, it *identifies the information that clinicians in US SNFs need to coordinate care for elderly patients* who were recently discharged from acute care and (2) through a well-established human factors technique, called heuristic evaluation, it *provides insight into how well US acute care providers' DSs currently support outpatient providers* who coordinate care for elderly patients.

Methods

The study included 2 phases. First, the data requirements of outpatient providers who coordinate care for elderly patients were identified through an exploratory, descriptive effort, and the knowledge gleaned from that effort was applied to specify 2 new guidelines for creating useful DSs. Second, the new guidelines were combined with 17 previously developed medical documentation usability heuristics [7] (see Multimedia Appendix 1) and applied to assess how well 4 examples of elderly patient discharge summaries support care coordination. The second part not only shed light on how difficult it can be for outpatient providers to use the discharge summaries currently being produced by inpatient providers' EHRs but also yielded several recommendations for improving the quality of EHR-generated discharge summaries. All research processes and procedures for both parts of this study were approved by Rowan University's Institutional Review Board, and exemptions were granted by the institutional review boards of the 2 hospitals that provided deidentified examples of discharge summaries.

Development of DS Content Guidelines

A literature review served as the first step towards identifying the data that are necessary or helpful when coordinating care for a recently discharged elderly patient. Aggregating the items identified at the Transitions of Care Consensus Conference [17], which includes 6 items that the Joint Commission mandates be included in all DSs [18], with the items in the standardized DSs used in Australia [19] and the items recommended in a Canadian study that focused specifically upon creating DSs for elderly patients [15], yielded a list of 26 items. See Multimedia Appendix 2 for items recommended by different sources. Next, 15 outpatient care providers who frequently care for elderly patients were interviewed. These care providers included primary care physicians, nurse practitioners, directors of nursing, social workers, transition-of-care nurses, and medical directors. They were asked to categorize each of those 26 items as "always necessary," "helpful, but not required," or "not relevant/distracting" and then invited to name any additional

data that they recommend be included in elderly patient DSs. After the 15 interviews, the list had grown to 36 items. See Multimedia Appendix 3 to view the structured interview questions. Those items were included in an online survey sent to 2500 members of a Continuing Care Risk Management community that asked participants to categorize the 36 items using the same 3 categories. See Multimedia Appendix 4 to view the survey questions. A majority of the 58 respondents indicated that all 36 items were helpful and that 29 of the 36 should always be included in elderly patient DSs. Thus, 2 content guidelines were established: One states that each of 29 items should be included in DSs, and the second recommends that the remaining 7 items be considered for inclusion (see Results section).

Creation of Simulated DSs

Two hospitals, which use systems from different EHR vendors, each provided 10 deidentified elderly patient DSs that were produced by their EHR system. Two of the DSs from each hospital were randomly selected. Simulations of those 4 DSs, which appeared the same as the original documents (eg, same font size and style, layout, headings), were created to keep heuristic evaluation participants blind to the hospitals. The safe harbor method was applied in accordance with the Health Insurance Portability and Accountability Act of 1996 Privacy Rule. This entailed replacing not only all protected health information about the patient (which had already been deidentified) but also all doctors' names and all health care organization names with fictitious data. The 4 simulated DSs, which are referred to as H1P1 (Hospital 1, Patient 1), H1P2 (Hospital 1, Patient 2), H2P1 (Hospital 2, Patient 1), and H2P2 (Hospital 2, Patient 2), were then reviewed for validity, including faithful replication of formatting, layout, and organization. Figures 1 and 2 show portions of 2 of the simulated DSs. See Multimedia Appendices 5-8 to view the full simulated DSs.

Discharge Diagnosis
1. Alcohol withdrawal, resolved
2. Rapid atrial fibrillation, resolved
3. Emphysema/COPD- in acute exacerbation
4. Hepatitis C, chronic

Admission Information
This is a XX-year-old male who had a past medical history significant for prior CVA, hepatitis C, hyperlipidemia, COPD, paroxysmal atrial fibrillation on apixaban in addition to alcohol abuse amongst other issues who presented to HOSPITAL1 ER after being found on the floor by his friend "not acting like himself." The patient was reportedly covered in his stool on his legs but there is no noted stool around his buttocks according to the ER provider. He came in with global weakness and had to be assisted from a private vehicle in front of the emergency room into the waiting room. He was reportedly last seen "completely normal" a few days ago. When asked how much the patient drinks on normal basis he states he only drinks 1 beer a day. He came into the hospital with an alcohol level of almost 500. He states that he "lives in the woods with his son." He otherwise is unable to provide much in the way of history surrounding the events today. He is very adamant that he only drinks "one beer per day." When further questioned on this he states that he may actually drink 2 sixpacks of beer a day. It is unclear if this is accurate information. The patient denies any difficulty breathing. He denies any chest pain. He states he takes his apixaban as prescribed for his history of atrial fibrillation. He notes that he smokes about 1 pack of cigarettes a day.

Of note the patient had a recent hospital stay from xx 26 to xx 4. During that hospitalization he was brought in by EMS unresponsive and only making grunting noises. He ended up being intubated and had some episodes of hypotension and bradycardia. He had a urine fentanyl screen which was positive. He went into alcohol withdrawal and was eventually placed on a Precedex drip. He was eventually discharged home. [1] The emergency department he was found to have an ethanol level of 475, CT of the head showed no acute intracranial pathology. He is acutely intoxicated with alcohol and previously had required Precedex drip for withdrawal. He was alert and oriented despite having such a high alcohol level. He was found to be in rapid atrial fibrillation with RVR and required IV diltiazem. He was also found to have an acute COPD exacerbation, he was admitted to the hospitalist service for further evaluation.

Hospital Course
Alcohol Withdrawal: Patient started to score on CIWA scale and started to withdrawal from alcohol while inpatient. He continued to score for alcohol withdrawal and required as needed Ativan. He was seen by substance use services, he was given information regarding outpatient services.
Acute COPD exacerbation: He required IV steroids for COPD exacerbation, his steroids were switched to oral and his breathing improved. He was discharged with a prednisone taper
Atrial Fibrillation with RVR: His rapid atrial fibrillation was likely secondary to his acute alcohol use and COPD exacerbation. He was restarted on his home medications of metoprolol and diltiazem with improvement in his rate control.

He was having significant gait instability and needed to be evaluated by PT/OT. Unfortunately his gait instability continued to persist and PT and OT therapies recommended SNF. He was cleared by speech therapy. Patient was adamant that he would not be discharged to SNF and decided to go home with VNA nursing, PT and OT services.

Heuristic Evaluation

Heuristic evaluation is a usability assessment technique in which 3-5 trained experts independently apply a set of design best practices, called heuristics, to identify potential usability problems [20]. The participants also rate the severity of the issues, and then all issues and ratings are analyzed collectively [21]. Participants are not expected to discover the same issues, but together they generally identify the most important usability problems [22]. Proponents of heuristic evaluation recommend developing a set of relevant heuristics for the particular type of item being assessed, which can serve as guidance for developing useable products as well as tools for assessing usability [20].

In this study, 5 human factors experts independently assessed each of the 4 simulated discharge summaries. Next, 5 clinical experts experienced in providing outpatient care each independently rated the severity of all of the potential issues identified by the human factors team. Clinical experts were also given the opportunity to report any additional issues they found in the simulated discharge summaries. This iterative approach to heuristic evaluation, which reduces the time required by clinical experts, has been used successfully to evaluate medical technology [7,23]. This approach is also consistent with Nielsen's recommendation that experts first be asked to use heuristics to identify issues and later be asked to rate the severity of all issues [24].

The human factors team was given a set of 19 assessment tools: 17 previously developed medical document usability heuristics [7] (see Multimedia Appendix 1) and the 2 new discharge summary content guidelines (see Results section) and instructions on how to apply the heuristics to assess discharge summaries. The 5 human factors team members independently identified potential usability issues by looking for violations of the heuristics or the guidelines. Once each team member had evaluated each document, the issues were aggregated into 4 lists (one per simulated discharge document). Then, the items in the lists were paraphrased, and duplicates were removed.

Each of the 4 issue lists was ordered and grouped based upon the way information was presented in the simulated discharge summaries and then described in a set of slides (see Figure 3). Next, 5 clinical experts independently reviewed the simulated discharge documents, provided severity ratings for each issue, and reported and rated any additional usability issues they identified. The clinical experts were provided with a 4-step severity scale. We adapted Sauro's 3-point scale [25] by adding a level 0 for "not an issue" and then replacing the term "critical" with the word "severe" for level 3. The latter change was intended to prevent participants from avoiding use of that rating; in prior work, some clinicians were reluctant to use "critical," reserving that for issues that indisputably cause harm [7]. Table 1 describes the levels and provides an example of an issue at each level.

Figure 3. Screenshot of a slide used to summarize potential issues found by the human factors team.

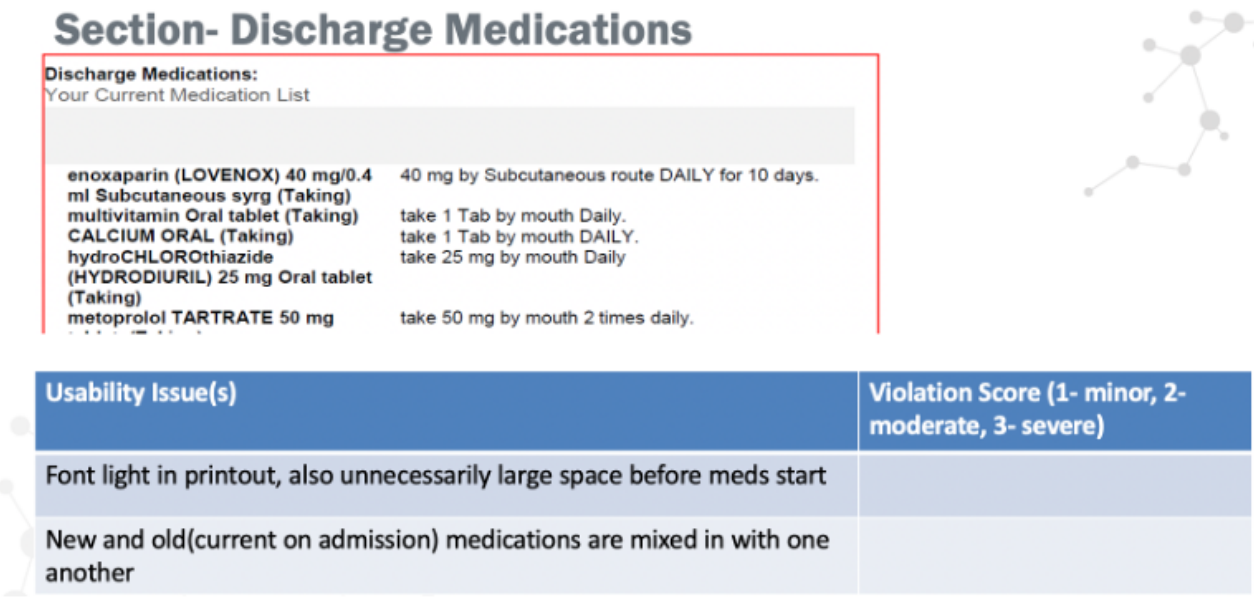

Table 1. Descriptions of the 4 levels used to rate the severity of issues found in simulated discharge summaries and examples of issues at each level.

Rating	Description	Example issue
0	Not a problem	Note stating that contents were produced using Dragon Dictate not needed
1	Minor: hesitation or slight irritation	Redundant information found in hospital course
2	Moderate: causes delays and moderate irritation	Nutritional status on discharge and Do not resuscitate orders “hidden” in relatively lengthy hospital course section
3	Severe: causes frustration or potential for error; must be fixed	No indication of whether medication is temporary or permanent

In some cases, the evaluators suggested specific solutions to issues (eg, restrict use of all CAPS, never abbreviate medication names, include page numbers in the format “page X of Y”). All solutions were summarized and grouped so that common themes could be extracted. These themes were transformed into recommendations (see Discussion section).

Results

The knowledge assembled during the literature review, interviews, and survey was applied to develop 2 guidelines for creating useful, easy-to-use discharge summaries. These guidelines are shown in Tables 2 and 3.

Table 2. First new guideline, with the list of items that should be included in elderly patient discharge summaries and how many of the 4 simulated discharge summaries were missing each item.

Guideline 1. Include each of the following in elderly patient discharge summaries	Number of documents missing this item (n=4)
Patient identifiers (eg, LAST name, first name, middle name, date of birth, age, gender, medical record number)	2
Date of admission/discharge	0
Hospital admission diagnosis	0
Principal/primary diagnosis (responsible for the largest portion of the patient's stay)	3
List of discharge diagnosis	0
Discharge medications (when patient is discharged from acute care)	0
History of present illness for hospitalization	2
Hospital course (events occurring during patient's hospital stay)	0
Procedures performed in hospital	0
Laboratory tests and investigation results (including pending results & tests due)	3
Patient physical and cognitive functional ability at discharge	3
Discharge status/Patient's discharge condition (how the patient is doing, relevant physical findings, patient's health status)	4
Medication on hospital admission	4
(Reasons for) Changes in medication during patient's stay in hospital	4
Adverse reactions during stay (including allergies to medications and other allergies)	4
Discharge instructions	2
Appointments after discharge	2
Life-sustaining treatments preferences (DNR[a], lifesaving instructions, POLST[b])	3
Nutritional status at discharge from hospital	3
Immunization history	4
Patient demographics (eg, address, phone number)	4
Follow-up issues	1
Emergency contact information	4
Nutritional status at hospital admission	4
Patient's physical and cognitive functional ability at admission	3
Goals of care and treatment plan during hospital stay	4
Discharging physician contact information	4
Contact information of clinician(s) who consulted patient in hospital	4
Patient weight	3

[a]DNR: do not resuscitate.

[b]POLST: portable medical orders.

Table 3. Second new guideline, with the list of items that should be considered to be included in elderly patient discharge summaries and how many of the 4 simulated discharge summaries were missing each item.

Guideline 2. Consider including the following items in elderly patient discharge summaries	Number of simulated documents missing this item (n=4)
Family history	4
Social and lifestyle history	4
Free-text comments (a field for clinicians to share miscellaneous notes about the patient)	3
Type of medical devices or equipment (eg, bariatric beds) that are needed for the patient in the SNF[a]	4
Goals of care and treatment plan post hospital discharge	4
Activities of daily living (ADL) status	4
Wound, skin, fall assessment	1

[a]SNF: skilled nursing facility.

When these 2 guidelines were combined with 17 previously developed medical document usability items (shown in Multimedia Appendix 1) and applied to assess the 4 simulated discharge documents, the human factors team identified 98 issues. See Multimedia Appendices 9-12 for the Powerpoint slides used to present these 98 issues to clinical experts. Clinical experts identified 19 additional issues. The average severity rating across all issues and all documents was 1.69, between minor and moderate. The total number of issues and average severity ratings for each of the simulated DSs were as follows: H1P1: 40, 1.91; H1P2: 30, 1.67; H2P1: 21, 1.73; H2P2: 26, 1.36. The entire set of issues was combined and then grouped based upon how they impact the 5 categories of document usability identified in a previous study [7]: readability, comprehensibility, minimalism, content, and organization. The counts and average severity ratings of the issues associated with each of these categories were as follows: comprehensibility: 8, 2.00; content: 42, 1.99; organization: 31, 1.77; readability: 36, 1.27; minimalism: 0. Finally, Table 4 lists all issues with average severity ratings greater than or equal to 2.

Table 4. Usability issues with average severity ratings ≥2.

Issue	Average severity rating
Postoperative patient with no wound care instructions	3
Treatable condition listed in discharge diagnoses, but patient status, plan, and medication missing	3
No indication whether medications are temporary or permanent[a]	3
Formatting makes medication section difficult to read or understand[a]	3
Medications need to be prioritized[a]	3
Medication frequency missing[a]	3
Length of time on IV[b] meds is missing[a]	3
No diagnosis linked to the medications[a]	3
Medication is missing information on “PRN” (when is it needed?) [a]	3
New and “old” medications are mixed in with one another[a]	2.67
Electronic signature gives name but no phone or email	2.67
Indenting gives impression that patient discharge condition and time spent on discharge are subordinate to physical exam	2.5
Nutritional status and Do Not Resuscitate orders “hidden” in Hospital Course section	2.33
No page numbers	2.13
Follow-up appointments listed in Hospital Course section	2.08
Heading with no content	2
Formatting made significant findings section hard to read	2

[a]Related to the section(s) listing medications.

[b]IV: intravenous.

Each of the clinical experts indicated that the simulated discharge summaries were representative of discharge summaries that they had seen before. They further characterized the examples as "fairly good" in quality when asked to compare them to those that they typically encounter. However, they agreed that each had significant room for improvement. They also agreed that it would be beneficial if DSs from all acute care providers could be standardized.

Discussion

Principal Findings

The knowledge developed through this effort may be broadly applied by acute care organizations seeking to assess or improve the usability of their discharge documents. More specifically, acute care providers can work with EHR vendors to apply the 2 guidelines introduced here to help ensure that they produce discharge summaries that contain the information that outpatient providers need to coordinate care for elderly patients. In addition, acute care providers should consider implementing the recommendations listed in the following sections, which are based upon the results of assessing 4 simulated discharge summaries that were based on real documents. These recommendations have been divided into 2 groups: The first contains those that can be implemented in software, and the second contains those that must be fulfilled by humans — though EHR software could definitely provide prompts or help verify these recommendations have been followed. See Multimedia Appendix 13 to review how several of the issues identified by clinical experts are associated with particular recommendations.

Recommendations

Textbox 1 and Textbox 2 include the recommendations for adapting EHRs so they produce more useable discharge summaries.

Textbox 1. Recommendations for adapting electronic health records (EHRs).

1. Require users to make sure that medication information is complete.
   a. For each medication, require and display the following: medication name; medication strength, dose, dosage unit, route of administration, and frequency; indication for the medication (which diagnosis or complaint is targeted by this medication; if PRN, ensure that the "as needed" criteria are defined within the medication section of the discharge summary); start date; end or refill date; indicator of whether the medication is temporary (end at completion of course) or permanent or chronic (will need refills).
   b. If any information (dose, frequency, end or refill date) is missing, prompt users to insert missing information.
2. Present all medication information clearly and consistently.
   a. Apply formatting and layout to draw attention to needed information (eg, bold the medication name, separate information with spaces or dashes).
   b. Do not use abbreviations.
   c. List medications by generic name only, not a mix of generic and brand names.
   d. Differentiate new start versus continued medications versus medications that should be stopped.
3. Provide a section for durable medical equipment, so it can be separated from medications.
4. Require and display contact information so outpatient providers can follow-up with an inpatient provider.
   a. Prompt for an email address or phone number if only a name is given.
5. Display start and end dates for all procedures.
   a. Prompt for dates if any are missing.
6. Print page numbers, in the form "xx of yy pages" when documents are printed, and display page numbers when viewed online to facilitate conversations where one person is viewing a print out and one is viewing online.
7. Use colors or shading that provide sufficient contrast if documents are printed in black and white.
8. Show all headings, even if there is no content in a section.
   a. When no accompanying text is provided, prompt for input or obtain user's approval to populate it with "—" so readers can verify that the section has been intentionally left blank.
9. Don't allow page breaks between section headings and section content.
10. Apply consistent font style, font sizing, spacing, layout, indentation, and heading style.
    a. Font size of the text must be at least 12 points to be easily readable. In some cases (eg, older audiences), selective use of a larger font (14 points) may be advisable, since it can help readers more easily see and focus attention on the most important information. Since the font size depends on the font type selected, maintain a size of 16 pixels at minimum [26].
    b. Maintain a line height that is 130% to 150% larger than the font size [27].
    c. Ensure that the section headings and subheadings stand out. Consider increasing the font size, or bold the heading text.

Textbox 2. Recommendations that require user action (but that software can prompt or try to verify).

1. Provide an explanation of patient's condition that includes at least a grade (eg, poor, good) and add a justification for any deviation from good.
2. Do not abbreviate medication or procedure names (eg, AMOX for amoxicillin) to ensure absolute clarity of the conveyed information.
3. Avoid using "all caps," which makes the content hard to read.
4. Emphasize important information. Ensure that the date of exam(s) or lab test(s) is prominently mentioned.
5. Ensure that all procedures undergone during an acute visit are listed. Examples include the use of feeding tubes, dietary restrictions, total parenteral nutrition (TPN), or urinary catheter.
6. Ensure that the content matches the headings and subheadings within each section.

Acute care providers may also consider working with EHR vendors to redesign after visit summaries (AVSs) based upon the these recommendations, since prior research has revealed that AVSs are frequently used to develop care plans [7]. Using an AVS, which is the document that is presented to a patient upon discharge from acute care, as a surrogate for a DS is not optimal practice. However, given the current practical limitations in EHR system provider-to-provider communication, it is in patients' best interests for acute care providers to adapt their AVSs so they contain the information that outpatient physicians need to coordinate care for recently discharged patients.

Limitations

While this work represents a necessary starting point for eventually standardizing adult patient discharge summaries, it has several limitations. Since the only incentive offered to survey recipients was access to survey results, only 58 out of 2500 (2.32%) of them responded, even after sending multiple reminders. Accordingly, the lists of important "discharge summary components" identified in this study need to be verified by a larger number of outpatient providers. Furthermore, a larger sample of discharge summaries or other usability testing methods may have revealed more issues, leading to additional recommendations. Finally, given the complexity and high level of customization of hospital EHR systems, it is currently unclear how difficult it would be for hospitals to configure their systems to output documents that follow our recommendations or to support users in following them. For example, some current systems are designed to group medication list items into Stop, Start, and Continue categories, which could make it hard to separate durable medical equipment from medications. On the other hand, it would make sense for inpatient providers to request that EHR vendors use the recommendations from this study to make changes to their products that could then be pushed out as software upgrades to *all* inpatient providers.

Comparison With Prior Work

A heuristic evaluation of 4 AVSs generated by acute care providers' EHR systems revealed formatting and organizational issues that made those documents very difficult to use [7]. The DSs evaluated in this study had fewer formatting and organizational issues, and those issues were rated lower in terms of severity than the ones found in the AVSs. The DSs in this study also had much less irrelevant or unhelpful text than the AVSs in the prior study. On the other hand, there were many more issues related to missing or unclear content in the DSs, and those issues were generally considered to be fairly severe (rated 2-3). This is not surprising because the content guidelines developed for this effort had not been established when the AVSs were evaluated, so their content was only assessed superficially, using the generic heuristics found in Multimedia Appendix 1.

Australia and the United Kingdom have developed national standards for electronic DSs [18,28], and Canadian researchers have explored standardizing DSs in Nova Scotia [29]. In contrast, most US research aimed at increasing patient safety during care transitions focuses upon improving discharge planning processes (eg, training clinicians to generate more useful discharge documentation [30,31] or involving patients and caregivers in discharge planning [31,32]).

A few US organizations have developed templates, outlines, or checklists to standardize their own DSs [33-35], but each of them organizes patient information differently. Moreover, even though a 2009 Transitions of Care Consensus Conference produced a list of items that participants recommended be included in transition records [17], recent research indicates that EHR-generated discharge summaries in the United States continue to omit data that outpatient providers need to effectively coordinate care [27,36-39].

Conclusions

In summary, this project addresses 2 current gaps in knowledge among inpatient providers and EHR vendors: (1) What data do outpatient providers need to coordinate care for elderly patients recently discharged from acute care facilities to an outpatient facility? and (2) How well do the EHR-generated DSs currently being produced by acute care providers meet outpatient providers' needs? This work revealed not only that documents currently being produced do not fully meet outpatient provider needs but also that 2 DSs produced by the same acute care provider organization can vary significantly in layout, organization, structure, and content. The current heterogeneity among DSs makes it unnecessarily difficult for outpatient providers to coordinate care for recently discharged patients. This puts patients at risk of adverse events and may contribute to outpatient provider burnout. This work is especially timely given that the Office of the National Coordinator for Health Information Technology and the Centers for Medicare and Medicaid Services recently released proposed rules to facilitate "seamless and secure" electronic transfer of patient data [40]. Seamlessly and securely sharing patient information is not sufficient to ensure high-quality care coordination. Patient data must be delivered in a form that enables clinicians to quickly and easily locate and understand the information most relevant to them. In short, there is an urgent need for additional applied

human factors research focused upon improving the quality of the clinical documentation produced by EHR systems. This research should be conducted in parallel with ongoing interoperability efforts, so that once it is possible for EHRs to seamlessly transfer patient data, they will be shared in a concise, well-organized, easy-to-understand form.

Acknowledgments

This work was funded by ECRI. A guidance article based upon the recommendations derived from this work was privately published, with access limited to ECRI's hospital members, in December of 2019. The authors gratefully acknowledge the valuable contributions from the following individuals: Elizabeth Anderson, Paul Anderson, Ellen Bernier, Joseph Conti, Ann Dimapalis, Kelly DiPaolo, Yvonne Fast, Dave Jamison, Susan Jilinski, Heather Kern, Nami Kim, Joseph Libby, Amy Moeller, Ankur Patel, Emily Patterson, Lorraine Possanza, Vic Rose, Firas Saidi, Karen Schoelles, Erin Sparnon, Richard Stefanacci, Ilene Warner-Maron. The authors also wish to thank an anonymous reviewer for suggesting that we add the recommendation that durable medical equipment be separated from medications.

Authors' Contributions

PT and PS designed the study, analyzed the data, and generated the recommendations. The human factors evaluation team consisted of PT, AA, CG, JK, and PM. Deidentification of actual elderly patient discharge summaries was performed by MK and EW. PS created the simulated discharge summaries from the deidentified examples. The initial draft of the paper was produced by PT.

Abstract

Background: Acute kidney injury (AKI) is commonly encountered in clinical practice and is associated with poor patient outcomes and increased health care costs. Despite it posing significant challenges for clinicians, effective measures for AKI prediction and prevention are lacking. Previously published AKI prediction models mostly have a simple design without external validation. Furthermore, little is known about the process of linking model output and clinical decisions due to the black-box nature of neural network models.

Objective: We aimed to present an externally validated recurrent neural network (RNN)–based continuous prediction model for in-hospital AKI and show applicable model interpretations in relation to clinical decision support.

Methods: Study populations were all patients aged 18 years or older who were hospitalized for more than 48 hours between 2013 and 2017 in 2 tertiary hospitals in Korea (Seoul National University Bundang Hospital and Seoul National University Hospital). All demographic data, laboratory values, vital signs, and clinical conditions of patients were obtained from electronic health records of each hospital. We developed 2-stage hierarchical prediction models (model 1 and model 2) using RNN algorithms. The outcome variable for model 1 was the occurrence of AKI within 7 days from the present. Model 2 predicted the future trajectory of creatinine values up to 72 hours. The performance of each developed model was evaluated using the internal and external validation data sets. For the explainability of our models, different model-agnostic interpretation methods were used, including Shapley Additive Explanations, partial dependence plots, individual conditional expectation, and accumulated local effects plots.

Results: We included 69,081 patients in the training, 7675 in the internal validation, and 72,352 in the external validation cohorts for model development after excluding cases with missing data and those with an estimated glomerular filtration rate less than 15 mL/min/1.73 m2 or end-stage kidney disease. Model 1 predicted any AKI development with an area under the receiver operating characteristic curve (AUC) of 0.88 (internal validation) and 0.84 (external validation), and stage 2 or higher AKI development

with an AUC of 0.93 (internal validation) and 0.90 (external validation). Model 2 predicted the future creatinine values within 3 days with mean-squared errors of 0.04-0.09 for patients with higher risks of AKI and 0.03-0.08 for those with lower risks. Based on the developed models, we showed AKI probability according to feature values in total patients and each individual with partial dependence, accumulated local effects, and individual conditional expectation plots. We also estimated the effects of feature modifications such as nephrotoxic drug discontinuation on future creatinine levels.

Conclusions: We developed and externally validated a continuous AKI prediction model using RNN algorithms. Our model could provide real-time assessment of future AKI occurrences and individualized risk factors for AKI in general inpatient cohorts; thus, we suggest approaches to support clinical decisions based on prediction models for in-hospital AKI.

acute kidney injury; recurrent neural network; prediction model; external validation; internal validation; kidney; neural networks

Introduction

Acute kidney injury (AKI) is a common clinical condition that can be attributed to multiple causes in various clinical settings. AKI increases mortality, morbidity, length of hospital stay, and health care costs [1-4]. According to the National Confidential Enquiry on Patient Outcomes and Death reports, approximately 17% of AKI is estimated to be avoidable and preventable [5]. Therefore, many research efforts have been expended to detect AKI early on and to manage patients with high risk [6]. Nevertheless, the reported incidence of AKI is 17%-25% in the hospital setting [7,8] and it has continued to rise globally during the recent decades [9]. Markedly increasing amounts of electronic health record (EHR) data and recent developments in machine learning techniques offer greater possibilities for the improvement of quality of care and medical research [10]. Various clinical decision support systems that use EHR and machine learning have been increasingly reported for various diseases [11-14]. Machine learning methods can incorporate tremendously large number of features in the model compared with conventional regression models and thus enable the use of nonlinear algorithms. As a result, in AKI research, several studies have adopted machine learning methods such as random forest and neural network models and reported improved model performance [15-17]. Major risk factors associated with in-hospital AKI include the use of various nephrotoxins, repeatedly measured laboratory findings, and vital signs that are dynamic rather than static variables [18-20]. The recurrent neural network (RNN) is a powerful tool used to handle such sequential data [21]; various RNN models have shown excellent performance in the field of natural language processing and time-series forecasting models [22,23]. Although the RNN model is a promising approach, time-updated predictive models for AKI using the RNN algorithm are still in their infancy [24]. Only a few studies have investigated these, and they have not been externally validated [20,25]. Moreover, despite their enhanced performance, these neural network models cannot provide insights into how to link clinical decision supports; therefore, interpreting the output using these models can be difficult. In this respect, neural network models have been criticized as being black-box models [26]. Previous studies on clinical decision support for AKI have not implemented predictions for AKI development but have only served as alarm systems for the timely diagnosis of AKI according to diagnostic criteria [27,28]. Therefore, in this study, we propose an externally validated RNN-based prediction model for in-hospital AKI and aimed to provide a framework to link the developed model with clinical decision support.

Methods

Study Population

This study was performed in accordance with the recommendations laid out in the World Medical Association Declaration of Helsinki. The study protocol was approved by the Institutional Review Boards (IRBs) of the Seoul National University Bundang Hospital (SNUBH; IRB No. B-1912/583-406) and Seoul National University Hospital (SNUH; IRB No. H-1911-043-1076). Written consent was waived by the IRB because of the retrospective nature of the study, and all data were completely anonymized. Study populations comprised all patients aged 18 years or older who were hospitalized for more than 48 hours at the SNUBH from 2013 to 2017 (training and internal validation cohorts) and at the SNUH from 2013 to 2017 (external validation cohort). These 2 tertiary hospitals are affiliated with each other. However, they are located in different regions of Korea and have different patient populations and EHR systems. The exclusion criteria were as follows: (1) no baseline or follow-up creatinine (Cr) measurements, (2) baseline estimated glomerular filtration rate (eGFR) less than 15 mL/min/1.73 m^2 or Cr greater than 4.0 mg/dL or end-stage kidney disease at admission, (3) no other laboratory test results used in the model, (4) no BMI or vital sign measurements, and (5) an AKI diagnosis at admission (day 1).

Data Collection

All demographics, laboratory values, vital signs, and clinical conditions were obtained from the EHR of each hospital. The features that are considered as risk factors of AKI from the related literature or are correlated with AKI development were selected for model development [18]. A total of 107 variables were included in the model. These are summarized in Multimedia Appendix 1. Each variable was classified as either static or dynamic. The static variables were assigned to time-invariant values during hospitalization, and the dynamic variables were assigned to values that were updated on a daily basis. Demographics and comorbidities were static variables, while laboratory tests, vital signs, and clinical conditions were dynamic variables. The use of medications during admission

was incorporated in the model as a dynamic categorical variable, and medication history before admission was treated as a static variable. Patient comorbidities were classified into 17 categories according to the International Statistical Classification of Disease and Related Health Problems (10th revision) codes from which the Charlson Comorbidity Index was assessed [29]. BMI was calculated from the height and weight measured at admission. Laboratory values included Cr, white blood cells, hemoglobin, platelets, albumin, sodium, potassium, chloride, aspartate aminotransferase, alanine aminotransferase, blood urea nitrogen, total CO_2, bilirubin, calcium, glucose, creatine kinase, lipase, and troponin I. The means of laboratory values that were measured more than once each day were used in our model. Medications included well-known nephrotoxic agents, such as nonsteroidal anti-inflammatory drugs, aminoglycoside, vancomycin, and colistin. Vital signs included systolic, diastolic, and mean arterial blood pressures; pulse; and body temperature, which were usually measured 3 times a day in general wards. Therefore, the mean, maximum, and minimum values of the vital signs during a day were used as different variables.

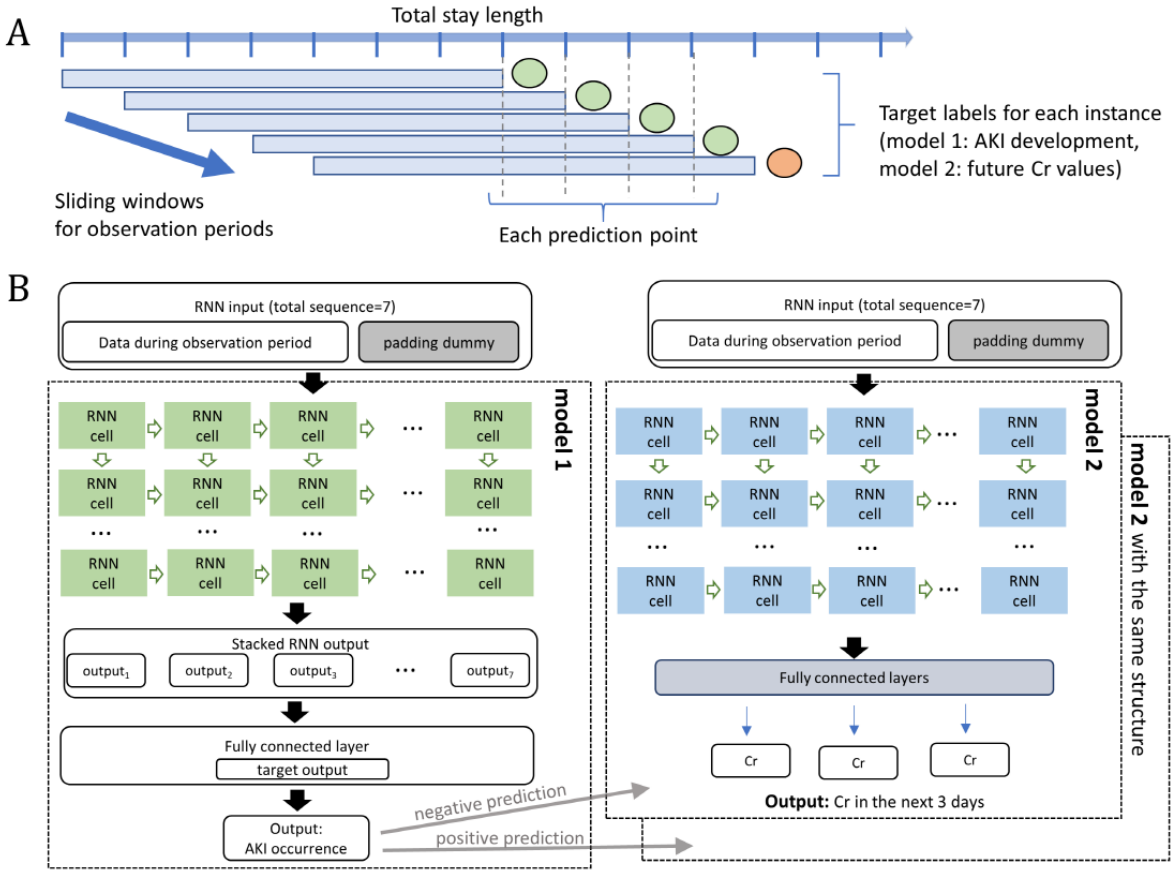
AKI and Baseline Creatinine Definitions

AKI was defined according to the Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guideline for AKI [30]. Because urine volume data were not available, AKI stage was defined based on serum Cr levels. Baseline Cr levels were determined by searching the minimum serum Cr level within a period of 2 weeks before admission. If there were no serum Cr measurements during this period, the minimum value of Cr measured within 90 or 180 days before admission was used as the baseline Cr. In the absence of Cr measurements up to 180 days before admission, the serum Cr value measured on the first day of hospitalization was defined as the baseline Cr.

Data Preprocessing and Statistical Analysis

During data collection, error values were treated as missing, and outliers of all variables were examined and removed after review by domain experts. Patients with missing variables at baseline were excluded according to the exclusion criteria. The last observation carried forward method was used for missing values after baseline. Variables were scaled using the min–max normalization before training the neural network. For continuous prediction of AKI, the training and validation data sets were organized as multiple sliding windows of features and target labels fed to the input layer of the RNN model (Figure 1A). The length of the sliding window was selected as 7 days and features up to 2 weeks after admission were utilized. Therefore, all time points were considered for both patients with AKI and non-AKI during the length of stay before AKI occurrence or discharge. The SNUBH data set was divided into a training set (69,081/76,756, 90%) and an internal validation set (7675/76,756, 10%) using the stratified random split. Categorical variables are expressed as numbers and percentages, and continuous variables as means (SD). The chi-square test and *t* test were used to compare differences in baseline characteristics between the training and validation cohorts. *P* values <.05 were considered statistically significant.

Figure 1. Architectural overview of the developed model using the recurrent neural network (RNN). (A) The sliding window approach for handling sequential data and (B) the 2-stage hierarchical model comprising models 1 and 2. Model 1 could predict the occurrence of acute kidney injury (AKI) in the next 7 days from the present, and model 2 could provide the predicted value of serum creatinine (Cr) for the next 3 days.



Model Development and Assessment

We developed 2 different models (models 1 and 2) with stacked RNN algorithms. Model 1 had a many-to-one architecture with 7 sequential inputs and 1 prediction output. The outcome variable for model 1 was the occurrence of AKI in the next 7 days. Padding and masking techniques were used for instances with sequences shorter than the length of the sliding window. The padded sequences were not used in training and inference processes. To compare the performance with model 1, we developed an additional gradient boosting model based on the same training data set. The gradient boosting model was trained using the XGBoost algorithm. In model 2, we constructed a prediction model of the trajectory of Cr values after 24, 48, and 72 hours with available Cr values during the observation window. Model 2 had a many-to-many structure with an output length of 3 on 7 input sequences. To improve the predictive accuracy of model 2, we developed a 2-stage hierarchical RNN prediction model. That is, based on the results of model 1, different types of model 2 were applied. These are the models for each patient group that are or are not predicted to have AKI. The architectures of models 1 and 2 are illustrated in Figure 1. The optimal hyperparameters of each model were determined using a fivefold cross validation. The tuned hyperparameters include number of hidden RNN neurons, number of hidden layers, dropout, activation functions, and batch size in the stacked RNN model, and learning rate, depth of a tree, and minimum child weight in the XGBoost model. Cross entropy loss function and the AdamW optimizer were used to train the RNN models. The entire data set was imbalanced due to the relatively low incidence of in-hospital AKI. Therefore, we applied a class weight parameter to the loss function to handle class imbalances. Alpha dropout, L2 regularization, and early stopping approaches were implemented to prevent overfitting. Batch normalization was applied to each RNN layer for efficient and effective learning. The learning rate was set to 10^{-4} for pretraining, then to 10^{-6} for early stop learning. In the process of model development, different sample sizes were tested to evaluate the sensitivity of the developed models. As shown in Table 1 in the *Results* section, the overall distribution of features is quite different between the training and external validation data sets. Therefore, we additionally fine-tuned our models to overcome the heterogeneity of independent data sets. Specifically, we refitted our model using a small proportion of data (7234/72,352, 10%) from the external data set. The refitted model was validated with the rest of the external data set (65,118/72,352, 90%). Model performances were assessed based on the area under the receiver operating characteristic curve (AUC), accuracy, sensitivity, specificity, positive predictive value, negative predictive value, and F1 score for model 1 and based on the mean-squared error (MSE) for model 2.

Model Explainability for Clinical Decision Support

The neural network algorithm cannot directly offer any explanations regarding the clinical meaning of features.

Therefore, to identify the association between multiple features and response (the occurrence of AKI), we examined the following approaches using model-agnostic methods in model 1: (1) global interpretation with Shapley Additive Explanations (SHAP), partial dependence plots (PDPs), and accumulated local effects plots; and (2) instance-wise interpretation with individual conditional expectation (ICE) plots. The SHAP method is based on Shapley values from game theory [31]. Shapley values indicate marginal contribution of a feature to the difference between the actual prediction and the mean prediction for all possible coalitions of features [32]. The global feature importance was presented by SHAP feature importance plots. PDP provides average marginal predictions across all instances when the feature of interest is forced to be a certain value [33]. Similarly, ICE plots indicate an average marginal effect of a feature for individual instances. PDP and ICE plots can intuitively show the relationship between specific features and the outcome variable [34]. In model 2, we applied ICE to predict the future Cr values, whereby the model output was estimated from new instances with modified feature values as well. Given that PDP is not reliable when the features are highly correlated, we also presented accumulated local effects plots. In an accumulated local effects plot, feature values are divided by set intervals and the differences in the prediction between the upper and lower bounds of the interval are calculated [33]. The estimated differences are accumulated, and the mean prediction is centered at 0.

Results

Study Population

A total of 482,467 patients (182,976 in the SNUBH and 299,491 in the SNUH) were initially screened from the EHR data obtained from each participating hospital. After considering the exclusion criteria, 69,081 patients were finally included in the SNUBH training data set, 7675 in the SNUBH internal validation data set, and 72,352 in the SNUH external validation data set (Multimedia Appendix 2). The characteristics of the study population are listed in Table 1. Patients in the training data set were older than those in the external validation data set (59.8 versus 57.1 years). The mean baseline eGFR was higher in the training data set than in the external validation data set (94.9 versus 89.4 mL/min/1.73 m^2). Although more patients had hypertension or diabetes in the training data set, the mean Charlson Comorbidity Index was higher in the external validation data set. There was no difference in baseline characteristics between the training and internal validation data sets. During the 2-week period after admission, the cumulative incidence of AKI (any stage) was 5.91% in the training data set and 3.63% in the external validation data set (Multimedia Appendix 3). The cumulative incidence of severe AKI (stages 2 or 3) was 1.58% and 1.11% in the training and external validation data sets, respectively.

Table 1. Baseline characteristics of the training and validation data sets.

Variables	SNUBH[a] training set (n=69,081)	SNUBH validation set (n=7675)	SNUH[b] validation set (n=72,352)	*P* value[c]
Age (years), mean (SD)	59.8 (16.5)	59.6 (16.6)	57.1 (16.0)	<.001

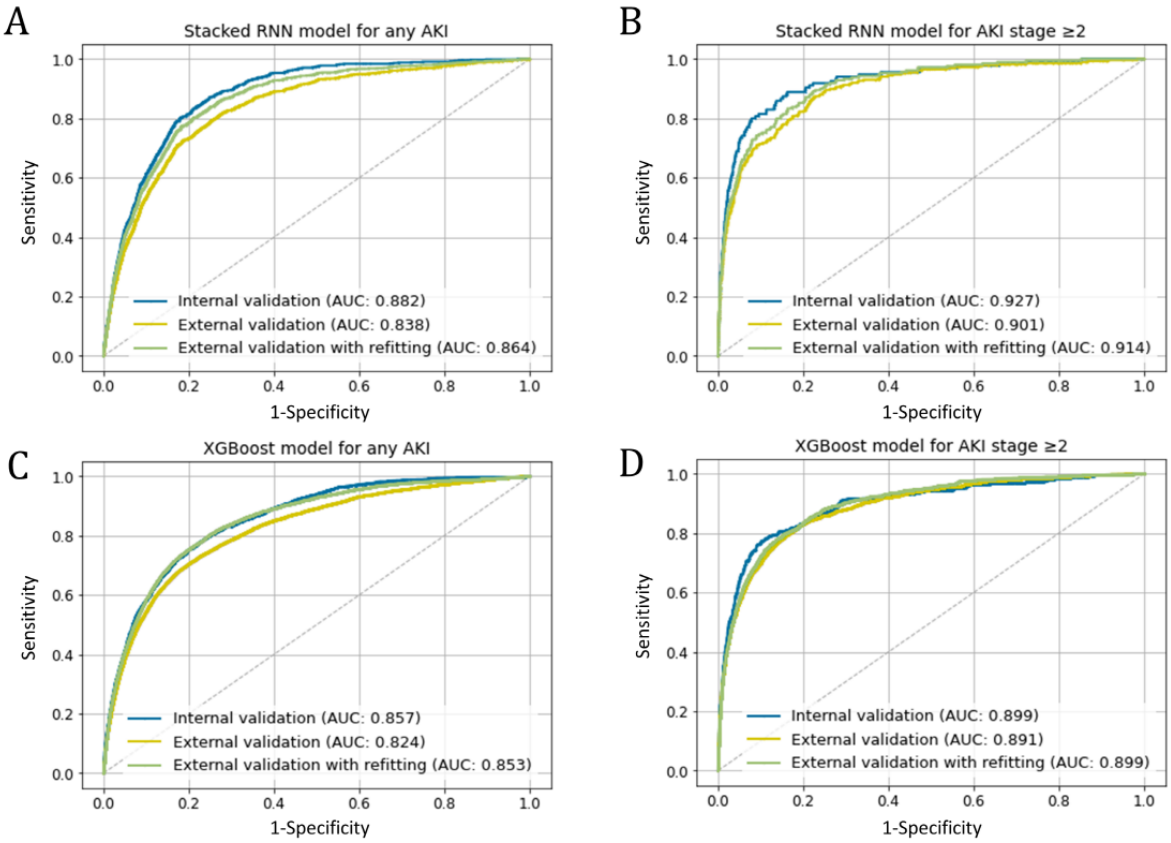
Prediction of AKI Development

First, we assessed the performance of model 1 to predict AKI development (any stage and stage 2 or higher) within the next 7 days based on different algorithms. Overall, the AUC was higher in the stacked RNN model than in the XGBoost model for any AKI and stage 2 or higher AKI. The AUC of the RNN model was 0.88/0.84 (internal/external validation) for any AKI and 0.93/0.90 (internal/external validation) for stage 2 or higher AKI, while the AUC of the XGBoost model was 0.86/0.82 (internal/external validation) for any AKI and 0.90/0.89 (internal/external validation) for stage 2 or higher AKI (Figure 2). Overall, better performance was found with the larger training sample size, which might be due to the class imbalance of the data set, suggesting that 80%-90% of the split ratio was sufficient in training (Multimedia Appendix 4). The model performance on the external validation set was slightly lower than that on the internal validation set. However, the performance of the updated model was improved, reducing the difference in the AUC between the internal and external validation sets. The RNN model to predict stage 2 or higher AKI revealed the highest performance. The evaluation metrics other than AUC are shown for different probability cutoff values in Multimedia Appendices 5 and 6. We evaluated model 2 based on model 1 for any AKI, considering the AKI incidence rate.

Figure 2. The receiver operating characteristic curve for model 1. (A) The stacked RNN model for any AKI, (B) the stacked RNN model for AKI stage 2 or higher, (C) the XGBoost model for any AKI, and (D) the XGBoost model for AKI stage 2 or higher. AKI: acute kidney injury; RNN: recurrent neural network.



Prediction of Creatinine Trajectory

We constructed and validated the prediction model (model 2) for Cr trajectory separately in the positive and negative prediction groups based on the prediction results of model 1 for any AKI. The MSE values are presented in Table 2, and ranged from 0.03 to 0.06 in the internal validation case, and from 0.06 to 0.09 in the external validation case. The refitted model in the external validation data set showed the improved MSE of 0.03-0.08. Overall, the MSE values at different prediction points (24, 48, and 72 hours) were comparable to each other.

Table 2. Predictive performance of model 2 for the future value of serum creatinine (Cr).

Subgroup and validation method	MSE at different time points		
	24 hours	48 hours	72 hours
Positive prediction			
Internal validation	0.04	0.04	0.06
External validation	0.06	0.06	0.09
External validation (refitting)	0.05	0.06	0.08
Negative prediction			
Internal validation	0.03	0.04	0.04
External validation	0.06	0.06	0.08
External validation (refitting)	0.03	0.05	0.05

Application of Interpretability Techniques on the Developed Models

Application of model 1 allows the identification of patients with high AKI risk. Moreover, the future values of Cr can be predicted using model 2. However, risk assessment and predicted laboratory values are insufficient for the management of patients with high risk. The prediction model itself could not provide measures on how to manage or prevent AKI. First, we examined feature importance obtained by mean SHA*P* values in model 1 (Multimedia Appendix 7). Baseline eGFR and serum Cr were the top 2 features in both RNN and XGBoost models.

The remaining features showed relatively less impact on prediction. To determine the feature importance in the RNN model, the SHA*P* values were also averaged over the sequence length (7 days); thus, many static variables were of high rank. However, the importance ranking of some dynamic features, such as pulse rate, diuretic use, and white blood cell count, was found to increase over time (Multimedia Appendix 8). To illustrate the relationships between the AKI risk and each feature, we have presented PDP and ICE plots in Multimedia Appendix 9, where yellow lines denote the average probability of AKI versus the selected feature values in the studied patients (PDP), and each black line represents an individual's probability (ICE plot). These plots provide global and instance-level model explanations. They primarily offer visual representations of a selected feature's effect on AKI probability. Overall, substantial changes in AKI probability with the level of features were observed, especially for aspartate aminotransferase, platelet count, white blood cell count, and vital signs (eg, blood pressure and pulse rate). The patterns of ICE plots were quite different in individual patients. However, PDP could not fully explain the feature–response relationship in each patient. We did not find a clear effect of some clinically meaningful features such as hemoglobin and albumin on AKI prediction. However, accumulated local effects plots better showed the association between these features and AKI prediction (Figure 3). Therefore, we performed an additional analysis using accumulated local effects plots to evaluate the feature effects at different time gaps from the prediction point (Figure 3 and Multimedia Appendix 10). Vital signs, white blood cell counts, and Cr levels had the greatest effect the day before the prediction point, while albumin and hemoglobin showed the greatest effect 5-6 days before the prediction point. Some dynamic features, such as the use of medication, could be considered as correctable features in actual, clinical settings. In this regard, we estimated the predicted trajectories of serum Cr values according to the use of nephrotoxic drugs. Predicted values of Cr with and without nephrotoxic drug administration are shown in Figure 4. The presented cases represent the past Cr values (green lines), predicted values (blue lines), and predicted values after the discontinuation of nephrotoxic drugs (orange lines). These approaches could help clinicians make decisions regarding the prevention and intervention for future AKI occurrence.

Figure 3. Accumulated local effects plots for the selected variables at the different time gaps from the prediction point. The same y-scale was used for all plots. AST: aspartate aminotransferase; ALT: alanine aminotransferase; BUN: blood urea nitrogen; Hb: hemoglobin; WBC: white blood cell count.

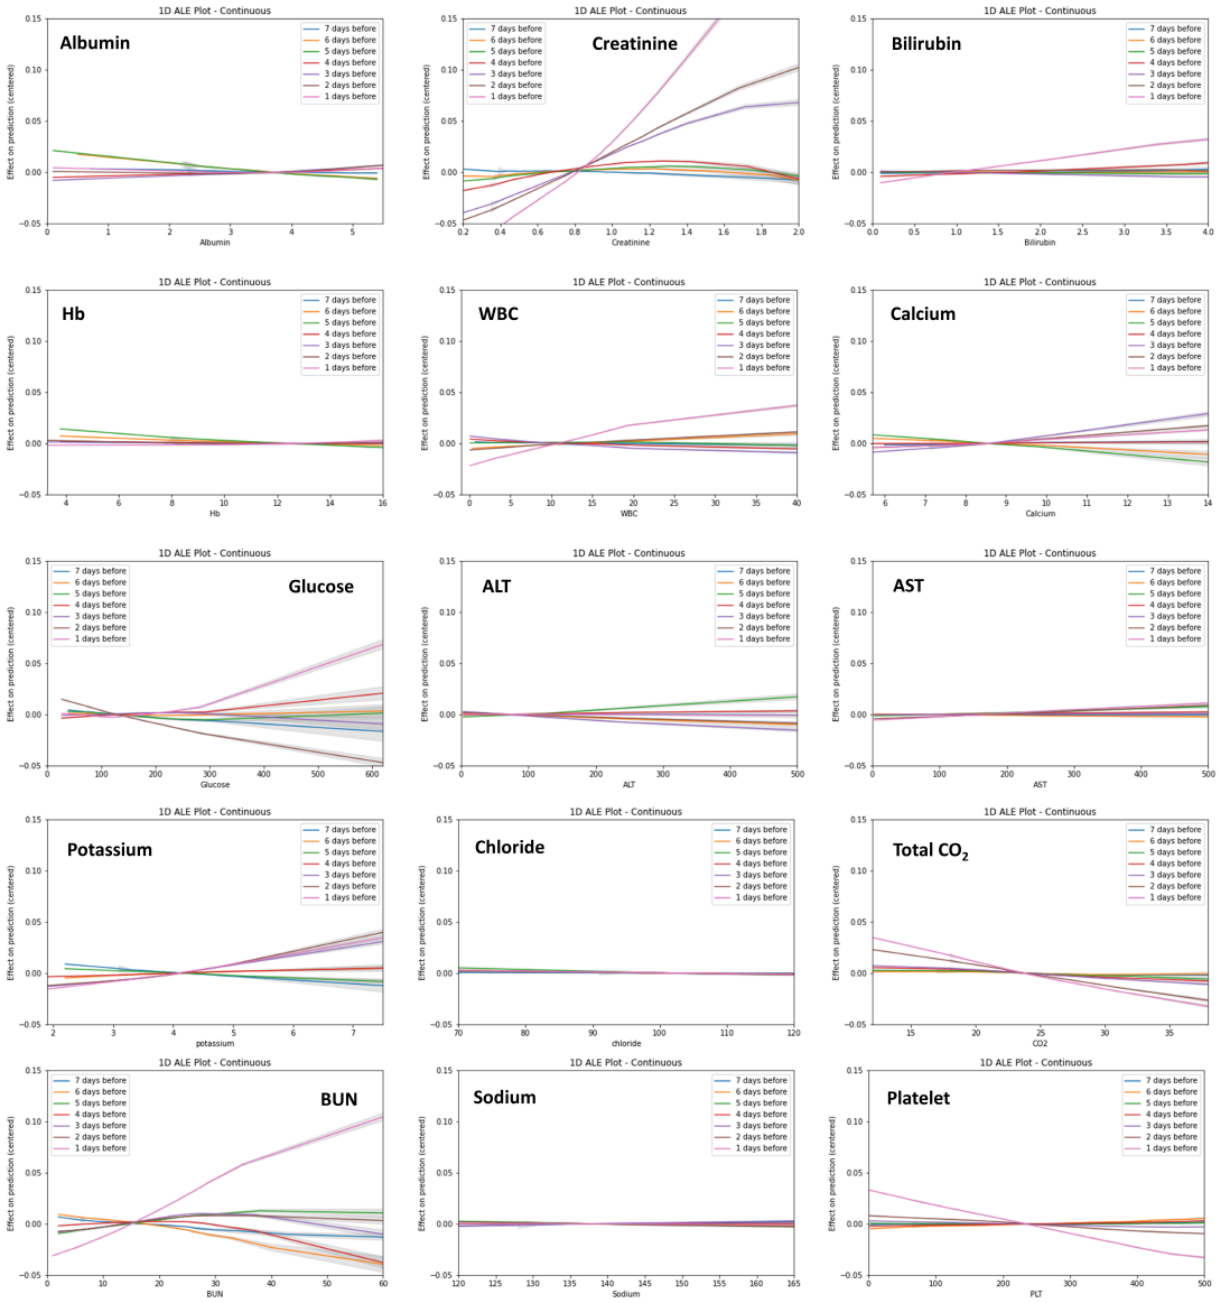


Figure 4. Individual interpretation with individual conditional expectations (green lines: the past Cr values; blue lines: predicted Cr values on certain nephrotoxic drugs; orange lines: predicted Cr value when nephrotoxic drugs are discontinued; and dotted red lines: prediction point). Modified drugs are NSAIDs in these 4 cases. AKI: acute kidney injury; Cr: creatinine; NSAIDs: nonsteroidal anti-inflammatory drugs.

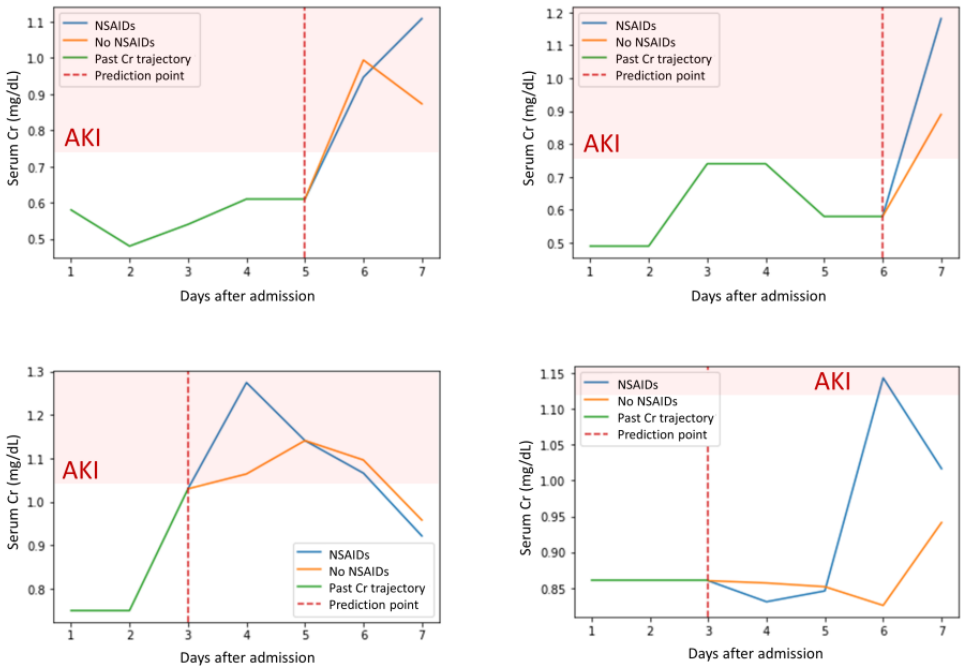

Discussion

Principal Findings

In this study, we developed a continuous prediction model for in-hospital AKI using the RNN algorithm with external validation and demonstrated its applicability for the support of clinical decision making. The developed model was constructed for all general inpatients based on the use of various dynamic and static clinical features, showing relatively good performance. External validation was performed with data from an independent center. Furthermore, we showed examples relevant to the presentation of feature information to help actual clinical decisions at the global and individual patient level using several model-agnostic interpretation methods.

To prevent and manage AKI more effectively, timely diagnosis and intervention are emphasized. Thus, AKI is an area of interest for the application of predictive clinical models. To date, numerous studies have been published on predictive models related to AKI [18]. The identification and appropriate management of patients with high risk could improve patient outcomes and reduce economic burden in health care facilities [35]. Nevertheless, previous studies of the AKI prediction model have mainly focused on specific population groups, such as patients who are critically ill or those who underwent cardiovascular surgery, thus making generalization difficult [36-38]. Moreover, most models have not been externally validated, and there are only few models that are capable of real-time assessments. In a recent report of artificial intelligence research, only 6% of conducted studies performed external validation [39]. Many predictive models used clinical or laboratory data collected at the time of admission or at specific time points, such as during the preoperative period or admission [40-42]. However, the definition of AKI is dynamic and includes the concept of time duration (Cr increase by at least 0.3 mg/dL in 48 hours or 1.5 times over 1 week) as shown in the KDIGO definition [30]. Not only the changes in Cr levels, but also the changed rates or slopes were important in clinical decisions [43]. In this regard, the RNN algorithms could have a considerable strength and could fully utilize the sequential information of feature values. The RNN models were found to be effective in learning sequential data and demonstrated superior model performance over conventional models developed using data at one time point [44-46]. These reflect the trends of clinical variables and are expected to be advantageous for real-time risk assessment.

In this study, we developed 2-stage hierarchical prediction models (model 1 and model 2) using the stacked RNN structure. Model 1 focused on the distinction of patients with high risk of AKI from those without risk. Model 1 using stacked RNN layers predicted any AKI with an AUC of 0.84-0.88 and stage 2 or higher AKI with an AUC of 0.90-0.93. In particular, the RNN model outperformed the XGBoost-based model for both any AKI and stage 2 or higher AKI. Gradient boosting algorithm has been frequently utilized for the model of AKI prediction in recent related studies. The overall performance of the gradient boosting models was reported to have an AUC of 0.67-0.77 for AKI stage 1 or higher and an AUC of 0.84-0.87 for AKI stage

2 or higher in the next 48 hours [47-49]. Model 2 intended to predict the future values of serum Cr that could help physicians understand and interpret the models in a more intuitive manner. We adapted a study design that is updated on a daily basis because most laboratory tests or medications usually do not change more than once a day in the general ward of institutions. Similarly, to minimize the burden of real-time data processing, a daily AKI alert system was implemented into the EHR, which demonstrated its effectiveness for the diagnosis of unlooked AKI [28]. In this study, the overall model performance was somewhat different between the internal and external validation cohorts. It may be attributed to different patient characteristics, such as age and comorbidities, and to the patterns of clinical practice in the 2 centers. Specifically, the incidence of AKI stage 1 was quite different between the 2 centers. In this regard, some authors suggest multiple external validations for a generalized prediction model [50]. The construction of a generalizable prediction model in superpopulations is burdensome in terms of time and cost. Therefore, we additionally fine-tuned our model to overcome the heterogeneity of independent data sets. This approach has been employed in recent related studies [32,49]. Although only a small amount of data was used for refitting, the model performance was greatly improved. The results of the refitted models were comparable to those of the internal validation data set.

However, machine learning–based models do not explain why their decisions are right, and it is uncertain how they relate the results to clinical decision making. To apply the prediction results in clinical practice, clinicians must understand how the risk assessment is derived. Unlike conventional regression models, neural network models process enormous amounts of input data through complex, multiple hidden layers and weight parameters that make it difficult for clinicians to understand and interpret the network structure. In this context, machine learning models are usually referred to as black boxes. Therefore, we presented some model-agnostic interpretation approaches, such as the SHAP feature importance, PDP with ICE plots, and accumulated local effects plots. These methods are practical and helpful in utilizing neural network–based models and could help us identify correctable risk factors at the individual patient level. ICE plots could offer insights into how selected features affect prediction results in the black-box model. As shown in ICE plots, quite different relationships between feature values and prediction outcomes were observed in each patient. This suggests interindividual heterogeneity of feature contributions. PDP does not reflect the heterogeneous effects between individuals and requires an assumption of independence [33]. In this regard, the accumulated local effects plot provides a better interpretation of the association between features and predictions. Accumulated local effects plots are unbiased and superior to the PDP when evaluating feature effects in data sets with correlated features. Nevertheless, the interpretation methods themselves do not indicate causal inferences between features and the model output. Currently, various feature engineering techniques are actively being studied and constitute promising fields of artificial intelligence. Therefore, human-friendly interpretable models that reflect possible causal inferences will be developed in the future.

Limitations

There are some limitations associated with this study. First, we used retrospective data in model training and validations. Thus, our results do not indicate the performance of the model in actual clinical practice. Second, because the model is updated daily, its application is more appropriate for patients in general wards than for those who are critically ill. Nevertheless, we developed an AKI prediction model with a relatively high performance and validated it externally. We presented the model interpretation methods for the RNN model based on sequential data and showed an example of the effective utilization of an AKI prediction model.

Conclusion

Our study demonstrated how to support clinical decisions based on RNN-based prediction models in the clinical setting. Our model can provide real-time assessment of future AKI occurrences and individualized risk factors for AKI in general inpatient cohorts.

Abstract

Background: Asthma affects a large proportion of the population and leads to many hospital encounters involving both hospitalizations and emergency department visits every year. To lower the number of such encounters, many health care systems and health plans deploy predictive models to prospectively identify patients at high risk and offer them care management services for preventive care. However, the previous models do not have sufficient accuracy for serving this purpose well. Embracing the modeling strategy of examining many candidate features, we built a new machine learning model to forecast future asthma hospital encounters of patients with asthma at Intermountain Healthcare, a nonacademic health care system. This model is more accurate than the previously published models. However, it is unclear how well our modeling strategy generalizes to academic health care systems, whose patient composition differs from that of Intermountain Healthcare.

Objective: This study aims to evaluate the generalizability of our modeling strategy to the University of Washington Medicine (UWM), an academic health care system.

Methods: All adult patients with asthma who visited UWM facilities between 2011 and 2018 served as the patient cohort. We considered 234 candidate features. Through a secondary analysis of 82,888 UWM data instances from 2011 to 2018, we built a machine learning model to forecast asthma hospital encounters of patients with asthma in the subsequent 12 months.

Results: Our UWM model yielded an area under the receiver operating characteristic curve (AUC) of 0.902. When placing the cutoff point for making binary classification at the top 10% (1464/14,644) of patients with asthma with the largest forecasted risk, our UWM model yielded an accuracy of 90.6% (13,268/14,644), a sensitivity of 70.2% (153/218), and a specificity of 90.91% (13,115/14,426).

Conclusions: Our modeling strategy showed excellent generalizability to the UWM, leading to a model with an AUC that is higher than all of the AUCs previously reported in the literature for forecasting asthma hospital encounters. After further optimization, our model could be used to facilitate the efficient and effective allocation of asthma care management resources to improve outcomes.

KEYWORDS

asthma; forecasting; machine learning; patient care management; risk factors

Introduction

Background

In the United States, 7.7% of people have asthma, which causes 188,968 hospitalizations, 1,776,851 emergency department (ED) visits, and 3441 deaths annually [1]. To reduce asthma hospital encounters covering both hospitalizations and ED visits, many health care systems and health plans deploy predictive models to prospectively find patients at high risk and offer them care management services for preventive care. The University of Washington Medicine (UWM), Intermountain Healthcare, and Kaiser Permanente Northern California [2] are 3 examples of such health care systems. Examples of such health plans include those in 9 of the 12 metropolitan communities [3]. Once a patient is deemed to be at high risk and enrolled in a care management program, a care manager will regularly assess the patient's asthma control, adjust the patient's asthma medications if necessary, and help the patient make appointments for health and related services. Using effective care management, as many as 40% of future hospital encounters by patients with asthma can be avoided [4-7].

Owing to its limited service capacity, a care management program normally enrolls at most 3% of patients with a particular condition [8]. To maximize the benefits of this resource-intensive program, it is crucial for the program to only enroll the patients who are at the highest risk. After all, the deployed predictive model's accuracy (or lack thereof) places an upper bound on the program's effectiveness. Several other research groups have built multiple models for forecasting future asthma hospital encounters of patients with asthma. Every model examined only a few features [2,9-22]. Overlooking some important features in the model degrades model accuracy, making the model miss at least half of the patients who will experience future asthma hospital encounters and incorrectly forecast future asthma hospital encounters for many other patients with asthma. These errors result in impaired patient outcomes and wasted health care spending [23]. In nonmedical fields, people frequently adopt the modeling strategy of examining many candidate features to enhance the accuracy of machine learning models [24-27]. Embracing this modeling strategy for medical data, we built a new machine learning model to forecast future asthma hospital encounters of patients with asthma at Intermountain Healthcare, a nonacademic health care system [23]. Our Intermountain Healthcare model raised the area under the receiver operating characteristic curve (AUC) to 0.859, which is higher than that of every previously published model by 0.049 or more. Although this progress is encouraging, it is unclear how well our modeling strategy generalizes to academic health care systems, which normally care for more complex and sicker patients than nonacademic health care systems [28].

Objective

This study evaluates the generalizability of our modeling strategy to the UWM, an academic health care system. Similar to the Intermountain Healthcare model [23], our UWM model uses clinical and administrative data to forecast future asthma hospital encounters of patients with asthma covering both hospitalizations and ED visits. There are 2 possible values of the categorical dependent variable: whether the patient with asthma will experience asthma hospital encounters in the subsequent 12 months. This paper reports on the development and evaluation of the UWM model.

Our Contributions

This study makes the following 3 innovative contributions:

1. We conducted the first evaluation of the generalizability of our modeling strategy to an academic health care system.
2. We evaluated the predictive power of 71 new features, which were not used in our previous study [23], for forecasting asthma hospital encounters.
3. We evaluated the generalizability of our Intermountain Healthcare model to the UWM and the generalizability of our UWM model to Intermountain Healthcare. To the best of our knowledge, this is the first study to evaluate model generalizability in both directions. Previously, model generalizability was evaluated solely in one direction by assessing the performance of a model built using one site's data on another site's data [17].

Methods

Study Design and Ethics Approval

The institutional review boards of the UWM and Intermountain Healthcare approved this secondary analysis study on clinical and administrative data.

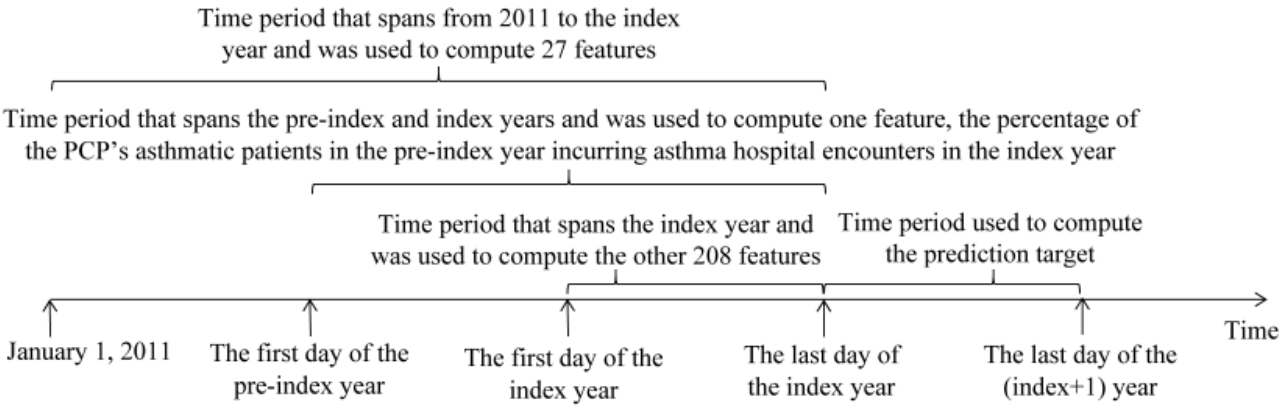
Patient Cohort

The UWM is the largest academic health care system in Washington State. Its enterprise data warehouse contains clinical and administrative data from 3 hospitals and 12 clinics for adults. Our patient cohort covered adult patients with asthma (age ≥18 years) who visited any of these UWM facilities between 2011 and 2018. We defined a patient as having asthma in a specific year if the encounter billing database contained at least one asthma diagnosis code (International Classification of Diseases, Ninth Revision [ICD-9]: 493.0x, 493.1x, 493.8x, 493.9x; International Classification of Diseases, Tenth Revision [ICD-10]: J45.x) record of the patient in that year [10,29,30]. As the sole exclusion criterion, we eliminated patients who passed away in that year.

Prediction Target (Dependent Variable)

The prediction target was from our previous study [23]. We defined an asthma hospital encounter as a hospitalization or an ED visit with asthma as its principal diagnosis (ICD-9: 493.0x, 493.1x, 493.8x, 493.9x; ICD-10: J45.x). As Figure 1 shows, for each patient deemed to have asthma in a specific year, we used any asthma hospital encounter at UWM in the subsequent 12 months, that is, the 12 months after the end of this year, as the outcome of interest. We adopted the patient's data by the end of this year to forecast the patient's outcome in the subsequent 12 months.

Figure 1. The time periods used to compute the features and prediction target for an index year and patient pair. PCP: primary care provider.



Data Set

The UWM enterprise data warehouse supplied a structured data set that contained clinical and administrative data on our patient cohort's encounters at the 3 UWM hospitals and 12 UWM clinics between 2011 and 2019.

Features (Independent Variables)

Similar to our previous study [23], we examined 234 candidate features describing a wide variety of characteristics. Table S1 of Multimedia Appendix 1 describes these features calculated on the structured attributes in our data set, with the 71 new features not used in our previous study [23] marked in italics. Throughout this paper, every mention of the number of a particular kind of items such as medications counts multiplicity whenever the word differing is absent. For instance, consider a patient who was ordered medications twice in a given year. The first time, medications 1 and 2 were ordered for the patient. The second time, medications 2 and 3 were ordered for the patient. Then, the total number of medications ordered for the patient in this year was 4. The total number of differing medications ordered for the patient in this year was 3.

Every input data instance to the predictive model addresses a unique index year and patient pair and is used to forecast the patient's outcome in the subsequent 12 months, that is, the 12 months after the end of the index year. For that pair, we computed the patient's age and primary care provider (PCP) on the last day of the index year. The PCP identified was the patient's last PCP recorded in the electronic medical record system on or before the last day of the index year. As Figure 1 shows, adopting the data in the preindex and index years, we computed 1 feature: the percentage of the PCP's patients with asthma in the preindex year incurring asthma hospital encounters in the index year. Using the data from 2011 to the index year, we computed 25 features: the number of years from the first encounter related to asthma in the data set, the number of years from the first encounter related to chronic obstructive pulmonary disease in the data set, family history of asthma, 15 features related to the problem list, and 7 allergy features. We derived the other 208 features from the data in the index year.

Data Analysis

Data Preparation

Our UWM data set included peak expiratory flow values, which were absent in the Intermountain Healthcare data set adopted in our previous study [23]. Adopting the lower and upper bounds supplied by a clinical expert in our team, we deemed all peak expiratory flow values more than 700 biologically implausible. Adopting the data preparation approach used in our previous paper [23] and this criterion, we pinpointed biologically implausible values, marked them missing, and normalized data. As the outcome of interest came from the subsequent year, our data set included 8 years of effective data (2011-2018) over the 9-year period of 2011-2019. To be consistent with future model use in practice, we used the 2011-2017 data to train the models and the 2018 data to evaluate model performance.

Performance Metrics

As presented in Table 1 and the formulas below, we evaluated model performance using 6 standard metrics: accuracy, AUC, sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV).

$$\text{Accuracy} = (TP + TN)/(TP + TN + FP + FN) \quad \textbf{(1)}$$

$$\text{Sensitivity} = TP/(TP + FN) \quad \textbf{(2)}$$

$$\text{Specificity} = TN/(TN + FP) \quad \textbf{(3)}$$

$$PPV = TP/(TP + FP) \quad \textbf{(4)}$$

$$NPV = TN/(TN + FN) \quad \textbf{(5)}$$

Here, TP stands for true positive. TN stands for true negative. FP stands for false positive. FN stands for false negative.

Table 1. The confusion matrix.

Outcome class	Future asthma hospital encounters	No future asthma hospital encounter
Forecasted future asthma hospital encounters	True positive	False positive
Forecasted no future asthma hospital encounter	False negative	True negative

We performed a 1000-fold bootstrap analysis [31] to calculate 95% CIs for the 6 performance measures. For instance, we computed our final UWM model's performance measures for each bootstrap sample of the 2018 data. The 2.5th and 97.5th percentiles of the 1000 values we obtained for every performance metric gave the 95% CI of the corresponding performance measure. We rendered the receiver operating characteristic curve to show the sensitivity-specificity tradeoff.

Classification Algorithms

As in our previous paper [23], our predictive models were built using Waikato Environment for Knowledge Analysis (Weka) Version 3.9 [32]. Weka is a core open-source software package for data mining and machine learning. It integrates a large number of popular feature selection techniques and machine learning algorithms. We checked the extreme gradient boosting (XGBoost) machine learning classification algorithm [33] implemented in the software package XGBoost4J [34] and the 39 native classification algorithms in Weka listed in our previous paper's web-based multimedia appendix [23]. As an efficient and scalable realization of gradient boosting, XGBoost is a form of an ensemble of decision trees. As XGBoost accepts only numerical features, we used one-hot encoding to transform categorical features into numerical features before giving them to XGBoost. We used the 2011-2017 training data and the automatic machine learning model selection method developed in our previous work [35] to automatically select the feature selection technique, classification algorithm, data balancing method for handling imbalanced data, and hyperparameter values among all of the pertinent ones. On average, our method can reduce the model error rate by 11% and search time by 28 times compared with the modern Auto-WEKA automatic machine learning model selection method [35,36].

This study mainly evaluated our modeling strategy's generalizability to the UWM by using the UWM training set to train multiple models and then checking their performance on the UWM test set. In addition, we conducted 2 experiments to evaluate the generalizability of our models across health systems.

Evaluating the Generalizability of Our Intermountain Healthcare Model to the UWM

In the first experiment, we evaluated the generalizability of our Intermountain Healthcare model to the UWM. Previously, we developed both a simplified model and a full model on the Intermountain Healthcare data set [23]. Our simplified Intermountain Healthcare model uses the top 21 features whose importance values calculated by XGBoost on that data set are ≥0.01 [23]. Compared with our full Intermountain Healthcare model using 142 features, our simplified Intermountain Healthcare model retained nearly all of its predictive power. Our UWM data set contained the top 21 features and missed some other features adopted in our full Intermountain Healthcare model. We evaluated the performance of our simplified Intermountain Healthcare model on the UWM test set twice. The first time, we retrained our simplified Intermountain Healthcare model on the UWM training set. The second time, we did not perform retraining and directly applied our original simplified Intermountain Healthcare model trained on the Intermountain Healthcare training set.

Evaluating the Generalizability of Our UWM Model to Intermountain Healthcare

In the second experiment, we evaluated the generalizability of our UWM model to Intermountain Healthcare. We used a simplified UWM model, which used only the top features whose importance values calculated by XGBoost on the UWM training set were ≥0.01. For any top feature that was newly introduced in this study and was not used in our previous study [23], we computed the feature on the Intermountain Healthcare data set. We evaluated our simplified UWM model's performance on the Intermountain Healthcare test set twice. The first time, we retrained our simplified UWM model using the Intermountain Healthcare training set. The second time, we did not perform retraining and directly applied our simplified UWM model trained on the UWM training set.

Results

Demographic and Clinical Characteristics of Our Patient Cohort

Each data instance addresses a unique index year and patient pair. Tables 2 and 3 show the demographic and clinical characteristics of our UWM patient cohort during 2011-2017 and 2018, respectively. The characteristics were similar across the 2 periods. During 2011-2017 and 2018, 1.74% (1184/68,244) and 1.49% (218/14,644) of data instances were linked to asthma hospital encounters in the subsequent 12 months, respectively.

Table 2. Demographic and clinical characteristics of patients with asthma at the University of Washington Medicine during 2011-2017.

Characteristic	Data instances (N=68,244), n (%)	Data instances connecting to asthma hospital encounters in the subsequent 12 months (n=1184), n (%)	Data instances connecting to no asthma hospital encounter in the subsequent 12 months (n=67,060), n (%)
Age (years)			
<40	23,459 (34.38)	466 (39.36)	22,993 (34.29)

As the Chi-square 2-sample test showed, for both the 2011-2017 and 2018 data, the data instances connecting to future asthma hospital encounters and those connecting to no future asthma hospital encounter exhibited the same distribution for anxiety or depression occurrence (P=.74 for the 2018 data and P=.09 for the 2011-2017 data), bronchopulmonary dysplasia occurrence (P=.99), cystic fibrosis occurrence (P=.99), eczema occurrence (P=.99 for the 2018 data and P=.90 for the 2011-2017 data), gastroesophageal reflux occurrence (P=.29 for the 2018 data and P=.06 for the 2011-2017 data), and sleep apnea occurrence (P=.79 for the 2018 data and P=.32 for the 2011-2017 data). These 2 sets of data instances exhibited differing distributions for gender (P=.002 for the 2018 data and P<.001 for the 2011-2017 data), ethnicity (P<.001), insurance category (P<.001), race (P<.001), systemic corticosteroid prescription (P<.001), inhaled corticosteroid prescription (P=.02 for the 2018 data and P<.001 for the 2011-2017 data), inhaled corticosteroid and long-acting β-2 agonist combination prescription (P=.02 for the 2018 data and P<.001 for the 2011-2017 data), short-acting inhaled β-2 agonist prescription (P=.006 for the 2018 data and P<.001 for the 2011-2017 data), long-acting β-2 agonist prescription (P<.001), leukotriene modifier prescription (P=.01 for the 2018 data and P<.001 for the 2011-2017 data), and chronic obstructive pulmonary disease occurrence (P<.001). For the 2011-2017 data, these 2 sets of data instances exhibited differing distributions for mast cell stabilizer prescription (P=.003), obesity occurrence (P<.001), sinusitis occurrence (P<.001), allergic rhinitis occurrence (P=.04), and smoking status (P=.003). For the 2018 data, these 2 sets of data instances exhibited the same distribution for mast cell stabilizer prescription (P=.52), obesity occurrence (P=.89), sinusitis occurrence (P=.25), allergic rhinitis occurrence (P=.36), and smoking status (P=.19).

As the Cochran-Armitage trend test [37] showed, the data instances connecting to future asthma hospital encounters and those connecting to no future asthma hospital encounter exhibited the same distribution for age (P=.06) in the 2018 data and differing distributions for age (P<.001) in the 2011-2017 data. With regard to the 2018 and 2011-2017 data, these 2 sets of data instances exhibited differing distributions for the number of years from the first encounter related to asthma in the data set (P<.001).

Table 4 shows the number of patients with asthma and their number of visits in each year between 2011 and 2018.

Table 4. The number of patients with asthma and their number of visits in each year between 2011 and 2018.

Year	Number of patients with asthma	Number of visits by patients with asthma
2011	6852	32,910
2012	7768	40,730
2013	7754	39,385
2014	9785	58,953
2015	10,587	69,285
2016	12,072	78,605
2017	13,426	87,403
2018	14,644	94,875

Classification Algorithm and Features Adopted by Our Final UWM Model

Our automatic machine learning model selection method [35] selected the XGBoost classification algorithm [33]. XGBoost is a form of an ensemble of decision trees that can naturally deal with missing feature values. As described in Hastie et al [38] in detail, XGBoost automatically calculates the importance value of each feature based on its apportioned contribution to the model. Our final UWM model was formed using XGBoost

and 71 features displayed in descending order of their importance values in Table S2 of Multimedia Appendix 1. XGBoost automatically removed the other features because they had no additional predictive power.

Performance Measures Yielded by Our Final UWM Model

On the UWM test set, our final model yielded an AUC of 0.902 (95% CI 0.879-0.924). Figure 2 shows the receiver operating characteristic curve of the model. Table 5 lists the model's performance measures when the cutoff point for making binary classification was placed at different top percentages of patients with asthma with the largest forecasted risk. When the cutoff point was placed at the top 10% (1464/14,644), the model yielded an accuracy of 90.6% (13,268/14,644; 95% CI 90.13-91.06), a sensitivity of 70.2% (153/218; 95% CI 63.8-76.0), a specificity of 90.91% (13,115/14,426; 95% CI 90.45-91.38), a PPV of 10.45% (153/1464; 95% CI 8.90-11.97), and an NPV of 99.51% (13,115/13,180; 95% CI 99.39-99.62). Table 6 presents the confusion matrix of the model in this case.

Several features, such as a family history of asthma, were calculated on 2 or more years of data. When we dropped these features and checked solely those features calculated on 1 year of data, the AUC of the model decreased from 0.902 to 0.899. If we used only the top 17 features in Table S2 of Multimedia Appendix 1 whose importance values are ≥0.01 and ignored the other 217 features, the model's AUC decreased from 0.902 to 0.898 (95% CI 0.874-0.919). In this case, when we placed the cutoff point for making binary classification at the top 10% (1464/14,644) of patients with asthma with the largest forecasted risk, the model's accuracy decreased from 90.6% (13,268/14,644) to 90.59% (13,266/14,644; 95% CI 90.11-91.06), sensitivity decreased from 70.2% (153/218) to 69.7% (152/218; 95% CI 63.6-75.5), specificity remained at 90.91% (13,114/14,426; 95% CI 90.42-91.37), PPV decreased from 10.45% (153/1464) to 10.38% (152/1464; 95% CI 8.82-11.97), and NPV decreased from 99.51% (13,115/13,180) to 99.5% (13,114/13,180; 95% CI 99.38-99.61).

Figure 2. The receiver operating characteristic curve of our final University of Washington Medicine model.

Forecasted future asthma hospital encounters	153	1311
Forecasted no future asthma hospital encounter	65	13,115

Performance Measures Yielded by Our Simplified Intermountain Healthcare Model on UWM Data

For our original simplified Intermountain Healthcare model trained on the Intermountain Healthcare training set [23], when we did not retrain the model and applied the model directly to the UWM test set, the model yielded an AUC of 0.861 (95% CI 0.835-0.885). When we placed the cutoff point for making binary classification at the top 10% (1464/14,644) of patients with asthma with the largest forecasted risk, the model yielded an accuracy of 90.29% (13,222/14,644; 95% CI 89.81-90.77), a sensitivity of 59.6% (130/218; 95% CI 53.4-65.7), a specificity of 90.75% (13,092/14,426; 95% CI 90.28-91.20), a PPV of 8.88% (130/1464; 95% CI 7.46-10.34), and an NPV of 99.33% (13,092/13,180; 95% CI 99.20-99.46).

After we used the UWM training set to retrain our simplified Intermountain Healthcare model [23], the retrained model yielded on the UWM test set an AUC of 0.874 (95% CI 0.848-0.896). When we placed the cutoff point for making binary classification at the top 10% (1464/14,644) of patients with asthma with the largest forecasted risk, the model yielded an accuracy of 90.34% (13,230/14,644; 95% CI 89.85-90.80), a sensitivity of 61.5% (134/218; 95% CI 54.6-67.7), a specificity of 90.78% (13,096/14,426; 95% CI 90.32-91.23), a PPV of 9.15% (134/1464; 95% CI 7.62-10.66), and an NPV of 99.36% (13,096/13,180; 95% CI 99.22-99.49).

Performance Measures Yielded by Our Simplified UWM Model on Intermountain Healthcare Data

Our simplified UWM model used only the top 17 features with importance values of ≥0.01. For our simplified UWM model trained on the UWM training set, when we did not retrain the model and applied the model directly to the Intermountain Healthcare test set, the model yielded an AUC of 0.814 (95% CI 0.798-0.830). When we placed the cutoff point for making binary classification at the top 10% (1926/19,256) of patients with asthma with the largest forecasted risk, the model yielded an accuracy of 89.76% (17,285/19,256; 95% CI 89.32-90.18), a sensitivity of 47.2% (383/812; 95% CI 43.8-50.6), a specificity of 91.64% (16,902/18,444; 95% CI 91.24-92.03), a PPV of 19.90% (383/1925; 95% CI 18.16-21.60), and an NPV of 97.52% (16,902/17,331; 95% CI 97.28-97.75).

After we used the Intermountain Healthcare training set to retrain our simplified UWM model, the retrained model yielded on the Intermountain Healthcare test set an AUC of 0.846 (95% CI 0.831-0.859). When we placed the cutoff point for making

binary classification at the top 10% (1926/19,256) of patients with asthma with the largest forecasted risk, the model yielded an accuracy of 90.11% (17,351/19,256; 95% CI 89.64-90.56), a sensitivity of 51.2% (416/812; 95% CI 47.6-54.5), a specificity of 91.82% (16,935/18,444; 95% CI 91.43-92.21), a PPV of 21.62% (416/1,925; 95% CI 19.81-23.41), and an NPV of 97.72% (16,935/17,331; 95% CI 97.48-97.93).

Discussion

Principal Findings

We built a model on UWM data to forecast asthma hospital encounters of patients with asthma in the subsequent 12 months. Table 7 reveals that our final UWM model yielded an AUC that was higher than the previously reported AUC of every existing model [2,9-23], that is, our modeling strategy of examining many candidate features to enhance model accuracy showed excellent generalizability to the UWM. After further optimization to boost its accuracy and automatically provide explanations of its predictions [39,40] to allow clinical interpretability, our UWM model could be used to facilitate efficient and effective allocation of asthma care management resources to improve outcomes.

In Table S2 of Multimedia Appendix 1, both the 5 most important features and multiple other features within the top 17 indicate a loss of asthma control. It is important to note that the loss of asthma control could be partly because of factors not well captured in our data, such as socioeconomic circumstances, variable management practices among providers, access to subspecialty clinicians, and nonadherence to medications and treatments. Variable asthma severity across patients over time also influences this process.

We checked 234 candidate features. Our final UWM model used 30.3% (71/234) of them. Despite being correlated with the outcome, many unused features had no extra predictive power on the UWM data set over the features adopted in our final UWM model.

For our original simplified Intermountain Healthcare model trained on the Intermountain Healthcare training set [23], when we did not retrain the model on the UWM data and directly applied the model, the model yielded an AUC of 0.861 on the UWM test set. This AUC is 0.041 lower than our final UWM model's AUC, but is still larger than the previously reported AUC of every existing model for forecasting future hospitalizations and ED visits of patients with asthma (Table 7). Therefore, our simplified Intermountain Healthcare model showed excellent generalizability to the UWM.

Compared with our full UWM model using 71 features, our simplified UWM model retained nearly all of its predictive power. For our simplified UWM model trained on the UWM training set, when we did not retrain the model on the Intermountain Healthcare data and directly applied the model, the model yielded an AUC of 0.814 on the Intermountain Healthcare test set. This AUC is 0.045 lower than our full Intermountain Healthcare model's AUC but is still larger than the previously reported AUC of every existing model developed by others for forecasting future hospitalizations and ED visits of patients with asthma (Table 7). Therefore, our simplified UWM model shows excellent generalizability to Intermountain Healthcare.

Table 7. A comparison of our final University of Washington Medicine model and several existing models for forecasting future hospitalizations and emergency department (ED) visits of patients with asthma.

Model	Prediction target	Number of data instances	Number of features the model adopted	Classification algorithm	Sensitivity (%)	Specificity (%)	PPV[a] (%)	NPV[b] (%)	AUC[c]

[e]The initial paper showing the model did not give the performance measure.

Comparison With the Previous Work

Researchers have built multiple models to forecast future hospitalizations and ED visits of patients with asthma [2,9-23]. Table 7 compares our final UWM model with these models, which cover all the relevant models described in the systematic review by Loymans et al [17]. The final UWM model's AUC was 0.902. The AUC of our Intermountain Healthcare model was 0.859. All other existing models have a previously reported AUC 0.81 [2,9-22], which is lower than our final UWM model's AUC by at least 0.091.

It is important to consider the prevalence of the outcome of interest when comparing the performance of different predictive models. Compared with other existing models, the model by Yurk et al [16] achieved a higher sensitivity and PPV mainly because it adopted a different prediction target: asthma hospital encounters or at least 1 day lost for diminished activities or missing work for asthma. This prediction target had a 54%

prevalence rate in patients with asthma and was therefore easier to forecast. If the model by Yurk et al [16] were used to forecast asthma hospital encounters, an outcome that had a <2% prevalence rate in patients with asthma, the model's sensitivity and PPV would likely drop.

The recurrent neural network model by Xiang et al [22] reached a low AUC of 0.7, mainly because it used mostly inpatient data with little outpatient data; adopted only 3 types of attributes: medication, diagnosis, and demographics; and did not merge individual asthma medications into asthma medication categories such as nebulizers and short-acting β-2 agonists, that is, the low AUC does not prove that the recurrent neural network is ineffective at predicting asthma outcomes, but is mainly because of incomplete data and insufficient feature modeling. In comparison, to build our final UWM model, we used both inpatient and outpatient data, adopted many types of attributes, and merged individual asthma medications into asthma medication categories to better capture and model the relationship among different asthma medications.

Excluding the model by Yurk et al [16], every existing published model has a sensitivity 53.69%, which is significantly lower than our final UWM model's sensitivity of 70.2%. For patients with asthma who will have future asthma hospital encounters, sensitivity is the percentage of them identified by the model. The difference in sensitivity can have a significant impact on health care use. Owing to the high prevalence rate of asthma, for every 10% increase in the identified percentage of patients with asthma who would have future asthma hospital encounters, up to 7759 more hospitalizations and 71,074 more ED visits could be avoided in the United States each year with effective care management [1,4-7].

The prevalence rate of targeted poor outcomes greatly impacts the PPV of any predictive model [41]. In our UWM test data set, 1.49% (218/14,644) of patients with asthma had future asthma hospital encounters. When we placed the cutoff point for making binary classification at the top 10% (1464/14,644) of patients with asthma with the largest forecasted risk, an impeccable model in theory would yield the highest possible PPV of 14.89% (218/1464). Our final UWM model yielded a PPV of 10.45% (153/1464), which is 70.18% of the highest possible PPV in theory. In comparison, our Intermountain Healthcare model achieved a PPV of 22.65% [23]. This is 53.69% of the highest possible PPV that an impeccable model in theory would yield on the Intermountain Healthcare test set. The model by Lieu et al [18] yielded a PPV of 18.5% on a data set where 6.9% of patients with asthma had future asthma hospital encounters. The model by Schatz et al [19] yielded a PPV of 22% on a data set where 6.5% of patients with asthma had future asthma hospital encounters. Compared with our case with UWM, both populations have a higher prevalence of asthma hospital encounters, which allows the PPV to be higher. Excluding these PPVs and the PPV by the Yurk et al [16] model, no other existing published model's PPV exceeds 5.6%.

Our final UWM model and our Intermountain Healthcare model [23] have similar top features with importance values of ≥0.01. In both models, many top features are related to previous ED visits and asthma medications. We did not identify several candidate features at the time of constructing our Intermountain Healthcare model. They appeared as top features and affected the ranks and importance values of the other top features in our final UWM model.

Differing models in Table 7 were built using different patient cohorts and used similar but not necessarily identical prediction targets. Some features used in the models built by other researchers, such as certain features computed from patient-reported outcomes and patient surveys, are unavailable in our UWM data set. Therefore, we were unable to show the performance measures that the models built by other researchers would achieve on our UWM data set. However, we are confident that the techniques used in this study improved prediction accuracy. Our final UWM model was built using a state-of-the-art machine learning algorithm, XGBoost. Compared with statistical methods such as logistic regression, machine learning can enhance prediction accuracy with less strict assumptions on data distribution [8,42,43]. Compared with the models built by other researchers, our final UWM model was built using more patients and a more extensive set of candidate features constructed with careful feature engineering, both of which are known to often help improve prediction accuracy [24-27,32]. As partial evidence for this, we built predictive models for asthma hospital encounters using data from 3 health care systems: UWM, Intermountain Healthcare [23], and Kaiser Permanente Southern California [44]. For each of the 3 health care systems, we started model building with approximately 20 candidate features and obtained unsatisfactory accuracy. This motivated us to examine several hundred candidate features. Ultimately, for each of the 3 health care systems, we built a model with an AUC that is higher than all of the AUCs other researchers previously reported in the literature for forecasting asthma hospital encounters [23,44]. This demonstrates the generalizability of our modeling strategy for forecasting asthma hospital encounters.

Considerations Concerning the Potential Clinical Use

Our final UWM model has an AUC that is higher than all of the AUCs previously reported in the literature for forecasting asthma hospital encounters, but still had a seemingly low PPV of 10.4% (153/1464). Nevertheless, this model could be valuable in clinical care. First, health care systems such as UWM, Intermountain Healthcare, and Kaiser Permanente Northern California [2] use proprietary models to allocate asthma care management resources. These models and the models that were formerly built by others have similar performance measures. Our final UWM model has an AUC that is higher than the previously reported AUCs of all these models.

Second, as explained earlier, even an impeccable model in theory would reach a low PPV because the poor outcome of interest has a low prevalence rate in our data set. For such an outcome, sensitivity better reflects the model's potential clinical value than PPV. Our final UWM model had a higher sensitivity than the previously reported sensitivity of every existing model using a comparable prediction target. It is important to note that while asthma hospital encounters have an overall low prevalence rate in the population of patients with asthma, they have

significant financial and clinical impacts at both the population and individual patient levels.

Third, a PPV of 10.45% (153/1464) is useful for identifying high-risk patients with asthma to receive low-cost preventive interventions. The following are 4 examples of such interventions: training the patient to record a diary about environmental triggers, coaching the patient to use an asthma inhaler correctly, coaching the patient to use a peak flow meter correctly and giving it to the patient to self-monitor symptoms at home, and asking a nurse to do extra follow-up phone calls with the patient or the patient's caregiver. These interventions could have a significant impact on patient outcomes.

The final UWM model used 71 features. Reducing the number of features could ease the clinical deployment of our model. To this end, if a minor decrease in prediction accuracy could be tolerated, one could adopt the top few features whose importance values are greater than a given threshold, such as 0.01, and drop the other features. The importance value of a feature varies across health care systems. Ideally, the importance values of the features should first be calculated on a data set from the target health care system before choosing the features to retain.

As is typical with complex machine learning models, an XGBoost model using many features is difficult to interpret. This can limit clinical understandability and adoption, particularly by clinicians who are resistant to using automated tools. In the future, we plan to adopt our previously developed method [39,40] to automatically explain the prediction results of our final UWM model.

The final UWM model was constructed using XGBoost [33]. For binary classification of imbalanced data, XGBoost leverages a hyperparameter, scale_pos_weight, to balance the weights of the 2 outcome classes [45]. To maximize the AUC of our UWM model, our automatic model selection method [35] altered scale_pos_weight to a nondefault value to balance the 2 outcome classes [46]. This incurs a side effect of significantly shrinking the model's forecasted probabilities of having future asthma hospital encounters to values much less than the actual probabilities [46]. This does not preclude us from choosing the top few percent of patients with asthma with the greatest forecasted risk to receive various preventive interventions. To prevent this side effect from occurring, we could retain scale_pos_weight at its default value of 1 without doing any balancing. As a tradeoff, the AUC of the model would decrease from 0.902 to 0.885 (95% CI 0.861-0.907); however, this decreased AUC is still larger than all of the AUCs previously reported in the literature for forecasting asthma hospital encounters.

Limitations

This study has at least 4 limitations that could be interesting topics for future work, as follows:

1. It is possible to further increase the model accuracy by using features other than those checked in this study. For example, features derived from environmental and physiological data gathered by intelligent wearable devices can have this potential.
2. This study used purely structured data and checked only nondeep learning classification algorithms. It is possible to further increase the model accuracy by using deep learning as well as features derived from unstructured clinical notes using natural language processing techniques [40,47].
3. Our UWM data set contained no data on patients' health care use outside of UWM. Therefore, we limited the prediction target to asthma hospital encounters at UWM instead of asthma hospital encounters anywhere. In addition, the features we checked were derived from patients' incomplete administrative and clinical data [48-51]. It would be worth investigating how model accuracy would vary if we have more complete administrative and clinical data of patients [52].
4. This study evaluated the generalizability of our modeling strategy to an academic health care system on a single outcome of a complex chronic disease. We recently showed that our modeling strategy also generalizes well to Kaiser Permanente Southern California for the same predictive modeling problem [44]. We plan to investigate our modeling strategy's generalizability to other diseases, outcomes, and health care systems in the future.

Conclusions

In the first evaluation of its generalizability to an academic health care system, our modeling strategy of examining many candidate features to enhance prediction accuracy showed excellent generalizability to the UWM and led to a model with an AUC that is higher than all of the AUCs previously reported in the literature for forecasting asthma hospital encounters. After further optimization, our UWM model could be used to facilitate the efficient and effective allocation of asthma care management resources to improve outcomes.

Acknowledgments

The authors would like to thank Katy Atwood for helping with the retrieval of the UWM data set and Michael D Johnson for useful discussions. GL, SM, and GD were partially supported by the National Heart, Lung, and Blood Institute of the National Institutes of Health under award R01HL142503. The funders had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript. YT did the work at the University of Washington when she was a visiting PhD student.

Authors' Contributions

YT participated in data analysis and the writing of the first draft of the paper. GL conceptualized and designed the study, performed a literature review, participated in data analysis, and rewrote the whole paper. AM, AW, SM, GD, and PS provided feedback on various medical issues, contributed to conceptualizing the presentation, and revised the paper.

Conflicts of Interest

None declared.

Abstract

Background: With the prevalence of cardiovascular diseases increasing worldwide, early prediction and accurate assessment of heart failure (HF) risk are crucial to meet the clinical demand.

Objective: Our study objective was to develop machine learning (ML) models based on real-world electronic health records to predict 1-year in-hospital mortality, use of positive inotropic agents, and 1-year all-cause readmission rate.

Methods: For this single-center study, we recruited patients with newly diagnosed HF hospitalized between December 2010 and August 2018 at the First Affiliated Hospital of Dalian Medical University (Liaoning Province, China). The models were constructed for a population set (90:10 split of data set into training and test sets) using 79 variables during the first hospitalization. Logistic regression, support vector machine, artificial neural network, random forest, and extreme gradient boosting models were investigated for outcome predictions.

Results: Of the 13,602 patients with HF enrolled in the study, 537 (3.95%) died within 1 year and 2779 patients (20.43%) had a history of use of positive inotropic agents. ML algorithms improved the performance of predictive models for 1-year in-hospital mortality (areas under the curve [AUCs] 0.92-1.00), use of positive inotropic medication (AUCs 0.85-0.96), and 1-year readmission rates (AUCs 0.63-0.96). A decision tree of mortality risk was created and stratified by single variables at levels of high-sensitivity cardiac troponin I (<0.068 μg/L), followed by percentage of lymphocytes (<14.688%) and neutrophil count (4.870×10^9/L).

Conclusions: ML techniques based on a large scale of clinical variables can improve outcome predictions for patients with HF. The mortality decision tree may contribute to guiding better clinical risk assessment and decision making.

KEYWORDS

heart failure; machine learning; predictive modeling; mortality; positive inotropic agents; readmission

Introduction

Heart failure (HF) syndrome is a life-threatening chronic disorder with a global prevalence that has been rising consistently over recent decades because of population aging, shifts in disease spectrums, and improved survival rates among patients with various cardiovascular diseases [1,2]. HF is characterized by complex therapeutic regimens, frequent hospitalizations, and a poor prognosis, resulting in a tremendous health care burden [3]. In certain instances, these issues are also fundamental targets of a strategy for HF prevention and treatment [4,5]. It is crucial to discriminate accurately among patients with HF to identify those who have a high risk of in-hospital mortality and readmission, as well as to guide the use of different therapies based on patients' features.

A prediction model was developed as an important risk assessment tool and used in various health care areas over the past decades. It has been recognized to facilitate early identification of patients at disease or event risk and enables effective interventions for those who might benefit most from identifying specific risk factors [6,7]. Previous studies in the field of cardiology, generally based on different populations with HF, have constructed models that are relevant to prognosis prediction, including the Seattle Heart Failure Model (SHFM) [8], Munich score [9], Enhanced Feedback for Effective Cardiac Treatment (EFFECT) scale [10], and Acute Decompensated Heart Failure National Registry (ADHERE) [11]. Moreover, several available parameters related to increased mortality have been identified as well, such as age [10,12,13], concentration of B-type natriuretic peptide (BNP) [14,15], urea nitrogen level [10,12], and systolic blood pressure (SBP) [9,13]. Although the model's construction from such cohorts or databases provides a level of concrete evidence, it is typically limited to large volumes of clinical resources and unstructured data [16]. Given the growing popularity of big data use and mining, data derived from electronic health records (EHRs) are becoming more available and accessible for clinical research.

Besides this, predictive models have been constructed in various health care domains with a certain degree of success by automated mining of EHRs, combined with machine learning (ML) approaches [17], specifically for the prediction of HF outcomes [18-20]. In contrast to previous studies of predictive models for HF outcomes that apply traditional methods, recent research is adopting ML techniques for predicting HF mortality, readmission, and medication adherence, which might demonstrate better performance in their predictions because of their consideration of higher order and nonlinear relationships between multidimensional variables [21].

In our study, we explored the use of the traditional method—logistic regression (LR)—and the four novel ML approaches—support vector machine (SVM), artificial neural network (ANN), random forest (RF), and extreme gradient boosting (XGBoost)—to predict prognostic outcomes for subjects with HF in real-world settings. We demonstrated the development of EHR-based models to predict the 1-year in-hospital mortality, use of positive inotropic agents, and all-cause readmissions in a single year.

Methods

Patients and Data Source

We collected the EHR data from hospitalized patients diagnosed with HF at the First Affiliated Hospital of Dalian Medical University (Liaoning Province, China) over 7 years between December 2010 and August 2018. All patients with HF were diagnosed and treated according to institutional guidelines. Because the diagnostic terminologies of EHRs have been structured and normalized according to the International Statistical Classification of Diseases and Related Health Problems, 10th Revision (ICD-10 [22]), newly diagnosed patients with HF (aged >18 years) were screened by a dynamically updated big data intelligence platform developed by an artificial intelligence technology company in collaboration with hospitals (Yidu Cloud Technology Co., Ltd). Each patient's data were extracted from various EHR systems integrated into a single platform, including the hospital information system, electronic medical record, radiation information system, laboratory information system, ultrasound system, and electrocardiogram system. The study was finally approved by the ethics committee of the First Affiliated Hospital of Dalian Medical University. Written informed consent was waived due to the retrospective design.

Selection of Variables

The platform incorporates comprehensive and detailed data on patients' routine health care. Common and cardiovascular-specific variables were structured and normalized by natural language processing, ML techniques, and well-defined logical rules. Considering the large scale of EHR data and the advantages of ML techniques, candidate variables with known clinical significance and inaccessible through traditional medical records were collected in our study. We excluded variables with missing values greater than 20%. Finally, a total of 79 variables related to the first hospitalization were extracted from a big data intelligence platform. The features were as follows: demographics (age and sex), personal history (smoking and drinking), history (comorbidities and surgery), etiology, vital signs, routine laboratory examinations, interventions, and medication use on admission (Multimedia Appendix 1). Repeated measurements of vital signs and laboratory tests from patients with HF were taken over different periods to ensure data accuracy.

Outcomes

We established models using 5 algorithms separately to predict the primary outcome: all-cause in-hospital mortality within 1 year. The secondary outcomes were (1) use of positive inotropic agents for patients with HF and (2) all-cause readmission. Mortality was defined as a clear record of death of an inpatient within 1 year of hospitalization. The following commonly used positive inotropic agents in clinical practice were selected for our study: dopamine, dobutamine, milrinone, levosimendan, and deslanoside. Readmission was defined as any patient with an interval of more than 1 day from the last discharge until the next admission; no readmitted patients died within 1 year of hospitalization. Therefore, enrolled patients were labeled as "deceased" or "survivors."

ML Model Development and Performance Evaluation

The synthetic minority oversampling technique was first employed to address the imbalance in the data set, with a ratio of 1:1 between deceased patients and survivors. It is common for a minority to be oversampled by deriving new, "synthetic" samples to alleviate imbalance [23].

The hold-out method was used to divide the data set into a training/validation data set (90%) and a hold-out test set (10%). Five approaches were explored with 10-fold cross-validation for building models and adjusting parameters: LR, RF, SVM, ANN, and XGBoost. The hold-out test set was used to evaluate the best-performing models created with the training set. The area under the curve (AUC) of the receiver operating characteristic (ROC) curve was chosen as the primary evaluation metric for our models, including accuracy, precision, and recall. The Brier score (range of 0 to 1)—the average squared error between the predicted and the actual value—was also commonly represented as a "calibration" for overall measurement. Shapley additive explanation (SHAP) values were used to evaluate feature importance.

LR Method

LR is the most basic dichotomous linear method of model selection that makes classification decisions. LR is superior in measuring the probability between "0" and "1" based on the relationships of binary classifications in continuous or categorical variables [24]. We used the sklearn.linear module to develop the LR models.

RF Method

RF is an algorithm that integrates multiple decision tree classifiers. Each node of the decision tree represents a predictive variable to separate the outcome classes by setting the optimal threshold. The importance of features can also be obtained with the sum of weights of the classifier's nodes [25]. The RF method is generally used to deal with thousands of input variables without dimension reduction. We used the RF classifier from the sklearn.ensemble module to develop the models. The related parameters (n_estimators, max_features, max_depth, and min_samples_split) were adjusted to prevent poor results and overfitting.

SVM Method

As a dichotomous supervised algorithm, SVM can be used in high-dimensional feature space. The best hyperplane can be achieved using a kernel-based function for separating two classes at maximum intervals [26].

ANN Method

A multilayer perceptron (MLP) classifier was implemented using the sklearn.neural_network module to develop models [27]. MLP is a popular ANN method that generally consists of neurons from the input, hidden, and output layers. The data were processed through weighted connections and activation functions in the hidden layers [28]. In our study, the two hidden layers had 40 and 20 neurons. The rectified linear unit was chosen as their activation function.

XGBoost Method

XGBoost is one of the boosting methods; this algorithm aims to integrate weak classifiers into a single robust classifier in an iterative fashion [29]. This algorithm constructs a scalable classification and regression tree in a boosting ensemble manner on a gradient boosting decision tree basis, which can learn nonlinear relationships among variables and outcomes flexibly and accurately [30]. The small learning rate (0.1) indicates better generalization. The tree number and maximum depth were limited to 80 (estimators) and 3, respectively.

Statistical Analysis

All ML algorithms were performed using the scikit-learn (version 0.21.1) package in Python (version 3.6.5; Python Software Foundation), and statistical analysis was conducted using an open-source Scipy (version 1.3.0) database from Python (version 3.6.3). All categorical data were presented as percentages. All continuous data performing a normal distribution were presented as mean (SD); otherwise, they were expressed as median (IQR). Student *t* tests or chi-square tests were applied for group comparisons. *P* values <.05 were considered statistically significant.

Results

Baseline Characteristics

A total of 13,602 hospitalized patients with newly diagnosed HF were enrolled in this study, of whom 3.95% (n=537) died in hospital within 1 year. The usage rate of positive inotropic agents was 20.43% (n=2779). The overall all-cause readmission rates of 30 days, 60 days, and 1 year for patients with HF were 4.83%, 14.77%, and 21.16%, respectively (n=657, n=2009, and n=2878, respectively, of 13,602 cases). The eligible population's baseline characteristics were compared between 2 groups according to survival status (Table 1). Patients in the deceased group were older than those in the survivor group (77 years, IQR 66.5-83.0 years versus 72 years, IQR 63.0-80.0 years, respectively). The proportion of male patients in both groups was 52.5% (282/537 and 6860/13,065 in the deceased group and survivor group, respectively). The number of patients with comorbid diagnoses of diabetes, hypertension, and tumors was remarkably different between the 2 groups (all *P*<.001). Concerning the etiology of HF, the number of patients with cardiomyopathy and cardiac arrhythmia was found to be different between the deceased and survivor groups (both *P*<.001). There was a significant difference in the vital signs (heart rate and blood pressure) of patients with HF between the 2 groups (all *P*<.001). In-hospital medication use (angiotensin-converting enzyme inhibitors [ACEIs] and aldosterone receptor antagonists [ARBs]) was higher among subjects who survived in the hospital (*P*<.001).

1-Year In-Hospital Mortality Models

Predictive models for 1-year in-hospital mortality risk assessment were conducted using 5 algorithms. Figure 1A shows the performances of models in the form of AUC. The AUC values for LR, RF, SVM, ANN, and XGBoost were 0.91, 1.00, 0.99, 0.99, and 0.99, respectively. RF had relatively higher AUC than the other algorithms. The calibration plots of our 5 methods are presented in Figure 2A. Four ML models had an accuracy of higher than 95%. Regarding precision, the RF and ANN algorithms emerged as the best, achieving the highest precision (0.96), followed by the SVM (0.93) and XGBoost (0.91) algorithms. The Brier score for RF and ANN was the lowest (0.03) (Table 2).

Figure 1. Receiver operating characteristic (ROC) curves using the synthetic minority oversampling technique for the logistic regression, random forest, support vector machine, artificial neural network (ANN), and extreme gradient boosting (XGBoost) models in predicting (A) 1-year in-hospital mortality, (B) use of positive inotropic agents, and (C) 1-year all-cause readmission. AUC: area under the curve.

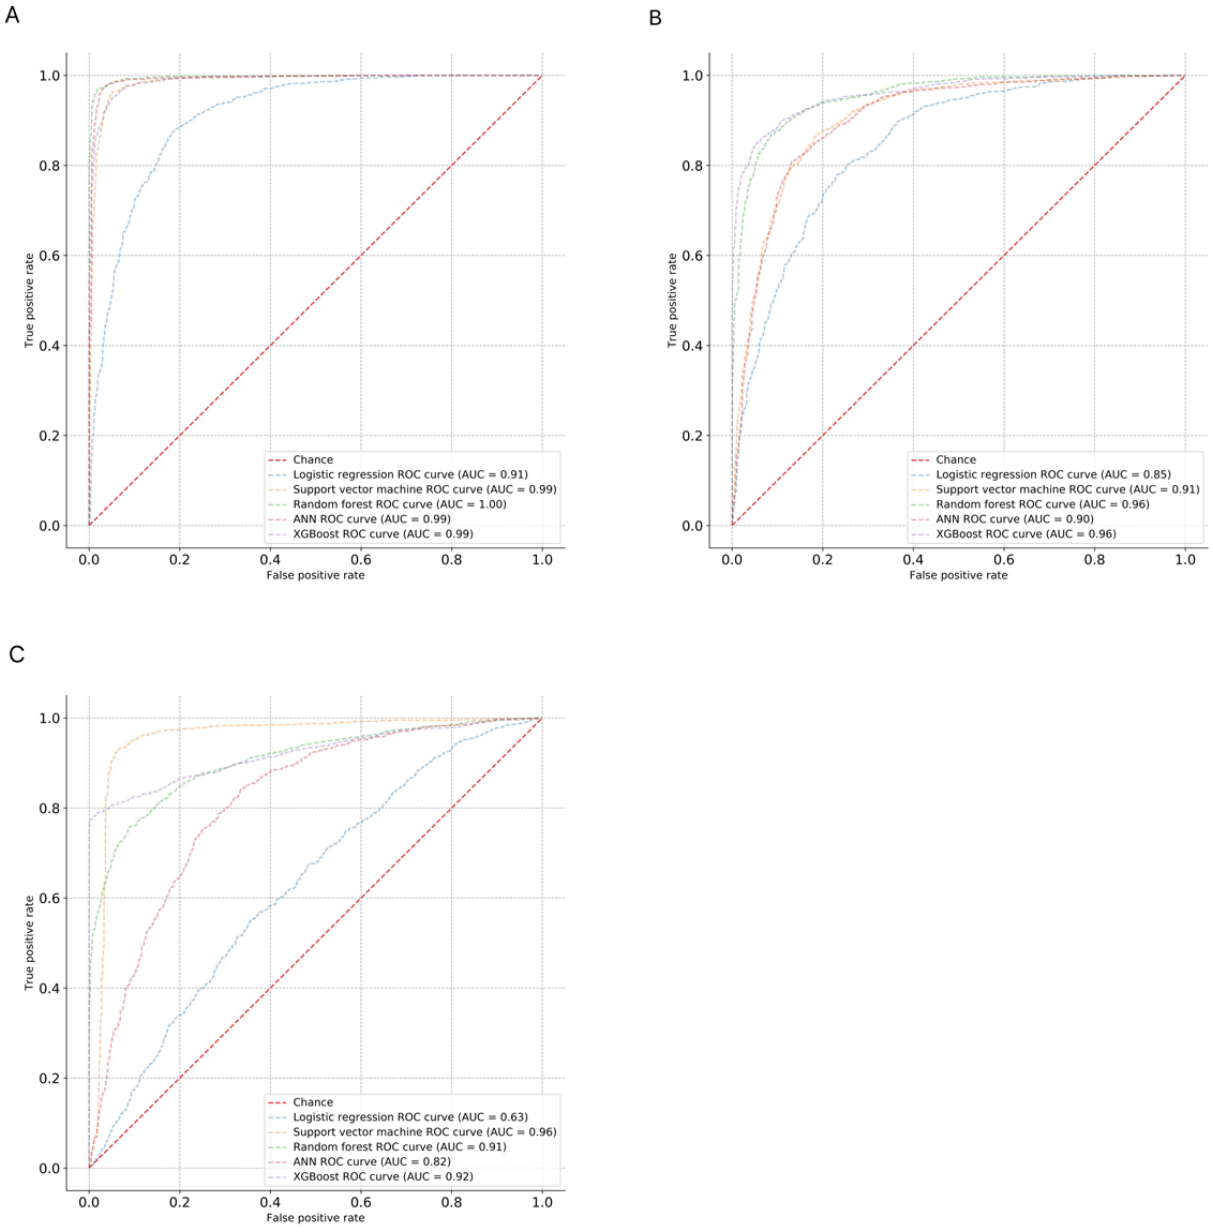

Figure 2. Calibration plots using the synthetic minority oversampling technique for the logistic regression, random forest, support vector machine, artificial neural network (ANN), and extreme gradient boosting (XGBoost) models in predicting (A) 1-year in-hospital mortality, (B) use of positive inotropic agents, and (C) 1-year all-cause readmission.

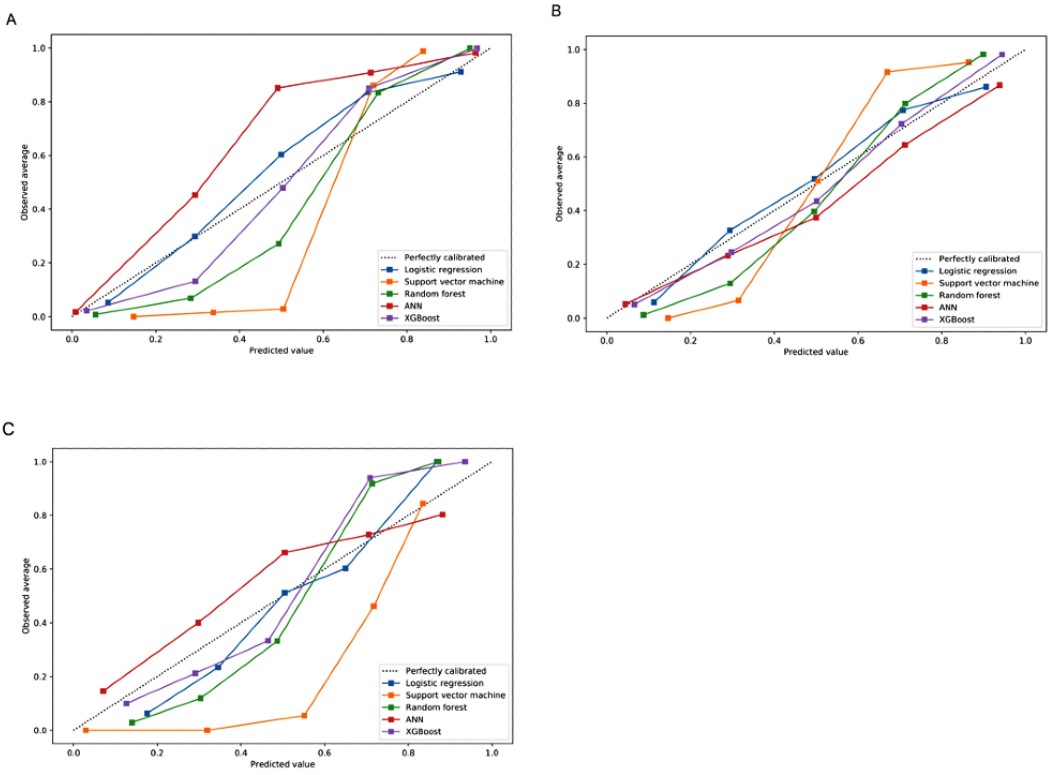

Table 2. Performance of the machine learning approaches for the estimation of 1-year in-hospital all-cause mortality.

Model	AUC[a]	Accuracy	Precision	Recall	F1	Brier score
LR[b]	0.91	0.83	0.86	0.80	0.83	0.12
RF[c]	1.00	0.97	0.96	0.98	0.97	0.03
SVM[d]	0.99	0.94	0.93	0.96	0.94	0.16
ANN[e]	0.99	0.97	0.96	0.98	0.97	0.03
XGBoost[f]	0.99	0.94	0.91	0.98	0.94	0.05

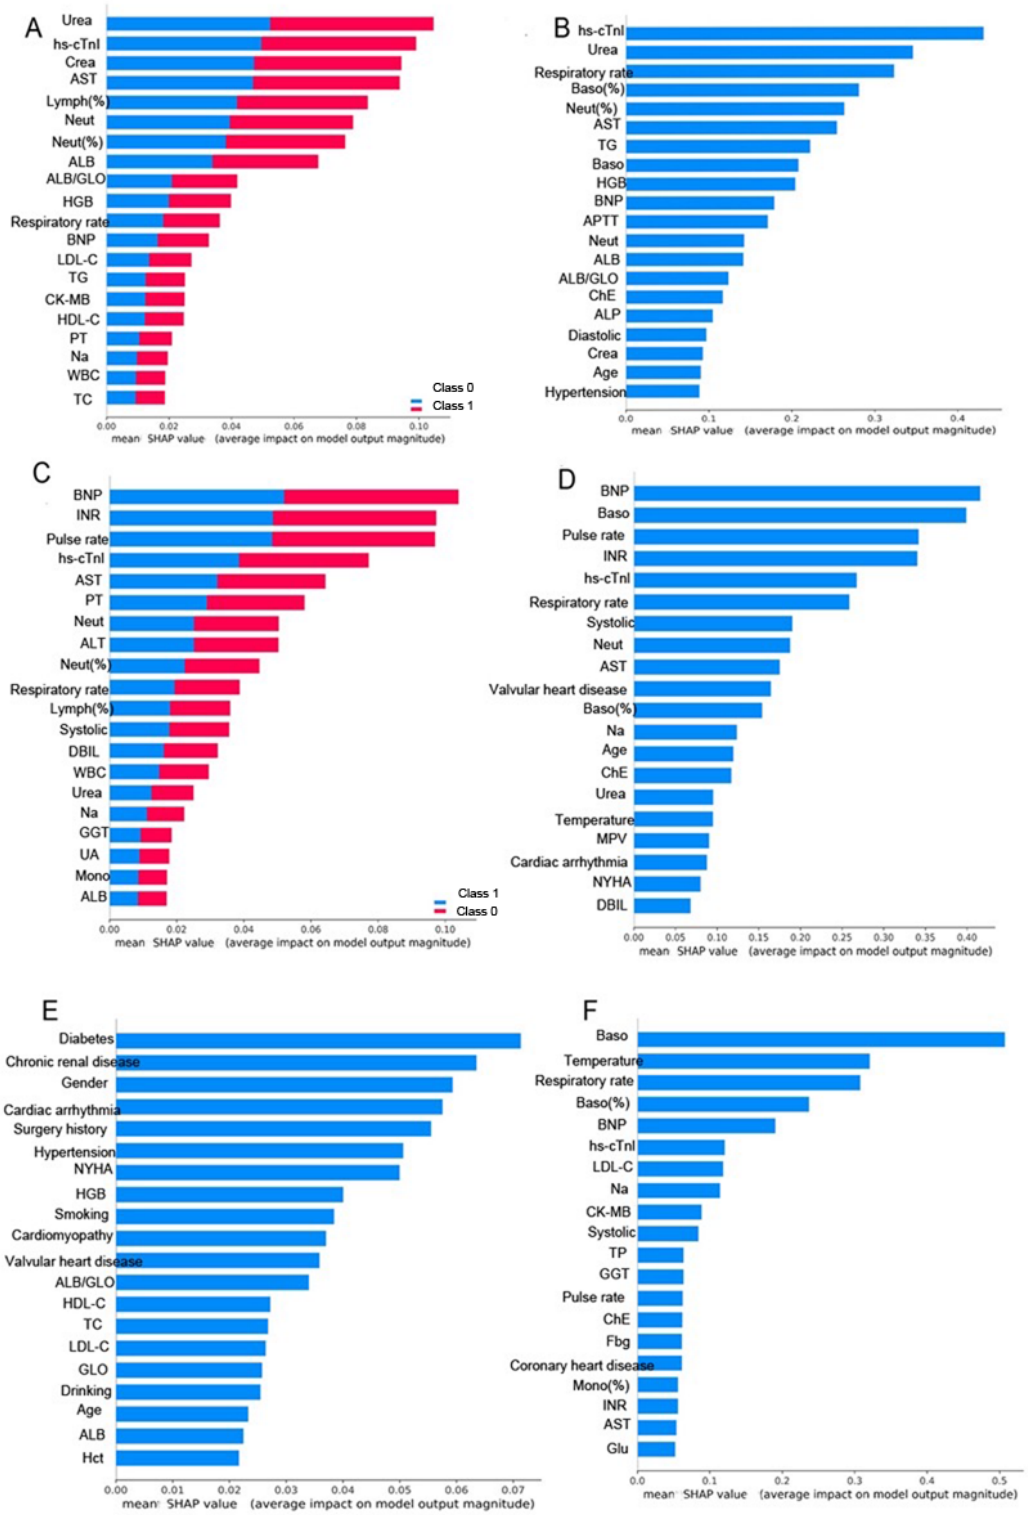
[f]XGBoost: extreme gradient boosting.

Furthermore, we explored the importance of the features that affect mortality prediction by applying RF and XGBoost approaches (Figure 3), with the weight assignment of each feature expressed as a SHA*P* value based on whether it favored judgment in survival. As shown in Figure 3A and 3B, blood urea, high-sensitivity cardiac troponin I (hs-cTnI), creatinine, aspartate aminotransferase (AST), and percentage of lymphocytes were the top 5 related variables in mortality prediction. In contrast, hs-cTnI was the most crucial marker identified using the XGBoost algorithm, followed by urea, respiration rate, percentage of basophils, and percentage of neutrophils.

Figure 3. Shapley additive explanation (SHAP) plots for the machine learning models in predicting (A) 1-year in-hospital mortality using the random forest (RF) method, (B) 1-year in-hospital mortality using the extreme gradient boosting (XGBoost) method, (C) use of positive inotropic agents using the RF method, (D) use of positive inotropic agents using the XGBoost method, (E) 1-year all-cause readmission using the support vector machine (SVM) method, and (F) 1-year all-cause readmission using the XGBoost method. ALB: albumin; ALP: alkaline phosphatase; APTT: activated partial thromboplastin time; AST: aspartate aminotransferase; Baso: basophils; BNP: B-type natriuretic peptide; ChE: cholinesterase: CK-MB: creatine kinase MB; COPD: chronic obstructive pulmonary disease; Crea: creatinine; DBIL: direct bilirubin; Fbg: fibrinogen; GGT: gamma-glutamyl transferase; GLO: globulin; Glu: glucose; Hct: hematocrit; HDL-C: high-density lipoprotein cholesterol; HGB: hemoglobin; hs-cTnI: high-sensitivity cardiac troponin I; INR: international normalized ratio; LDL-C: low-density lipoprotein cholesterol; Lymph(%): percentage of lymphocytes; Mono: monocytes; MPV: mean platelet volume; Na: sodium; Neut: neutrophils; NYHA: New York Heart Association; PT: prothrombin time; TC: total cholesterol; Systolic: systolic blood pressure; TG: triglycerides; TP: total protein; UA: uric acid; WBC: white blood cells.



Positive Inotropic Agent Use Models

Figure 1B demonstrates the ROC of the predictive models in patients' use of positive inotropic agents. In comparing AUCs among the 5 models, the XGBoost and RF models had the highest AUC value (0.96), followed by the SVM model (0.91), ANN model (0.90), and LR model (0.85). In consideration of precision (0.85) and recall (0.91) values, RF was determined to be the best method for prediction (Table 3). As shown in calibration curves (Figure 2B), a nonparametric plot of the RF algorithm was close along the ideal diagonal line and had the lowest Brier score (0.10).

Table 3. Performance of the machine learning approaches for the estimation of use of positive inotropic agents.

Model	AUC[a]	Accuracy	Precision	Recall	F1	Brier score
LR[b]	0.85	0.78	0.77	0.79	0.78	0.16
RF[c]	0.96	0.87	0.85	0.91	0.88	0.10
SVM[d]	0.91	0.85	0.83	0.88	0.84	0.17
ANN[e]	0.90	0.83	0.78	0.94	0.84	0.12
XGBoost[f]	0.96	0.84	0.79	0.94	0.86	0.11

[a]AUC: area under the curve.

[b]LR: logistic regression.

[c]RF: random forest.

[d]SVM: support vector machine.

[e]ANN: artificial neural network.

[f]XGBoost: extreme gradient boosting.

Interestingly, BNP, international normalized ratio (INR), pulse rate, hs-cTnI, and AST were the top 5 markers predicting use of positive inotropic agents by the RF approach. BNP was also identified as a critical marker for forecasting positive inotropic agent use in the XGBoost model, followed by basophil counts, pulse rate, INR, and hs-cTnI (Figure 3C and 3D).

1-Year All-Cause Readmission Models

The discrimination of different models for 1-year all-cause readmissions represented by AUCs is shown in Figure 1C. The SVM method achieved the best performance in terms of 1-year readmission prediction (AUC 0.96). XGBoost showed the lowest Brier score for calibration plots (0.12), followed by RF (0.13), SVM (0.16), ANN (0.18), and LR (0.24) (Figure 2C and Table 4).

Table 4. Performance of the machine learning approaches for the estimation of 1-year all-cause readmission.

Model	AUC[a]	Accuracy	Precision	Recall	F1	Brier score
LR[b]	0.63	0.57	0.57	0.59	0.58	0.24
RF[c]	0.91	0.82	0.83	0.81	0.82	0.13
SVM[d]	0.96	0.90	0.86	0.96	0.91	0.16
ANN[e]	0.82	0.74	0.74	0.75	0.74	0.18
XGBoost[f]	0.92	0.83	0.82	0.84	0.83	0.12

[a]AUC: area under the curve.

[b]LR: logistic regression.

[c]RF: random forest.

[d]SVM: support vector machine.

[e]ANN: artificial neural network.

[f]XGBoost: extreme gradient boosting.

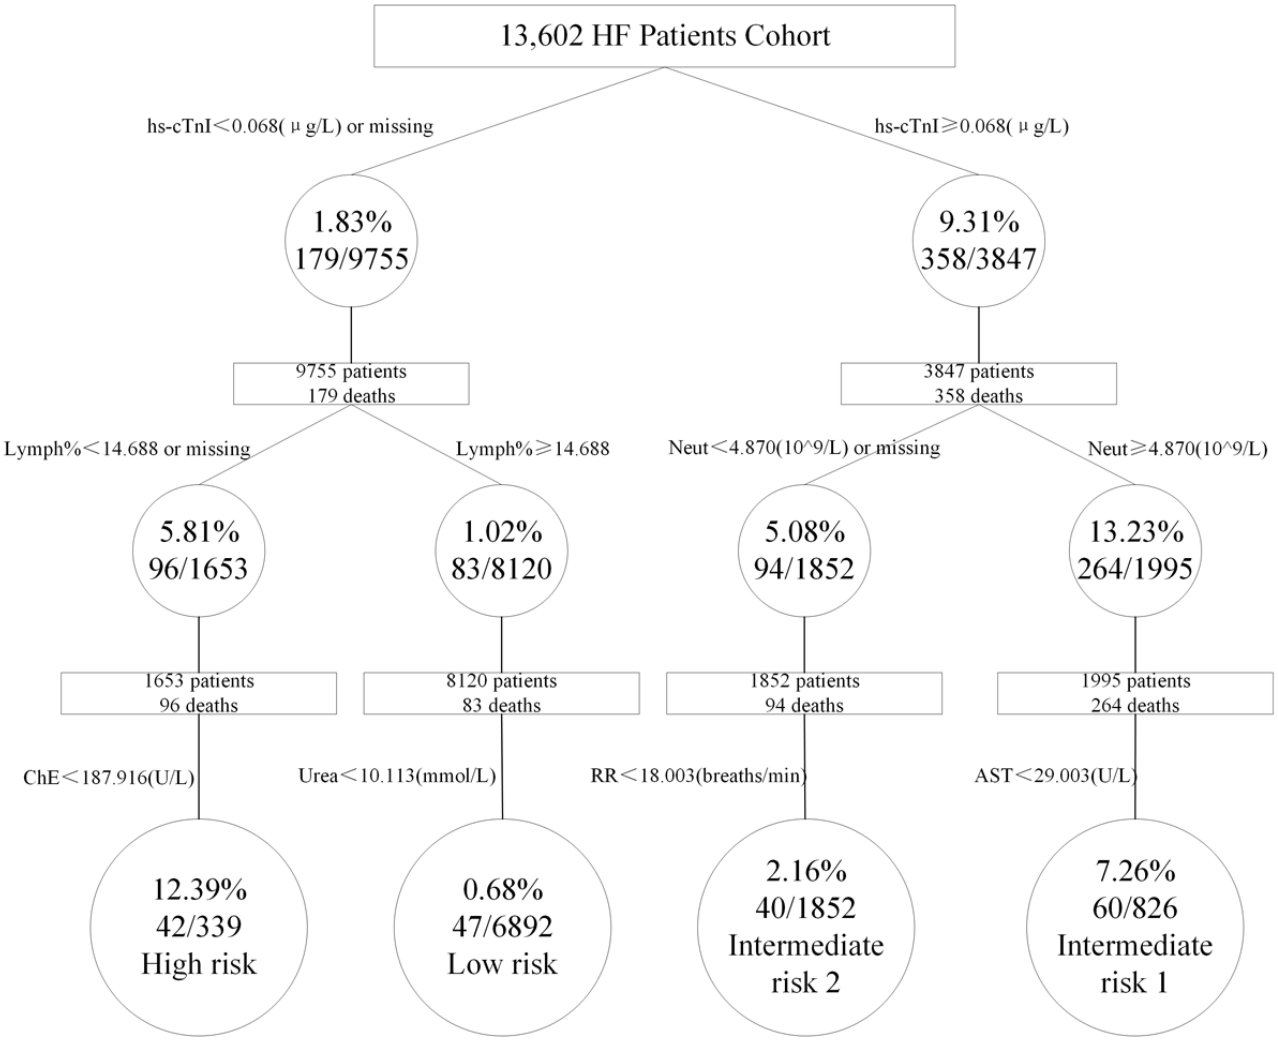
Of the 79 variables analyzed, the presence of diabetes was identified as the most important marker for prediction of 1-year all-cause readmission using the SVM method, whereas basophil count was a significant predictor of readmission using the XGBoost algorithm. There appeared to be a certain discrepancy in the ranking of other features derived by the two methods (Figure 3E and 3F).

Mortality Risk Assessment Model

The patients were divided into subgroups of high-, intermediate-, and low-risk in-hospital mortality according to the cutoff value of various variables obtained using the XGBoost algorithm (Figure 4). Of the 79 variables, the hs-cTnI level (<0.068 μg/L) was identified as the first single predictor to discriminate between deceased and surviving patients. The next discriminator

in the left node of hs-cTnI was the percentage of lymphocytes at a discrimination level of <14.688%; conversely, the next discriminator in the right node of hs-cTnI was neutrophil count at a cutoff value of less than 4.870×10^9/L. Subsequently, the patients with HF were stratified by these branch points: high risk (hs-cTnI <0.068 μg/L, percentage of lymphocytes <14.688%, and cholinesterase <187.916 U/L); low risk (hs-cTnI <0.068 μg/L, percentage of lymphocytes ≥14.688%, and urea <10.113 mmol/L); intermediate risk 1 (hs-cTnI ≥0.068 μg/L, neutrophil count ≥4.870×10^9/L, and AST <29.003 U/L); and intermediate risk 2 (hs-cTnI ≥0.068 μg/L, neutrophil count <4.870×10^9/L, and respiratory rate <18.003 breaths/min).

Figure 4. Predictors of 1-year in-hospital mortality and risk stratification using an extreme gradient boosting (XGBoost) algorithm. AST: aspartate transaminase; ChE: cholinesterase; HF: heart failure; hs-cTnI: high-sensitivity cardiac troponin I; Lymph%: percentage of lymphocytes; neut: neutrophil count; RR: respiration rate.



Discussion

Principal Findings

In our study, the EHR data–driven prognostic models based on 5 different ML algorithms were developed for predicting 1-year in-hospital mortality, use of positive inotropic agents, and all-cause readmissions within 1 year for patients with HF in a single Chinese class A tertiary comprehensive hospital. These ML models produced better predictive values for prognostic outcomes by growing interpretability than traditional linear methods. Besides, the novel ML techniques could take advantage of a large scale of complex, high-dimensional variables to widen the scope of HF predictive indicators concerning prognostic outcomes.

An integrated EHR system comprises various data resources, including patients' demographic data, diagnostic information, laboratory test results, and prescriptions. However, many experts revealed that the availability of EHR-derived data is a prerequisite for promoting real-world studies [31,32]. In our study, the structured EHR data from over 10,000 patients in different years can be used directly for analysis without bias of data collection and clinical definitions. A total of 79 variables were applied from EHRs, including demographic information (n=4), current and previous disease history (n=8), HF diagnosis (n=3), vital signs (n=5), laboratory measurements (n=48), interventions (n=4), and medications (n=7). In general, the final target of using rich data derived from mature EHR systems is also patient outcome predictions. With the advancement of data science, different kinds of ML techniques have been broadly employed for model training because of their deep data

processing and decision-making capabilities [33]. Compared with previous studies using the traditional LR method [11,20], our results provide better discrimination of risk for prognostic outcomes in a population of patients hospitalized for HF by using ML approaches. The strength of the algorithm could establish complex models and make accurate decisions in relevant big data sets. Besides, far more variables were allowed for modeling by using ML algorithms. Given the 5 methods in the present study, LR was considered the commonly used method in various fields of medicine [12,18]. The RF algorithm involves multiple decision tree creations that identify important predictive features with better accuracy in processing large numbers of highly nonlinear data [20,34]. ANN is a complex network method connected by a large number of simple neurons and simulates the human brain in parallel processing and nonlinear transformation [35]. The SVM approach is designed to build a good classifier using a nonlinear decision boundary between classes of variables that enables the labels from one or more feature vectors [36]. From the perspective of AUC values, it is important to mention that XGBoost performed better than the other 4 methods in predicting 1-year in-hospital mortality, use of positive inotropic agents, and 1-year all-cause readmission in patients with HF. The method's dominant advantages are its ability to deal with missing values and integrate the power of weaker classifiers by creating combined and weighted variables. Relevant parameters were set to particular values.

Several traditional prognostic models have been established to estimate mortality in hospitalized patients with HF. Our results are consistent with the previous studies of 1-year mortality prediction while demonstrating a better predictive capability. Our study, which predicted outcomes for 13,602 patients with HF using 79 predictive variables, indicated that the ML approaches are superior to the EFFECT method (AUC 0.77) in predicting mortality, with an average AUC of 0.81 [10]. The classic SHFM study showed mortality prediction results within 1 year with AUCs of 0.729-0.76 [37], although the AUC value can be enhanced to 0.78 by combining the SHFM with the BNP level [38]. Furthermore, variables known to be associated with mortality in patients with HF were demonstrated in various previous models. Age, SBP, and level of blood urea nitrogen (BUN) were confirmed as the strongest independent predictors by the EFFECT model [10]. In the landmark Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial model [39], platelet counts, albumin, INR, and AST were associated with 1-year mortality in the HF population with implantable devices. The New York Heart Association class; use of beta-blockers, ACEIs, or ARBs; and presence of heart valve disease or atrial fibrillation remarkably influenced all-cause mortality in the Cardiac and Comorbid Conditions Heart Failure (3C-HF) score [40]. Our study obtained similar findings, demonstrating that in addition to specific biomarkers of HF or myocardial damage, renal function, coagulation indicators, and inflammation indicators are also critical factors regarding prognosis. Therefore, perhaps adopting a large scale of EHR-derived data could enhance discrimination and the predictive range of prognostic outcomes.

Readmission rate is a common index used to assess the quality of health care services for patient populations. Currently, most hospitals and institutions still implement traditional readmission risk models and certain variables to infer readmission probability [41]. Like previous prediction models, we found that the accuracy of mortality prediction was moderate, but the model was relatively poor at predicting readmission rates. Golas et al [42] suggested that the overall 30-day readmission rate was not improved by various ML algorithms, with AUC values around 0.66. Even compared with the established models for HF readmission (AUCs 0.6-0.7), our best ML model is still encouraging [43]. The variables that influenced mortality in the ML models were different from those of readmission among patients with HF. We believe that conventional diagnostic biomarkers (BNP) and vital signs (respiration rate and temperature) could dominate readmission prediction. However, diabetes, coronary heart disease, and gender were the top 3 significant features for predicting readmission using the SVM method. At an interpretable level, a high model AUC does not necessarily indicate that it best fits the scenario.

Positive inotropic agents are a kind of drug that can increase myocardial contractility and cardiac output and are often used to treat patients with HF. Among the drugs included in our study, dopamine and dobutamine have mainly inotropic effects, whereas milrinone, lanatoside C, and levosimendan have extra vasodilation functions [44]. However, they have been gradually limited because of poorer outcomes of patients after accepting inotropic therapy. Thus, controversy still exists regarding their reasonable use in clinical practice. Our study was found to have better performance than two other prognostic models in predicting the use of positive inotropic agents (AUCs in the range of 0.87 to 0.96). Furthermore, this study's findings are consistent with Aljundi et al [45], who reported that the conventional cardiac biomarker BNP was predictive of inotropic agent use. Many studies have confirmed that comorbidities—such as dyslipidemia, chronic renal and liver impairment, and hyperglycemia—are associated with a higher likelihood of accepting inotropic treatment. Other critically associated variables (INR, AST, and basophil count) were obtained from our models and showed consistent results with common clinical thought. Our models provided good discrimination among patients at high risk for mortality, use of positive inotropic agents, and readmission. Incorporating more variables based on traditional models is of great significance to public health transformation for early identification and individualized intervention of people at high risk of HF outcomes.

The study's strength was that we also developed a stratified risk assessment tool for the prediction of 1-year in-hospital mortality using the XGBoost algorithm. Far more features—including hs-cTnl, percentage of lymphocytes, percentage of neutrophils, cholinesterase, urea, respiratory rate, and AST—were identified for the first time using an ML approach for mortality prediction. Neutrophilia was reported to be associated with an increased incidence of acute decompensated HF (ADHF) in patients with acute myocardial infarction, and lymphopenia is related to poor prognosis in patients with HF [46,47]. Results from Seo et al [48] showed that cholinesterase was a simple marker for predicting adverse outcomes in patients with ADHF and tended to provide more accurate prognostic information than other

objective nutritional features. These results can be attributed to the dimensionality and breadth of EHR-based data, facilitating the real-world study of HF in risk stratification, decision making, and disease management from multiple perspectives. Various HF risk models for predicting mortality have been developed abroad. The ADHERE risk tree by regression analysis [12] has demonstrated that patients with ADHF at low, intermediate, and high risk for in-hospital mortality can be easily identified using BUN, SBP, and creatinine obtained on hospital admission. The MUSIC risk model [49] showed that risk markers including atrial fibrillation, hyponatremia ≤138 mEq/L, N-terminal pro-brain natriuretic peptide >1.000 ng/L, and troponin positive were associated with cardiac mortality in a real-life setting. However, a limitation of the previous model is that it was based on a specific population of patients with HF (ie, symptomatic chronic HF). It should be noted that the etiology, clinical characteristics, and treatments of different phenotypes of HF are quite distinct. Therefore, we compiled all types of patients with HF in this study; it follows that the risk factors predicting mortality are likely to have been more comprehensive and provide new insights for further studies in specific subgroups. These markers possibly provide a more accurate risk evaluation of patients with HF, allowing early implementation of the appropriate intervention in daily public health practice, which leads to better outcomes in patients with HF.

There are several limitations to our study that are worth mentioning. First, this was an in-hospital outcome prediction study based on retrospective use of EHR-derived data. Although our models' performances were considerable on their own, the predictive power could be further adjusted and compared with the established reference tools. Second, the number of patients who died was small compared with the number of surviving subjects; although rich in terms of clinical variables, the imbalance problem remained. Third, validation in an external cohort was not done in the present study but is planned for subsequent analysis. Fourth, different phenotypes of patients with HF should be taken into account in further model developments.

Conclusion

EHR-driven models, using novel ML algorithms, were developed to predict 1-year in-hospital mortality, use of positive inotropic agents, and 1-year all-cause readmission in patients hospitalized with HF. The discrimination and performance of our models also outperformed the existing tools constructed using traditional techniques. Besides, identifying a greater range of variables can further improve decisions regarding risk assessment for patients with HF.

Abstract

Background: Multimodal recruitment strategies are a novel way to increase diversity in research populations. However, these methods have not been previously applied to understanding the prevalence of menstrual disorders such as polycystic ovary syndrome.

Objective: The purpose of this study was to test the feasibility of recruiting a diverse cohort to complete a web-based survey on ovulation and menstruation health.

Methods: We conducted the Ovulation and Menstruation Health Pilot Study using a REDCap web-based survey platform. We recruited 200 women from a clinical population, a community fair, and the internet.

Results: We recruited 438 women over 29 weeks between September 2017 and March 2018. After consent and eligibility determination, 345 enrolled, 278 started (clinic: n=43; community fair: n=61; internet: n=174), and 247 completed (clinic: n=28; community fair: n=60; internet: n=159) the survey. Among all participants, the median age was 25.0 (SD 6.0) years, mean BMI was 26.1 kg/m^2 (SD 6.6), 79.7% (216/271) had a college degree or higher, and 14.6% (37/254) reported a physician diagnosis of polycystic ovary syndrome. Race and ethnicity distributions were 64.7% (176/272) White, 11.8% (32/272) Black/African American, 7.7% (21/272) Latina/Hispanic, and 5.9% (16/272) Asian individuals; 9.9% (27/272) reported more than one race or ethnicity. The highest enrollment of Black/African American individuals was in clinic (17/42, 40.5%) compared to 1.6% (1/61) in the community fair and 8.3% (14/169) using the internet. Survey completion rates were highest among those who were recruited from the internet (159/174, 91.4%) and community fairs (60/61, 98.4%) compared to those recruited in clinic (28/43, 65.1%).

Conclusions: Multimodal recruitment achieved target recruitment in a short time period and established a racially diverse cohort to study ovulation and menstruation health. There were greater enrollment and completion rates among those recruited via the internet and community fair.

Introduction

Polycystic ovary syndrome, initially described in 1935 [1], is now considered the most common endocrine disorder in reproductive-aged women [2]. Affecting 10% to 15% [2], prevalence estimates range from as low as 8% [3] to as high as 26% [4], depending on the definition used and population studied. The disorder is characterized by clinical or biochemical androgen excess, menstrual irregularity, and the presence of polycystic ovarian morphology on ultrasound visualization [5]. Clinical androgen excess typically presents as acne, hirsutism, or androgenic alopecia [6-8]. Women with polycystic ovary syndrome may also experience infertility, insulin resistance, and obesity [9-12].

Existing research on polycystic ovary syndrome is typically conducted in either small clinical cohorts or larger epidemiologic studies. The latter have variable ascertainment of the disease or disease features which may increase misclassification of disease state and bias estimates of risk [13]. Preliminary studies on polycystic ovary syndrome in existing population-based cohorts such as the Nurses' Health Study 2, the Framingham Heart Study, and the Cape Cod Health Study were limited by poor correlation of polycystic ovary syndrome self-reports compared to medical records [14], too few reported cases of menstrual irregularity [15], and inadequate determination of phenotype [16], respectively. Inaccurate classification using single yes or no questions to identify women with polycystic ovary syndrome may bias estimates of the disease.

Existing epidemiologic cohorts were also limited with respect to race and ethnic diversity; more than 90% of participants were White in these 3 cohorts [16-18], thereby limiting the ability to detect differences in prevalence and etiological associations across racial and ethnic groups. Racial and ethnic-specific differences in androgen excess and metabolic syndrome symptoms are well established but the reasons for this are not well understood [19-21].

The Ovulation and Menstruation Health Pilot Study was conducted to (1) determine the feasibility of enrolling participants from diverse backgrounds using varied recruitment modalities, and (2) understand how survey completion status differed by participant characteristics.

Methods

Design

The Ovulation and Menstruation Health study website consists of a short animated educational recruitment video, a web-based consent form, screening questions, and a survey instrument. The animated video was designed to appeal to a diverse audience, as its illustrations included women of all races and body types. The goal of the Ovulation and Menstruation Health Pilot Study was to recruit at least 200 reproductive-aged women over a 1-year period. Those who were menstruating or had the capacity to menstruate were eligible (trans-male and other). Individuals who were <18 years or >45 years of age; identified as male; were pregnant at the time of the survey; had a hysterectomy/oophorectomy, amenorrhea due to radiation, or chemotherapy; or were unwilling or unable to provide an email address were deemed ineligible. The survey instrument was publicly accessible from August 21, 2017 to February 26, 2018 on the study website and was used in each recruitment modality. The Boston Medical Center and Boston University Medical Campus Institutional Review Boards approved the study (IRB H-35075).

Incentive

The first 200 participants who completed the survey were entered into a lottery for a US $200 gift card. All who were approached for recruitment were offered free earphones.

Recruitment

The multimodal recruitment locations were in clinic, a Boston-based community event, and the internet. The recruitment approach was adapted to meet the needs of each recruitment location.

In-Clinic

In-clinic recruitment occurred from September to October 2017. Approximately 2000 informational recruitment letters including the study website were sent during this recruitment period to patients with an upcoming visit to the Department of Obstetrics and Gynecology (OB/GYN) at Boston Medical Center (BMC). For 20 days, research assistants showed the study website and the promotional video via an electronic tablet to interested persons at 2 OB/GYN waiting rooms.

Community Event

A recruitment table was set up at the Boston Women's Market in the Jamaica Plain neighborhood of Boston on September 17, 2017. This community event was an opportunity for those who identify as female or supporters of women's causes to sell products from their small businesses.

Internet

Internet-based recruitment methods included sending out email communications, creating study social media engagement accounts, and sharing recruitment materials on individual social networks of the study staff. The study website and social media pages were discoverable on any internet search. Boston University Medical Campus (BUMC)–wide electronic communications, which included a brief description of the study, eligibility requirements, incentive, and study contact information, began in September 2017 and ran for the duration of the enrollment period. The study website link was shared on personal networks of study personnel (RM, MN, AW) with the Boston University Masters of Medical Science Class of 2018 and the Bates Feminist Collective Facebook groups in September 2017.

Physical flyers and business cards (paper materials) were posted around the BUMC campus for the duration of the study, and at Boston Skin Solutions, a center that treats excess facial and body hair on September 27, 2017.

Informed Consent, Screening, and Survey Initiation

The web-based consent form included questions on a participant's interest in follow-up surveys, other studies, and contributing biospecimens. Once consented, the individual was presented with an eligibility screener. Eligible participants recruited in clinic were able to start the survey in the waiting room. For eligible participants from the community event and the internet, a unique link to the survey was emailed to the participant's email address. For all enrolled participants, up to 3 reminders were sent on consecutive days to those who did not complete the survey.

Survey Description

The Ovulation and Menstruation Health Pilot Study survey had a total of 10 sections, with 219 questions; however, most respondents had fewer questions due to skip patterns. The About You section included questions on current residence and whether they ever received care at BMC. The Demographics section included questions on race and ethnicity, education, birth country, and income. The Anthropometrics section captured data regarding height, weight, and body shape using a pictorial tool. The Menstrual Cycle section asked about menarche, regularity of cycles, and cycle tracking. The Hormone Usage section obtained data on hormonal contraceptive usage, history and reasons for hormone usage. The Health and Body section included questions for self-reported androgen excess using a pictorial tool for androgenic alopecia and hirsutism based on the modified Ferriman-Gallwey scale [22]; polycystic ovary syndrome status (questions specific to polycystic ovary syndrome diagnosis, symptoms for diagnosis, and medication and supplement use, and family history of polycystic ovary syndrome); reproductive health (history of infertility, uterine fibroids, endometriosis, and premature ovarian failure); general health (diagnosed medical conditions such as hypertension, diabetes, and other chronic conditions and their treatment); diet and lifestyle (limited questions about alcoholic, nonalcoholic beverage consumption, and smoking habits); obstetric history (ever pregnant, number of prior pregnancies, and each pregnancy outcome, including stillbirths and miscarriages, and live births). For every livebirth, an additional question was asked regarding gestational length and birth outcomes such as birth weight. Study data were recorded and stored on encrypted servers at the Boston University School of Public Health Biostatistics & Epidemiology Data Analytics Center. The Ovulation and Menstruation Health Pilot Study survey can be found on the Harvard Dataverse [23].

Data Analysis

Participant characteristics were evaluated by recruitment location and survey completion. Those who started the survey via the internet included those who input the link into their web-browser after learning of the study from any web-based or printed recruitment materials and completed the web-based consent and screener. Survey initiation was defined as anyone who started the "About You" section. Survey completion was defined as having completed the first question of the "Pregnancy and Birth History" upon entering the total number of pregnancies experienced. Those who entered 0 pregnancies had no further questions to complete. Those who entered 1 or more had additional pregnancy related questions to complete. For both nulliparous and multiparous responses, completing the survey was as entering the total number of pregnancies experienced. To assess the geographical catchment area associated with the survey, participants' self-reported home states were mapped.

Results

Recruitment and Enrollment

Recruitment exceeded our target of 200 women in 8 weeks. During the 6-month recruitment window, 438 women began the consent process, 384 were assessed for eligibility, and 345 women were screened and included (88.7% of those assessed for eligibility). Of the 345, 278 women started the survey, of whom 66 were recruited in clinic, 61 were recruited from the community event, and 174 were recruited from the internet. Figure 1 displays the study enrollment flow chart. Spikes in cumulative enrollment coincided with the active in-clinic recruitment and the community event (Figure 2). Out of the 384 participants who consented and completed screening, only 39 (10.2%) were excluded. Of the individuals who were excluded, 18 were no longer menstruating, 16 were unwilling or unable to provide email addresses, and 5 were over the age of 45 years. Among those who initiated the survey and responded to re-contact questions, agreement for re-contact was high—96.0% (266/277) consented to be re-contacted for additional information, 81.2% (225/277) for biological samples, 96.4% (267/277) for a follow-up survey, and 79.4% (220/277) for a different research study.

Figure 1. Flowchart of participants enrolled in the Ovulation and Menstruation Health Pilot Study.

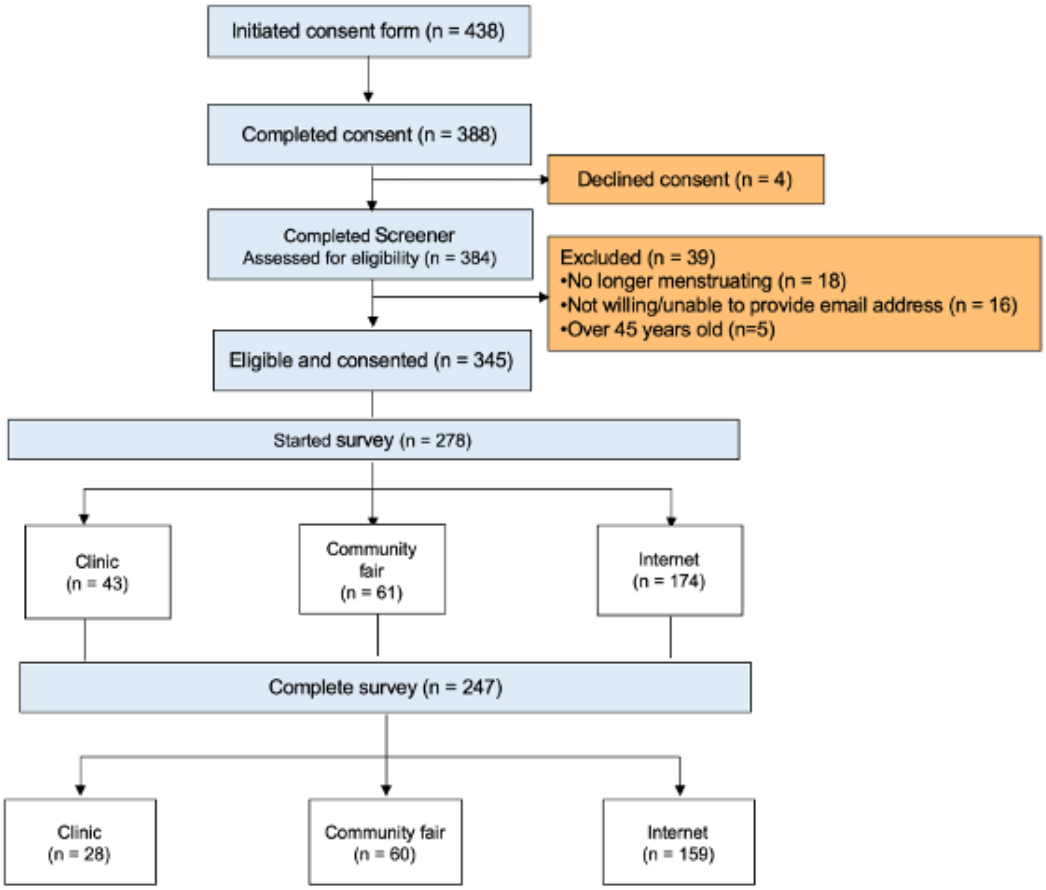

Figure 2. Ovulation and Menstruation Health Pilot Study enrollment graph.

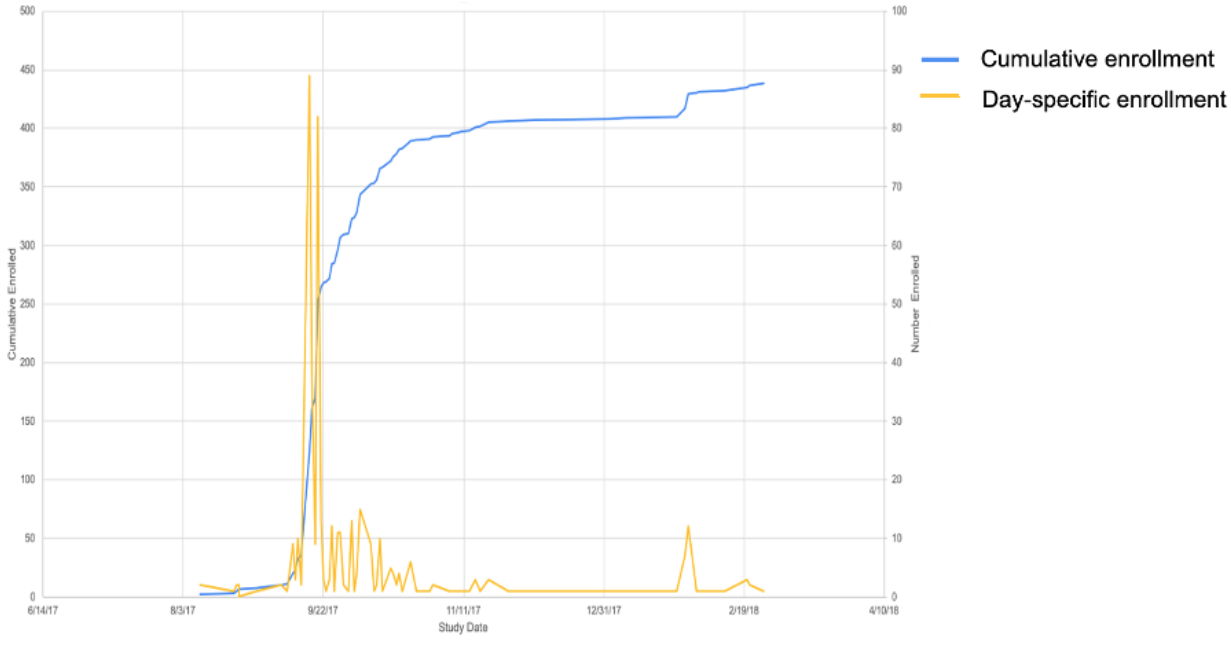

Participant Characteristics

Among the 278 women who started the survey, the average age was 27.3 years and the median age was 25.0 (SD 6.0), with the majority (224/273, 82.1%) born in the United States (Table 1). Participants were White (176/272, 64.7%), Black/African American (32/272, 11.8%), Latina/Hispanic (21/272, 7.7%), and mixed race (27/272, 9.9%). Two individuals identified their

gender as other (nonbinary or gender queer). While the majority (216/271, 79.7%) had a 4-year college degree or more, 7.0% (19/271) had a high school degree or less education. Participants were distributed across all income categories, with 21.3% (58/272) in the less than $25,000 category. The mean BMI was 26.1 kg/m^2 (SD 6.6), with 15.4% (41/266) in the overweight category; 13.1% (32/245) had smoked at least 100 cigarettes over their lifetime. The reported prevalence of doctor-diagnosed polycystic ovary syndrome was 14.6% (37/254), and 82.3% (218/265) had ever used hormonal contraception. The geographic distribution of the cohort included 20 states (Figure 3). The majority of the participants were recruited from Massachusetts (n=173) and Missouri (n=50).

Figure 3. Ovulation and Menstruation Health Study participant population map.

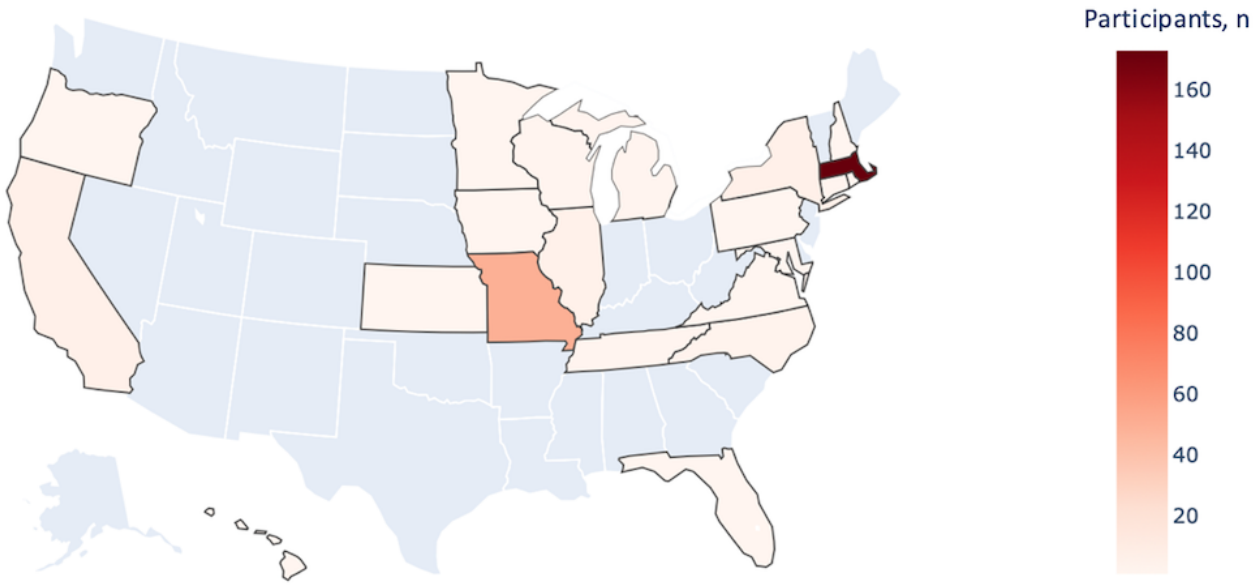

Table 1. Demographics in the Ovulation and Menstruation pilot study.

Characteristic	Value (n=278[a])
Age (years), median (SD)	25.0 (6.0)
Born in the United States, n (%)	224 (82.1)
Race, n (%)	
White	176 (64.7)
Latina/Hispanic	21 (7.7)
Black/African American	32 (11.8)
Asian	16 (5.9)
More than one race	27 (9.9)
Educational attainment, n (%)	
High school graduate/GED or less education	19 (7.0)
Some college or 2-year degree	36 (13.3)
4-year college graduate	101 (37.3)
More than 4-year college degree	115 (42.4)
Total annual household income, n (%)	
Below $25,000	58 (21.3)
$25,000 to $49,999	70 (25.7)
$50,000 to $74,999	44 (16.2)
$75,000 to $99,999	20 (7.4)
$100,000 or more	43 (15.8)
Prefer not to answer	17 (6.3)
Don't know	20 (7.4)
Smoked at least 100 cigarettes over lifetime, n (%)	32 (13.1)
BMI[b], n (%)	
Underweight (<18.5 kg/m^2)	8 (3.0)
Normal weight (18.5-24.9 kg/m^2)	153 (57.5)
Overweight (25.0-29.9 kg/m^2)	41 (15.4)
Obese (≥30.0 kg/m^2)	64 (24.1)

Population Demographic Characteristics by Recruitment Location

Differences were found in age, birth country, race, educational attainment, BMI, and physician-diagnosed polycystic ovary syndrome, by location of recruitment (Table 2). Women recruited in clinic tended to be older (median 34.0 years, SD 6.7), born outside the US (26/42, 61.9%), and with lower educational attainment, 19.0% (8/42) were high school graduate/GED or less education compared to women recruited at the community fair and via the internet. Women recruited in clinic were also more likely to be obese (18/38, 47.4%), have had a physician diagnosis of polycystic ovary syndrome (12/33, 36.4%), and less likely to have ever used oral contraceptives (23/37, 62.2%) compared to women recruited at the community fair and via the internet. Those from the community fair and internet were more likely to be born in the US (58/61, 95.1% and 150/170, 88.2%, respectively), White (47/61, 77.0% and 121/169, 71.6%, respectively), and have greater than a 4-year college degree (24/61, 39.3% and 83/168, 49.4%, respectively) than those recruited from the clinic. Women recruited from outside the clinic were younger (community fair: median 23.0, SD 4.0; internet: median 25.0, SD 5.4 years), leaner BMI (community fair: 23.3 kg/m^2 SD 4.8; internet: 23.5 kg/m^2 SD 7.0) and had a lower prevalence of physician diagnosed polycystic ovary syndrome (community fair: 3/61, 4.9%; internet: 22/160, 13.8%). Of note, 46.4% of women recruited in clinic (13/28) had been pregnant compared to 3.3% (2/61) and 17.0% (27/159) for the community fair and internet participants, respectively. Income and smoking status were similar among recruitment locations.

Table 2. Demographic characteristics by recruitment location.

Characteristic	Location		
	Clinic (n=43)[a]	Community fair (n=61)[b]	Internet (n=174)[c]
Age (years), median (SD)	34.0 (6.7)	23.0 (4.0)	25.0 (5.4)
Born in the United States, n (%)	16 (38.1)	58 (95.1)	150 (88.2)

Survey completed, n (%)	28 (65.1)	60 (98.4)	159 (91.4)

[a]Missing—born in the US: n=1 (2.3%); race: n=1 (2.3%); education: n=1 (2.3%); income: n=1 (2.3%); smoking status: n=15 (34.9%); BMI: n=5 (11.6%); polycystic ovary syndrome diagnosis: n=10 (23.3%); ever pregnant: n=15 (34.9%); hormonal contraceptive: n=6 (14.0%); self-rated current health: n=6

(14.0%).

[b]Missing—smoking status: n=1 (1.6%).

[c]Missing—born in the US: n=4 (2.3%); race: n=5 (2.9%); education: n=6 (3.5%); income: n=5 (2.9%); smoking status n=17 (9.8%); BMI: n=7 (4.0%); polycystic ovary syndrome diagnosis: n=14 (8.1%); ever pregnant: n=15 (8.6%); hormonal contraceptive: n=7 (4.0%); self-rated current health: n=10 (5.7%).

[d]BMI: body mass index.

[e]Gravidity among women who were ever pregnant (n=42).

Survey Completion

Among the 278 women who started the survey, 247 (88.8%) completed it. The median time to completion was 12.6 minutes (range 1.03 minutes to 92 days); 7 participants took more than 24 hours to complete the survey. Women completing the survey were more likely to be US born (210/246, 85.4% vs 14/27, 51.9%), White (165/245, 67.3% vs 11/27, 40.7%) and have 4 years of college education or more (200/244, 81.9% vs 16/27, 59.2%) compared to those who did not complete the survey (Table 3).

We also found that the women who did not complete the survey were older and had higher annual household income compared to those who completed the survey. Among the 31 women who did not complete the survey, dropout seemed equally distributed across section categories (Figure 4).

Table 3. Demographic characteristics by survey completion status (N=278).

Characteristic	Complete (n=247)[a]	Incomplete (n=31)[b]
Age (years), median (SD)	25.0 (5.7)	29.0 (7.4)

Discussion

We determined the feasibility of a multimodal recruitment approach for a study of ovulation and menstruation health by comparing in-clinic, community-based, and internet-based recruitment activities. Among the recruitment modalities, the majority of women were recruited via the internet after encountering advertising materials informing them of the study website. The race and ethnicity of the cohort was notably similar to the US population [24]. Based on census data from 2018, the US population was comprised of 166,038,755 women which was 50.8% of the total population. Of those women, 60.3% were White, 17.8% were Latina or Hispanic, 12.9% were Black or African American, 5.9% were Asian, and 2.2% identified as being of more than one race [24].

The participant characteristics did differ by recruitment location, suggesting that multimodal recruitment is a feasible solution to increase the variation in participant characteristics including race, ethnicity, and health characteristics such as BMI, oral contraceptive use, and whether physician diagnosed. These different characteristics may reflect differences in the source population. For example, approximately 59% of the patients at BMC come from an underserved population [25], whereas the community event was held in Jamaica Plain, a neighborhood that has a 53.6% White population and a median household annual income of $55,861 [26]. While use of the internet usage demographics are reported as 92% of White, 86% of Hispanic, and 85% of Black individuals in the US [27], those accessing the study via the internet were recruited through flyers, email communications, and personal social media networks. The geographic distribution of the participants was notable for the majority in Massachusetts, with second-highest participation in Missouri, corresponding to the personal network of 1 research assistant.

Similarly, another study [28] was also successful in recruiting racially and ethnically diverse participants using a combination of 340 recruitment sites and digital campaigns. Among the core participants of that study [28], 51% were considered non-White, whereas participants in traditional reproductive health cohorts have been 83% Caucasian [29] and 89% White [14]. Furthermore, while participants from the original Framingham Heart Study were 100% White, racial diversity increased in subsequent studies with inclusion of 28% African American, 42% Hispanic American, and 24% Asian American participants within the Framingham-related Omni Cohort [30].

The completion rate among those who started our survey (247/278, 88.8%) was high. This completion rate is comparable to those of the Pregnancy Study Online [29], with 72% of enrolled participants completing the baseline survey, and the most recent Framingham Heart Study [31], with participants using an electronic survey (85% completion). It is possible that our survey was shorter than those used in those studies [29,31] and as such had a slightly higher completion rate. Furthermore, the Ovulation and Menstruation Health survey was designed for an 8th grade reading level and underwent cognitive and usability testing to facilitate question comprehension [32], potentially supporting a pleasant participant experience. While participants could skip any question, the rate of missing responses was low. Birthplace outside of the US was a key

variable noted to be missing among a small proportion of women who did not complete the survey.

This study has several strengths. We achieved target recruitment in half the expected time, which may have been due to the appealing web-based study platform that included an educational cartoon featuring women from multiple backgrounds or the monetary incentive. Use of a cognitively tested survey designed for an 8th grade reading level may also have facilitated the high completion rate. The broad inclusion criteria also allowed for those with and without polycystic ovary syndrome to be included. Most importantly, the multimodal recruitment approach enabled us to recruit a more diverse cohort, which is comparable to those in other studies using a similar multimodal recruitment strategy for other health conditions [33].

However, the study also has some key limitations. While racial and ethnic diversity were improved compared to existing large epidemiologic cohorts, the proportion of Latina or Hispanic women was slightly lower than that in the US population, possible due to language access issues. We recently translated the Ovulation and Menstruation Health Platform for availability in Spanish language to test in future studies. Also, completion rate by those born outside the US may be improved by having the survey in the primary language of the participant. In the future, using paid advertisements may not only lead to high click-through rates to the study website, but may also provide for a unique opportunity to engage with specific targeted demographics depending on advertisement dissemination. For example, the Nurses' Health Study 3 [17] sent recruitment postcards to minority-dense zip codes doubling the enrollment rate of African American and Hispanic women.

Furthermore, we considered whether bias in multimodal recruitment exists. We do not believe that multimodal recruitment increased the likelihood of selection bias since enrollment would need to be related to both the exposure and outcome under study for such a bias to occur [34-37]. The multimodal recruitment strategy increases the generalizability of the study and increases its ability to examine effect measure modification by racial and ethnic group by ensuring sufficient numbers in each category. Because differences exist in racial or ethnic-specific risks for a variety of health outcomes potentially due to structural racism and other inequities [38], a multiethnic cohort is needed to assess health outcomes subsequent to polycystic ovary syndrome diagnosis and to determine ideal windows for risk-reducing interventions.

Multimodal recruitment was feasible and established a more racially and ethnically diverse cohort for the study of ovulation and menstruation health than those of prior studies [14,28,29]. Samples from 3 different recruitment locations demonstrated variability in racial, ethnic, and other demographic and health-related features.

Abstract

Background: Most patients use the internet to search for health information. While there is a vast repository of searchable information online, much of the content is unregulated and therefore potentially incorrect, conflicting, or confusing. Abortion information online is particularly prone to being inaccurate as antichoice websites publish purposefully misleading information in formats that appear as neutral resources. To understand how antichoice websites appear neutral, we need to understand the specific website features of antichoice websites that impart an impression of trustworthiness.

Objective: We sought to identify the characteristics of false or misleading abortion websites that make these websites appear trustworthy to the public.

Methods: We conducted a cross-sectional study using Amazon's Mechanical Turk platform. We used validated questionnaires to ask participants to rate 11 antichoice websites and one neutral website identified by experts, focusing on website content, creators, and design. We collected sociodemographic data and participant views on abortion. We used a composite measure of "mean overall trust" as our primary outcome. Using correlation matrices, we determined which website characteristics were most associated with mean overall trust. Finally, we used linear regression to identify participant characteristics associated with overall trust.

Results: Our analytic sample included 498 participants aged from 22 to 70 years, and 50.1% (247/493) identified as female. Across 11 antichoice websites, creator confidence ("I believe that the creators of this website are honest and trustworthy") had the highest correlation coefficient (strongest relationship) with mean overall trust (coefficient=0.70). Professional appearance (coefficient=0.59), look and feel (coefficient=0.59), perception that the information is created by experts (coefficient=0.59), association with a trustworthy organization (coefficient=0.58), valued features and functionalities (coefficient=0.54), and interactive capabilities (coefficient=0.52) all demonstrated strong relationships with mean overall trust. At the individual level, prochoice leaning was associated with higher overall trust of the neutral website (B=−0.43, 95% CI −0.87 to 0.01) and lower mean overall trust of the antichoice websites (B=0.52, 95% CI 0.05 to 0.99).

Conclusions: The mean overall trust of antichoice websites is most associated with design characteristics and perceived trustworthiness of website creators. Those who believe that access to abortion should be limited are more likely to have higher mean overall trust for antichoice websites.

KEYWORDS

abortion; website trust; internet use; reproductive health; misinformation

Introduction

Most patients use the internet to search for health information [1-3]. While there is a vast repository of searchable information online, much of the content is unregulated and therefore has potential to be incorrect, conflicting, or confusing. As such, the accuracy of online health information remains variable [4]. Despite warnings that patients should remain cautious when accessing health-related websites, patients often view inaccurate health information encountered online as trustworthy [5,6].

Abortion is one of the most common medical services in the world, with approximately 30 million safe abortions accessed annually [7]. Although the abortion rate in the United States (abortions per 1000 females aged 15 to 49 years) has declined over the last decade, internet searches for abortion-related information have steadily increased [8,9]. As the demand for online abortion information rises, many top search results contain incorrect and misleading information [10]. Many misleading websites are created by crisis pregnancy centers (CPCs) and other antichoice organizations, which seek to dissuade patients from accessing abortion and other reproductive health care services [11]. These websites provide deliberately incorrect information about reproductive health, including abortion, often by overstating the risks of abortion and contraceptive options [12,13]. In addition, these antichoice organization websites often appear neutral in order to intercept patients who are potentially seeking an abortion [14].

Previous research identified website design and layout, interactive features, tone or partiality of content, owner's authority, and the website's relationship with an organization or sponsor as key elements impacting the perceived trustworthiness of a website [15-25]. Abortion websites may utilize these characteristics to make the misinformation they seek to perpetuate seem trustworthy. It is therefore important to understand what features of abortion websites impact trustworthiness. In this study, we sought to identify the characteristics of false or misleading abortion websites that make these websites appear trustworthy to the public.

Methods

Recruitment

We conducted a cross-sectional study using an anonymous online survey. We recruited respondents between March 14, 2019, and April 8, 2019, via Amazon's Mechanical Turk (MTurk) platform. MTurk is an online crowdsourcing tool that recruits anonymous users to participate in a variety of computer-based tasks, including assessment of web content [26]. Participants were eligible to respond if they were over 18 years of age, English speaking, and given the "Masters Qualification" by MTurk. Amazon designates participants as "Masters" if they demonstrate reliability in completing a large number and variety of tasks posted by different requesters [27]. We advertised the survey task as "Public Opinion about Abortion Websites." We compensated participants US $2.50 to complete the assignment. After the first 425 responses, we increased compensation to US $3.00 for the final 75 responses in order to increase recruitment. Participants were limited to responding to the survey once based on their unique worker ID number that is assigned by Amazon and is attached to their taxpayer number [27]. The study was reviewed and approved by the Oregon Health & Science University institutional review board.

Website Selection

We selected our websites from a database of abortion websites used in a previous study [10]. For each website in that database, three investigators determined the slant (prochoice, neutral, or antichoice) and slant clarity (easy, moderate, or difficult to determine website slant) based on their impression of the website. All three researchers have published abortion-related research. We then selected 11 websites categorized as both "antichoice" and "difficult to determine" in slant (Multimedia Appendix 1). These 11 antichoice websites included one state government website (Alaska Department of Health and Social Services), four CPC pages associated with brick and mortar establishments, and six websites that detail abortion risks and side effects. We included one website that was rated as being "neutral" in slant and "easy to determine" in slant clarity (The Louisiana Department of Public Health website on "Methods & Medical Risks"). We selected the Louisiana website as a comparator for the antichoice websites.

We used previously validated studies measuring website trust [17-20,24,25] to develop our survey (Table 1). We included items across the following four domains: creators, design, content, and overall trust (Table 1). Participants viewed each website and responded to statements about website characteristics using a 7-point Likert scale ranging from −3 ("strongly disagree") to 3 ("strongly agree") [20,21,25,28]. We assigned each participant to assess three randomly selected antichoice websites and the Louisiana website. Therefore, all participants viewed the Louisiana website but only a subset of participants viewed each of the 11 antichoice websites. Our survey displayed all four websites in random order, and users had 18 minutes to complete the survey and rate all four websites.

Table 1. Website questions.

Category	Question number	Question tag	Statement about the website characteristic
Creators	q0	Creator confidence	I believe that the creators of this website are honest and trustworthy.
Creators	q1	Expert quote	There are experts quoted or referenced on this website.
Creators	q2	Organization	This website notes an association with a trustworthy organization.
Creators	q3	Expert info	Experts wrote information on this website.
Creators	q4	Nonprofit	This website is run by a nonprofit organization.
Design	q5	Interactive	I like the interactive aspects of this website.
Design	q6	Images	I like the use of images on this website.
Design	q7	Up to date	This website appears up to date.
Design	q8	Ads	I can distinguish ads from website content.
Design	q9	Look	I like the look and feel of this website.
Design	q10	Features	This website includes all relevant features/functionalities that I value on websites.
Design	q11	Design	The design of this website is similar to websites I like to use.
Design	q12	Professional	This website appears professional.
Design	q13	Navigate	This website is easy to navigate.
Content	q14	Errors	This website contains errors (spelling or grammar, not accuracy of content).
Content	q15	Address	This website provides an address or phone number.
Content	q16	Contact	This website makes it easy to contact its creators.
Content	q17	Promotional	This website has limited advertising or other promotional material.
Overall trust	q18	Info trust	I trust information from this website.
Overall trust	q19	Quality	Overall, this website is a quality resource.
Overall trust	q20[a]	Biased	This website is biased.
Overall trust	q21	Recommend	I would recommend this page to a friend who is searching for information on this topic.

[a]Question 20 was removed from the overall trust domain owing to poor correlation with other overall trust questions.

We compiled our primary outcome (“mean overall trust”) by averaging three of the four items comprising the overall trust domain. During analysis, we excluded one item “this website is biased” from the primary outcome owing to low correlation with the other questions in the trust domain. We reverse coded responses to items 14 “this website contains errors” and 20 “this website is biased,” so that all positive Likert scale responses become markers of a favorable characteristic.

After participants evaluated all four websites (responses were not required to move on to the next question), we asked sociodemographic questions, including questions on age, race/ethnicity, gender, educational background, state of residence, residential density (rural, urban, and suburban), and internet use (hours per week online) [29]. Unfortunately, an error in the MTurk survey assigned Alabama to those who did not respond to the item regarding state of residence. Finally, we asked about views on abortion, including whether abortion should be legal (no law limiting abortion, some limits, severe limits, or should be illegal in all circumstances) and self-rated abortion knowledge (1-10, with 1 being no knowledge and 10 being expert knowledge).

Analysis

We used RStudio Version 1.2.1335 for all analyses [30]. We used descriptive statistics to characterize the overall demographics of our participants. Due to small numbers, we collapsed race and ethnicity into a binary category (white vs not white). We then conducted analyses for individual items and domains at the website level and multivariate analysis to determine relationships between demographic variables and overall trust.

For each website, we calculated mean scores for responses to the individual items as well as composite means for the four domains, including the primary outcome of mean overall trust. We tested bivariate associations between mean overall trust and each survey item from Table 1. We used correlation coefficients to measure the strength of the relationship of each individual item in the survey with the items comprising the “overall trust” category (info trust, quality, and recommend) as well as mean overall trust itself. Correlation coefficient scores range from “1” (perfect positive correlation) to “−1” (perfect negative correlation), with “0” meaning there is no correlation between two items. In order to test the robustness of our findings, we assessed these correlations in the following three ways: for all 12 websites combined, for the antichoice websites combined,

and for the prochoice Louisiana website alone. We set 0.5 as the cutoff for a "marked" correlation and considered coefficients between 0.4 and 0.5 as indicating "medium" correlation [31].

Last, we used linear regression to identify participant characteristics associated with mean overall trust, where mean overall trust was treated as a continuous variable. We excluded participants with missing items in the trust domain from multivariate modeling (36/498). We created two models. One model was created for the antichoice websites, and another for the Louisiana website alone in order to compare model findings stratified by slant. Variables in our model included race, age, self-rated abortion knowledge, abortion views, hours spent on the internet per week, educational attainment, and residential density. We selected these covariates based on bivariate relationships and prior literature suggesting that these variables impact website trust [24].

Results

Sample

We obtained surveys from 500 participants and excluded only two respondents who did not complete 50% of the website survey questions. We included all other partial responses. Of the 498 respondents, 403 (80.9%) completed all questions for all four websites. Of the 95 incomplete surveys, 53 (56%) missed only one item on one website and fully completed the other three website evaluations. An additional 20 (21%) missed two or three items total across the four websites. A total of 6 (6%) participants missed all 22 items from one website but completed all items from the other three websites.

Participant Characteristics

Full demographic characteristics are shown in Table 2. Respondent age ranged from 22 to 70 years, and 50.1% (247/493) identified as female. Just over half (279/495, 56.3%) of the respondents attained at least a bachelor's degree. The majority of our respondents were white (327/495, 66.1%), and an additional 20% identified as Asian. Participants were distributed across the US census region, with 16.7% (83/498) from the Northeast, 34.7% (173/498) from the South, 19.5% (97/498) from the Midwest, 20.1% (100/498) from the West, and 9.1% (45/498) not from the United States (Table 2). The MTurk error makes it likely that 34.7% is higher than the true proportion of respondents who are from the South. On average, respondents reported spending 35.6 hours per week on the internet (95% CI 1.0-72.8). The majority of participants self-identified as prochoice, with 80.3% (399/497) indicating that there should only be some limits or no law limiting access to abortion. We found self-reported abortion knowledge in our participants to be normally distributed with a mean of 5.9/10 (95% CI 2.4-9.4).

Table 2. Sample characteristics.

Demographics	Value, n (%) or mean (SD; min-max)
Gender (N=493)	
Female	247 (50.1)
Male	245 (49.7)
Other	1 (0.2)
Education (N=495)	
Less than high school and high school	60 (12.1)
Some college/associates	156 (35.12)
Bachelor's degree	213 (43.0)
More than bachelor's degree	66 (13.3)
Location (N=489)	
Rural	100 (20.5)
Suburban	215 (44.0)
Urban	174 (35.6)
Region (N=498)	
Northeast	83 (16.7)
South[a]	173 (34.7)
Midwest	97 (19.5)
West	100 (20.1)
Not United States	45 (9.1)
Race (N=495)	
White	327 (66.1)
Non-white	168 (33.9)
Access (N=497)	
No law	182 (36.6)
Some limits	217 (43.7)
Severe limits	68 (13.7)
Illegal	30 (6.0)
Other	
Age (years)	37.9 (9.9; 22-70)
Abortion knowledge score	5.9 (1.8; 1-10)
Internet hours	35.6 (19.0, 1-107)

[a]Those who left the region question blank were coded as from Alabama and subsequently the South.

Website Outcomes

Mean scores were calculated for each of the four domains (content, creators, design, and overall trust). The mean score of the overall trust domain is the primary outcome of mean overall trust. Domain scores ranged from −0.66 to 1.89, where −3 is highly unfavorable and 3 is highly favorable (Table 3). For the primary outcome of mean overall trust, the Louisiana State Health website had the highest score (1.89) and smallest standard deviation (1.27) (Table 3). In addition, the Louisiana State Health website had the lowest standard deviations in the content (1.27) and design (1.65) domains. By comparison, the Alaska State Health website received the highest score among all websites for creators (1.41), a high score for mean overall trust (1.63), and lower scores for content (1.05) and design (0.97) (Table 3).

Table 3. Responses by domain.

Website	Domain score[a], mean (SD)			
	Content	Creators	Design	Mean overall trust
Louisiana[b]	1.77 (1.44)	1.31 (1.64)	1.30 (1.65)	1.89 (1.27)
Abortion Facts	0.23 (1.80)	0.32 (1.88)	0.11 (1.88)	−0.24 (1.79)
Abortion Pill Risks	0.30 (1.70)	0.39 (1.91)	0.48 (1.91)	−0.04 (1.85)
Abortion Risks	0.41 (1.71)	0.99 (1.71)	0.32 (1.91)	0.49 (1.79)
Alaska	1.05 (1.70)	1.41 (1.58)	0.97 (1.77)	1.63 (1.38)
AmerPreg	1.26 (1.54)	0.97 (1.76)	1.04 (1.67)	0.92 (1.72)
Baby Gaga	0.02 (1.71)	−0.15 (1.64)	0.56 (1.80)	0.09 (1.80)
CareNet	1.61 (1.43)	0.55 (1.67)	1.16 (1.64)	0.92 (1.61)
PregCenter	1.77 (1.42)	0.82 (1.72)	1.61 (1.31)	1.45 (1.49)
RamaInternat	0.59 (1.75)	0.37 (1.80)	0.67 (1.80)	0.37 (1.89)
U Pregnancy	−0.14 (1.67)	−0.54 (1.62)	−0.23 (1.83)	−0.66 (1.59)
WomenRes	1.70 (1.46)	0.70 (1.89)	1.05 (1.71)	1.11 (1.73)

[a]For each item, the maximum rating is +3 and minimum rating is −3.

[b]The Louisiana website is displayed as a neutral website.

Eight of the 11 antichoice websites were associated with a positive mean overall trust score (Table 3). Abortion Facts, Abortion Pill Risks, and U Pregnancy received negative scores for mean overall trust, ranging from −0.66 to −0.04. In addition, Baby Gaga received a score of −0.15 in the creators domain and U Pregnancy received scores of −0.14 for the content domain, −0.54 for the creators domain, and −0.23 for the design domain.

Pooled correlation coefficient matrices were used to compare each item to the three items included in the primary outcome of mean overall trust as well as to the primary outcome of mean overall trust (Table 4, Table 5, and Table 6). We assessed if the correlation between website characteristics and mean overall trust was different for the antichoice websites and the neutral Louisiana website. For both the antichoice websites and the Louisiana website, the creator confidence item ("I believe that the creators of this website are honest and trustworthy") correlated most highly with mean overall trust (Table 5 and Table 6). For the Louisiana website, we found that the creator confidence item was the only item markedly correlated with mean overall trust (coefficient=0.66) (Table 6). In contrast, for the antichoice websites, professional appearance (coefficient=0.59), look and feel (coefficient=0.59), perception that the information is created by experts (coefficient=0.59), association with a trustworthy organization (coefficient=0.58), valued features and functionalities (coefficient=0.54), and interactive capabilities (coefficient=0.52) all demonstrated marked relationships with mean overall trust. Up-to-date appearance (coefficient=0.50), overall design (coefficient=0.49), ability to navigate the website (coefficient=0.48), and presence of images (coefficient=0.46) had medium correlation with mean overall trust. We found no correlation between presence of spelling or grammar errors and mean overall trust (coefficient=−0.07) (Table 5).

Multivariate Analysis

We performed multivariate analysis to identify associations between participant demographics and the primary outcome of mean overall trust. We found that preference for fewer abortion restrictions was associated with higher mean overall trust of the Louisiana website (*B*=−0.43, 95% CI −0.87 to 0.01) and with lower mean overall trust of the antichoice websites (*B*=0.52, 95% CI 0.05-0.99) (Table 7 and Table 8). In addition, white race was associated with lower mean overall trust of the antichoice websites (*B*=−1.41, 95% CI −2.26 to −0.55) (Table 8). Other participant characteristics were not associated with mean overall trust.

Table 7. Association between individual demographic factors and the primary outcome of mean overall trust (N=462) for the Louisiana website.

Variable	Estimate	95% CI
Intercept	5.16	2.75 to 7.57
White race	0.36	−0.45 to 1.16
Age	0.004	−0.03 to 0.04
Abortion knowledge	0.14	−0.05 to 0.32
Internet hours	0.0003	−0.02 to 0.02
Abortion access	−0.43	−0.87 to 0.01
Education	0.09	−0.32 to 0.50
Urban residence	0.05	−0.90 to 1.00
Suburban residence	−0.43	−1.35 to 0.49

Table 8. Association between individual demographic factors and the primary outcome of mean overall trust (N=462) for all websites except the Louisiana website.

Variable	Estimate	95% CI
Intercept	−0.49	−3.09 to 2.11
White race	−1.41	−2.26 to −0.55
Age	−0.008	−0.05 to 0.03
Abortion knowledge	0.33	0.13 to 0.53
Internet hours	0.01	−0.01 to 0.03
Abortion access	0.52	0.05 to 0.99
Education	0.08	−0.35 to 0.52
Urban residence	0.10	−0.92 to 1.13
Suburban residence	−0.58	−1.56 to 0.40

Discussion

In this study, we analyzed which characteristics of antichoice websites are highly correlated with mean overall trust. User opinion of website creators had the strongest correlation with mean overall trust, but esthetic and website interface factors were also important. Moreover, even with our predominantly prochoice respondent pool, eight out of the 11 antichoice websites received positive mean overall trust scores, consistent with their selection as websites with "difficult to determine" slant. We also found that a viewer's stance on abortion is inversely related to the mean overall trust of antichoice websites. If participants believed that abortion should be limited or banned, they were more likely to have higher mean overall trust in websites with incorrect information.

To examine the importance of website creators, we compared the high-quality neutral-stance Louisiana state health website with the poor-quality antichoice Alaska state health website. While the antichoice Alaska website received lower scores in the content, design, and overall trust domains than the neutral Louisiana website, the Alaska website received a higher score in the creators domain (1.41 vs 1.31) and was rated as the website with the second highest mean overall trust. Furthermore, we found that design items were less correlated with mean overall trust for the Alaska website than they were for the other antichoice websites. It is reasonable that users would be inclined to assume that an official state health website is trustworthy. Our results suggest that the belief that a website creator is trustworthy can override other aspects of the website with decreased vigilance to lower quality content.

To attract users, antichoice websites use a full array of internet tools that draw from all trust domains to give the impression of credibility [11]. In our study, nine out of 11 antichoice websites received a positive score for the creators domain. These websites use strategies similar to those that brick and mortar CPCs use, such as deceptive advertising, to attract patients [32]. While brick and mortar CPCs often present as though they offer services similar to abortion clinics (ultrasound, "options" counseling, and procedures), the online websites rely on website cues that resemble high-quality resource websites. For instance, many antichoice websites use generic URL titles like "americanpregnancy.org" and include features like "FAQs" that resemble accurate informational websites, but contain misleading information that misrepresents rare or impossible adverse outcomes and fail to refer patients to clinics that provide abortion care. Our findings support that these methods are effective by demonstrating that a website is more likely to have high mean overall trust scores if its appearance and design are highly rated.

Our trends are consistent with prior literature including research examining user trust in other online health contexts [17-20,24,25]. Shanley et al conducted a qualitative study on the perceptions of abortion websites and found that creator expertise and affiliation with an organization were important criteria when assessing website trustworthiness [25]. In addition, several studies describing the impact of health website characteristics on credibility noted that creator "authority" and esthetic attributes, such as design, are associated with trustworthiness [19,21,24]. Of note, several studies indicated that page ranking of search results affects user trust scores [15,20]. On Google web search, many CPC websites pay to become promoted search items and appear at the top of the page [33]. In response to CPC website tactics, reputable organizations should tackle search engine optimization, clearly identify website creators, and prioritize website design.

Our findings should be interpreted with several limitations. We only reviewed a limited sample of antichoice websites and compared them to a single standard "neutral website" in order to learn how these websites are perceived. However, our websites were selected from those most commonly found on a web search, and thus, they are more likely to be seen by the general public. Moreover, compared to prior studies that used qualitative interviews and contained small convenience samples, each one of our websites received over 130 unique evaluations from across the entire country [25]. Our participant pool leaned toward white, higher-educated, and prochoice individuals, consistent with previous studies on how MTurk workers may be demographically skewed [34-36]. However, there is evidence to suggest that MTurk studies are as reliable as studies involving other survey platforms [37,38]. Our study population was diverse as it included a nearly equal number of male and female participants, a wide age range, and participants from all US census regions. Furthermore our multivariate analysis allowed

us to control for many demographic characteristics. Finally, our study did not allow us to determine if causality exists between different website factors and mean overall trust scores. For example, study participants may have chosen to give high scores to all items for websites they regarded as trustworthy. However, many of our websites had low mean overall trust scores but still received high ratings for items in other domains.

This study highlights the characteristics of antichoice websites that are most associated with user trust and demonstrates that many antichoice websites are viewed as trustworthy by a lay audience. People who seek online medical information about abortion may be susceptible to deceptive websites and misinformation. For organizations and individuals seeking to disseminate accurate information about abortion, this study underscores that attention should be directed toward highlighting the credentials of website creators in addition to providing evidence supporting website content.

Abstract

Background: Digital phenotyping, the measurement of human behavioral phenotypes using personal devices, is rapidly gaining popularity. Novel initiatives, ranging from software prototypes to user-ready research platforms, are innovating the field of biomedical research and health care apps. One example is the BEHAPP project, which offers a fully managed digital phenotyping platform as a service. The innovative potential of digital phenotyping strategies resides among others in their capacity to objectively capture measurable and quantitative components of human behavior, such as diurnal rhythm, movement patterns, and communication, in a real-world setting. The rapid development of this field underscores the importance of reliability and safety of the platforms on which these novel tools are operated. Large-scale studies and regulated research spaces (eg, the pharmaceutical industry) have strict requirements for the software-based solutions they use. Security and sustainability are key to ensuring continuity and trust. However, the majority of behavioral monitoring initiatives have not originated primarily in these regulated research spaces, which may be why these components have been somewhat overlooked, impeding the further development and implementation of such platforms in a secure and sustainable way.

Objective: This study aims to provide a primer on the requirements and operational guidelines for the development and operation of a secure behavioral monitoring platform.

Methods: We draw from disciplines such as privacy law, information, and computer science to identify a set of requirements and operational guidelines focused on security and sustainability. Taken together, the requirements and guidelines form the foundation of the design and implementation of the BEHAPP behavioral monitoring platform.

Results: We present the base BEHAPP data collection and analysis flow and explain how the various concepts from security and sustainability are addressed in the design.

Conclusions: Digital phenotyping initiatives are steadily maturing. This study helps the field and surrounding stakeholders to reflect upon and progress toward secure and sustainable operation of digital phenotyping–driven research.

Introduction

Background

Digital phenotyping is the practice of collecting and analyzing objective, longitudinal, and possibly high-resolution data streams from personal devices, such as smartphones and wearables, which are descriptive of a person's real life and real-time behavior [1]. Digital phenotyping provides a new and much more detailed perspective on human behavior, with the potential to innovate both research and clinical outcome measures in the health care space.

The field is currently still experimental, featuring many studies reporting on methodologies and pilot data, but it has yet to deliver replicable findings that may prove useful for clinical translation [2]. At present, much of the current efforts concentrate on correlating smartphone-derived data with clinical diagnoses and symptoms domains, whereas the next steps will examine to what extent such data can be exploited to bring about real positive changes in clinical care [3]. In addition, the ethical aspects of digital phenotyping are examined [4]. At any rate, the pace of innovation is fast, the field is expanding rapidly, and the sample size of studies is steadily increasing, raising the question of whether the applications and services at the backend of such programs are up to the task of continuing to support the operations. More concretely, participating in large cohort studies and operating in regulated research spaces require us to ensure that our platforms are sustainable (ie, maintainable and scalable [5]) and, most importantly, secure [6]. Human research invariably requires the participation of individuals willing to participate in studies after obtaining appropriate informed consent. Establishing trust and continuity is key, given the sensitivity of the data that we collect and the context in which we operate [7].

The current state of the art shows that security and sustainability are not at the forefront of design and execution of digital phenotyping initiatives, despite some awareness of security and privacy implications [8] and the high cost of sustainability [9] in the currently available tools. However, the uptake in the field dictates a necessary shift from the implementation of a limited set of security measures to a more mature and holistic conception of all aspects of sustainability and security as integral parts of software engineering, starting at the very first stages of design. In many current reports on behavioral monitoring platforms, these factors are only discussed in a limited fashion [10-12]. We do not want to suggest that these initiatives are necessarily insufficient in this respect, but in general, there appears to be a focus on the scope of phenotypic outcomes captured by the platform, whereas attention to aspects related to security and sustainability is relatively peripheral.

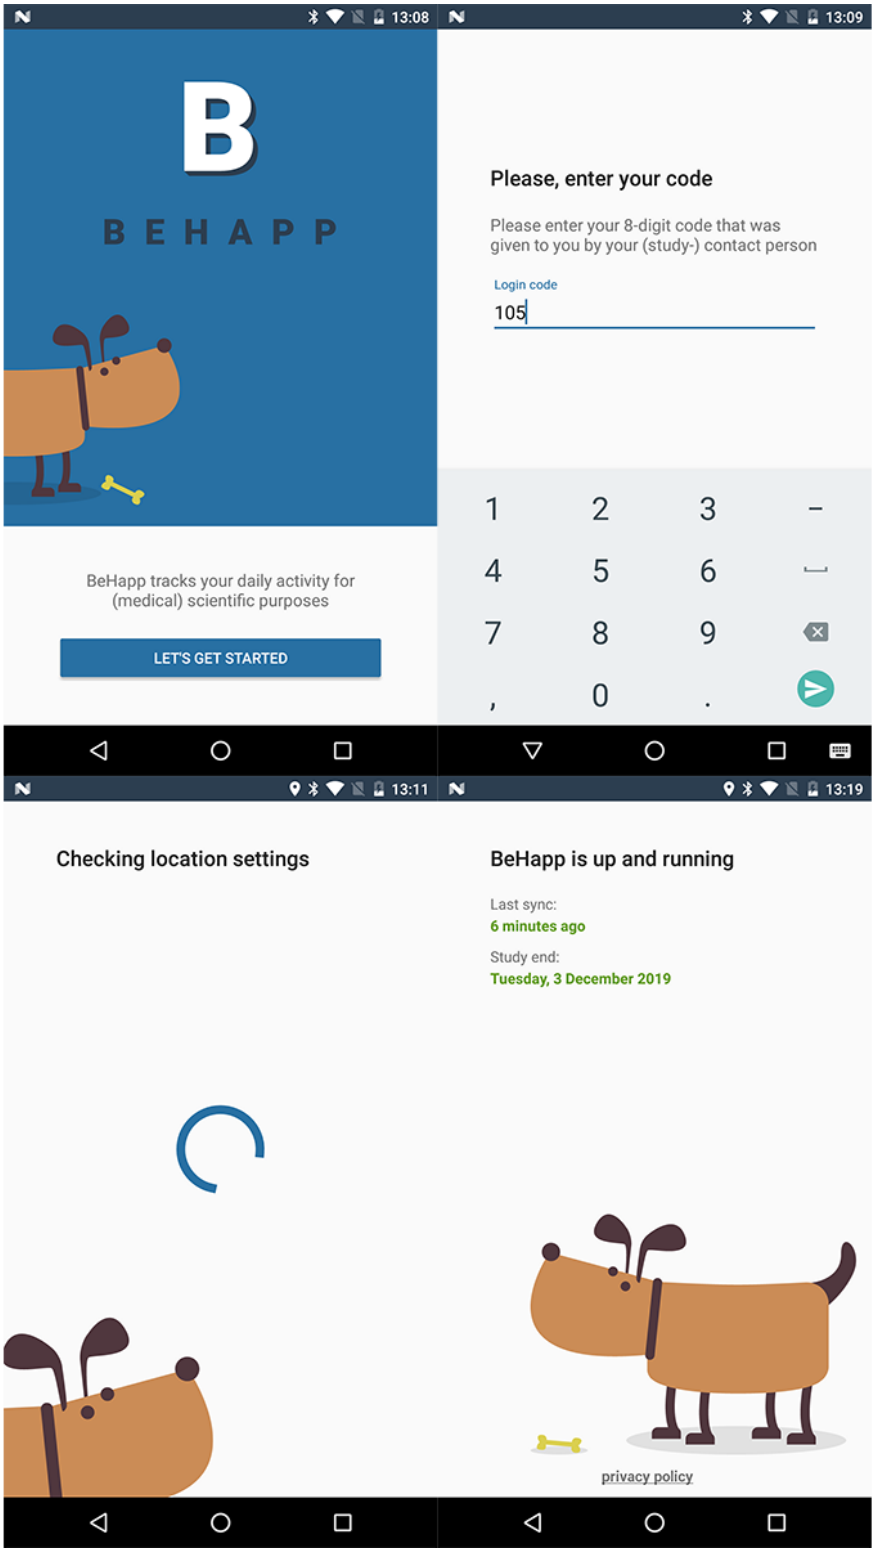
To address this gap, we present here a detailed description of the requirements and guidelines to responsibly develop and operate a behavioral monitoring platform, with specific consideration of the aforementioned concerns.

About BEHAPP

This research is part of the BEHAPP project [13]. BEHAPP is a research platform that features the following 2 components:

1. The front end (Figure 1): a mobile app originally conceptualized for mobile passive monitoring (MPM) of human subjects. As a subfield of digital phenotyping, MPM refers to the practice of naturalistic observation through personal mobile devices exclusively relying on the collection of data that do not require any active input from the participant (an example of active input would be queries probing for emotions or situations such as in the experience sampling methods [14]).
2. The backend, which is the focus of this study: the backend is designed following the software as a service paradigm supporting multicenter studies for international research consortia, academic institutes, and the pharmaceutical industry. The work presented stems directly from our experience in accommodating the needs of industry partners and research groups representing large-scale study cohorts.

Figure 1. Screenshots of the installation and activation flow of the BEHAPP smartphone app.

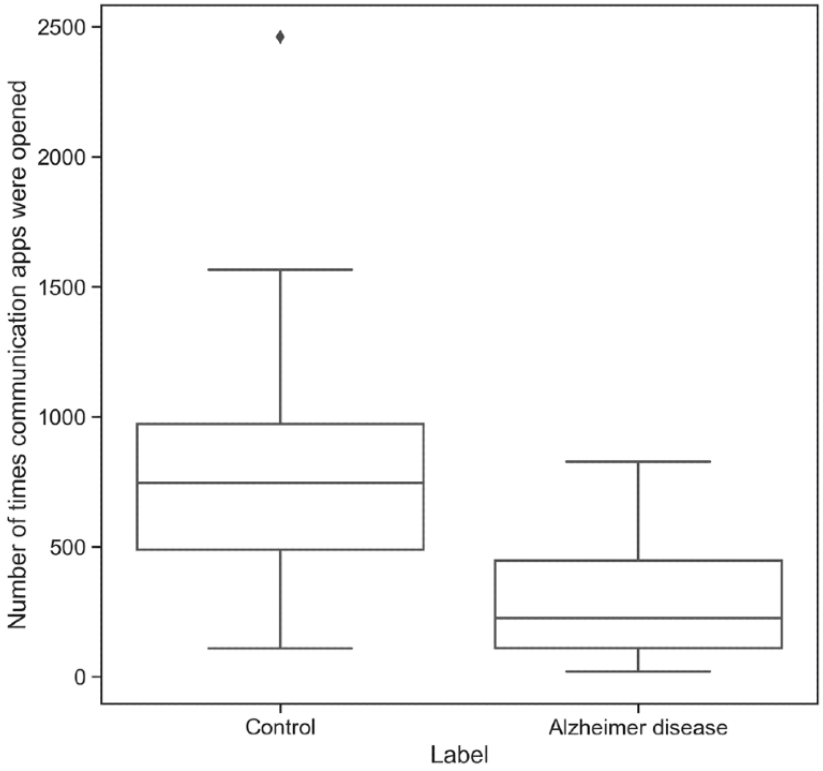


BEHAPP is comparable with initiatives such as MindLamp (Division of Digital Psychiatry, Beth Israel Deaconess Medical Center) [11], Beiwe (Onnela Laboratory, Harvard T H Chan School of Public Health) [15], Funf Open Sensing Framework [16], and the AWARE Framework [17]. All these platforms have in common that they collect various data streams through individual smartphones with the purpose of facilitating the study of human behavior in real time and in a natural (real-world) setting. BEHAPP also draws from a wide array of data collection sources that can be tailored to the needs of specific studies.

From the backend perspective, however, BEHAPP is different from the aforementioned initiatives. The alternatives require research teams to set up, manage, monitor, and secure the basic technical infrastructure themselves. Rather, BEHAPP is designed to be offered as a fully managed service aimed at low effort integration in (existing) studies. BEHAPP is currently used as an exploratory research instrument in general behavioral

and clinical intervention studies. From these studies, we have provided a proof of principle demonstrating that these tools, the resulting data, and the clinical measures that we extract can be used to distinguish between neuropsychiatric patient and control groups [18], courtesy of the Psychiatric Ratings Using Intermediate Stratified Markers (PRISM) program [19]. For example, as depicted in Figure 2, we highlight a feature of communication app use. In this example, we observe that the overall frequency of communication app use is lower for the group with Alzheimer disease when compared with age-matched healthy controls. The service is currently exclusively used as a research instrument and is not employed as a tool to assist in the diagnosis, prevention, monitoring, treatment, or alleviation of disease, that is, at this moment in time, BEHAPP is not a medical device [20].

Figure 2. A group comparison data example on communication app use between Alzheimer disease patients and age-matched healthy controls (n=30) demonstrating the ability to observe differences in behavior through the use of BEHAPP's behavioral monitoring platform. We measured a statistically significant difference in the number of times that communication apps were opened (median 746.5 and 226.0 times communication apps were opened; *P*=.003). The median age was 66.5 years (60% male and 40% female).



Methods

Overview

We focus on security and sustainability as a starting point for the development and operation of a behavioral monitoring platform. Within the concept of security, we address measures such as data isolation and encryption and highlight the importance of organizational security. We continue to discuss sustainability, explaining what is required to ensure that our platforms remain in service in a secure and stable way.

Security

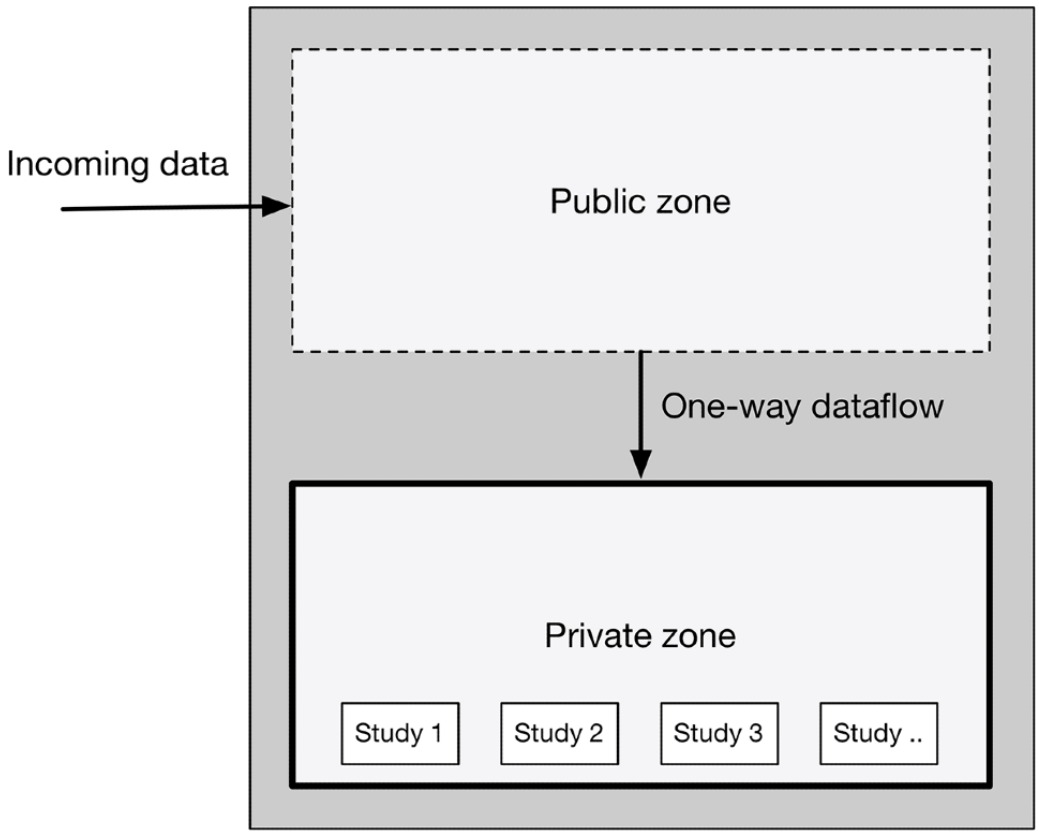
Security refers to the "absence of unauthorized access to information systems" [21]. Given the sensitivity of the data collected, the risk of (accidental) data leaks is a key consideration in setting up the platform. The current state of affairs on information security teaches us to step back and reflect critically on the design of our systems [22]. Regulatory frameworks such as the European General Data Protection Regulation (GDPR), in effect since 2018, must also be considered, given their important impact on technology development [23]. The GDPR expects initiatives involved with personal data to carry out a data protection impact assessment (DPIA) [24]. In a DPIA, we evaluate data sensitivity and how these data must be handled to prevent unauthorized access to and loss of personal data. Formulating a defense in-depth strategy is one such approach to address these concerns [25]. Defense in-depth strategies aim to ensure security by layering security measures at both the technical and organizational levels.

Data Isolation

Data isolation aims to minimize the exposure of data to data consumers. Data consumers can be both technical elements, such as (web) servers, and researchers interacting with data. The intent is to keep high-risk technical elements away from sensitive data. Technical elements connected to the public internet are particularly high risk because anyone can interact with and potentially exploit possible vulnerabilities of these elements. The most threatening are zero-day exploits, which are novel vulnerabilities that, by definition, are unpublished and thus difficult to protect against [26]. To address these risks, isolation of all sensitive data from publicly exposed technical elements is essential. This was achieved through network segmentation [27]. For BEHAPP, we established a public and

private zone of operation, which are strictly separated (Figure 3). The public zone, which carries a higher risk profile, is responsible for receiving participant data from the outside world and immediately transmitting these data to the private zone. The private zone, which has limited outside world connectivity, receives and permanently stores participant data.

Figure 3. Public and private zone isolation overview featuring separated data storage.



Furthermore, we defined a set of rules specifying the flow of data within the BEHAPP platform:

- Participant data may not be stored in a publicly exposed zone: The platform *needs* access to the public internet to receive data from smartphones and wearables. However, as explained, exposure to public internet access carries the risk of (part of) the platform (unknowingly) becoming compromised. Therefore, as a rule, any technical element that lives in BEHAPP's public zone may not (temporarily) store any sensitive participant data, regardless of its encrypted state.
- Participant data may only flow in one direction, from the public to the private zone: Publicly exposed elements may only serve as an ingestion point for sensitive data to flow through to isolated private zones. Technical elements in BEHAPP's public zone do not have any capability to interact with or retrieve participant data from the private zone and are completely unaware of the existence of these data.
- Participant data must be stored in a separate database for each study: The principle of least privileges dictates that automated operations and researchers only need to be assigned the absolute minimal set of authorizations to perform their task [28]. Therefore, any data collected by BEHAPP is segmented into separate data sets for each study, thereby further isolating the data allowing for granular access permissions. By separating study databases, our researchers can be authorized to access only specific studies. Furthermore, researchers are only given permission to *read* the data, which guarantees data integrity. This limits the potential fallout from data being lost or corrupted because of accidental leaks or compromised user accounts.

Note that data isolation by itself does not necessarily limit the processing of data. A private zone of operation can feature technical elements that perform automated data analysis tasks such as data enrichment and annotation, extraction of clinical endpoints, and data compliance and quality control checks. The results can then be written back to the public zone to enable direct reporting to study partners on the condition that the resulting information is fully anonymized. Finally, the resulting information can also be used for signaling purposes, for example, to address potential data quality and compliance issues that are found during automated data analysis runs. At BEHAPP, we are currently in the process of developing such capabilities.

Encryption

Data encryption is the practice of obfuscating data by "converting information from an intelligible form into an unintelligible form" [29], thus rendering data unusable in case of a data leak. *The main challenge lies not in the application of encryption itself but in adequately managing encryption keys.* Protecting encryption keys is equally as important as protecting raw data; otherwise, the added level of protection will be de

facto limited or nonexistent. A layered approach allows for responsible key and, subsequently, data management.

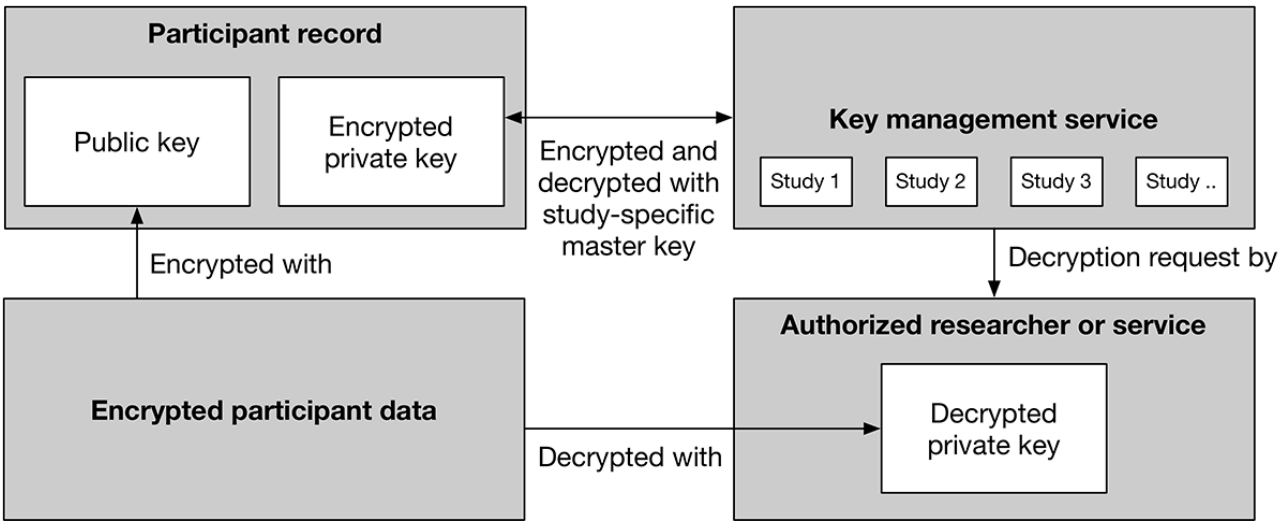
For BEHAPP, we employ a combination of symmetric and asymmetric encryption techniques to establish a closed encryption hierarchy. The main difference between both encryption techniques is in the key material used for the encryption and decryption of data. Symmetric encryption uses one key that is used for both encryption and decryption purposes. Asymmetric encryption uses 2 keys (a key pair), consisting of a public key and a private key. The public key is meant to encrypt data and therefore can be freely shared. The private key is meant for decrypting data and therefore needs to be stored safely [30].

The aforementioned encryption hierarchy consists of 2 levels:

1. Each study participant on the platform is assigned an asymmetric key pair. The key pair is generated in a private zone to prevent leakage of private key information. This key pair is used for encryption and decryption operations on sensitive participant data, such as the raw data that are collected.
2. Each private key is then encrypted itself before being stored in a central database. Private keys are encrypted using a key management service (KMS) [31] using symmetric encryption. A core characteristic of KMSs is that the key material itself never leaves the service. Instead, cryptographic operations are performed based on user authorization. This closes the encryption hierarchy because (unauthorized) database access by itself is not sufficient to decrypt data. Instead, access to both the database and KMS is required. For BEHAPP, we provide study-specific master keys within our KMS, segmenting the encryption hierarchy. The concept of isolation applies here as well, resulting in limited access to cryptographic operations on a per-study basis.

This results in a 3-step encryption model, where (1) the researcher first loads the encrypted private key for a specific participant, (2) the researcher requests a decrypted version of this private key from the KMS, and (3) the researcher loads encrypted participant data from the database and decrypts the data using the decrypted private key obtained from the KMS (Figure 4). Authorizations such as data access permissions and permissions for cryptographic operations are checked at all stages of this process.

Figure 4. Three-step encryption model: (1) load a participant-bound encrypted private key, (2) request a decrypted version of the private key from the key management service, and (3) load participant data and decrypt with the decrypted private key.



Finally, we adhere to the following rule on the use of encryption on the platform: data may only be collected, transported, and stored in an encrypted state. Encryption measures are continuously required to remain in place at all stages of the data lifecycle. In other words, data are only decrypted when necessary and discarded immediately after use. This means that data must be encrypted directly when they are collected through a smartphone or wearable device. For BEHAPP, we achieved this goal relying on the use of asymmetric encryption, as discussed earlier. We send a participant's public key, which is safe to share, to their privately owned devices to be used by our app to encrypt any data that are collected. The encrypted data then remain in this state until they arrive at their destination in the private zone. Analytical workloads naturally require a decrypted view of the data. They are performed by keeping sensitive data in volatile memory only for the purpose of exploration, experimentation, and extraction of outcome measures. The data are then purged from memory.

Information Security Culture

Technical measures alone are not sufficient to protect sensitive data collected by behavioral monitoring platforms. Users of information systems, such as researchers, play an important role in the secure use of information systems and, subsequently, any data under study. Raising awareness about security issues and safe practices is of paramount importance. Indeed, security incidents as a consequence of lack of awareness or negligence are common occurrences [32]. Researchers and newly entering Doctor of Philosophy (PhD) students, in particular, represent a class of users who, by the nature of their work, require access to sensitive data but who may not have any prior experience in the safe handling of these data. The challenge is to balance

between maintaining security while not inhibiting (experimental) workflows of researchers [33]. We recommend the following guidelines to promote information security: (1) provide training and messaging to raise general security awareness and (2) provide seamless security to end users only minimally confronting them with security and compliance decisions [34].

First, raise awareness by establishing an information security policy (ISP) and ensure that all research staff are given an information security briefing. This briefing can be part of a general onboarding process, and its contents must be based on the ISP. An ISP is a document that defines "the rights and responsibilities of information resource users" [35]. The aim of this document is to explain how users responsibly handle sensitive data on a daily basis as part of their work. An effective document is understandable, practical, and inclusive of the needs of researchers. The ISP of the BEHAPP project is targeted at an audience with above-average computer literacy (PhD students, postdocs, and principal investigators). Given this audience and the sensitive data that we use, we specify concrete rules for high-risk areas of attention, such as data flow. For example, we concretely specify that data may only reside on the central server and that local copies on individuals' devices may temporarily exist for analytical purposes only. We also clearly specify that the data may not be uploaded or transferred to any other service or device (eg, for data enrichment purposes) without discussing the purpose and scope of this intention with the team.

Second, seamless security is provided through software development effort. We recommend investing in the development of custom toolkits that are responsible for the heavy lifting around safely loading, decrypting, exploring, and analyzing data. Furthermore, user authentication should be based on multifactor authentication strategies adhering to modern password security guidelines, as defined in National Institute of Standards and Technology 800-63-3 [36]. This considerably eases the burden of security compliance–conscious behavior. At BEHAPP, we developed an internal tool based on these exact principles, called the behapp-data-kit. The kit is a Python package or library aimed at ease of use and security, offering a simple programming interface for data exploration and analysis. Meanwhile, security compliance is handled hidden from the researchers' perspective. For example, the data kit automatically manages local copies of data, ensuring that these copies are encrypted and removed when they are older than 14 days. Furthermore, when loading the data into active working memory for analysis, the kit ensures that the decryption keys necessary for decrypting the data are only held in memory for the shortest amount of time, explicitly deleting these keys when they are no longer required. Finally, the kit relies on a single multifactor authentication strategy, which results in a high level of trust without researchers having to deal with multiple sets of credentials.

Third, schedule and hold weekly team meetings to discuss any (potential) use of sensitive data. Reflect on whether the use complies with the ISP and if the ISP still holds relevance or if an adjustment is required. Be especially mindful of *shadow security.* Shadow security refers to ad hoc practices devised by security-conscious employees that are not compliant with formally prescribed security policies in an effort to achieve a more optimal balance between getting work done and protecting information security [37]. Kirlappos et al [37] recommend learning from these practices, arguing that without engaging with users on these practices, one cannot claim that a specified security infrastructure exists as intended. For example, at BEHAPP, over time, the security policy proved to be difficult to accommodate to researchers who were not directly affiliated with the team, such as graduate students working on temporary assignments. The logistics of account and hardware security key provisioning did not fit the short and temporary character of these projects. Thus, the following shadow security practice emerged: manual data exports were generated for graduate students, but these exports were limited to fully anonymized clinical measure overviews. Although initially any form of manual data exports was formally prohibited, the adjustment of providing anonymized exports offered a workable middle ground and has been adopted as a standard practice.

Sustainability

Sustainability refers to the ability to ensure availability, support, and improvement of the software products and services that we create [38]. We highlight 3 qualities that are closely connected to the concept of sustainability: maintainability, reliability, and scalability [5].

Maintainability is the degree of effectiveness at which software products can be modified [39-41], which depends on multiple factors such as documentation, design, and the consistent application of clean coding standards. Maintenance is an essential part of operating a software service. *The foundations that we built upon, such as mobile operating systems and web application frameworks, change continuously and thus require frequent modification of our own code.* Failure to do so results in diminished service performance, possible loss of functionality, and increased exposure to security threats. Maintenance is especially relevant with regard to mobile apps that we employ as our measurement instruments. Each yearly upgrade of mobile platforms brings about changes that often directly impact the quality of the data that we intend to collect. In addition, noncompliance with continuously changing Apple's App Store and Google's Play Store policies may result in apps being removed altogether. Thus, keeping up with maintenance-related tasks is essential in that it avoids or at the very least mitigates the potential negative impact of platform upgrades and policy changes. Unfortunately, negative changes cannot always be avoided. For example, over the current 4-year development span with BEHAPP, we have experienced many changes in Google's terms of service for the distribution of our Android (Google) app through the Play Store. One change, in particular, revolved around Google's strides to curb malicious apps invading the privacy of their users. This change, which came into effect in March 2019, limited access to call and text messaging logs for the majority of apps distributed through Google's Play Store [42]. This change was unfortunate, as call logs are very expressive of the communicative behavior of participants. Fortunately, we could work around this problem by directly distributing our app to our end users and thus circumvent the Play Store through sideloading.

Reliability refers to the probability of failure-free operation of a software product [43]. The goal is to ensure that our platforms are highly available, keeping service downtime at a minimum. However, it must be noted that experimental research initiatives may typically have wider tolerances for service uptime requirements. This changes when our behavioral monitoring platforms evolve to a stage where they are involved with mission critical workloads, for example, when their continuity is essential to large-scale research endeavors or when they provide important information to clinical care processes.

Scalability is the ability of a software product to adapt to changing circumstances in demand [44]. The rapid adoption of behavioral monitoring platforms and increasing cohort sizes require us to ensure that our software products can sustain the stresses of increases in demand.

Finally, note that the aforementioned quality attributes and the corresponding responsibilities not only apply to the programs and code behind our platforms but also to every supporting information technology (IT) infrastructure element that is required to bring our platform into service. This can span the full range of elements such as networking, storage, physical servers, virtualization, operating systems, and web server software. All these elements require setup and maintenance for stable and continued secure operation. The proverb that a chain is only as strong as its weakest link applies here: a vulnerability or weakness in any supporting IT element will affect the other elements as well, including our behavioral monitoring platforms. *Thus, we are not only required to develop a secure and sustainable behavioral monitoring platform but we also need to ensure that the supporting IT infrastructure is equally secure and sustainable.* Unfortunately, both the knowledge and resources required to do so are extensive and form a barrier to entry.

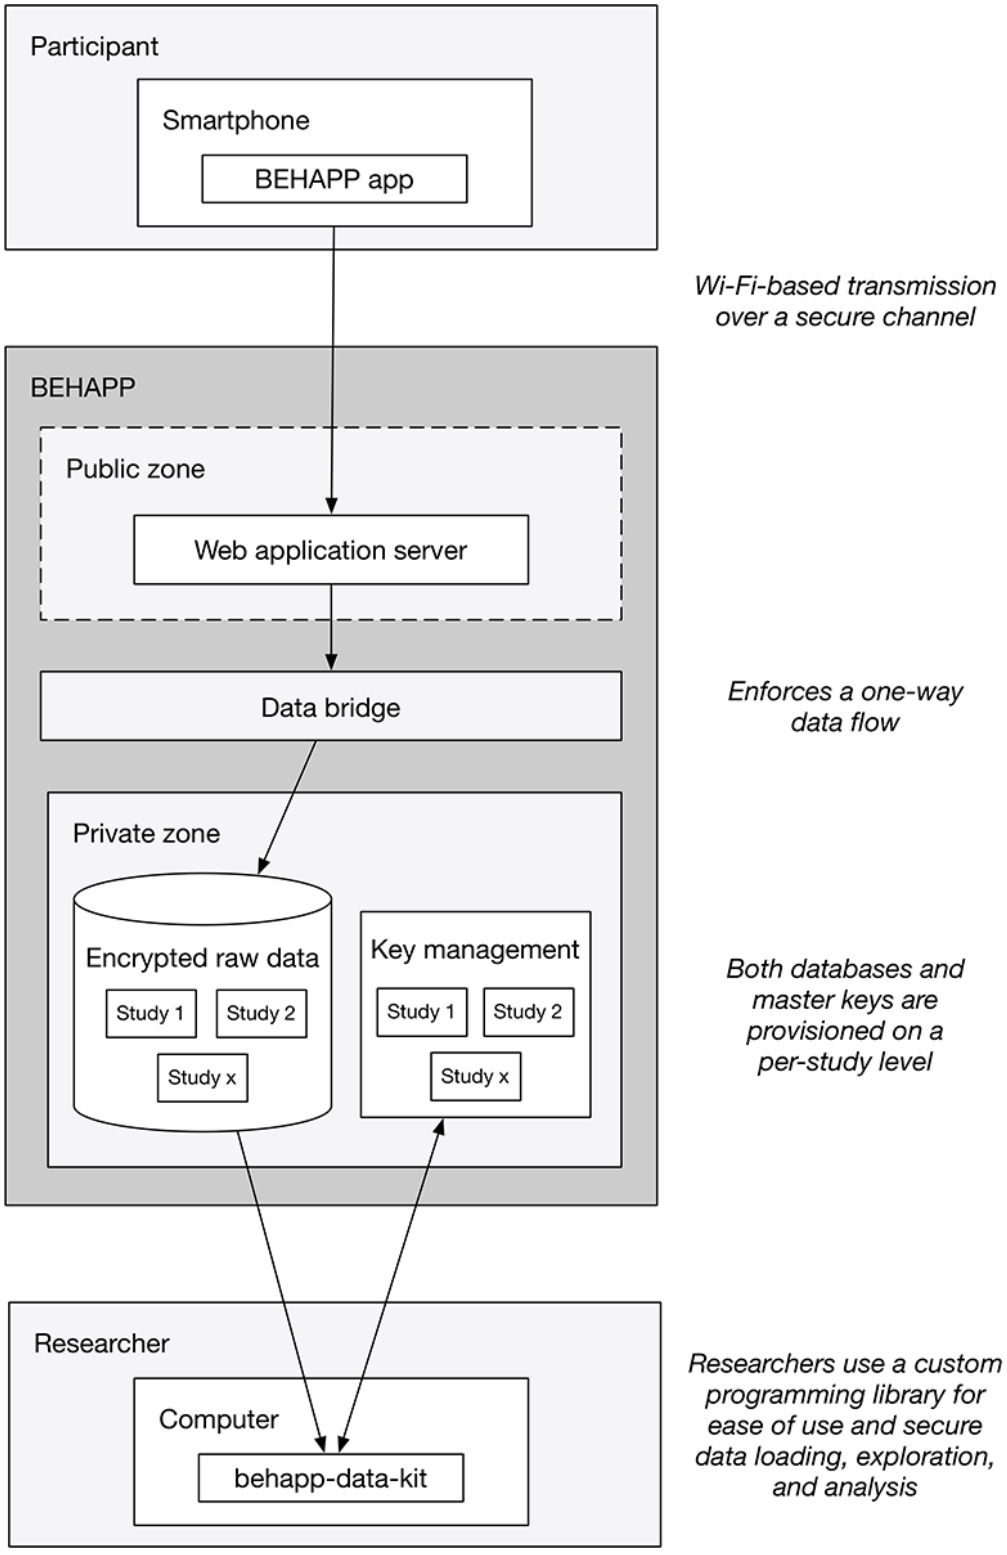
At BEHAPP, we have built a service relying on fully managed IT infrastructure components offered by large cloud providers, focusing in particular on an upcoming class of products known as serverless computing. With serverless computing, the cloud provider is responsible for maintaining and securing the majority of the required IT infrastructure, leaving us to focus on our platform only [45]. This includes the ability to (rapidly) scale, which means that we can flexibly meet any changes in demand.

Results

Here, we introduce the base BEHAPP data flow for the collection and analysis of raw data (Figure 5). The flow implements the requirements and guidelines, as discussed in the aforementioned sections:

1. Data collection starts at the personal devices of participants that run the BEHAPP smartphone app. The app unobtrusively collects various types of data descriptive of the participants' behavior. Any data collected were encrypted immediately and temporarily stored on the device.
2. The data are sent to the public facing the web application server. The smartphone app is programmed to upload these data on a fixed interval and attempts to do so on the condition that a Wi-Fi (or unmetered network) is available. Given that some modes of data collection can yield substantial amounts of data, we do not want to risk accidentally consuming the data plans of our participants. Data transmission always occurs over a secured connection. Once received, the web application server immediately passes the data on to the data bridge.
3. The *data bridge* is not a formal concept but represents a technical construct responsible for enforcing a one-way data flow, which can be achieved in multiple ways. BEHAPP employs message queues configured with minimized permissions to realize unidirectional flow of data.
4. The private zone receives data from the bridge and is responsible for placing the raw data in the corresponding study database. In this way, researchers can access only a select number of databases instead of being able to access the full data set.
5. Finally, researchers use a custom programming library, the behapp-data-kit, designed for ease of use and security. The kit supports data loading, exploration, and analysis and is aimed at security and ease of use. Security compliance, such as maintaining data encryption and enforcing short-lived life cycles of decrypted and locally stored data, is hidden from view. This allows researchers to focus on the task of data analysis while maintaining a secure level of use.

Figure 5. BEHAPP data flow for the collection and analysis of data using smartphone-based participant data.



Discussion

Principal Findings

We present a data flow design that includes a set of requirements and operational guidelines for the realization and responsible operation of a digital behavioral monitoring platform. Having done so, we recognize the following limitations in the proposed work.

First, the proposed data isolation measures prevent the public elements of the platform from accessing (raw) sensitive data. In other words, by design, researchers will not be able to retrieve sensitive data in an automated way. Instead, data are provided (both raw and extracted features) manually on request. This may not be an alluring policy, as it implies that researchers cannot have immediate data access. However, given the risk profile of publicly connected technologies, we opted to go for a risk-averse approach and stand by the decision to strictly

separate sensitive data to protect the participants under observation by the platform. In line with the aforementioned data isolation rules, once received, any form of sensitive data may not leave the service through a publicly connected element. However, there are ways to automate the retrieval of sensitive data, for example, through the use of secure file transfer mechanisms initiated in private zones, which should be the focus of further development and future studies.

Second, by implementing both technical and organizational measures to protect the data of our participants, we realize that there is room for improvement on the data protection front by the application of anonymization methods. BEHAPP's data, while fully encrypted, are not fully anonymous and have, considering the location data that are collected from, the potential for direct identification of individuals. However, although strategies exist for anonymizing location data, its effectiveness is still under debate [46]. As a consequence, analytics endeavoring down the line could be limited by the application of anonymization strategies. For example, we would lose the ability to retrospectively annotate locations by adding meaning to specific points (eg, schools, hospitals, and sports). However, note that although raw location data are considered as identifiable information, the behavioral features that we extract and subsequently report are not. Features such as *total time spent at home* and *total number of unique places visited* are highly interpretable and expressive of one's mobility without having to refer to any geographical type of data and as such can reside in publicly connected zones.

Third, considering our aforementioned proof of principle, we demonstrate the capability to accurately distinguish between patient and control groups. We feel it is time to look ahead and ensure that the models that we intend to build, be it for predictive or classification purposes, are not only properly validated but also compliant and sustainable from an ethical perspective. Many unintuitive and unverifiable inferences can be drawn from personal data, which can potentially result in negative consequences for the individuals for whom the inferences are drawn. Although the GDPR demands model transparency, the subject of inferential analytics is not well regulated [47]. Given our medical scientific operating context, we should tread carefully and actively work toward the creation of transparent models with limited application scopes to avoid negatively affecting our subjects under study.

Fourth, despite our efforts to simplify the design and minimize the operational overhead of running a behavioral monitoring platform, we realize that the level of complexity and the demands imposed on a research team may still leave this type of instrumentation out of reach for many independently operating research groups. However, we strongly feel that this is the minimum standard for responsibly operating such a platform. Self-hosted open-source models may be vulnerable in this regard and, therefore, are not the most secure and sustainable way forward. As argued in this paper, the responsible operation of such platforms extends beyond installing a client and server application, and we have to consider the underlying IT infrastructure as well. In our experience, the broad level of responsibilities tied to operating a behavioral monitoring platform warrants the inclusion of a dedicated team responsible for development, maintenance, monitoring, and security tasks. A more workable model would be to concentrate the required operational effort in a limited number of initiatives capable of supporting multiple studies. With BEHAPP, we aim to be one of these initiatives.

However, the open-source model is not without merit. Indeed, Torous et al [1,10] regularly raise a valid and important point about the lack of interoperability and interpretability of results across the whole spectrum of digital phenotyping initiatives. The open-source model and, consequently, the free distribution of these platforms is meant to address that problem by putting the technology in the hands of many, thereby ultimately contributing to a more uniform approach toward data collection and analysis. However, we think that the solution to interoperability and comparability does not rely on a single developer, mainly because the underlying problem is an overall lack of transparency in the methodology and specifications descriptive of data collection and data processing flows. Importantly, we need scientific reports to be accompanied with metadata descriptive of the format of data (attributes, shape, size, and semantics) at every stage of collection and analysis, starting from raw data to the clinical measures that we extract. These aspects, just as security and sustainability, are largely overlooked in most scientific reports. With phenotypic outcomes currently taking center stage, we unfortunately limit ourselves in building collective knowledge toward enabling reproducible science.

Conclusions

In search of strategies for secure and sustainable digital phenotyping, we identified a gap in the available knowledge related to the establishment of secure and sustainable platforms that drive such research initiatives. Here, we address it by providing a foundation including requirements and operational guidelines focusing on key elements such as the application of encryption, data isolation, and organizational security culture. Members of ethical research boards should consider using the security principles outlined in this manuscript in their evaluation of the privacy of study participants in research proposals. Principal investigators should account for these essential components while budgeting their grant proposals, keeping in mind that security and maintenance must be adequately addressed in any research plan that includes the use of a digital phenotyping platform. Taken together, this work contributes to the foundations on which digital phenotyping strategies can be operated in a safe and sustainable way, allowing for the collection of real-time, quantitative, and longitudinal behavioral data that are expected to generate novel insights and possibly support concrete innovations in clinical care.

Abstract

Background: Social media networks provide an abundance of diverse information that can be leveraged for data-driven applications across various social and physical sciences. One opportunity to utilize such data exists in the public health domain, where data collection is often constrained by organizational funding and limited user adoption. Furthermore, the efficacy of health interventions is often based on self-reported data, which are not always reliable. Health-promotion strategies for communities facing multiple vulnerabilities, such as men who have sex with men, can benefit from an automated system that not only determines health behavior risk but also suggests appropriate intervention targets.

Objective: This study aims to determine the value of leveraging social media messages to identify health risk behavior for men who have sex with men.

Methods: The Gay Social Networking Analysis Program was created as a preliminary framework for intelligent web-based health-promotion intervention. The program consisted of a data collection system that automatically gathered social media data, health questionnaires, and clinical results for sexually transmitted diseases and drug tests across 51 participants over 3 months. Machine learning techniques were utilized to assess the relationship between social media messages and participants' offline sexual health and substance use biological outcomes. The F1 score, a weighted average of precision and recall, was used to evaluate each algorithm. Natural language processing techniques were employed to create health behavior risk scores from participant messages.

Results: Offline HIV, amphetamine, and methamphetamine use were correctly identified using only social media data, with machine learning models obtaining F1 scores of 82.6%, 85.9%, and 85.3%, respectively. Additionally, constructed risk scores were found to be reasonably comparable to risk scores adapted from the Center for Disease Control.

Conclusions: To our knowledge, our study is the first empirical evaluation of a social media–based public health intervention framework for men who have sex with men. We found that social media data were correlated with offline sexual health and substance use, verified through biological testing. The proof of concept and initial results validate that public health interventions can indeed use social media–based systems to successfully determine offline health risk behaviors. The findings demonstrate the promise of deploying a social media–based just-in-time adaptive intervention to target substance use and HIV risk behavior.

Introduction

Men who have sex with men are disproportionately affected by HIV and other sexually transmitted infections. In the United States, men who have sex with men accounted for two-thirds of incident HIV infections and more than half of new syphilis diagnoses in 2018 [1-3]. Substance use has been a persistent driver of the ongoing HIV epidemic in men who have sex with men. Research suggests substance use is highly associated with high-risk sexual behaviors such as condomless anal sex, multiple sex partners, and sex trading for drugs [4-6].

Web-based communication tools such as social networking sites (eg, "hookup apps," dating websites) have been used among men who have sex with men to seek sexual partners and share information and resources about substance use [7-10]. In the early 2010s, 85% of men who have sex with men used the internet to find sexual partners [9], and this figure grew to 96% in 2019 [11]. However, the rising popularity of these technologies has also raised concerns about their role in facilitating sexual risk behaviors. Studies [12] have shown that men who have sex with men are more likely to engage in condomless anal sex with sex partners met online compared to partners met offline and have demonstrated that men who have sex with men who seek partners online have greater numbers of sexual partners compared to those who do not seek partners online. Furthermore, men who have sex with men who identify sexual partners online have a greater likelihood of substance use [13], although the evidence is equivocal [8,14,15]. Further studies are needed to provide empirical evidence of the association between online social networking technologies and offline sexual and substance use behaviors.

With more than 40% of health care consumers utilizing social media for their health-related decision making, social networks have indeed caught the attention of the public health domain [16]. Population-based analyses and in-person interventions are costly, both in time and resources [17]. Health spending is projected to grow at an average rate of 5.5% per year, totaling $6.0 trillion by 2027, nearly one-fifth of the United States gross domestic product [18]. Given these costs, the opportunity for high user engagement, and accessibility of social media data, social networks provide a new opportunity to public health. In recent years, social media have been employed in behavioral and public health research and has demonstrated its effectiveness in prevention, education, and treatment [19,20]. For instance, analyzing user activity on social media platforms has been an effective way to estimate the risk and time of HIV infection [21]. A separate study [22] found that the strength of associations in a social network, its network shape, and size are predictors of HIV and sexually transmitted infection risk.

Public health studies have also begun using social media platforms to understand and intervene in sexual health and substance use risk behaviors among men who have sex with men; however, these methodologies remain nascent in that they still rely on self-report and costly data collection as a means of developing and testing interventions [23-25]. Research demonstrates the need to utilize big data in social media and machine learning to understand communication and patterns about substance use and observe and predict real-time risk behaviors [26-28]. These strategies can inform just-in-time adaptive interventions [29] that are responsive to the individual technology use patterns of research participants; however, before deploying any social media–based intervention, the feasibility and efficacy behind employing such a modality for public health initiatives in risk reduction must be determined.

In practice, adaptive intervention systems are driven by an ability to determine health risks. Placed in the context of social media data, it is encouraging to learn that assessing health risk using textual sources has shown promising results in disease-specific risk evaluation and in identifying individuals at higher risk of depression and self-harm [30-32]. While text collection from electronic health records is extremely effective in determining a diagnosis, it is not a readily available resource for continuous risk assessment. Meanwhile, social media text data have the advantage of being abundantly available and cost-effective. While these data are not as domain constrained as clinical notes, they remain promising channels to explore for risk assessment.

Additionally, system interventions should be able to accurately evaluate when an individual is about to engage in a targeted health risk behavior with high probability followed by successfully reducing such behaviors. Maher et al [33] reviewed the effectiveness of past social network interventions, concluding with a call for stronger evidence in interventions that incorporate online social networks. Our paper responds to this call by evaluating the efficacy of social media data in determining health risk behavior. We are guided by the following questions: (1) Can we further substantiate the association between online social networking technologies and offline sexual and substance use behaviors? (2) Can we extract health risk scores from social media data that align with public health expert evaluation?

In this paper, the practicality of social media as an intervention modality is evaluated through social media data to identify health risk behavior in a sample of men who have sex with men from Los Angeles, California. The contributions of this paper are the following: (1) an end-to-end platform that continuously collects data from common social media platforms and specialized social networks tailored to the men who have sex with men community, and in tandem, biological data and personal health questionnaires were collected at baseline, 1-month, and 3-months from intake; (2) health behavior risk scores that are comparable to adapted risk scores created by the Centers for Disease Control and Prevention (CDC) using natural language processing techniques; and (3) the application of machine learning techniques to determine the extent to which social media messages can be used to directly predict verified biological outcomes of substance use and sexual risk, reflected as sexually transmitted disease diagnoses.

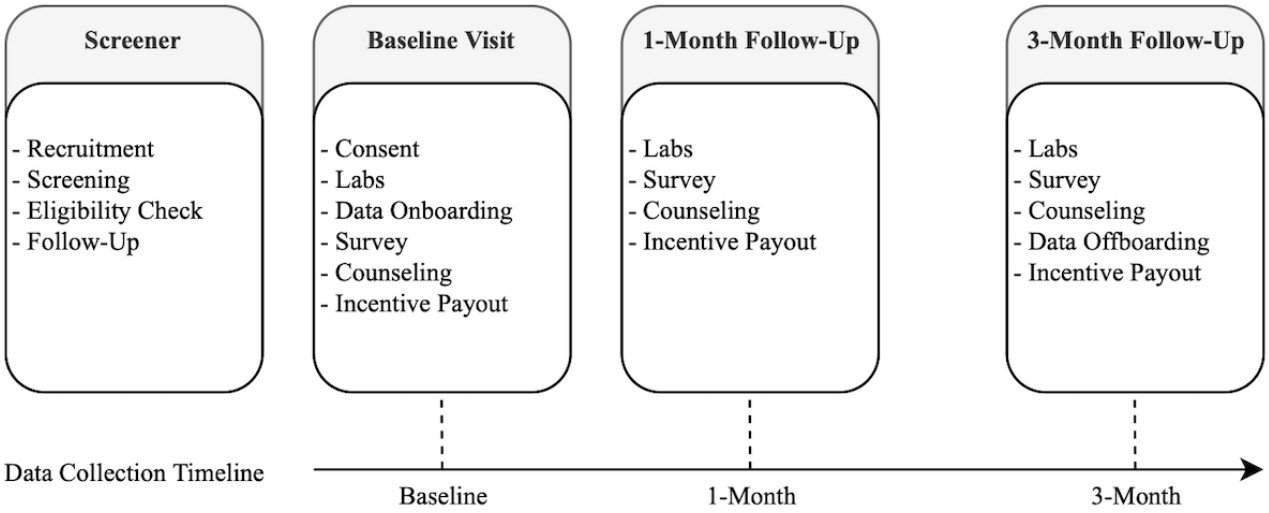
Methods

Study Protocol

The study protocol consisted of 4 milestones: (1) screener, (2) baseline visit, (3) 1-month follow-up, and (4) 3-month follow-up

(Figure 1). In the screener, flyers, online advertisements, and referrals were used to recruit potential participants. Further screening took place over the phone or through an web-based survey. Criteria such as age, sexual orientation, substance use, online dating, and social media activity were used to determine each participant's eligibility for the study.

Figure 1. Different phases of the study protocol and data collection.



Qualified participants were invited to an initial clinical visit to review the study in detail, ask for informed consent, and answer any of their remaining questions. Afterward, a series of lab tests were conducted to determine their substance use and the presence of sexually transmitted diseases. Site testing was conducted for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* with pharyngeal, urethral, and anal swabs. Further tests included a rapid plasma reagin blood test for syphilis, a rapid oral test for HIV, and a urine drug screen. Additionally, a survey was completed by the participants which asked a series of questions regarding demographic characteristics, sexual risk behavior, illicit substance use, and online behavior. Finally, participants provided their log-in credentials for a set of social media sites on which they had been. The user credentials were registered in a custom data collection platform for each website and the participants authorized the data collection system to pull their daily online activity. We collected participant social media data for up to 3 months after onboarding. We found this to be a reasonable duration considering the need to follow participants long enough to observe any changes in social media use and behaviors over time that can be measured by follow-up surveys and their biomarkers.

The system began collecting participants' daily social media activity immediately after the baseline visit. One month into the study, they were scheduled to revisit the clinic and redo lab tests and surveys. A final follow-up was set for 3 months after the baseline visit to recollect lab and survey data in addition to conducting required off-boarding procedures, including the discontinuation of participant data collection.

This study protocol was approved by the University of California, Los Angeles institutional review board (IRB 17-000408). Informed consent was obtained from all individual participants included in the study. Each participant was provided with up to US $150 in cash incentives based on their participation. Certain medical conditions identified within this study were also reported to appropriate agencies as required by federal and state laws. Proper consultation and referrals were provided to each participant before and after reporting each screening test.

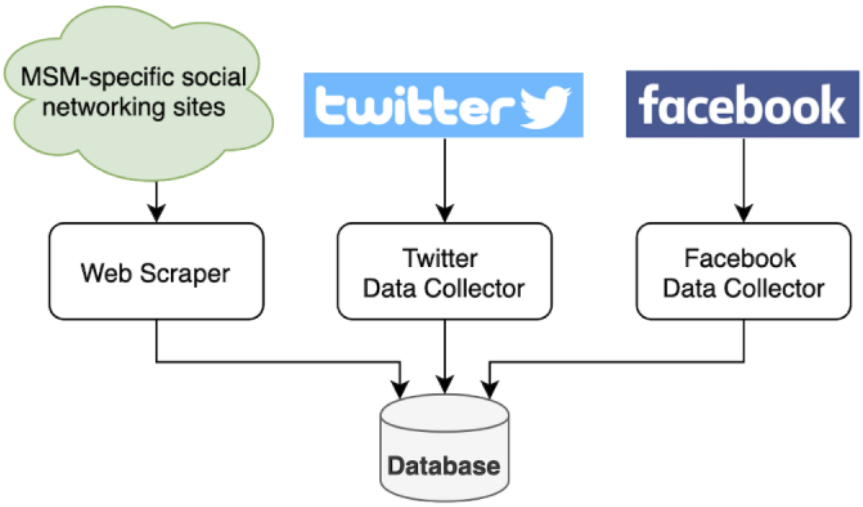
System Architecture

Data from Facebook and Twitter was automatically collected through official application programming interfaces (API). The APIs were used to query the content (eg, messages, posts) generated by each participant; however, it is important to note that Facebook changed its API policy during the study. Standard permission requests could no longer be used to access user data. To mitigate this issue and re-enable the permission to read user content, the participants enrolled as testers of a custom Facebook app developed during the study.

In addition to these major social media platforms, we collected similar data fields for men who have sex with men–specific social networks. The software implementation slightly differed from that of Facebook and Twitter in that a unique web scraper was built to collect data. Due to the study's privacy protocol, the name of each site was omitted. The websites, labeled Website A and Website B, are one of the most established websites in the men who have sex with men community, with over 10 million users overall. Qualitative interviews and input from a community advisory board further informed the decision to include these websites. Each scraper used a combination of browsing automation tools and web parsers to mimic a user going online and accessing their profile. URL requests were made using Selenium, a browsing tool that can conduct automatic authentication, search, and navigate each site of interest [34]. Participants explicitly provided consent and their usernames and passwords per institutional review board protocol approvals. These credentials were used by Selenium to automate logging into a website and navigating to pages where the system was able to collect profiles and messages between users. The data were extracted from each website of interest using the BeautifulSoup Python Package and later saved to the database [35]. Figure 2 provides a visualization of the study's overall

database schema. MySQL, a free and open-source database server, was used to store and query user messages and metadata including usernames and respective access tokens from each website. To maintain high data-quality, a hashing of the data and timestamp was created within the database to prevent duplication.

Figure 2. A visualization of the database schema used in this study. MSM: men who have sex with men.



We validated that the system collected participant messages consistently and reliably by maintaining a group of test users. Before and throughout the study, various mixed-media data were sent across these platforms to make sure all types of generated data were correctly collected and accurately represented. The data consisted of text, videos, and emojis.

Due to the sensitive nature of collecting online social media activity, providing security and privacy was of paramount importance. Therefore, the data collection system was designed to offer protection on multiple levels: at the system-level and the data-level. At the system-level, the user data were stored on a dedicated private server behind a firewall, protecting against outside cyber-attacks and malicious software. At the data-level, the user data went through a data sanitation process. Participants' identifiers in the data collection system were anonymized and could only be matched with a reference datasheet stored externally on a cloud storage service compliant with the Health Insurance Portability and Accountability Act (HIPAA). The cloud storage service was also used to store all other data, such as participant questionnaires and drug screening results.

Defining Health Behavior Risk

Given the ambiguous nature of identifying health risk behavior in social media messages, a map between commonly used colloquial terminology and risk behavior topics was curated. To gain a more nuanced understanding of online strategies and behaviors around seeking drugs and sexual partners, 24 men who have sex with men community members in Los Angeles who self-disclosed risky sex, illicit drug use, and usage of dating apps were qualitatively interviewed. The response to the following question became the foundation for the risk behavior dictionary: “What are some of the terms that you use on websites, chatrooms, message boards, and apps to find drugs, drug use partners, and/or sex partners?” The words were organized into topics (Table 1). All terms were vetted by a community advisory board throughout the study. The resulting risk behavior dictionary was leveraged to facilitate the modeling of the relationship between social media messages and health behavior risk.

Sexual health and illicit drug use risk was also evaluated for each participant using the CDC Risk Assessment Tool [36]. Each assessment was adjusted based on participants' weekly text message diary responses on illicit substance use. Scores for each participant were available at baseline intake, 1-month, and 3-month checkpoints.

Table 1. Sexual and substance use topics associated with colloquial terms found in text conversations based on qualitative interviews with men who have sex with men community members.

Topic	Words
Alcohol	drunk, drinking, booze, party, liquor
Marijuana	toke, pipe, weed, pot, mary jane
Cocaine	crack, blow, snow, yayo, powder
Methamphetamine	meth, speed, ice, crank, crystal
Amyl nitrate	poppers, rush, pops, amyl
Heroin	dope, smack, junk, tar
Ecstasy	X, Ex, molly, rolling, mdma
GHB	G, roll, water
Ketamine	K
Type of substance other/general	pills, favors, DMT, party, party favors
Snorting	snort, sniff, rack, rail, lines
Inhaling	smoke, blow clouds, hit, puff
Injection	straight to the point, straight to the poinT, slam, slamming, shoot, shooting
Anal insertion	booty bumping, butt rocket, plug, plugging
Substance use behavior other/general	gen, generous, friends with benefits
Buying drugs	Do you have a connect, I can contribute, can you do me a big/little/huge favor
Masturbation	JO, jack, stroke, HJ, jack off
Oral sex	blow, head, gloryhole, suck, BJ
Anal intercourse	top, bottom, fuck, power top, power bottom
Group sex	3some, 3way, gang bang, orgy, bukkake
Sex work	$, roses, generous, pro, GEN
Anonymous	anon, discreet, discrete, anonymous, random play
Sex with condoms	condoms, rubber, safe sex, play safe, safe
Condomless sex	Bareback, bare, raw, seed, seeding
Substance use and sex	Party and play, smoke and stroke, pnp, party, partying
Sexual behavior general/other	69

Data Set Processing and Auditing

Data were cleaned to maximize consistency and accuracy. The messages were first screened using Python regular expressions to pattern match texts identified as spam or in-app advertisements. Pattern personal identifiable information such as addresses and phone numbers were tokenized. For instance, if a phone number was provided in a message, it was replaced with “phonenumbertoken.” Data were deduplicated and the privacy of those that communicated with our participants was protected. This was done by only considering the participants' sent messages, resulting in data for 48 individuals. Some messages also consisted of notifications such as when a participant's profile was seen, clicked on, or had a request to unlock their photos—all of which were tokenized with the suffix “token.” One data source in the study was excluded because it failed to produce data due to changes in the site's data collection policy. Furthermore, we focus our analysis on biomarkers that were present in at least 10% of participants.

After data cleaning, the messages went through an automated pattern matching pipeline using regular expressions to identify terms in the risk behavior dictionary defined in Table 1. The mapping was utilized to flag words and colloquial terms associated with health risk behaviors in each message. As an example, if the word in a given message was “rail,“ it was matched to the topic of snorting.

Biomarker Prediction With Social Media Messages

The relationship between participants' social media behavior and illicit substance use and sexual risk behaviors was examined; data collected across social media accounts were leveraged to predict participant’s respective offline substance use and sexual health biomarkers.

Standardized counts of each tokenized word and text-summary features, such as message length, were used as simple features to predict drug use and sexually transmitted diseases. Each outcome was treated as its own binary classification task. Logistic regression, linear support vector machine, naïve Bayes,

and random forest models were employed to predict the outcomes at 1-month and 3-month follow-up. Given the relatively small data set and the challenge of class imbalance, stratified 5-fold cross-validation was used to assess the generalizability of the predictive models. The performance of each model was assessed using the precision, defined as *true positive* / (*true positive* + *false positive*); recall, defined as *true positive* / (*true positive* + *false negative*); and F1 score, defined as 2 × *precision* × *recall* / (*precision* + *recall*).

Message-Based Risk Scores

Health risk behavior was assessed on a per-message level using available social media text correspondence. A risk score was given for each message based on how likely its words were associated with those in the risk behavior dictionary.

Identifying Health Risk Behaviors Using Social Media Messages

Natural language processing techniques were employed to create a risk score using social media data. We employed a Skip-Gram Word2Vec model which allowed us to extract word representations to determine the association between words in social media messages and words in the risk behavior dictionary [37]. The Skip-Gram Word2vec model constructs a word representation, or word embedding, based on how well it predicts the words that surround it within a given radius. Given all the words in the message corpus, w_1, w_2, w_3,..., w_T, the model tries to predict the probability of observing the context word w_{t+j} given a target word w_t.

The resulting model constructs a vector space that identifies context-dependent similarity between words used by the participants in the selected social networks monitored.

Health Behavior Risk Scoring

Once contextually similar instances of risky text messages are found, a risk score is constructed with cosine similarity, similar to the approach used by Kiros et al [38]. Given user *i*'s *t*th message, the risk score is defined as the average cosine similarity between the word in the message,  , and the risky word *w* from each risk topic *d* set of risky words.

The distance between the words found in messages and those from the risk behavior dictionary was used to decide when a user was displaying a risky textual correspondence. Afterward, similarity between the risk scores generated by the model and those provided by the CDC risk assessment tool was assessed for each participant.

Results

Data

A total of 15,695 sent messages were collected in the 3-month timeline for 48 participants across 4 different platforms: Twitter, Facebook, Website A, and Website B after preprocessing. 6.5% (1026) of the messages were advertisements filtered out by our data processor. As shown in Table 2, the majority of messages, 75.7% (11,877), came from Website A, followed by Website B with 21.2% (3327), Facebook at 2.2% (352), and Twitter with 0.89% (139) of messages. Participant activity across all platforms is displayed as a heatmap in Figure 3, with participants 28, 40, and 42 showing the highest activity after initial onboarding.

The distribution of each topic is visualized in Figure 4. The topics with the most discussion across the social media sites were anal intercourse and methamphetamines use. In the messages themselves, tokens such as "clickedprofiletoken," "unlockedphotostoken," and "phonenumbertoken" were the highest occurring tokens across all messages. This makes sense, as activity in dating sites is heavily based on interacting with photos and other information exchange, potentially leading up to an offline connection.

In terms of clinical data, the distribution of each outcome can be seen in Table 3, where the majority of selected outcomes suffer from a 10% to 15% imbalance.

Table 2. Messages sent across social media platforms by participants.

Source	Messages sent, n (%[a])	Cumulative messages sent, n (%[a])
Twitter	139 (0.9)	139 (0.9)
Facebook	352 (2.2)	491 (3.1)
Website[b] A	3327 (21.2)	3818 (24.3)
Website[b] B	11,877 (75.7)	15,695 (100)

[a]Percentage of total messages.

[b]Specific to men who have sex with men.

Figure 3. A heatmap of user activity across all sources of data during the study.

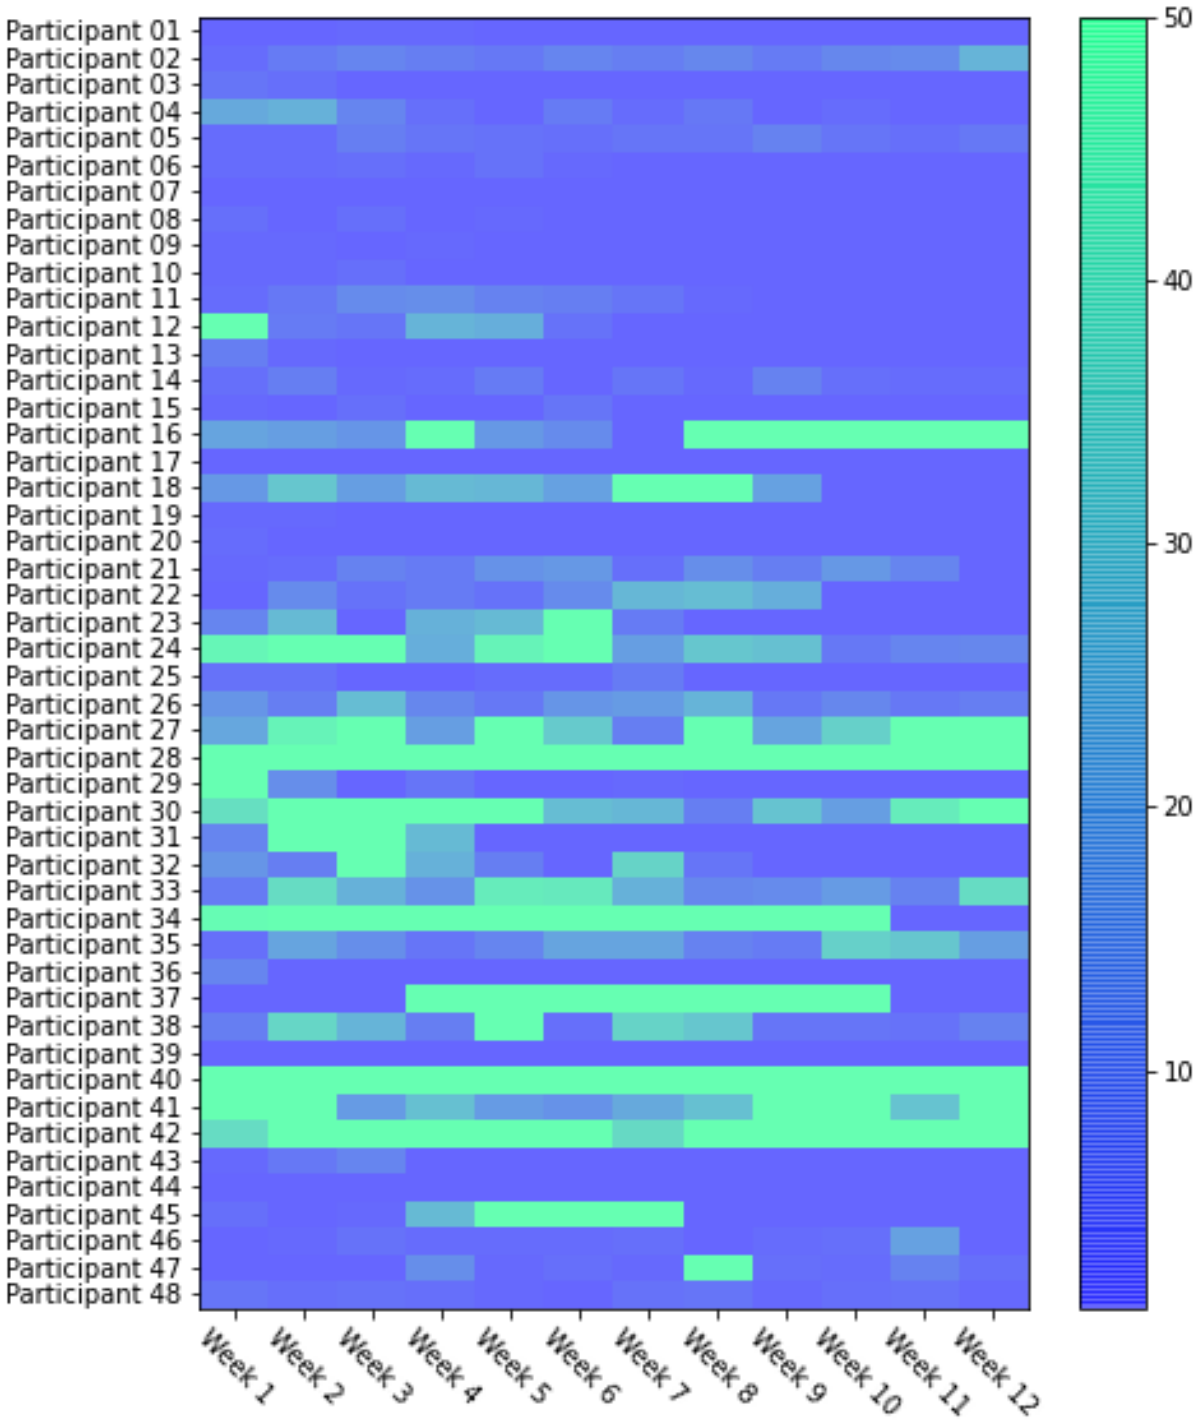


Figure 4. Topics found in messages using the risk behavior word dictionary provided by public health experts.

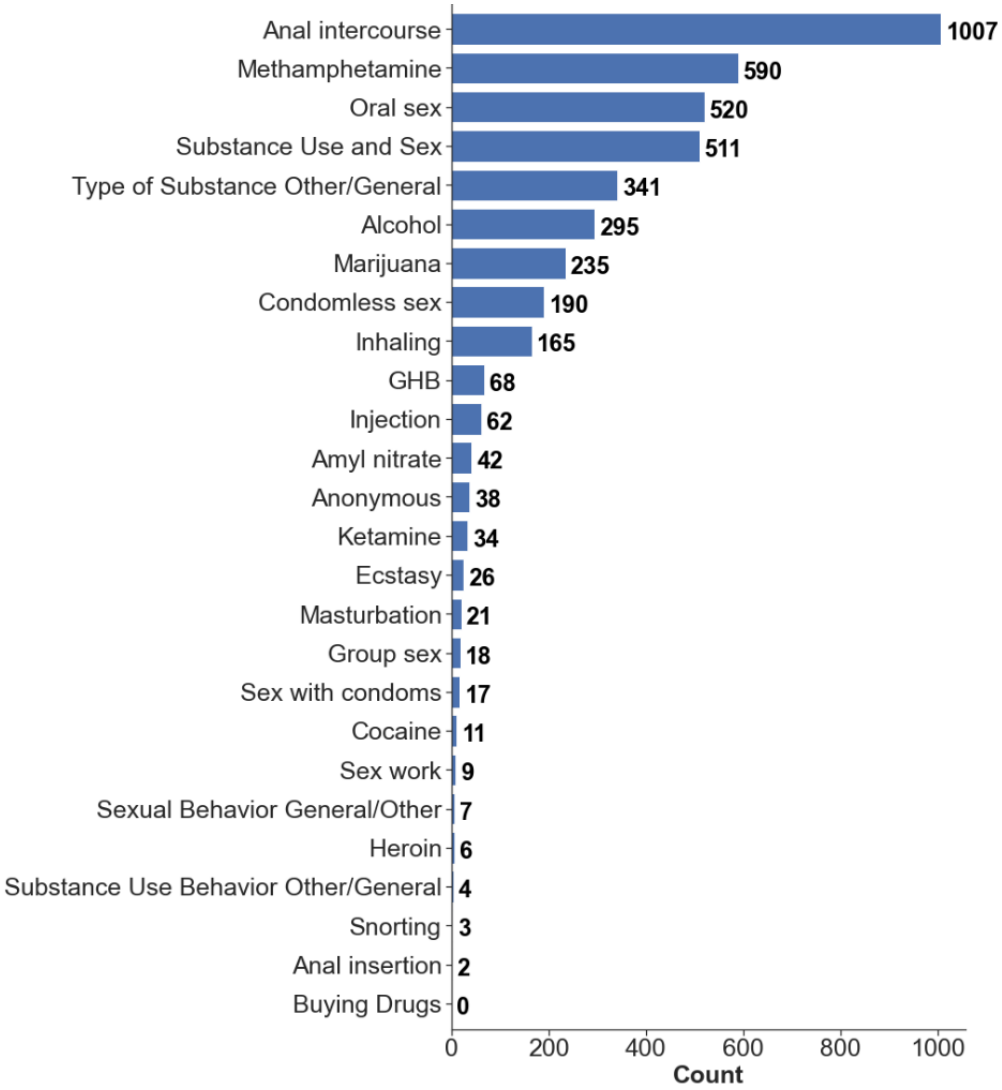

Table 3. Distribution of biomarker outcomes in a 1-month and 3-month follow-up after participants' initial onboarding.

Test and outcome	1-month follow-up (n=48), n (%)	3-month follow-up (n=48), n (%)
Sexually transmitted disease		
HIV[a]		
Positive	20 (41.7)	23 (47.9)
Negative	28 (58.3)	25 (52.1)
Substance use		
Amphetamine		
Positive	24 (50.0)	21 (43.8)
Negative	24 (50.0)	27 (56.2)
Methamphetamine		
Positive	25 (52.1)	22 (45.8)
Negative	23 (47.9)	26 (54.2)
THC[b]		
Positive	20 (41.7)	18 (37.5)
Negative	28 (58.3)	30 (62.5)

[a]HIV: human immunodeficiency virus.

[b]THC: tetrahydrocannabinol.

Biomarker Prediction

Of the 4 biomarkers, only 3 reflect an F1 score greater than 80%—HIV, amphetamine, and methamphetamine (Table 4). Although the tetrahydrocannabinol outcome did not suffer from severe class imbalance, one reason that may explain the significantly poorer performance is that the topic was heavily impacted by polysemy. As an example, participants alluded to marijuana usage with words and phrases that had multiple meanings. The phrase "blowing clouds" could refer to smoking marijuana or smoking methamphetamines.

For these 3 offline biomarker outcomes, the random forest model resulted in the highest F1 scores. Amphetamine usage was the best predicted outcome for all 4 models.

Table 4. F1 scores for each respective model and outcome in a 1-month and 3-month follow-up period after participants' initial onboarding.

Outcome and model	F1 Score, %	
	1-month follow-up	3-month follow-up
HIV[a]		
Support vector machine	70.5	81.6
Random forest	73.4	82.6
Naïve Bayes	69.6	82.1
Logistic regression	68.5	81.4
Amphetamines		
Support vector machine	88.2	85.9
Random forest	88.3	85.9
Naïve Bayes	88.0	85.5
Logistic regression	88.1	85.8
Methamphetamines		
Support vector machine	88.3	85.1
Random forest	88.3	85.3
Naïve Bayes	88.1	84.8
Logistic regression	88.2	85.0
THC[b]		
Support vector machine	11.1	7.4
Random forest	5.0	0.5
Naïve Bayes	24.0	4.7
Logistic regression	10.9	9.1

[a]HIV: human immunodeficiency virus.

[b]THC: tetrahydrocannabinol.

Associating Words With Health Behavior Risk

A dimensionality reduction technique, *t*-distributed stochastic neighbor embedding, was used to observe the relationship between word embeddings [39]. Figure 5 shows the resulting vector space as words are projected onto a 2D plane. Intuitively, the resulting proximity between words can be interpreted as their similarity. As a result, natural groupings between drug and sex-related words form. For instance, the word "Smurff," a term used to describe oral sex, is grouped with the term "head," a known colloquial term for oral sex.

Health behavior risk scores were calculated using the Word2Vec word vector space. Risk scores were created each day for a given user in addition to their average risk score along with risk scores provided by public health experts. While the constructed daily scores vary across time, there is a visible similarity between the generated risk score and expert scores, on average (Figure 6).

Figure 5. A t-distributed stochastic neighbor embedding visualization of the resulting vector space after running Word2Vec: drug-related words, sex-related words, and randomly chosen words.

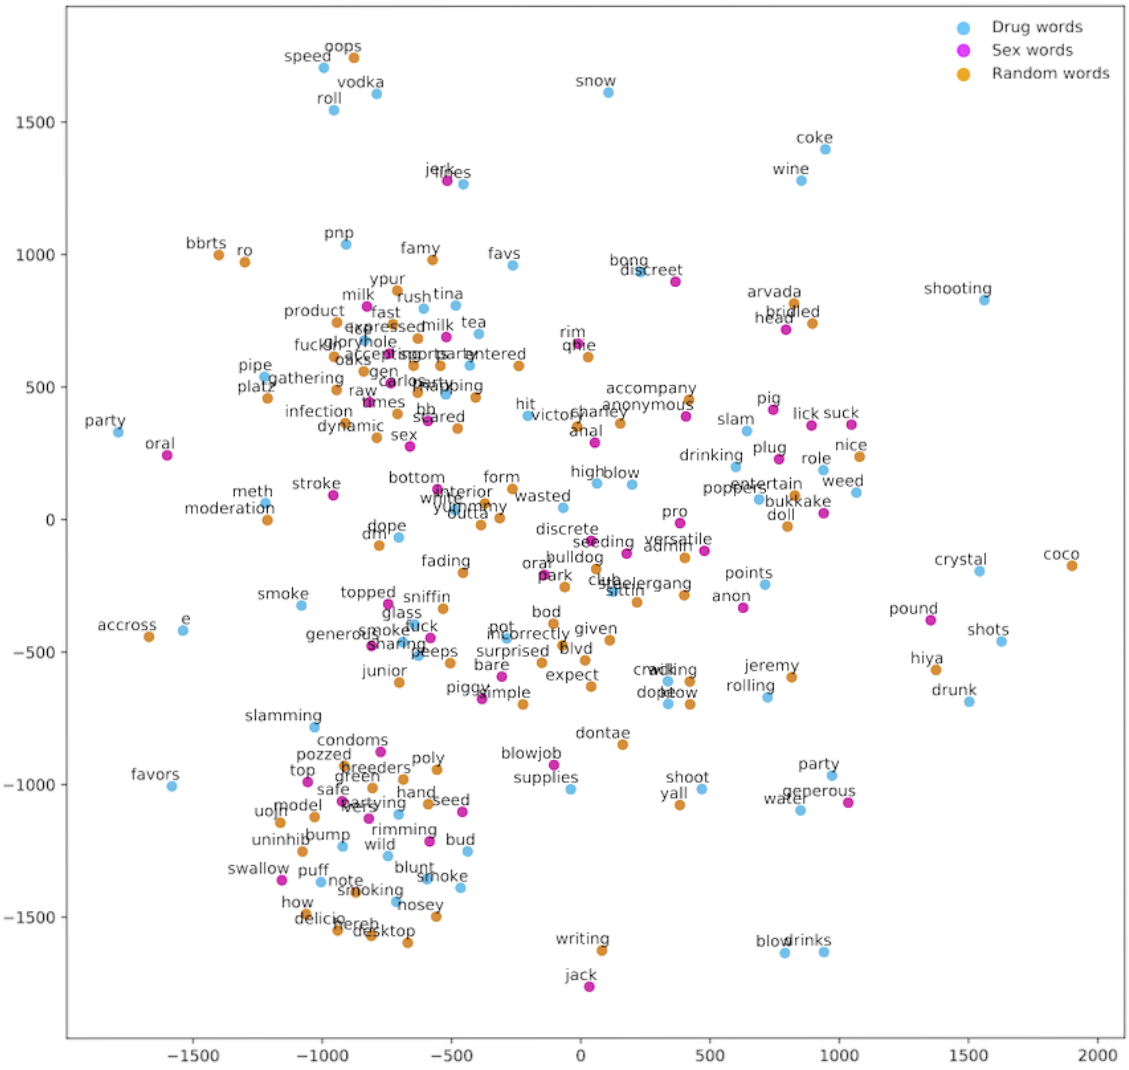

Figure 6. Normalized expert risk evaluation for drug and sex at 1 month and 3 months.

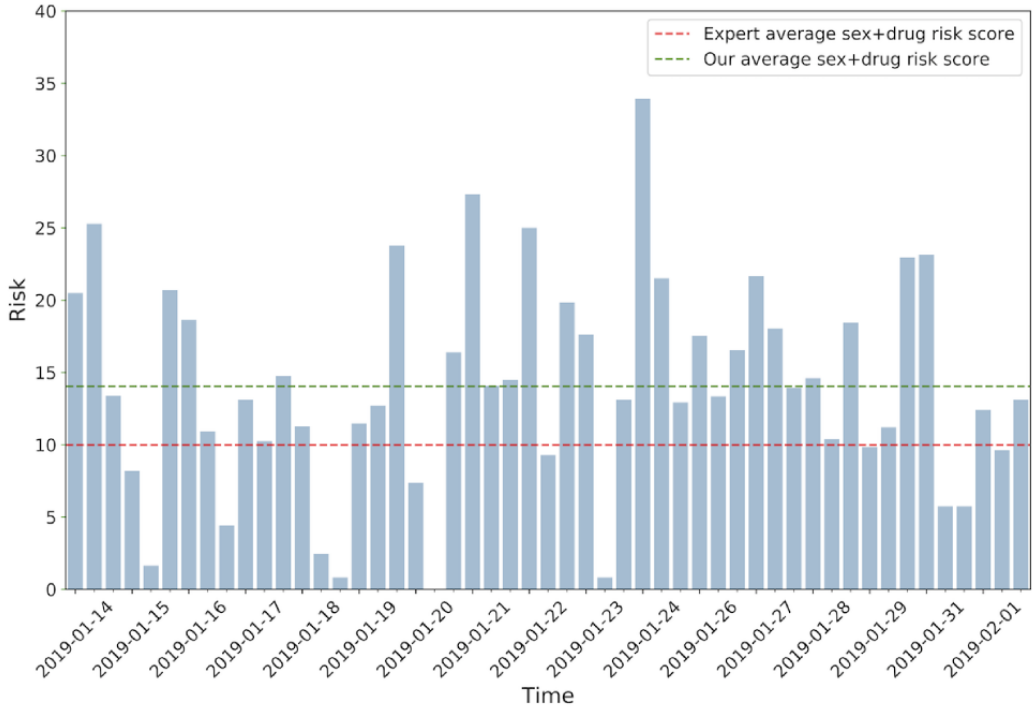

Discussion

Principal Results

To our knowledge, our study is the first empirical evaluation of a social media–based public health intervention framework for men who have sex with men. Our qualitative work highlighted the ways in which men who have sex with men use coded language online to refer to specific substance use behavior and HIV risk. We investigated the association between social media data and offline health risk behavior by operationalizing social media data across several networking sites. We built a system that automated social media data collection, which allowed us to predict offline substance use and sexual health biomarkers and construct daily health behavior risk scores.

In conducting an exploratory data analysis to check for data quality, we validated that the system was indeed able to collect participant messages consistently and reliably using the proposed system architecture. It was reasonable to observe that most messages came from men who have sex with men–specific social networks, as individuals may be more reserved around topics related to health risk behaviors over platforms with a larger audience such as Facebook and Twitter. Furthermore, we observed that after the topic of anal intercourse, the topic of methamphetamines was the most frequent in risk behavior conversation (Figure 5).

We tested the extent to which social media data could provide meaningful insight into health risk behaviors by predicting offline sexual health and substance use biomarkers. We found that across the models and clinical timelines, there was a consistently high F1 score when predicting HIV, amphetamine, and methamphetamine use. These results are validated by the fact that methamphetamines are one of the most commonly used drugs in among men who have sex with men [5]. Moreover, these findings align with existing literature pointing to the association between methamphetamine use and increased risk for HIV [4-6,10,13]. Most importantly, we validate the significance of social media data in its association with substance use and sexual health biomarker outcomes.

Daily health risk scores were created for participants using only social media data. The method was validated by the observation that the constructed risk scores, on average, were comparable to adapted risk scores created by the CDC risk assessment tool. The results were promising at a fundamental level, as we observed how words in social media messages can indeed cluster with known drug and sex-related words when mapped to a vector space (Figure 5). In constructing an average risk score for participants, we used their text messages and respective contexts to extract risk; we assumed that the public health risk dictionary was most accurate and encompassing of health risk behavior terminology. The health behavior risk scores were constructed on a daily level. Only social media data were used to construct the risk score, while public experts used biologically verified results and self-reported data to construct monthly risk scores by adapting a version of the CDC risk assessment tool. Yet, even with this significant difference in methodology, the average risk was still quite similar to the expertly assessed risk. This suggests that the community-based participatory approach used to create the data dictionary was crucial to the risk score creation process. Hence, the success of using such an approach heavily relies on involving end users in the creation of social media tools.

Limitations

The technical setup and maintenance needed for a social media data collection platform is an important consideration for scalability. Extensive effort and resources were required to achieve HIPAA compliance for our system. Additionally,

creating the data collector required custom handling of each data source. For instance, Facebook's policy change called for a completely different approach to data collecting in the middle of the study. To provide a scalable solution, the data collection platform should be flexible enough to adjust to a new collection regime due to circumstances outside of the study's control.

Several outcomes did not pass our exclusion criteria filter at the beginning of the study due to a significant imbalance in their respective distributions, leading to challenges for biomarker prediction. Additionally, employing methods that handle class imbalance may improve our current F1 scores. At a higher level, it is also important to note that the scope of this paper is somewhat limited since we only collected data from a few websites, which may not be used by the entire community of men who have sex with men.

Implications

Self-report is a common form of feedback for health behavior interventions. While useful, it is often flawed because of biases such as recall bias and social desirability bias. Therefore, the health behavior data in this study were combined with biologically verified data to calculate risk. We found that social media may serve as a valid intervention modality as it provides both valuable and relevant feedback. Overall, we determined that combining self-report data with biologically verified outcomes and social media data mining gives a more nuanced and accurate picture of health behavior risk. These findings suggest that it is feasible to use social media data for future public health intervention.

Conclusions

In this study, we created an end-to-end system that leverages social media data for health behavior risk identification, serving as a proof of concept for social media–based behavioral intervention. We demonstrated that it is possible to build an integrative system across multiple platforms that effectively collects meaningful social media data. We determined that social media messages are a valuable source of examining the relationship between health risk behaviors and biologically verified sexual diseases such as HIV and illicit usage of amphetamines and methamphetamines among men who have sex with men. Adapted CDC health risk scores were compared against social media–based behavioral risk scores and found to be, on average, similar to the expertly assessed scores. This validates the feasibility of employing a social media–based behavioral intervention. The contributions made in this paper are stepping stones toward building an automated, cost-effective, fully scalable social media intervention system that serves the public health domain.

Acknowledgments

We thank all the participants of this study for their time and cooperation. We are grateful for our collaborators and researchers. We would like to thank Christian Paneda, Omkar Patil, Tom Weng, and Amrutha Srinivasan for helping to maintain the data collection system. IWH and ESCW are supported by the California HIV/AIDS Research Program (RP15-LA-007) and the University of California, Los Angeles Center for HIV Identification, Prevention, and Treatment Services (P30 MH058107). This study was also partially supported by National Institute on Drug Abuse (R03 DA039752).

Conflicts of Interest

None declared.

Abstract

Background: Digital mental health promotion interventions (MHPIs) present a scalable opportunity to attenuate the risk of mental health distress among nonclinical cohorts. However, adherence is frequently suboptimal, and little is known about participants' perspectives concerning facilitators and barriers to adherence in community-based settings.

Objective: This study aimed to examine participants' perceptions of facilitators and barriers to adherence in a web- and mobile app–based MHPI for a nonclinical cohort.

Methods: This qualitative study used inductive, reflexive thematic analysis to explore free-text responses in a postintervention evaluation of a 10-week digital MHPI. The intervention was administered using a web and mobile app from September to December 2018. Participants (N=320) were Australian and New Zealand members of a faith-based organization who self-selected into the study, owned a mobile phone with messaging capability, had an email address and internet access, were fluent in English, provided informed consent, and gave permission for their data to be used for research. The postintervention questionnaire elicited participants' perceptions of facilitators and barriers to adherence during the intervention period.

Results: Key factors that facilitated adherence were engaging content, time availability and management, ease of accessibility, easy or enjoyable practical challenges, high perceived value, and personal motivation to complete the intervention. The primary perceived barrier to adherence was the participants' lack of time. Other barriers included completing and recording practical activities, length of video content, technical difficulties, and a combination of personal factors.

Conclusions: Time scarcity was the foremost issue for the nonclinical cohort engaged in this digital MHPI. Program developers should streamline digital interventions to minimize the time investment for participants. This may include condensed content, optimization of intuitive web and app design, simplified recording of activities, and greater participant autonomy in choosing optional features. Nonetheless, participants identified a multiplicity of other interindividual factors that facilitated or inhibited adherence.

Introduction

Background

Mental distress and disorders are increasingly prevalent [1], and mental health promotion interventions (MHPIs) present opportunities to enhance the well-being of nonclinical groups, decreasing the risk of mental health distress. The widespread availability of digital technology offers unprecedented accessibility, portability, and cost-effectiveness for implementing such interventions on a wide scale. However, adherence, defined by Kelders et al [2] as "the extent to which individuals should experience the content (of the intervention) to derive maximum benefit from the intervention, as defined or implied by its creators," is often suboptimal [3], and little is known about participants' perceptions of facilitators of and barriers to adherence for nonclinical cohorts in community-based settings.

Considerable research has been undertaken by researchers and program developers to facilitate optimum adherence to digital health initiatives. Methods used to promote participant adherence include the adoption of a robust set of persuasive system design principles [2,4,5], provision of rewards and incentives, positive feedback [6], implementation of gamification techniques [7,8], and various forms of human support [9]. However, adherence to digital interventions remains to be problematic [3], and there is a paucity of research elucidating participant perspectives on the factors that impact adherence [10] in community-based, nonclinical groups. Importantly, factors that may hamper adherence in a clinical population (eg, disease and disorder symptoms) [11,12] may be dissimilar to the influences on adherence in healthy nonclinical cohorts.

Several qualitative studies have addressed participant perspectives on perceived barriers to and facilitators of adherence in MHPIs for nonclinical cohorts in workplace settings. A stress management intervention, using mindfulness training, found that participants' attitudes (eg, motivation, previous interest in mindfulness, and positivity toward change), awareness of treatment effectiveness, curiosity, and alignment with personal preferences for managing stress were facilitators of adherence [13]. Conversely, barriers included insufficient detail or evidence provided as a rationale for the strategy used, length of time required for completing activities, and program intensity [13]. Carolan and de Visser [14] explored employee perspectives on workplace digital mental health interventions and found that lack of time was considered the core barrier to adherence. Notably, anonymity, convenience, and flexibility were deemed to have dual impacts (ie, considered both a facilitator and barrier). Employees described their ideal workplace intervention as one that was short, that was easily accessible, that was available for an indefinite period, updated regularly, and that provided some form of e-coaching support [14]. Research by Blankenhagel et al [15], which focused on the perspectives of various stakeholders in digital stress management programs, found that certain requirements of interventions were needed for nonclinical users who often have substantial work responsibilities. These intervention requirements were prioritizing time efficiency (5- to 15-minute sessions), splitting larger goals into smaller goals, providing flexibility for users to design their own personal notification or reminder schedule, featuring an intuitive and simple web or app design, prioritizing individualization (ie, tailoring), providing high autonomy, fostering some degree of human interaction, facilitating comparability to peers, and offering high mobility [15]. The aforementioned requirements related to a work-based setting for a nonclinical cohort; however, although there may be similarities, variant influences on adherence may be present in a community-based context.

This study sought to broaden the understanding of factors that both facilitate and hinder adherence in a nonclinical cohort participating in a digital MHPI within a community-based situation. This study builds on quantitative data collected during a randomized comparative study that examined the impact of different levels of human support on well-being outcomes [16] and attrition and adherence [17] in a digital MHPI for a nonclinical cohort. Quantitative data revealed improvements in mental well-being irrespective of the level of human support offered, and adherence did not differ significantly between groups. Notably, using the aforementioned definition of adherence by Kelders et al [2], participants were advised to view one video weekly and complete daily and weekly experiential activities over a 10-week period to gain optimal benefit from the intervention. Overall, attrition and adherence were suboptimal [17]. A total of 605 subjects indicated an interest in the intervention by filling out a preliminary web-based enrollment form, with 24.3% (147/605) of these subjects not fully registering by failing to complete the prequestionnaire. Of those who completed the prequestionnaire (n=458), a further 30.1% (138/458) did not complete the postquestionnaire, resulting in a completion rate of 69.9% (320/458). Primary adherence was measured by the number of videos viewed, with 34% (109/320) of the cohort watching less than half of the videos, 18.9% (60/320) viewing 5 to 9 videos, and 47.1% (151/320) viewing all 10 videos. Secondary adherence was measured by the points scored for completing assigned daily and weekly activities. Participants could score a total of 1000 points (ie, 100 points weekly throughout the 10-week intervention) to be considered fully adherent. The mean score for the cohort was 362, indicating low adherence to challenge activities [17].

Objectives

This study aims to increase knowledge regarding participant adherence in digital MHPIs by revealing participant perceptions about the facilitators and barriers to watching the videos and their completion of daily and weekly experiential activities. The findings will assist researchers and developers to refine and improve the design and implementation of interventions to optimize the adherence of participants in future MHPIs in nonclinical settings.

Methods

Overview

This qualitative study stems from the aforementioned study, which reported the quantitative results of the intervention

[16,17]. These qualitative responses were recorded as part of the postquestionnaire administered at the conclusion of the intervention. Participants were allocated a 2-week period, immediately after the intervention period, to complete the postquestionnaire on either the provided app or the web platform. Therefore, the following section of this paper is a summary of the methods used in the aforementioned study, with details only provided for those areas related to the qualitative components of this study.

Setting and Participants

Advertising was used to direct potential participants (Australian and New Zealand members of the Seventh-day Adventist Church) to a website that explained the intervention, outlined the inclusion criteria, and provided an opportunity to self-enroll as a potential participant. To be included in the study, subjects were required to be aged above 18 years, own a mobile phone with SMS text messaging capability, have internet access, be an Australian or New Zealand resident, be fluent in English, provide informed consent, and give permission for their data to be used for research [16]. Participants who completed the MHPI were invited to provide free-text responses to 2 statements within the postquestionnaire.

Intervention

The intervention program, known as the *Live More Project* or *Lift Project*, introduced participants to aspects of neuroscience and a combination of evidence-based strategies to enhance mental well-being from the disciplines of lifestyle medicine and positive psychology. Designed to be implemented as a weekly session for 10 weeks, the content of the program was shared in a 30-minute audiovisual presentation followed by participation in daily and weekly practical activities to consolidate learning. Video sessions were released weekly with a lock/unlock system so that participants watched the presentations in sequential order. An intervention and activity overview is provided in Multimedia Appendix 1.

Subjects chose to access the program on a web-based learning management system (eLMS) or a mobile app. Along with the audiovisual content, the eLMS or mobile app included a place to complete the pre- and postquestionnaire, a section to log experiential activity and earn points, an opportunity to interact with other participants through a public feed, and gamification strategies (eg, points on a leaderboard or badges) to induce adherence. As an optional extra, previously introduced experiential activities could be repeated and logged in forthcoming weeks to earn extra points. This resulted in an increasingly longer list of activities to complete as the intervention progressed. Screenshots of the web- and mobile app design are shown in Multimedia Appendix 2.

Participants were divided into 3 groups that differed according to the mode of human support allocation. The first group received automated email support only, the second group received automated email support along with text messages (2-3 times weekly), and the third group received weekly videoconference support along with email support [16].

Data Collection

After completing the intervention, each participant was asked to complete the postquestionnaire within a 2-week period on either the web or mobile app. As part of the postquestionnaire, participants responded to 2 adherence-related statements in an expanding text box with no imposed word limits. These statements were as follows:

- *Statement 1*: thinking about your personal experience as a participant in the Live More Project over the last 10 weeks, if it was *easy* for you to watch the video presentations and complete the daily and weekly challenges, please describe/list all the factors that contributed to this.
- *Statement 2*: thinking about your personal experience as a participant in the Live More Project over the last 10 weeks, if it was *difficult* for you to watch the video presentations and complete the daily and weekly challenges, please describe/list all the factors that contributed to this.

Data Analysis

An inductive, reflexive thematic analysis (RTA) approach [18-20] was used to extract meaning from the data set. The inductive approach is sometimes described as *bottom-up*, or data-driven, as the themes are generated from within the data [20]. The RTA method suited one researcher (MR) performing the initial coding, followed by 2 additional coders reviewing the progress. MR had multiple roles in the study and functioned as the technical support person; therefore, this approach, in which multiple coders reviewed the data (as recommended by O'Brien et al [21]), reduced the possibility of personal bias.

The coding researcher adopted the 6 phases of thematic analysis by Braun and Clarke [20] as a structured approach and used a spreadsheet (Microsoft Excel) and a qualitative analysis program (NVivo software) to assist in collation, analysis, and coding of the deidentified data. All identifying information was removed before coding, and participant identification numbers were used instead. In phase 1, the researcher read through the data set twice to maximize familiarity with the data. During phase 2, all comments were systematically analyzed by constructing and labeling codes in a descriptive and interpretive manner until all data were coded. In an additional immersion stage, coding was reviewed and code names were edited. In phase 3, the researcher scrutinized the codes for patterns, relationships, and similarities. The codes were clustered together based on broad themes. During phase 4, after repeated scrutiny to ensure that the code names accurately matched the data and that the developing themes represented the participants' descriptions of their most typical experiences, clusters were formed into broad themes and several subthemes to develop a thematic map, as recommended by Braun and Clarke [18]. To ensure that the themes and subthemes accurately reflected the original data set as a whole, and the coded data, a final revision of the themes and codes was undertaken by the original coding researcher in consultation with 2 other researchers. During this process, the coders analyzed the themes and subthemes in relation to the original intention of the study. This procedure enabled the coders to identify any mismatches between the theme and subtheme names and the original data. Furthermore, the coders identified any themes, subthemes, codes, or data within codes that were

deemed of low relevance to the overall themes or this study's intention. This relevance-based scrutiny was followed by analysis of any codes that were characterized by very few participant quotes. This way, we were able to determine the *weightiness* or key ideas across the entire data set. In cases where relevance and the number of participant responses were considered to be low, the subtheme or code was discarded from the overall thematic map.

In the final phase of coding, the original coder and consulting coders collaboratively identified the main focus and extent of each theme. Some names of the main themes and subthemes were also modified to increase the alignment between the documented theme and subtheme labels and the data they each contained. This refinement of the theme and subtheme definitions informed the final write-up phase.

The Standards for Reporting Qualitative Research checklist was used as a guide for reporting (Multimedia Appendix 3) [21], and ethics approval was granted by the Avondale Human Research Ethics Committee (approval 2018.09).

Results

Overview

Most participants were female (262/320, 81.9%), and 50.3% (161/320) of the participants were aged 40 to 60 years. Almost one-third of the cohort (91/320, 28.4%) were aged 25 to 39 years, 15.6% (50/320) were aged 61 to 81 years, and 5.6% (18/320) were aged 18-24 years. Two-thirds of the cohort (212/320, 66.2%) worked either full or part time, 6.2% (20/320) identified as students, and the remaining 27.6% (88/320) identified as being unemployed or doing *home duties*. The majority of the cohort (240/320, 75%) provided a codable response describing facilitators of adherence, and almost all participants (314/320, 98.1%) provided codable responses related to barriers.

As the participants were asked to respond to 2 separate statements (one focusing on facilitators and the other focusing on barriers), responses to these 2 statements were analyzed separately. However, in some cases, participant responses overlapped and issues were reported as both a facilitator and a barrier. Broad themes that emerged were time, program components, personal factors, system design, technology, and human support. Notably, comment frequency regarding barriers to adherence were more than double the comments specifying facilitators of adherence. Table 1 (facilitators of adherence) and Table 2 (barriers to adherence) outline the thematic framework of responses.

During the development of the thematic map, it became evident that there was strong alignment between themes and subthemes in both sets of responses, that is, the thematic map illustrates the two-fold nature of most themes, with the order of reporting of the themes reflecting the most important themes first, as assessed by the coding researcher, according to relevance and volume of comments received. The issue of time emerged as a dominant theme in the data, with the vast majority of participants mentioning *time* across their responses.

Facilitators of Adherence

Time

Time was perceived as a facilitator of adherence when participants believed that they had time available and efficiency was optimized. Each weekly lesson was released on a Sunday, and this timing was viewed positively. Expediency afforded by being retired, living alone, or not working also facilitated adherence:

> *I liked that the videos were released on Sunday, even if some Sundays were busy and we couldn't make time to watch them that day. Sunday is a day it's easier to make time to watch the full set of lesson videos.* [ID 2614]

Some participants prioritized, scheduled, and multitasked to ensure that the program components were completed each week. Specific factors that permitted time availability or efficiency included being at home, not traveling, completion of usual duties, incorporation of tasks into daily activities, a high level of organization or planning, and having children in a regular sleep routine:

> *When I made specific time to sit down and watch the program it made it easier to participate and plan how I can incorporate the challenges.* [ID 2278]

Program Components

This theme refers specifically to video content and the completion of practical activities. A total of 3 subthemes related to the program's components emerged from the analysis: the overall program, video presentations, and experiential activity.

Although some participants perceived that the overall program was of high quality, easy to understand, and engaging, the key program components perceived as facilitators of adherence were the video presentations and the experiential challenges. Engaging video content has been frequently reported as a facilitator of adherence. The terms used to describe the videos included *humorous*, *entertaining*, *interesting*, *motivating*, and *easy to understand*. Participants appreciated the lighthearted presentation style, which included just enough information and interesting facts, to avoid information overload:

> *The videos were funny and engaging. Had enough info to be interesting but not overly filled with over-your-head stuff.* [ID 2380]

The daily and weekly experiential challenges that participants completed and recorded were perceived as fostering adherence because they were relevant, easy to accomplish, enjoyable, simple to log or record, and readily incorporated into daily life. Some challenges could be easily doubled up and, for some participants, recording their challenge activity provided a sense of accomplishment:

> *The small daily challenges were able to be absorbed into the day without having to find extra time and it felt like many could become habits.* [ID 2302]

> *I found a lot of the challenges crossed into another which made it easier such as being in the green and blue and going for a walk covered two challenges.* [ID 2550]

Personal Factors

There are numerous personal reasons that may influence adherence, including beliefs, motivation, personal well-being, and a broad array of diverse circumstances. During coding, several key personal subthemes were developed that included motivational factors, beliefs about the value or relevance of the program, level of personal well-being, and individual capacity.

Motivation and perceived value were identified as subthemes that positively influenced adherence at a personal level. Participants reported positive motivation through a high level of readiness, commitment to the intervention, and a personal

desire to improve their health. Some participants were motivated to maintain their adherence to the program based on their belief that the intervention would be personally beneficial to them. They recognized a number of enabling aspects of the program, including the way it reinforced positive lifestyle choices; recognized that even small changes would be worthwhile; and identified the value of immediate effects. Participants also benefited from the multifactorial approach:

> *I looked forward to the video presentations because they were so relevant to my life, very interesting and well presented. I have been experiencing problems with sleep issues for many years and even taking herbal sleeping supplements, but after applying the information I received from the Live More sessions, I've been a good 7 to 8 hours sleep every night. This has been mainly the result of all the walking I've been doing - between 1 to 2 hours a day and more. I'm now taking more notice of nature and enjoying more green and blue. Having recently moved from [name of Country], I had no friends and felt lonely. So I went to the local Library and Community Centre and got a booklet with the different activities for retired people. I joined a group of like-minded people and enjoyed the activities they provided.* [ID 2419]

System Design

This theme relates to the various design and accessibility features of the web or mobile app and primarily includes the methods used to disseminate weekly video content and record experiential activities in the digital setting. Additional features such as gamification (ie, earning points), the ability to view what others were doing, and accessibility to extra resources were also included. Similar to other themes, the system design facilitated adherence for some participants and was perceived as a barrier for an almost equal number.

Two key design concepts were reported by users as positive influences on adherence: accessibility and convenience of the mobile app. Participants appreciated flexible access to view and review the content. This was amplified with easy portability through a mobile app:

> *I could do it when it was suitable for me. Whether 10pm or 6am. The flexibility made it possible.* [ID 2195]

Barriers to Adherence

Time

Participants overwhelmingly perceived lack of time as problematic to adherence, with noticeably more comments referencing time as a barrier to adherence rather than a facilitator. Furthermore, time was mentioned substantially more often than any other factor recognized as a barrier. The 3 subthemes generated in relation to lack of time were daily life, life events, and the intervention period.

The demands of daily life were the foremost barriers and predominantly included work, study, and family commitments and the various combinations of all three:

> *Small child needing attention, lack of help from spouse due to work commitments; other extra-curricular activity; helping my elderly parents with household tasks and other daily activities.* [ID 2538]

Major life events were perceived as hindering adherence and included the death of a loved one, relocation, major illness, or a combination of trials that consumed major amounts of time:

> *The timing of this project was the one of the busiest 10 weeks in my life! Moved house. Solo parented for 4 weeks. My sister's wedding. School holidays. The sickest our family has been in 10 years. Term 4 after-hours school events as part of my work responsibilities. We moved house the week the program started and then went straight into school holidays of which we were away the whole time. Then we were really sick for three weeks whilst I was solo parenting. So I just never got the chance to get started.* [ID 2214]

The intervention was conducted from September to early December 2018. The lead up to Christmas and the added pressures that often accompany the Christmas period in the work and social environment were deemed barriers. In addition, for this cohort (ie, a faith-based population), church activities were perceived as adding further to the time pressures already experienced at this time of year:

> *Making a commitment at this time of year was more difficult than I thought; this time of year is hectic for my job which also probably means my answers at the end could actually be worse than at the start, because of how tired I have been.* [ID 2630]
>
> *If it was at another time of year I probably would have completed it. This time of year is crazy for me at work, I'm a preschool assistant, and I am involved with helping with Road to Bethlehem [Christmas program]. The last few weeks I just found it difficult to think much about what I was doing.* [ID 2417]

Program Components

Some users deemed the overall program too intense and too long. Video segments were perceived as lengthy, and some users found the content unappealing and disliked the presentation style, describing it as *cliché*, *corny*, and *over the top*:

> *The videos were too long. I'd prefer 2-3 shorter ones per topic. That would be easier to watch while in train or fitting between other things I had to do.* [ID 2318]
>
> *While the actual science was interesting, much of the video content felt patronising and the jokes fell flat.* [ID 2142]

Most perceptions about the program components were directly related to difficulties with experiential activities. Time was viewed as a hindrance for both completing and logging the activity, and some participants perceived the activities as being too hard. Although some participants completed the daily and weekly experiential challenges, they disliked recording their

activities, felt overwhelmed by the increasingly growing list of activities to record, or simply forgot to log their activities:

> *Having the challenges compound each week to record them meant that it was too overwhelming and I gave up logging on to record. I think having reminders about the previous weeks challenges is great, but filling in that many challenges every day is too hard!* [ID 2287]

Personal Factors

Numerous personal factors hindering adherence were grouped under 2 subthemes: personal well-being and capacity. Personal illness was the dominant factor affecting well-being. Other factors influencing well-being included the presence of a mental disorder, stress, and fatigue, with several respondents specifically identifying screen fatigue. Comments regarding capacity were equally divided among 3 key areas: a reported lack of motivation, discouragement at lagging behind in viewing content or completing experiential activities, and simply not prioritizing the intervention:

> *When I had downtime I didn't have the motivation to intently watch the videos & do the thinking & work required so it was easy to fall behind.* [ID 2204]

> *Also, with working full time (looking at a screen) all day, I really didn't want to sit in my home office to look at another screen, so I failed to keep on top of the weekly presentations.* [ID 2563]

System Design

Several design features and difficulty navigating the website were perceived as negative influences on adherence. Most comments were made in relation to the lock restrictions, the lack of some desirable features, dissatisfaction with the gamification setup, and the perceived tedious system for logging experiential activity. Although participants were provided with a recommended 10-week schedule for engaging with the intervention content, some participants emphatically opposed the lack of autonomy in how and when they consumed the information:

> *I don’t mind having to unlock videos - just please don’t constrict it to a week at a time!!! And let me do any or all of the challenges at the start or when I unlock things in my own time - don’t make me wait 7 days / a fortnight / 3 weeks etc to engage in all the challenges just because! Let me unlock them at my pace.* [ID 2142]

Desirable features that were noted as missing included an audio-only option, the ability to predownload the video content, and the option to read the material instead of viewing a video. A readable script was actually provided, although it was not explicitly recommended as an alternative to viewing video content. Although gamification was included as a way to enhance adherence, for some participants it was perceived negatively and a deterrent to further adherence:

> *It's very demotivating having a leaderboard for someone who's not near the top.* [ID 2549]

The system setup for recording experiential activity was seen as a barrier because it was perceived as difficult to use, with one participant describing it as “glitchy and not particularly intuitive” with “long and clunky lists” [ID 2142]:

> *Prompts on challenge input boxes were too vague about what the user needs to write. Should the user explain anything or just state that the challenge was completed? It was not clear whether the user's statement in the challenge input box would we shared with others (user had to just try it and see what happens during the first session). I could not log more than one challenge on the interface at a time (I had to change to another page and then come back to the challenges to log another one).* [ID 2391]

Technology

Technology (ie, data availability, internet access, and device suitability) was deemed a barrier, mainly because of poor internet accessibility or personal device problems.

Internet access problems included slow download speeds, internet outages, and no internet access at home. Personal device problems included old or faulty smartphones that could not download the mobile app, small screen size, sound problems, and perceived inability to correctly operate the device:

> *We had some difficulty watching the videos on my tablet, the volume is not loud enough, we really need a PC or to data project to a bigger screen for optimal viewing/listening.* [ID 1767]

Human Support

Human support offered to participants varied depending on the group allocation they received. All participants received automated email reminders to engage with video content and record their practical activities. One group received regular text messages, and the other group was offered weekly videoconference sessions as an extra measure of support. Despite human support being the focus of the original study [16], perceptions about the support offered did not feature strongly. However, some participants reported that adherence was impeded because of human support factors or lack thereof. A lack of prompting and accountability were stated as reasons for difficulty in adherence. In the group that received videoconferencing support, some of the group members reported that videoconferencing support was problematic for a range of reasons, most commonly that the meetings were held at an unsuitable time:

> *Timing of online groups sessions didn’t work for me with my responsibilities during that time period. I needed a later evening session. 9pm! Or a 5:30am session. The timing of the first 5 weeks would have been difficult for me regardless.* [ID 2214]

Discussion

Principal Findings

This study provides novel insights into participants’ perspectives regarding facilitators and barriers to adherence in a digital MHPI

for a community-based nonclinical population. Themes often had dual impacts, deemed as both facilitators and barriers. Facilitators of adherence included engaging in video content, achievable experiential activities, time availability, user-friendly web and mobile app design, and high personal interest or motivation. Conversely, a perceived lack of time was the main barrier to adherence. Completing and logging practical activities, a range of personal influences, problematic design features, technological issues, and a lack of support or prompting were also identified as barriers.

As barriers were the predominant focus of participants' perspectives, it is clear that an MHPI is a difficult endeavor for a nonclinical group and that time is the foremost issue in relation to adherence. Similarly, other qualitative studies in workplace settings [14,15] have concluded that time scarcity is a major inhibitor of adherence and that participants need interventions requiring only small time commitments. It is evident that certain features or problems (eg, difficult website navigation and restrictions on video viewing) consumed inordinate amounts of the participants' time, thereby negatively impacting their adherence. Similarly, such issues have previously been exposed as barriers to the success of web-based learners in educational settings [22,23]. Therefore, time efficiency must be a core consideration by researchers in every aspect of the intervention design. It is vital to design interventions to minimize time and energy investment for participants while concurrently optimizing outcomes.

An important element that underpinned the data was the participants' desire to easily incorporate core components of the program (ie, videos and challenge activities) into their everyday lives. A key priority in the design and development of future interventions should be to collaborate with potential users in designing interventions that enable autonomous, optimal integration of the essential intervention elements into daily life. Practical examples may include the provision of multiple options to access the content (eg, video, print, or audio), choice of methods to log activities, and recommendations on combining some activities to make optimal use of time.

The preponderance of dual themes in this study sheds more light on an important element that has been identified previously [24], that is, individual differences have a substantial influence on adherence to MHPIs. Although previous research by Banerjee et al [13] identified several twofold themes in a qualitative study focusing on engagement with a mindfulness intervention, a study by Zarski et al [24] on adherence to a digital stress management intervention noted that, even after accounting for socioeconomic demographics, personal well-being status, and human support, many individual variances in nonadherence were inexplicable. This study highlights some of these differences.

Understandably, the high prevalence of individual variance confounds efforts to crystallize a precise set of factors influencing adherence to digital interventions. Plausibly, future research should embrace individual differences by examining ways to prioritize participant autonomy in tailoring interventions according to personal preferences. This could be achieved by offering an eclectic, self-directed approach that encourages participant choice in activating or deactivating a range of optional features (eg, gamification or type and frequency of human support) as desired. This constructivist-style approach, commonly used in educational settings, is well supported by research as an efficacious method [25,26].

The original study, from which this qualitative study was derived, focused on the influence of varying levels of human support on outcomes and adherence to an MHPI [16,17]. However, in this qualitative analysis, human support did not have a strong influence on adherence. Considering that the quantitative analysis revealed that adherence was not impacted by different levels of support and that participants achieved improvements in outcomes irrespective of the human support provided, this is not surprising. Although numerous studies have demonstrated that human support may improve outcomes [9,27,28], there is substantial evidence that well-designed, self-guided interventions can be successful without added human support [9,29-32] and their associated costs.

Strengths and Limitations

The large cohort and inclusive age range (18-81 years) of participants were strengths of this study. Furthermore, participants were not restricted to the length of their responses and could write as little or as much as desired. All comments were coded, and participants received no guidance on what topics to comment on, eliminating preconceptions by researchers.

Recruitment bias could be seen as a potential limitation to this study as participants were self-selected into the study, and the target group were Seventh-day Adventist Church members who typically share common health practices (eg, abstinence from alcohol or smoking) and may be more inclined to take a greater interest in health than the general population. In addition, recruits were largely tertiary educated (262/320, 81.9%), White (280/320, 87.5%), and female (262/320, 81.9%). Although a high female proportion is the characteristic of an internet intervention [33,34], it limits transferability to the wider population. In addition, participants were not given the opportunity to indicate whether they used the web-based platform, the mobile app, or a combination of both, which prohibited a comparison of data based on the different delivery methods.

By allowing participants to comment freely on an open-ended statement, the assumption must be made that participants only reported on factors most relevant to their personal experiences. Therefore, the study does not contain all the views of the participants. As researchers, we adopt the position that the predominant issues are exposed and that the volume of comments depicts saturation on crucial issues.

Notably, 2 other factors may have inadvertently influenced participants' perceptions. First, barriers, particularly *time*, may have been augmented by the period that the intervention was conducted (mid-September to early December 2018). Avoiding administering an intervention that ends in December is a learning for future implementation. Second, the website and mobile app design, in permitting recording of an increasing array of experiential activities as the weeks progressed (rather than just

the activities for the current week), may have augmented dissatisfaction with the logging or recording component, introducing an element that went beyond the intentions of the original intervention design.

Conclusions

Although there are a diversity of factors influencing adherence, highly engaging content encourages adherence and time efficiency is a principal consideration for a nonclinical, community-based cohort. Therefore, intervention designers should place a concerted focus on streamlining interventions to reduce the time required by participants and simplify all program elements. Other considerations to increase adherence include allowing participants to create their own experience by choosing what optional features to include or exclude, enhancement of the website and mobile app to facilitate a more intuitive experience, shorter video presentations that are easily accessible and provide high autonomy in the way they are consumed, simplified and limited recording of experiential activities, and options for personal choice in accountability. In future research, it will be important to consider the views of users in relation to adherence and respond with an adequate level of agility that assures an ever-improving experience for participants to ensure optimal adherence and sustainability.

Acknowledgments

This work was supported by the South Pacific Division of the Seventh-day Adventist Church that provided free access to all participants who participated in the study. The authors would like to thank Jared Madden for coordinating the technical support throughout the study.

Authors' Contributions

MR and DM conceptualized this study. MR completed the data analysis in consultation with DM and MN. All authors contributed to the revision and editing of the manuscript.

Conflicts of Interest

DM manages a *profit-for-purpose* trust that uses a version of the intervention without receiving personal remuneration. GP is employed with the South Pacific Division of the Seventh-day Adventist Church (administrator of the intervention). No other authors have any financial interests or conflicts of interest to declare.

Abstract

Background: Cardiac rehabilitation (CR) is clinically proven to reduce morbidity and mortality; however, many eligible patients do not enroll in treatment. Furthermore, many enrolled patients do not complete their full course of treatment. This is greatly influenced by socioeconomic factors but is also because of patients' lack of understanding of the importance of their care and a lack of motivation to maintain attendance.

Objective: This study aims to explore the potential benefits of virtual reality (VR) walking trails within CR treatment, specifically with regard to patient knowledge retention, satisfaction with treatment, and the overall attendance of treatment sessions.

Methods: New CR patients were enrolled and randomized on a rolling basis to either the control group or intervention group. Intervention patients completed their time on the treadmill with VR walking trails, which included audio-recorded education, whereas control patients completed the standard of care therapy. Both groups were assisted by nursing staff for all treatment sessions. Primary outcomes were determined by assessing 6-minute walk test improvement. In addition, secondary outcomes of patients' cardiac knowledge and satisfaction were assessed via a computer-based questionnaire; patient adherence to the recommended number of sessions was also monitored. Cardiac knowledge assessment included a prerehabilitation education quiz, and the same quiz was repeated at patients' final visit and again at the 2-month follow-up. The satisfaction questionnaire was completed at the final visit.

Results: Between January 2018 and May 2019, 72 patients were enrolled—41 in the intervention group and 31 in the control group. On the basis of the results of the prerehabilitation and postrehabilitation 6-minute walk test, no significant differences were observed between the intervention and control groups (P=.64). No statistical differences were observed between groups in terms of education (P=.86) or satisfaction (P=.32) at any time point. The control group had statistically more favorable rates of attendance, as determined by the risk group comparison (P=.02) and the comparison of the rates for completing the minimum number of sessions (P=.046), but no correlation was observed between the study group and reasons for ending treatment.

Conclusions: Although no improvements were seen in the VR intervention group over the control group, it is worth noting that limitations in the study design may have influenced these outcomes, not the medium itself. Furthermore, the qualitative information suggests that patients may have indeed enjoyed their experience with VR, even though quantitative satisfaction data did not capture this. Further considerations for how and when VR should be applied to CR are suggested in this paper.

KEYWORDS

virtual reality; VR; cardiac rehabilitation; patient experience; patient education; outpatient therapy; exercise

Introduction

Background

Cardiac rehabilitation (CR) is an underutilized but vital part of recovery following a cardiac event. However, many patients do not attend or complete the recommended number of treatment sessions. According to the Million Hearts Initiative, only approximately one-third of all eligible patients participate in CR treatment [1]. Previous studies have shown that CR decreases "morbidity and mortality, improves clinical outcomes, enhances psychological recovery, and decreases the risk for secondary cardiac events" [1] and that a 12-week program can reduce cardiovascular risk factors for over a year post treatment [2]. A myriad of social, economic, and cultural factors contributes to the low percentage of patients who participate in CR [3]. However, even among patients who can attend and afford sessions, many do not complete their entire course of treatment. Research has shown that a lack of motivation [4] and a lack of understanding [5] contribute to this behavior.

A fundamental part of outpatient CR treatment is access to education. At many CR centers, such as the Jefferson Health Methodist CR facility, nursing staff conduct periodic lectures while patients exercise. However, because of the number of patients or timing of sessions, most educational materials are distributed in paper format, either on bulletin boards or as handouts.

To address the lack of interest in treatment and difficulties in providing access to patient education, we decided to pursue the use of digital technologies as an alternative, potentially more engaging way of conveying information to patients. This was founded on the work of the Digital Innovation and Consumer Experience (DICE) Group. The DICE Group used technology to advance the future of health care and education at Jefferson Health. Originally formed within the DICE Group, the XR (extended reality) Lab works to create a collaborative environment in which health care meets XR technology. XR is an all-encompassing term for augmented, virtual, and mixed reality technology. This team studies the potential benefits of XR technology for education and patient care and has pursued projects using XR, including patient experiences during bone marrow biopsies, advanced cardiac life support training for resident physicians, anatomy education for medical students, in-clinic vestibular therapy exercises, and nursing education for patient falls prevention.

Virtual reality (VR) has previously been employed in areas of health care, ranging from preoperative patient anxiety [6] to poststroke patient education [7], but it has rarely been used in conjunction with CR. Most notably, several studies have examined VR in combination with stage 3 CR when patients continue their physical activity at home. One survey revealed that 64% of patients felt motivated to continue exercising with the VR application after primary program completion [8]. At the time of this project's development, there was a lack of conclusive evidence about VR's effect on stage 2 outpatient rehabilitation.

Objectives

This study intends to address the lack of interest and comprehension exhibited by many CR patients, which may contribute to incomplete treatment. Education was directly incorporated into patient time on the treadmill, thereby increasing the number of patient exposures to cardiac health information. In addition, digital technologies, including VR, were explored as an alternative way to increase patient engagement with care. Overall, this study aims to evaluate whether employing a VR program that incorporated patient education could increase patients' motivation, understanding, and adherence to CR treatment.

Methods

Study Design

The study procedures were approved by the Jefferson Institutional Review Board (IRB) in December 2017. Beginning in January 2018, participants were selected from patients enrolled in CR at the Jefferson Health Methodist CR program on a rolling basis. Sample size calculations indicated that 68 patients were required to achieve a target power of 90%. Patients were randomized via the Google random number generator, limited to a range of 1-2—1 signifying the control group and 2 signifying the intervention group. To prevent patient bias, the consenting process did not include VR terminology or any reference to VR walking trails.

Participants

Participants were recruited between January 2018 and May 2019. All patients were emailed or mailed a copy of the consent form to review with the rest of their welcome materials before visiting the facility. At patients' first visit, the facility staff stratified patients according to their risk: low, moderate, or high, as per facility standard guidelines. Initially, only moderate-risk patients were enrolled, but this was subsequently expanded to all risk-level stratifications (following approval from the IRB in July 2018) to increase enrollment numbers. Patients were deemed eligible to participate after agreement of 2 study staff members (Textbox 1). If the staff determined that a patient was eligible to participate, they were consented in a private room on the same day.

Textbox 1. Eligibility criteria for participation in trial.

Eligibility criteria

- Aged 18 years or older
- Ability to use a treadmill independent of aid (eg, walker and cane)
- Medically safe to use a treadmill for 15 minutes
- Ability to understand English
- Ability to give their own consent

At this time, patients were scheduled according to their assigned study group—control patients at 9 AM and 11 AM sessions and intervention patients at 8 AM, 10 AM, and 1:30 PM sessions. Patients who could not attend during one of their randomized time slots were excluded from the study and scheduled at their preferred time. Normally, the facility accommodates 10 patients per session. To account for space limitations, VR participants were limited to 5 per session to allow for adequate time with 1 of the 2 VR systems. The other slots in sessions that already contained 5 VR participants were filled by nonparticipants.

Admission to the study continued until 72 patients were enrolled: 31 in the control group and 41 in the intervention group. Patients in both the control and intervention groups completed a 6-minute walk test (6MWT) at their introductory visit to establish a baseline.

Intervention

Study Procedures

Immediately after consenting to participate, patients were given a 5-question education quiz (Textbox 2) to establish their baseline cardiac education level.

Textbox 2. Education questions for pretest, posttest, and 2-month follow-up test.

Education quiz

- How often should you exercise?
- What are the most important things to consider when grocery shopping for heart-healthy foods?
- How often should you take your blood pressure medication?
- What are the symptoms of heart failure?
- What type of medicine is used to control your cholesterol?

For their first 3 visits, participants spent approximately 5 minutes on the treadmill, increasing at intervals of 1 minute if deemed appropriate by the staff. The remainder of each session took place on other types of exercise equipment, as per standard of care. Beginning at their fourth visit, patients were allowed to use the treadmill for up to 15 minutes at each visit. Patients walked at a fixed walking speed as self-paced treadmills are not used at the facility. In addition, research has shown that participants using fixed walking speeds had increased stride length compared with participants on self-paced treadmills [9].

All patients were scheduled to complete between 18 and 36 sessions, as decided by their care team and insurance provider. Typically, low-risk patients were encouraged to complete between 18 and 24 sessions, moderate-risk patients were encouraged to complete between 24 and 30 sessions, and high-risk patients were encouraged to complete between 30 and 36 sessions. CR staff recommended that patients complete the maximum number of possible sessions for their risk level, but the final number was decided by the patient.

Patients were contacted again 2 months after their final CR treatment. It was decided to follow up with patients at 2 months postrehabilitation, as, on average, patients were expected to complete approximately 2 months of treatment. This phone call was designed to follow up on patients' health following treatment and to assess their retention of education by repeating the 5-question education test conducted at their initial and final visits. Previous studies have shown that the use of VR increases the retention of education in students learning complex anatomical concepts [10]. Patients who could not be reached by phone were contacted via email. Those who stopped attending CR sessions before their determined treatment length were also contacted to follow-up and debrief from the study. At least three attempts were made to contact each participant before considering them lost to follow-up.

Control

Patients allocated to the control group received standard of care CR, with the option for additional time on the treadmill, up to 15 minutes, beginning at session 4. Standard of care CR includes completing time on 4 types of exercise equipment, including treadmills, stationary bikes, ellipticals, and hand rowing machines.

Another standard part of CR is education on heart health. Patients are exposed to educational materials to help them understand how to better care for their heart during recovery and to give them tools to continue improving their health in the future. Control patients received standard of care education through handouts, bulletin board displays, and periodic group lectures.

Finally, participants were debriefed at their last scheduled session and informed about the VR intervention. At this time, they were able to try the VR walking trails if desired.

VR Intervention

Participants in the VR intervention group completed the standard of care CR for the majority of their exercise, except for time spent on the treadmill. While using the treadmill, they used the Bionautica Trails system [11], a VR walking trails platform designed and produced by Plas.md [12]. Nursing staff logged each patient with their unique study ID and allowed them to select 1 of 6 walking trails, including 5 nature trails of different themes and 1 outer space–themed trail (Multimedia Appendix 1).

At each log-in, patients had the option to continue from their saved place on a trail from the previous session or select a new one. As patients walked, visual tokens popped up on screen, and when the patient *walked through* them, a randomly chosen piece of cardiac education information was triggered to start (Multimedia Appendix 2). These were programmed to filter through all 109 audio files before repeating. These audio files were taken directly from the handouts and CR textbooks used by the nursing staff. A 2015 study showed that patients who received both auditory and visual cardiac education were more likely to participate in their treatment [13].

Materials

The VR platform, Bionautica Trails, was set up as a high-definition flat-screen television, oriented vertically on a stand in front of 1 of 2 treadmills designated for the study (Figure 1). This system was selected over head-mounted VR options for the safety of the patient. Each of the 2 systems was run on an individual computer hard drive and connected to a Bluetooth keyboard with a built-in trackpad. For the purposes of the study, the Bionautica Trails platform was not updated and remained frozen in the version initially used to maintain consistency between participant experience regardless of when they started treatment.

The educational audio files each intervention group patient heard during their treatment were recorded in a deidentified cloud-based server, via Microsoft Azure, to track individual exposure to education and frequency. Patients used on-ear, wireless headphones, connected to the walking trails via Bluetooth, to better immerse themselves and allow other patients to continue exercising without distraction. These were noise reducing but not noise canceling to ensure that patients could communicate properly with nursing staff. Headphones were disinfected using AF3 antibacterial wipes provided by the facility, as per standard infectious disease guidelines.

Figure 1. Vertically oriented television screen in front of a treadmill showing an example of Bionautica Trails.

Instruments

Survey Tool

At their last scheduled session, after finishing their exercise, patients completed a web-based survey housed on the Qualtrics platform [14], a Health Insurance Portability and Accountability Act–compliant survey tool, through an anonymous link. This survey was designed by the authors to address the patient population at the Jefferson Health Methodist CR facility. Patients completed the survey using their study ID number rather than any identifying information, and only 1 member of the study staff had access to responses for analysis to protect patient privacy. The key variables measured in this self-report questionnaire were knowledge retention, patient satisfaction, and engagement (Multimedia Appendix 3).

Knowledge Retention

Knowledge retention for this study was defined as the maintenance of cardiac health information over time. Patients were asked a series of 5 questions (Textbox 2) at 3 time points: their first visit, last visit, and 2-months post treatment. These questions were identified by nursing staff as being vital to patients' recovery and common areas of confusion for patients. Knowledge retention was scored out of 5 for all 3 time points, with each question worth 1 point.

Patient Satisfaction

Patient satisfaction is contentment with the care received and the overall experience of a health care interaction. Patients completed 6 questions rated on a 4-point Likert-type scale (extremely dissatisfied=1; dissatisfied=2; satisfied=3; extremely satisfied=4). Each question covered a different subtopic of satisfaction and was scored individually.

Engagement

Patient engagement is defined as an intrinsic interest in and participation in care. Patients completed 3 questions on their engagement, rating each feature on a scale of 1-10 wherein 1 was “not at all engaged” and 10 was “extremely engaged.”

Statistical Analysis

This study was powered by an increase in the distance traveled during the 6MWT. The 6MWT is considered the functional walk test of choice for assessing clinical improvement in cardiorespiratory patients [15]. To estimate the expected improvement, equivalent data from patients with chronic obstructive pulmonary disease were used, which suggested an average improvement of 446 m (SD 82 m) for moderate-risk patients [16]. It was considered reasonable that the experimental group would achieve an additional 15% increase in the distance walked over that of the control group or an additional 67 m in 6 minutes because of their increased motivation and education from the intervention. Power analysis showed that to detect a between-group difference in the 6MWT at a power level of 0.90 and an α of .05, 34 participants were required in each group.

The 6MWT analysis was conducted using a *t* test allowing unequal variances; the Levene test for the equality of variances was used to determine equal variances for 6MWT improvement. For knowledge retention, a 2-way multivariate analysis of variance (MANOVA) test was used to compare improvement between groups at each of the following time intervals: pretest to posttest, posttest to follow-up, and pretest to follow-up. The MANOVA root included calculations for the Pillai trace statistic, the Wilks λ statistic, the Hotelling trace criterion, and the Roy largest test.

Results

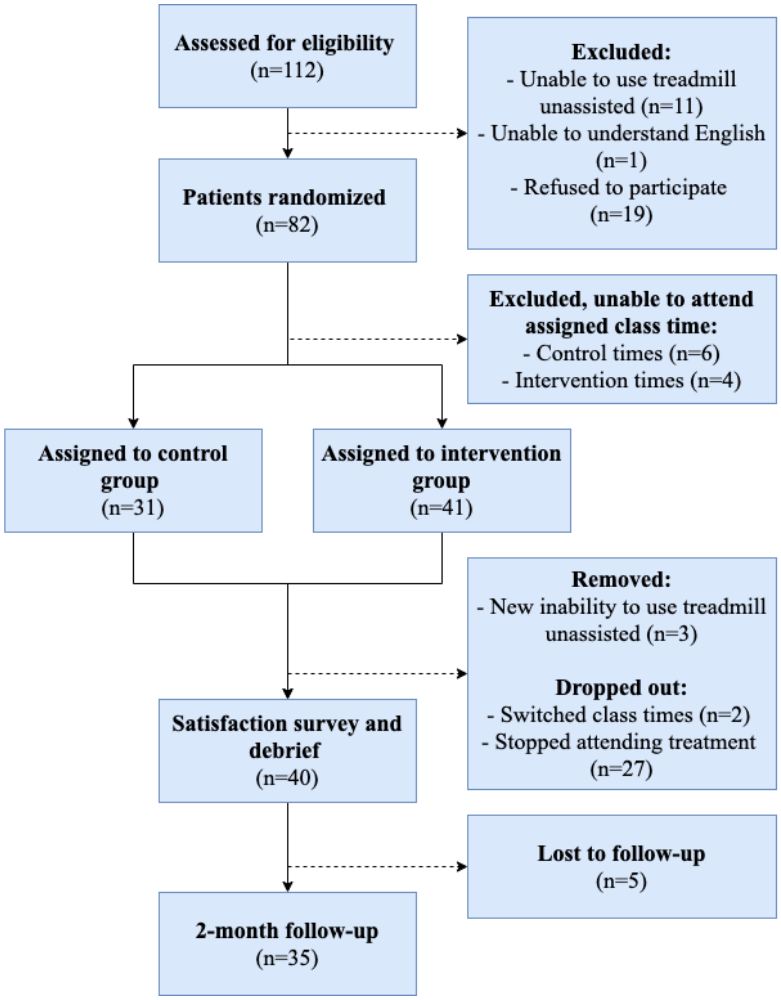
Patient Demographics

Between January 2018 and May 2019, 72 patients (male: n=52; female: n=20; age: range 32-81 years) were enrolled in the study to either the control (n=31) or intervention (n=41) group (Table 1). Of these, 3 participants were excluded from the study because of an inability to continue exercise on the treadmill, and 35 participants (control: n=19; intervention: n=16) completed all stages of the study (Figure 2).

Table 1. Patient demographic data (N=72).

Characteristic	Patients
Age (years), mean (SD)	61 (9.9)
Age (years), n (%)	
<40	2 (3)
40-49	7 (10)
50-59	19 (26)
60-69	32 (44)
70-79	11 (15)
≥80	1 (1)
Sex, n (%)	
Male	52 (72)
Female	20 (28)
Race, n (%)	
Asian	2 (3)
Black (non-Hispanic)	21 (29)
Hispanic	3 (4)
White (non-Hispanic)	45 (63)
Other	1 (1)

Figure 2. Flow diagram of research design and patient completion status.



Outcomes

6MWT

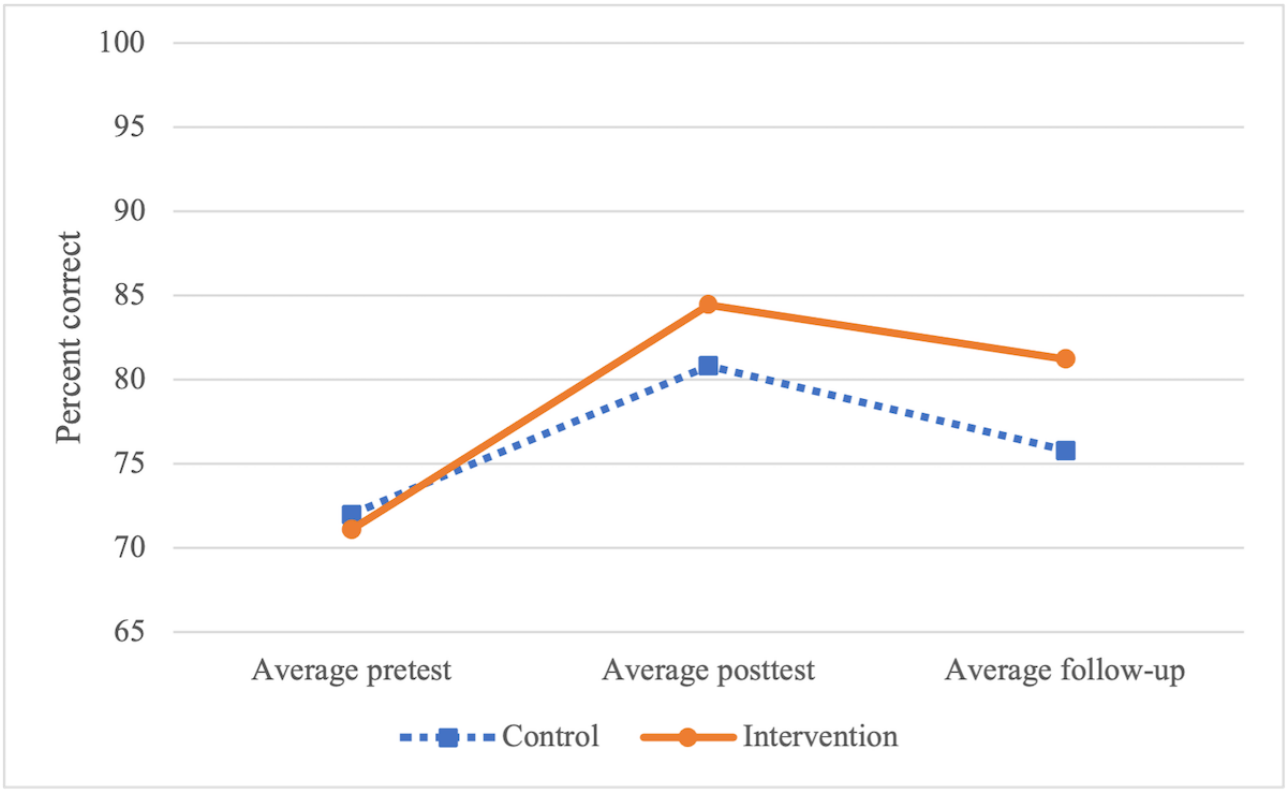
All patients (N=72) completed the 6MWT during their first treatment session. All patients who completed the program (n=34) completed a postrehabilitation 6-minute walk test (post-6MWT) as well. In addition, patients who chose to terminate their program early by notifying staff completed the post-6MWT (n=6) at their last scheduled session. All patients who did not finish treatment and did not notify staff before terminating their participation did not complete the post-6MWT (n=32). For these patients, their final session's distance walked was used to estimate their post-6MWT results for primary outcome improvement evaluation.

A blinded interim analysis was conducted in January 2019, which showed no statistical difference between improved distance walked relative to the 6MWT (P=.60; 95% CI −196.42 to 329.12). As no increased risk was seen in either group, it was decided to continue with the original intended sample size for complete analysis of the primary and secondary outcomes. At the final review, patients in both groups showed improvement between pre- and post-6MWT distances. The control group improved by an average of 298 feet and intervention group by 340 feet, without significance between groups (P=.64; 95% CI −224.14 to 139.52).

Knowledge Retention

Patient knowledge retention was evaluated at 3 time points: at the first visit, at the last visit, and at 2 months post treatment. Patients were asked to answer 5 multiple-choice questions at all time points (Textbox 2). No significant difference was seen between groups for baseline (P=.88; 95% CI −0.53 to 0.62), final visit (P=.56; 95% CI −0.79 to 0.43), or follow-up (P=.50; 95% CI −1.09 to 0.54) quizzes (Figure 3). Overall, patients in the intervention group improved by an average of 10.1% between pretest and follow-up compared with 3.8% for the control group (P=.86; 95% CI 0.71-0.59). Patients in the intervention group received an average of 115 pieces of audio education from a bank of 109 audio files, at an average of every 100 seconds of walk time.

Figure 3. Average education test scores for pretest, posttest, and 2-month follow-up.



Patient Satisfaction and Engagement

At their final visit, the patients completed a survey on their satisfaction. Patients were asked to rate their satisfaction with the education they received and their CR experience, based on several subtopics (Table 2). Participants from both groups responded positively to their treatment, and no significant difference was observed between the groups. Patients were also asked to rate their enjoyment of time spent on the treadmill (Table 3) and their engagement with this portion of their treatment (Multimedia Appendix 4). Additional questions were asked about patient engagement overall and specific to the education they received to help understand the breakdown of patient engagement. For education specific engagement, 56% (22/39) of patients selected a rating of 10 out of 10. For overall engagement, 70% (28/40) of patients selected a rating of 10 out of 10. Again, no significant differences were observed between the groups.

Table 2. Satisfaction survey questions (control: n=21 and intervention: n=19).

Question	Control, mean score (SD)	Intervention, mean score (SD)	*P* value
How satisfied are you with your CR[a] experience?			
How satisfied are you with your CR experience overall?	3.7 (0.7)	3.9 (0.3)	.32
How satisfied are you with your time spent on the treadmill?	3.5 (0.7)	3.6 (0.5)	.45
How satisfied are you with your interactions with staff?	3.9 (0.6)	4.0 (0.0)	.35
How satisfied are you with your CR education?			
How satisfied are you with the delivery of your CR education?	3.8 (0.4)	3.5 (0.5)	.06
How satisfied are you with the personalization of your CR education?	3.7 (0.5)	3.5 (0.5)	.23
How satisfied are you with the clarity of information?	3.8 (0.4)	3.6 (0.5)	.23

[a]CR: cardiac rehabilitation.

Table 3. Patients' response to "During most of your treatment sessions, you were allowed to use the treadmill for up to 15 minutes. Did you enjoy the time spent on the treadmill?"

Answer choice	Control, n (%)	Intervention, n (%)
"Yes, I would have enjoyed even more than the time I was allowed to spend on the treadmill."	6 (29)	5 (26)
"Yes, I enjoyed the time I spent on the treadmill. I did not need more than 15 minutes. It was the right amount of time for me."	13 (62)	14 (74)
"No, I did not enjoy it, so I did not use the full 15 minutes."	0 (0)	0 (0)
"No, I did not enjoy the treadmill. I do not enjoy that form of exercise."	1 (5)	0 (0)
"I am undecided."	1 (5)	0 (0)

Patients in the intervention group also completed the VR-specific questions (Table 4). Most participants responded negatively ("disagree") to negative statements and positively ("agree") to positive statements. Notably, the statement "I wanted to spend longer on the treadmill" resulted in a mix of positive, negative, and undecided responses.

Table 4. Virtual reality–specific satisfaction (n=19).

Question—"Because of the virtual reality walking trails..."	Disagree, n (%)	Undecided, n (%)	Agree, n (%)
"I looked forward to treatment sessions more."	1 (5)	5 (26)	13 (68)
"I enjoyed my treatment sessions more."	1 (5)	0 (0)	18 (95)
"I felt more engaged in my treatment."	1 (5)	1 (5)	17 (89)
"I wanted to spend longer on the treadmill."	7 (37)	6 (32)	6 (32)
"I gained a better understanding of my cardiac health."	2 (11)	0 (0)	17 (89)
"I did not see any impact on my treatment."	13 (68)	1 (5)	5 (26)
"I was unwantedly distracted from my treatment."	16 (84)	1 (5)	2 (11)
"I did not enjoy how I received my education."	17 (89)	0 (0)	2 (11)
"I felt isolated from the rest of my class."	15 (79)	0 (0)	4 (21)
"I dreaded my time on the treadmill."	15 (79)	1 (5)	3 (16)

Attendance

In addition, total patient attendance was recorded by group (Table 5). Each risk stratification had a different recommended number of sessions, but the Jefferson Health Methodist CR facility requires all patients to complete at least 18 sessions to be considered finished with treatment. As such, attendance was evaluated through both the recommended number of sessions and the completion of at least 18 sessions. Of the patients who were removed from or dropped out of the study (n=32), 4 control and 3 intervention patients continued with or returned to CR treatment after study dropout and were thus omitted from the attendance totals.

The comparison of attendance between each risk group showed that the control group had significantly higher completion rates (P=.02; 95% CI 0.04-0.53), as did the comparison of the rates for completing 18 sessions (P=.046; 95% CI 0.00-0.47). However, patients who stopped attending treatment sessions were asked to explain their choice, and no causal relationship was seen between poor attendance and VR walking trails. The reasons for ending treatment sessions early were mainly associated with other health issues (n=7), such as chronic pain, or a need to return to work (n=8); of those who needed to return to work, 2 patients switched to a new class time and 1 patient later returned to treatment but had already been debriefed about the study. Of the 29 patients who stopped attending treatment sessions, 11 left without explanation and could not be reached for follow-up.

Table 5. Patient attendance by completion of minimum required sessions and by recommended number of sessions.

Attendance	Control, n (%)	Intervention, n (%)
Completion of the minimum required treatment sessions		
Fewer than the required 18 treatment sessions completed	5 (19)	16 (42)
18 or more treatment sessions completed	22 (81)	22 (58)
Completion of the recommended number of treatment sessions		
Fewer than the recommended number of treatment sessions	8 (30)	22 (58)
Met or exceeded the recommended number of treatment sessions	19 (70)	16 (42)

Discussion

Principal Findings

This randomized controlled trial (RCT) focused on improving patients' experiences during CR treatment through an alternative VR solution. To the best of our knowledge, this is the first RCT focusing on VR for knowledge retention and motivation conducted in stage 2 outpatient rehabilitation. Previous studies related to VR's usage in stage 3 CR positively affected patient motivation compared with controls. The results demonstrated that there were no statistically significant outcomes, although this study provides valuable insights into the application of a virtual tool in outpatient CR.

Primary Outcome

It was hypothesized that VR-enhanced outpatient CR would be superior to conventional outpatient CR in improving 6MWT distances. This was chosen as the primary outcome as a means of standardization, as it is a common measure of improvement for patients undergoing CR. However, the results indicated that the intervention and control groups had comparable improvements in their 6MWT distances. These results may be related to limitations of the 6MWT, including its use of patient-initiated walking speed rather than the manual speed of the treadmills, and the fact that patients completed exercises on an average of 4 different types of equipment per session. These factors may have limited the 6MWT's ability to capture the value that VR can bring to a CR environment.

Furthermore, 44% (32/72) of patients did not complete a post-6MWT, severely limiting the sample size. We decided to use these patients' final treadmill sessions and extrapolate their distance walked in 6 minutes. However, as these were from manually set speeds, this extrapolation did not capture patient effort during the 6MWT, which may have been impacted by using Bionautica Trails.

Secondary Outcomes

Patient Engagement

Patient engagement was chosen as a secondary outcome because of evidence that VR has motivational benefits for patients in other rehabilitation settings, including during motor rehabilitation [17] and stroke rehabilitation [18].

Subjective measures of engagement were assessed through the patient survey, but an attempt was made to evaluate an objective measure of engagement based on the time spent on the treadmill. Patients were told they had up to 15 minutes of time on the treadmill, a duration chosen by the nursing care team to ensure patient safety and also fit within regularly scheduled sessions. By allowing patients to choose how long to spend on the treadmill, the hope was that they would spend time on the treadmill proportional to their interest level, based on the understanding that when participants are intrinsically motivated, they adhere better to exercise regimens [19].

This inference proved to be incorrect, as 62.5% (45/72) of patients, regardless of group, used the full 15 minutes at 60% of sessions or more. Those who did not use the full time typically cited coexisting health issues, such as arthritic joints, as reasoning for completing less than the full 15 minutes. Most patients likely chose to complete the full 15 minutes because many patients, particularly those of this age group, hear health care providers' instructions as recommendations rather than as choices [20]. To improve how engagement can be better assessed in a similar outpatient environment, future studies should explore how the phrasing of patient instructions affects their choices.

Patient Satisfaction

It was unlikely that the intervention would improve overall satisfaction, as at baseline, the Jefferson Health Methodist CR center already had incredibly high satisfaction scores. This has been largely attributed to the incredible care of the nursing staff. Patients reported that "the positive attitude and support of the staff was THE most critical factor" and the "staff took time to check-in regularly on physical and emotional health - Program clearly help[ed] me regain and improve my overall health not just cardiac."

Although no differences were seen between groups in terms of satisfaction, it is worth noting that many patients responded positively to Bionautica Trails. One participant reported, "It took me out of the room for a little bit; I really imagined hiking somewhere with my brothers," and others highlighted how "the walking trails made the walking experience enjoyable." The few patients who did not respond positively cited that they felt isolated from the social environment of the center or felt that the trails became repetitive. Although VR may not satisfy all patients, it should be mentioned that Bionautica Trails is still in use at the Jefferson Health Methodist CR center. Patients in both the treatment and maintenance programs use it regularly, and the nursing staff appreciate having the virtual trails as a tool for maintaining the focus of patients who need more attention.

Knowledge Retention

Previous research suggests that VR has the potential to improve patient comprehension of information [21] and long-term knowledge retention in students [10,22], possibly through spatial learning [22] or by increasing motivation to learn [23]. The knowledge retention test was limited to only 5 questions to minimize the amount of time added to required sessions, but it appears that this may have been too few questions to show a distinction between groups.

In addition, the questions themselves may have been too simplistic; at their initial visit, 86% (62/72) of patients knew that statins are used to treat cholesterol and 94% (68/72) knew how often blood pressure medication should be taken. It is difficult to show a significant change when there is little room for improvement. A more challenging set of questions, including a wider variety of complexities, should be used in future studies measuring the educational value of VR in this setting.

Attendance

Patient completion of the recommended number of rehabilitation sessions indicated statistical significance in favor of the control group. One possible explanation for this is that the enjoyment of VR could not overcome the considerable social and economic

factors that patients face, which contribute to low attendance [3]. Patients who stopped attending treatment sessions were asked to explain their choice, and no causal relationship was seen between poor attendance and virtual walking trails. One of the most common reasons for dropping out was the need to return to work (n=8). Patients would often say that they had to miss work to attend treatment or that their job would only cover so much sick leave. In addition, although only 1 patient reported dropping out of treatment because of their insurance, several patients completed only 2 days per week of treatment—rather than the recommended 3—to keep copay costs at a minimum.

Given the complexity of balancing work, finances, and treatment schedules, VR did not work as a tool to increase patient attendance at CR sessions. However, it highlights the importance of introducing digital tools in conjunction with practical strategies that address patients' needs.

Patient Safety

In total, 3 patients were excluded from the study because of a new inability to use the treadmill. Two of these patients experienced a change in their ability to use the treadmill related to their preexisting health conditions. The third patient discontinued participation in the trial because of self-described motion sickness, also referred to in the literature as "cybersickness" [24]. During the course of the study, 41 patients collectively completed 139.6 hours of virtual walking trails—almost 6 full days of content—and the third patient was the only patient to report any adverse side effects. Although cybersickness should still be considered when conducting research, the exceptionally low incidence rate in this study supports the use of VR regardless of age or previous experience using VR technology.

Blinding

Although not directly correlated to outcomes, it is worth discussing the difficulties faced when designing RCTs using VR. The nature of VR means that neither patients nor onsite study staff could be blinded to the study arm. Instead, the terms "virtual reality" and "virtual walking trails" were never mentioned during the consent process to blind patients to the study goal and limit response bias. Therefore, the patients were debriefed on their participation at their final treatment visit. At that time, those in the control group were offered the chance to try the walking trails. Most participants did not wish to try them when approached at the end of their last session, likely because they had already completed their workout and did not wish to spend additional time on the treadmill. However, post-6MWTs were occasionally conducted 1-2 sessions before the patient's expected end date, typically when multiple patients were expected to finish on the same day or if there was concern that the patient might not return for the final treatment session. Those who completed their post-6MWT early often chose to use Bionautica Trails for their final time(s) on the treadmill. It is unclear why this trend occurred, but based on qualitative responses from patients, it supports positive patient engagement with the trails. One such patient, when asked if they would have enjoyed the VR walking trails during regular treatment sessions, commented:

> *I feel like I missed out. It made the time pass so fast. It was great. It's different when you're looking at a picture, it makes it go quick [sic]*

Future Research

The use of VR in rehabilitation is a growing field, and there are numerous potential avenues for further research. Adaptations to this project could include expanding Bionautica Trails to other types of exercise equipment, such as a recumbent bike, to assess how continuity between exercise equipment and increased exposure would affect results. It would also be valuable to conduct a similar trial with a more robust education component, particularly expanding the number of questions and including variable question complexity.

Beyond this specific trial, research should continue to explore the gamification of treatment. In the version of Bionautica Trails used for this study, each token that patients *walked through* contributed to an overall score. These scores remained private, but the creation of a social network scoreboard could potentially increase the motivation to continue walking [25]. Furthermore, the newest version of Bionautica Trails includes a story mode that may encourage repeated use and promote behavioral changes through narrative communication [26]. Although it may still not increase attendance rates of this particular patient population, given the socioeconomic factors discussed previously, this addition may address patients' complaints about the repetitive nature of the trails. In addition, the use of a story mechanic lends itself particularly well to at-home or stage 3 treatment for maintaining user engagement without the external motivators inherent to the gym setting. Further research is needed to determine the most appropriate setting and population for using VR in the CR treatment process.

Conclusions

Given the importance of CR treatment, it is vital to continue studying methods of improving patient access to care and patient experience while in care. Despite the need for CR, many patients do not complete treatment. Although this particular tool did not show statistically significant improvements in outcomes, it provided anecdotal positive reactions from patients and their health care providers. The limitations of the study design likely contributed to the final results. Further studies are needed to determine whether virtual walking trails are worth implementing in stage 2 CR, particularly accounting for the numerous socioeconomic factors that influence patient access to care. VR tools such as Bionautica Trails should continue to be explored to improve the overall patient experience.

Acknowledgments

This study was internally funded by the DICE Group at Jefferson Health. Hardware and software for Bionautica Trails were provided by Plas.md for use in this study. Publication was made possible in part by support from the Thomas Jefferson University

Open Access Fund. The authors would like to thank the Jefferson Health Methodist CR facility staff, especially Mary Lou O'Neill, Barb Pettit, and Dottie Grimes, for their support and expertise.

Authors' Contributions

All authors contributed to this study and were involved in the conception and study design. Primary data collection was completed by VG. Statistical analysis was completed by Maclain Capron, the statistical analyst for DG's office. The manuscript was drafted by VG. All authors approved the final version of the manuscript for submission.

Abstract

Background: Preoperative anxiety is a common occurrence among children and is associated with a host of maladaptive postoperative behaviors. Consequently, increased attention has been placed on interventions to reduce preoperative anxiety and its associated outcomes. Child Life preparation prior to surgery includes evidence-based practices such as age-appropriate distraction and therapeutic play. Virtual reality (VR) is a promising addition to the Child Life toolbox to address anxiety prior to surgery. The current study evaluates the implementation and feasibility of a VR experience, "Doc McStuffins: Doctor for a Day Virtual Reality Experience" (*Doc*VR), developed by Disney Junior in collaboration with Children's Hospital Los Angeles, to target pediatric preoperative anxiety.

Objective: The primary aim of this study was to examine the feasibility and efficacy of *Doc*VR for preoperative anxiety. A secondary aim was to improve patient, caregiver, and health care provider satisfaction with the preoperative experience.

Methods: In this study, 51 patients (age 6-14 years) scheduled for surgery in the ambulatory surgery center and the main operating room at Children's Hospital Los Angeles were approached to participate in Disney's *Doc*VR experience. The patients played the *Doc*VR experience for an average of 18 minutes (3-55 minutes). Irrespective of surgical procedure, patients and their families were eligible, as long as they had no known marked cognitive or visual impairments that would interfere with completing the survey and engaging in the *Doc*VR experience.

Results: Patients who tried the *Doc*VR experience (n=51) responded overwhelmingly positively to both the VR technology and to the game itself. Patients experienced a statistically significant decrease in anxiety following DocVR game play (Z=–3.26, *P*=.001). On the Facial Affective Scale, the percentage of patients who chose the face with the most positive facial expression to represent their affect increased from 23% (12/51) pre-VR to 49% (25/47) post-VR. Furthermore, 97% (38/39) of patients reported feeling more comfortable at the hospital, and 74% (28/38) reported feeling less scared at the hospital after playing the game. The game was enjoyed by 94% (46/49) of patients, and 88% (30/34) of patients reported feeling both "Interested" and "Involved" in the game.

Conclusions: *Doc*VR is a feasible and beneficial VR experience to relieve pediatric preoperative anxiety and improve satisfaction in the preoperative area. The VR experience resulted in a decrease in overall anxiety and an increase in overall positive affect during the preoperative time. Patients also responded positively to the game, confirming their interest in the content and affirming

the quality of the *Doc*VR experience. The positive response to the game indicates that *Doc*VR has the potential to make the overall preoperative experience less anxiety-producing and more comfortable, which leads to improved patient satisfaction. Naturally, improved patient outcomes lead to improved caregiver and health care provider satisfaction.

Introduction

Nearly 5 million children undergo surgery in the United States annually, and 50-75% of these children experience preoperative anxiety [1]. Preoperative anxiety not only causes distress and suffering in children prior to surgery but is also associated with a slower, more painful recovery and negative postoperative behavior changes, such as separation anxiety, sleep disturbances, eating difficulties, and aggression towards authority [2,3]. Additionally, children who experience high preoperative anxiety are more likely to develop emergence delirium, a state of dissociated consciousness characterized by uncooperativeness, inconsolable crying, irritation, and incoherency that occurs upon waking from anesthesia [4,5].

Techniques for reducing preoperative anxiety in pediatric patients fall into 4 broad categories: preoperative sedatives, parental presence, preparation programs [6], and pain or anxiety management interventions. Although preoperative sedatives are regularly administered prior to surgery, anti-anxiety drugs can synergistically interact with anesthetics to produce undesirable side effects that prolong recovery [7]. Additionally, the use of sedatives may delay hospital discharge and consequently increase operational costs [6,8,9]. To date, research on the effect of parental presence for preoperative anxiety has yielded mixed results; although some studies have documented its efficacy, other studies have found no significant differences between anxiety levels of children whose parents were present versus absent at various stages of the preoperative process [10]. Thus, clinicians and researchers have long been interested in using other nonpharmacological interventions, such as procedural preparation programs and anxiety and stress management interventions, to combat preoperative anxiety. These combination interventions, which include Child Life programs and virtual reality (VR), among others, can work in tandem to provide potentially greater reductions in pediatric preoperative anxiety and distress, thus ultimately diminishing known features associated with medical trauma.

A variety of health care providers, including nurses, physicians, and psychologists, deploy VR for an array of health care–related interventions. In the preoperative space, Certified Child Life Specialists (CCLSs) are often the frontline professionals providing preparation and anxiety management strategies for patients in pediatric facilities. CCLSs are professional health care providers who help patients and their families cope with the challenges of the medical world, including, but not limited to, initial diagnoses, illness, hospitalization, and medical procedures [11]. CCLSs have spent decades continuously adding new innovations to their toolboxes to help children and families manage pain and anxiety associated with medical procedures [12-14]. For example, CCLSs capitalize upon the gate control theory of pain to help children cope with the unpleasant sensations caused by medical environments [15]. By providing engaging distractions like age-appropriate toys, electronic devices, and deep breathing techniques, CCLSs can divert the child's attention away from their upcoming procedure and close the child's "gate" for pain sensation. CCLSs also recognize the role of mental preparation and education in reducing preprocedural pain and anxiety. Numerous studies have shown that preparation programs can significantly reduce children's negative responses to medical procedures [16-20]. Mentally preparing patients and their families for upcoming procedures can involve giving tours of the operating room (OR), allowing children to familiarize themselves with medical equipment, and facilitating medical play sessions with dolls [16]. Whether providing distraction or education, CCLSs help align the perspectives of patients, caregivers, and health care providers to mitigate the oftentimes debilitating stresses of the medical environment.

VR has emerged as a promising nonpharmacological intervention to relieve pediatric preoperative anxiety and improve satisfaction. Incorporation of visual, auditory, and tactile stimulation within a 3D environment allows a child to "escape" to another world. The current study utilized a head-mounted display VR technology, which is the most common mode of technology for VR intervention-based studies. VR has been shown to reduce both pain and anxiety in pediatric populations for a variety of procedures, including phlebotomy [21], peripheral intravenous catheterization access [22], invasive dental procedures [23], and wound care and dressing changes [24]. A majority of pediatric VR studies for anxiety management focus on periprocedural timeframes, as cited earlier in this manuscript, and only a very limited number of studies have examined the use of VR for preoperative anxiety [25,26]. Additionally, there has been a call for a greater focus on anxiety management in VR research [27]. The current study's focus on both the preoperative timeframe and anxiety management makes it particularly relevant as VR research continues to charge forward.

Disney Junior, a television network owned by The Walt Disney Company, is a familiar staple in children's entertainment. Their television shows and online interactive games keep children engaged while reiterating life lessons of bravery, kindness, and friendship [28-30]. One of these shows is "Doc McStuffins: Toy Hospital," which follows a young girl who acts out her dream of becoming a pediatrician on her toys. Cast members from multiple Disney teams created "Doc McStuffins: Doctor for a Day" (*Doc*VR), a VR experience to engage, educate, entertain, and immerse patients into a "Doctor for the Day" role,

virtually conducting routine medical procedures, while waiting for their planned outpatient surgery. A multidisciplinary team from Children's Hospital Los Angeles (CHLA), including psychology, Child Life, and general pediatrics, implemented the Disney Junior *Doc*VR experience. Considering the medical context of the Doc McStuffins show, *Doc*VR is well-matched for pediatric medical centers, as it exposes and normalizes medical experiences, all in the tried-and-true format of an already beloved show. Incorporating VR, and particularly *Doc*VR, into the CCLS's preoperative processes has promising applications to more effectively manage preoperative anxiety.

This undertaking marks the first collaboration between Disney Junior and a children's hospital to build and pilot, respectively, a VR experience. This study assessed the feasibility of the *Doc*VR experience for preoperative anxiety and overall presurgical satisfaction. We hypothesized that *Doc*VR would reduce patient anxiety and overall distress, while improving patient, caregiver, and health care provider satisfaction in the ambulatory surgery center (ASC) or the main OR.

Methods

This study included data from 51 patients, ranging in age from 6 to 14 years old, collected from March 15, 2019 to April 12, 2019. Patients were accompanied by at least one caregiver in the room during the VR experience. Given the time-sensitive nature of the OR, patients were available to play *Doc*VR and to answer study questions for variable lengths of times. All activities for the current study were approved by the institutional review board.

Recruitment

Pediatric patients waiting for surgical procedures in either the CHLA ASC or the CHLA main OR were approached to participate in the feasibility pilot. Though most patients were approached in the waiting rooms, some were approached in the preoperative holding areas. The research team worked with CCLSs in the ASC and OR to screen for and approach eligible patients.

All patients between the ages of 6 and 18 years with normal vision and typical cognitive development were eligible to participate, irrespective of surgery type. Cognitive and visual impairments rendered patients ineligible as these would interfere with completing the survey or playing the *DocVR* game. Due to the varied consensus on the minimum age for VR headsets, 6 years old was the minimum age for participation.

Development of DocVR

Preparation

In 2016, Disney Junior and CHLA had a series of meetings to discuss creating a VR experience with Doc McStuffins for the purposes of entertainment and to comfort children in the hospital setting. After multiple brainstorming meetings, the Disney Junior creative staff (termed "cast members") iterated on the VR environment and organized a demonstration day at the hospital for CHLA stakeholders. Having received feedback regarding the user experience of the prototype and what children typically enjoy, the cast members finished the virtual environment, and the team planned for a launch date, including decorating the waiting rooms for the ASC and the main OR area. The Disney team decorated the waiting areas with specific Doc McStuffins decals, transforming the virtual experience into a "real" physical space.

Virtual Reality

Inside the VR experience, users choose to enter either a toy hospital (main experience; Figure 1) or a theater (supplementary experience). If the toy hospital is chosen, users help Doc McStuffins treat toy patients by completing a series of game-like VR tasks. If the theater is chosen instead, users can watch a selection of Doc McStuffins episodes and clips.

Figure 1. Doc McStuffins in front of the Toy Hospital along with Lambie Lamb and Stuffy.

Upon choosing the toy hospital experience, users are greeted by Dottie ("Doc") McStuffins, who instructs them to click on a set of doors to enter the virtual hospital (Figure 1). After entering the hospital, users arrive at the OR front desk, where Doc explains that users will assist as her "medical student for the day." Users are also introduced to Nurse Hallie Hippo and fellow medical student Lambie Lamb. Users then click on a book of patients to pick 1 of 5 toy characters to treat.

The 5 characters are a robot, Robot Ray; a blue dinosaur stuffed animal, Stuffy; a purple plastic shark, Mr. Chomp; a green toy monster, Globo; and a superhero action figure, Awesome Guy. Each character has a health issue that the user helps Doc treat (Figure 2). Robot Ray is sick with "Drainy Battery-itis," treatment of which requires users to open Robot Ray's back panel with a screwdriver, replace his batteries, and reclose the battery compartment door. Stuffy is afflicted with "Ripped Plush-Anemia," healing of which requires the sewing up of a rip in Stuffy's fur. Mr. Chomp suffers from "Stuck-Junk-itis," for which users can remove junk objects from Mr. Chomp's mouth. Globo has a diagnosis of "No-Glow-Atosis," which is treated by pointing a Sunlight Power-Upper at his many moving hands for recharging. Awesome Guy is aching from "Crackety-Crackatosis," recovery of which requires players to scrub his cracks clean and seal them with paste. Each character takes about 5 minutes to treat, amounting to a VR experience lasting up to 25-30 minutes.

Figure 2. A few examples of what a user sees when playing DocVR Experience.

Besides playing engaging games to treat the toys' afflictions, users are also exposed to the medical day-to-day of check-ups and diagnoses. For example, they use blood pressure cuffs to record the toys' energy levels, stethoscopes to listen to heartbeats, an x-ray machine to capture the toys' internal features, and magnifying glasses to examine cuts, cracks, and rips. Furthermore, Doc puts some of the toys to sleep before treating them, paralleling the experience of general anesthesia in a real OR.

Study Procedures

In collaboration with CCLSs, patients were identified and approached to pilot *Doc*VR. After confirming the patient's interest, a research assistant administered a pre-*Doc*VR web-developed survey on Qualtrics using an iPad. Questions in the survey assessed the patient's current levels of anxiety (Visual Analogue Scale [VAS] for Child Anticipatory Anxiety/Procedural Anxiety), current overall mood (Facial Affective Scale [FAS]), thoughts and feelings about the upcoming surgery, and familiarity with both the Doc McStuffins character and VR itself.

After the patient completed the pre-*Doc*VR experience survey, the research team launched the *Doc*VR application on a Google Pixel 2 phone and inserted it into the Google Daydream View VR, before fitting the headset on the patient (Figure 3). Using the handheld controllers, the patient was then instructed to click through 2 floating bandage icons to begin the *Doc*VR experience.

Figure 3. A Children's Hospital Los Angeles patient playing the DocVR Experience.

Following gameplay, the research assistant administered the patient's post-*Doc*VR experience survey. The post-*Doc*VR survey, similar to the pre-*Doc*VR survey, evaluated the patient's current/post-VR anxiety, satisfaction, and affect/emotions; issues pertaining to immersion in the *Doc*VR experience; issues related to overall satisfaction; and an opportunity for general comments and feedback about the *Doc*VR experience.

At the conclusion of the VR experience, the patient was given a Doc McStuffins–themed badge lanyard inscribed with Dr. (child's name), sticker sheets, and toys to celebrate completing the *Doc*VR experience.

To maintain good hygiene and eliminate infection disease concerns, each patient wore a disposable felt face mask under the VR headset and a hair net. Additionally, research staff sanitized the controller and headset between each patient with Sani-Cloth Germicidal Disposable Wipes.

Data Collection and Measures

VAS for Child Anticipatory Anxiety/Procedural Anxiety

The VAS anticipatory anxiety measure is a vertical VAS, anchored with 0 at the bottom indicating the least amount and 10 at the top indicating the greatest amount, in response to the instruction to rate "how nervous, afraid, or worried" they were about the upcoming medical procedure or surgery. This continuous measure also has color cues, graded from yellow at the bottom to dark red at the top, as well as a neutral face at the bottom and a face showing a negative expression at the top. Prior research has used the VAS to rate anticipatory anxiety and pain in children [19,31,32].

Facial Affective Scale (FAS)

The FAS is a cartoon face scale with 9 faces ranging from smiling widely (Face 1: least distressed) to crying (Face 9: most distressed) [33]. The scale measures both pain intensity and emotional affect, giving insight to the child's overall level of discomfort, both physical and emotional. The scale can be used objectively by caregivers and health care providers, or the child can point to the face he feels represents how he feels at a given point in time.

Additional Questions: VR Experience Survey

A Disney Junior/CHLA-developed survey was created to assess various aspects of the patient's experience with *Doc*VR. The questions assessed overall enjoyment of the *Doc*VR game and thoughts and feelings that occurred while playing the game. The survey also included questions that asked patients about game-specific elements, such as which characters they helped, which characters were their favorite, what they liked most and least about the game, and whether or not they found the game difficult. Patients were asked various questions about how familiar they were with both VR and Doc McStuffins before playing the game and how often they thought about their surgeries before and during the VR experience. Additionally, the post-VR survey included a 14-item questionnaire that assessed the degree of immersion in the VR experience. All self-reported answers on the immersion questionnaire were

scored on a 3-point Likert Scale reflecting "A Lot," "A Little," or "No/Not at All." Finally, a research assistant also noted the patient's gender, age, and number of minutes spent playing the *Doc*VR experience.

Statistical Analysis

Descriptive statistics were used to summarize quantitative data from patient surveys. A nonparametric Wilcoxon signed-rank test was conducted with SPSS version 26 to calculate the change in the pre- and postanxiety scores (VAS for anticipatory anxiety), since this was a continuous variable with nonnormally distributed data.

Results

Pre-DocVR

Though this study included 51 patients, due to the OR schedule and based on which questions patients wanted to answer, the response rates for each question varied and are noted as such.

Of the 51 patients, 76% (39/51) had heard of Disney Junior, 90% (46/51) had heard of Doc McStuffins, and 32 had watched Doc McStuffins on television. Regarding VR play, 71% (36/51) of patients had never played VR, and 29% (15/51) of patients had played VR in the past. Those patients had used VR an average of 2.4 times, but 4 patients had used it 4 or more times. Overall, the patients were highly familiar with Disney Junior and Doc McStuffins, but few had actually used VR in the past.

Time Spent Thinking About Their Surgeries

Before playing the VR experience (n=50), based on the 5-level categorical ranking of time spent that morning thinking about "today's" surgery, 86% (43/50) of patients reported thinking about their surgery "Sometimes," "Often," or "Almost Always," with just 14% (7/50) reporting "Never" or "Almost Never" (Figure 4). While playing *Doc*VR (n=38), 52% (20/38) of patients reported thinking about the surgery "Sometimes," "Often," or "Almost Always" while playing the game, while 48% (18/38) of patients reported that they "Never" or "Almost Never" thought about their surgery during gameplay, demonstrating a 34% decrease in "time spent thinking about [their] surgery" between the pre-*Doc*VR (n=50) and post-*Doc*VR (n=38) groups of patients (Figure 4). When patients were asked what they were thinking about during *Doc*VR, they reported a variety of statements ranging from "fun" to "nothing" (Table 1).

Figure 4. Self-reported time spent thinking about their surgery before and during the DocVR experience.

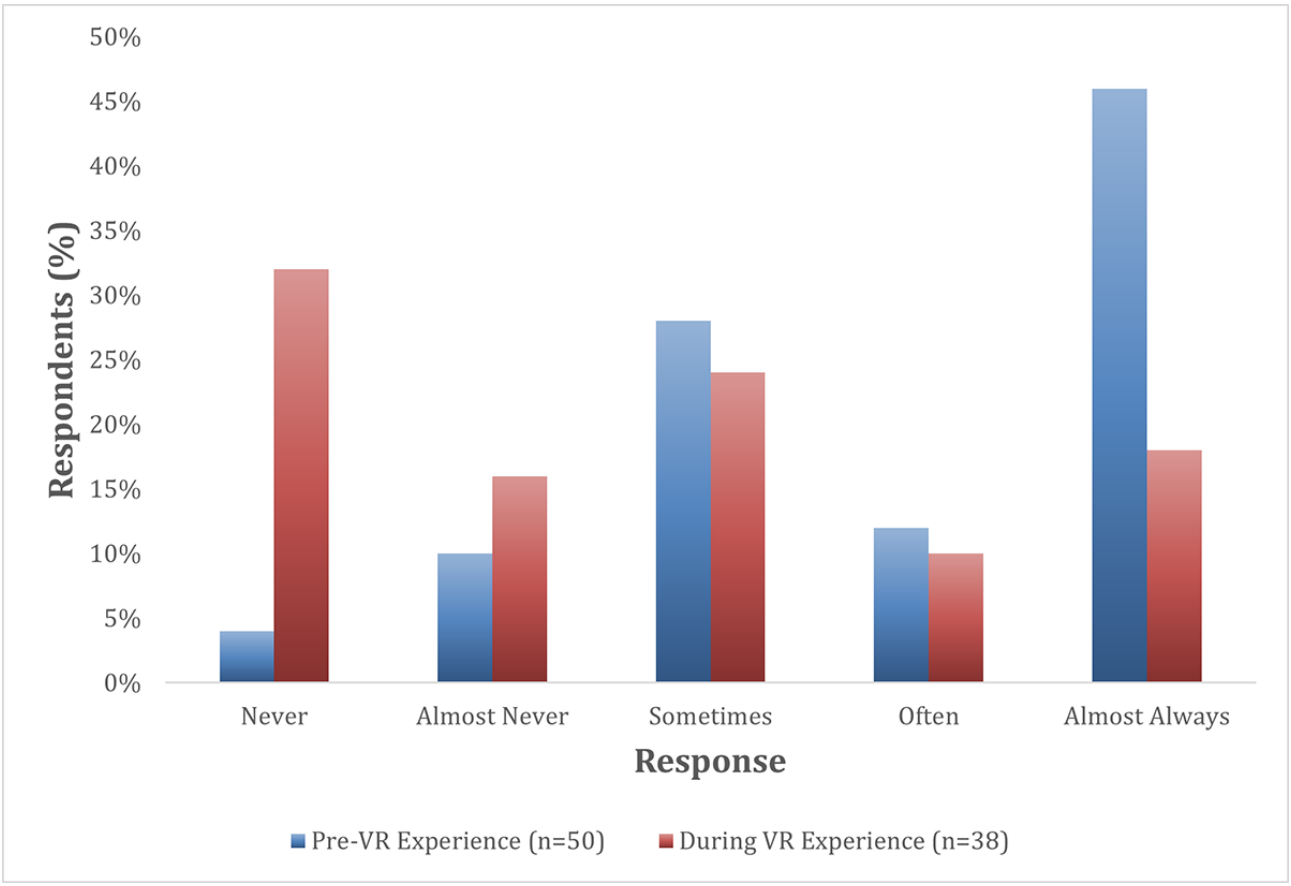

Table 1. Patients' thoughts during gameplay with DocVR, in response to the question "What did you think about during 'Doc McStuffins: Doctor for a Day?'"

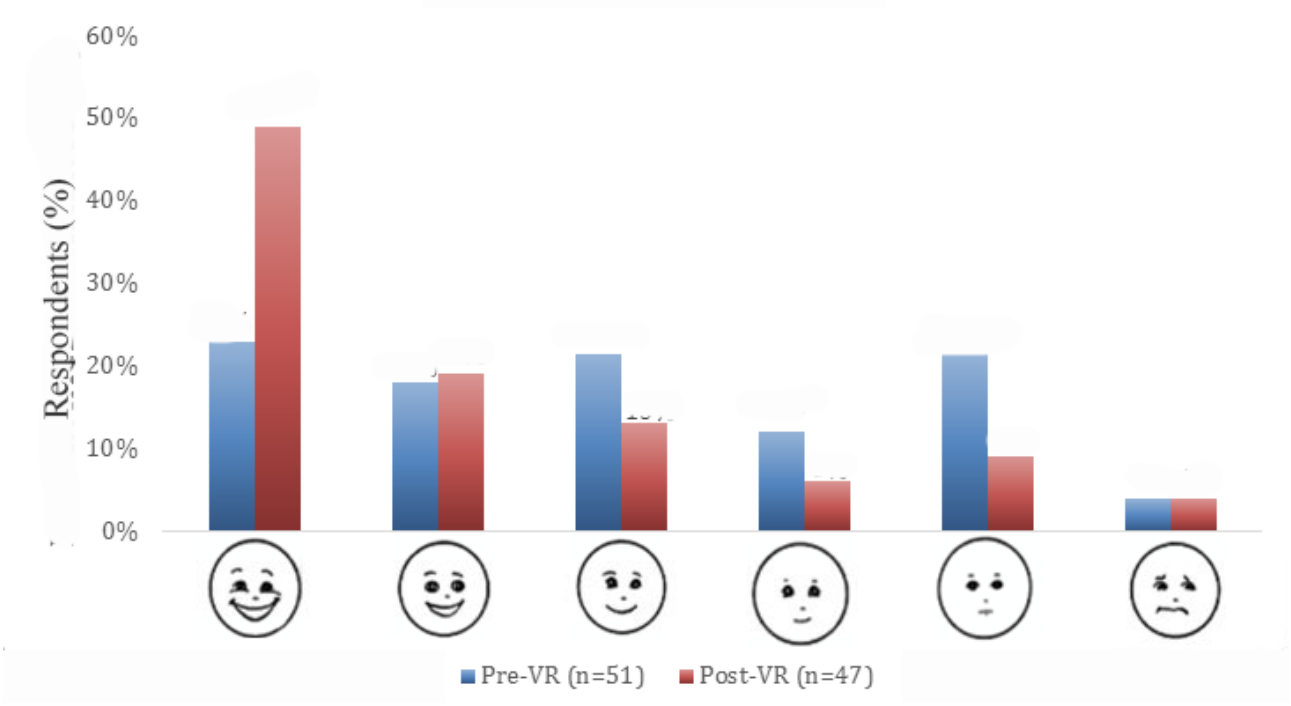
Response	Number of patients (n=24)
"It was fun"	10
"I felt good"	4
"Playing the game"	2
"Nothing"	1
"Excited"	1
"It was cool"	1
"It was hard"	1
"Surgery"	1
"I felt like a real doctor"	1
"That Doc was helping a lot"	1
"Nervous to help patients"	1

Pre- and Post-VR Affect and Anxiety

The median level of anxiety (n=51) reported by patients prior to *Doc*VR gameplay was 4.0 (IQR 0.60-7.43), while the median level of anxiety following gameplay (n=46) was 0.91 (IQR 0.30-4.60). Patients displayed a statistically significant decrease in anxiety after *DocVR* gameplay (Z=–3.26, *P*=.001).

Patients reported increases in positive affect from 23% (12/51) to 49% (23/47) following *Doc*VR gameplay (Figure 5). Similarly, a breakdown of the 3 most positive faces chosen versus the 3 most negative faces chosen shifted from 63% (32/51) and 38% (19/51) to 81% (38/47) and 19% (9/47), respectively, after playing the VR experience (Figure 5). Of the 9 faces in the FAS, no participants reported Faces 7-9 (faces that represent the 3 most distressed facial affects) pre- and post-*Doc*VR.

Figure 5. Self-reported affect pre- and post-DocVR gameplay experience. Faces 7-9 (faces that represent the 3 most distressed affects) were not selected by any participants pre- or post-DocVR and are thus not represented in the graph.



After *Doc*VR gameplay (n=39), 97% (38/39) of patients reported that playing the game made them feel more comfortable at the hospital: 51% (20/39) reported feeling "A Lot" more comfortable, and 46% (18/39) reported feeling "A Little" more comfortable. In addition, 74% (28/38) of patients reported that playing the game made them feel less scared at the hospital, with 29% (15/38) reporting "A Lot" less scared and 45% (17/38) reporting "A Little" less scared. When patients were asked about their feelings during *Doc*VR, they reported a variety of statements ranging from "a little better" to "good" (Table 2).

Table 2. Patients' feelings during gameplay with DocVR, in response to the question "How did you feel while playing 'Doc McStuffins: Doctor for a Day?'"

Response	Number of patients (n=23)
"Good"	6
"Happy"	5
"Fun and excited"	3
"Like a real doctor"	2
"Nervous"	2
"Cool"	2
"Like I was helping"	1
"Shy"	1
"A little better, because they had to go into a little surgery too"	1

Self-Reported Satisfaction With DocVR

On a 3-point anchor scale with responses of "No," "A Little," and "A Lot," 94% (46/49) of patients enjoyed playing the game, with 76% (37/49) reporting that they enjoyed the game "A Lot," and 18% (9/49) reporting "A Little." Of the 29% (15/51) of all patients who had played VR before, 100% (15/15) enjoyed *Doc*VR. Additionally, 88% (30/34) of patients reported feeling both "Interested" and "Involved" in the game, while 56% (19/34) reported their levels of interest and involvement as "A Lot," and 32% (11/34) reported it as "A Little." Of the patients, 97% (34/35) reported that playing the game "grabbed [their] attention"; 51% (18/35) reported it did so "A Lot," and 46% (16/35) reported it did so "A Little."

Of the patients, 88% (28/32) reported that *Doc*VR was also interesting compared to other computer games they had played; 41% (13/32) reported the game as being "A Lot" more interesting, and 47% (15/32) reported it as being "A Little" more interesting.

Of the patients, 97% (33/34) reported that they felt like they were "really" there in the VR world; 68% (23/34) reported feeling "A Lot" like they were there, and 29% (10/34) reported feeling "A Little" like they were there.

Of the patients, 53% (18/34) reported feeling sad or disappointed when the game ended; 18% (6/34) reported the level of their feelings of sadness or disappointment as being "A Lot," and 35% (12/34) reported the level of these feelings as "A Little."

No children reported known side effects to VR like dizziness, nausea, or light-headedness.

When patients were asked about they liked most about *Doc*VR, they reported a variety of statements ranging from "airplanes" to "helping people/patients/characters" (Table 3).

Table 3. Self-reported comments describing what the patients liked the most about the DocVR experience, in response to the question "What did you like MOST about 'Doc McStuffins: Doctor for a Day?'"

Response	Number of patients (n=28)
"Helping patients/people/characters"	12
"Helping Mr. Chomp"	3
"Everything"	2
"Fixing Stuffy"	2
"Playing"	2
"Helping Robot Ray with the batteries"	2
"Liked the patient going to sleep so it didn't feel any pain"	1
"It feels like I was really there"	1
"Airplanes"	1
"The surgery"	1
"The whole 3D environment"	1

"Doctor for a Day" Implementation Feasibility

Of the patients, 88% (29/33) reported that they would like to play the game again, with 61% (20/33) reporting "A Lot" and 27% (9/33) reporting "A Little." Of the patients, 97% (32/33) reported that they would recommend the game to another patient in the hospital or friend, with 70% (23/33) reporting "A Lot" and 27% (9/33) reporting "A Little." Responses to other feasibility questions are shown in Table 4.

Table 4. Patients' responses to a variety of virtual reality feasibility questions.

Question	Response, n (%)		
	A Lot	A Little	No
Did you get used to the game quickly? (n=38)	27 (71)	5 (13)	6 (16)
Were the controls easy to use? (n=38)	22 (58)	7 (18)	9 (24)
Did the things you saw look real? (n=33)	18 (55)	10 (30)	5 (15)
Was the headset comfortable? (n=34)	15 (44)	15 (44)	4 (12)
Were you worried about putting on the headset? (n=34)	4 (12)	3 (9)	27 (79)
Did it feel like you were in control? (n=34)	18 (53)	10 (29)	6 (18)
Did the way things moved look real? (n=33)	17 (52)	11 (33)	5 (15)

Discussion

The primary aim of this study was to assess the usability and feasibility of *Doc*VR, a novel, interactive, fully immersive 3D experience developed by Disney Junior and implemented by CHLA.

Key Findings

Findings suggest that the *Doc*VR is feasible, effective, and enjoyable and shows promise as a tool to alleviate pediatric preoperative anxiety and improve overall patient, caregiver, and health care provider experience during the preoperative period.

*Doc*VR significantly decreased patients' anxiety, leading them to think about things other than their apprehension about their procedures. Additionally, the virtual hospital setting of the VR experience made patients more comfortable in and less scared of the real medical space around them. Patients also responded positively to the DocVR content, reporting that they enjoyed the experience and found the game interesting. The game was very immersive, with a vast majority of patients reporting that they felt like they were "really there." The hardware itself was deemed both comfortable and user-friendly.

The authors found only 3 other studies that used VR as an exposure tool to alleviate pediatric preoperative anxiety. However, the VR experience for all 3 of these studies was an immersive guided tour of the operating theater [25,26,34]. While 1 of these 3 VR tours was conducted by another familiar childhood cartoon [26], the interactive nature of the *Doc*VR game allows patients to take an active role in medical play and provides an important addition to VR's cognitive load that ultimately is the key to alleviating cognitive states like pain and anxiety [35,36].

Patients' reports confirmed the excellent quality of the game. Many of the patients agreed that the virtual environment looked "real," and a large majority reported feeling like they were really in the virtual world. Patients were both interested and engaged, and a majority of patients said the game was also interesting compared to other video games they had played.

Effectiveness of DocVR

Patients experienced a strong statistically significant decrease in anxiety following *Doc*VR gameplay. After playing the *Doc*VR experience, patients also reported more positive overall affect, less fear, and less time spent thinking about their upcoming procedure. The VR experience also made patients more comfortable in the hospital, with 1 patient, when asked his favorite part of the game, saying, "I liked the patient going to sleep, so [the patient] didn't feel any pain." This response demonstrates the power of familiarizing pediatric patients with their upcoming procedures, putting them at ease for when the time for the procedure comes. *Doc*VR also made patients feel "Good" and "Happy."

While the hardware required for VR, including headsets and controllers, is rapidly deemed out of date due to the rapid expansion of VR innovation and development, the software nature of *Doc*VR makes it an effective product that can stay relevant as the VR world surges forward.

VR Age Restrictions

There is still some debate around the appropriate age for the use of VR in pediatrics. Most VR headset manufacturers (Sony, Google, Samsung, HTC, Oculus) recommend that their products should not be used by individuals younger than 12-14 years of age. The Google Daydream, the headset used in this study, "should not be used by children under the age of 13," according to the manufacturer's website [37]. The concerns for pediatric use can generally be thought of as being related to (1) legal and liability concerns and (2) safety concerns. The 1998 Children's Online Privacy Protection Act (COPPA) governs the collection and use of data generated by children under the age of 13 years by websites, mobile applications, and smart devices [38]. COPPA created rules for privacy policies, data collection, parental consent, and parent access to and control over a child's data. Importantly, COPPA does not prohibit the collection of data but, rather, creates a regulatory framework for how the data should be collected [39]. Since many VR headsets include creating user accounts, the COPPA rules apply to them. In our study, we did not have study patients create user accounts. From a regulatory standpoint, although a handful of VR applications have been approved by the US Food and Drug Administration, the regulatory environment is still evolving. In 2017, the Food and Drug Administration released its Digital Health Innovation Action Plan [40] and, in 2020, held a public workshop to convene industry, investigators, providers, and regulators to discuss best evaluation practices for medical extended reality [41]. When VR is used for distraction or entertainment, such as in this study, it is not considered a medical device [42].

Safety concerns for pediatric VR have focused on the physical fit of the device (headsets may be too big for some young children and, if not worn correctly, can cause physical discomfort), safety around device use (such as accidentally bumping into objects in the real world), and health impacts of VR. Some users experience dizziness, headaches, and motion sickness during or after VR, but over 15 years of pediatric studies have demonstrated the overall safety and minimal side effects of VR in children as young as 6 years [21,22,43-46]. In our study, which included 42 patients under the age of 12 years, no patients reported any symptoms after using the VR headset. While there have been concerns about the possible impact of VR on vision, the American Academy of Ophthalmology states that, although there have been no long-term studies, there is little reason to be worried about VR's impact on eye development or function [47]. A 2019 study of 50 children aged 4-10 years showed no significant impact on visuomotor function after VR use [48]. Finally, from a parenting and development standpoint, the American Academy of Pediatrics has stated that the 2016 media use guidelines [49] apply to a variety of media, including VR [50]. Parents should make sure content is developmentally appropriate for their children; that they adhere to overall screen time recommendations; to balance media use with media-free time for physical activity, education, play, sleep, and bonding; and whenever possible, to coview or coexperience media together. Various methods of delivering VR have been implemented to validate these data and to ensure that VR is a valid, ethical, and safe option for all pediatric patients [51].

Limitations

One limitation of this study is the small sample size that, though not uncommon in feasibility research, may limit the generalizability of the conclusions.

This pilot did not utilize a control group; all patients were given the option to play VR. Therefore, researchers were unable to compare the effects of playing *Doc*VR with the anxiety of children who did not play the game. Additionally, the observed positive impact of the *Doc*VR experience on the patients could have been confounded by the positive impact of research assistants' general active engagement with patients.

Another limitation to the pilot is that not all patients completed the entire *Doc*VR experience. There were 2 scenarios that would have prematurely terminated the VR experience: (1) the child deciding to take the headset off or (2) the child being called to the preoperative area by a health care provider.

A premature end to the VR experience resulted in incomplete playing time and therefore, an incomplete assessment of *Doc*VR for managing pain and anxiety (dose effects). The average time spent playing *Doc*VR may have been higher if the pilot had been conducted in a more controlled environment. However, because the pilot was conducted in a dynamic setting, parts of the protocol were adapted to accommodate clinical care.

In the scenario where children were quickly called back to the preoperative area by the health care provider, there was insufficient time for the post-VR survey to be administered. The results reported in this paper are thus impacted by incomplete data collection.

Other potential confounds include that 90% (46/51) of patients were familiar with Doc McStuffins, and 29% (15/51) of patients had played VR before. This prior exposure may have primed patients to benefit from a pre-existing relationship or experience with Doc, enjoying the *Doc*VR experience, or other content and technology confounds. Nonetheless, this patient population could be representative of a young, TV-watching population, indicating that familiarity may, in fact, be a beneficial component of relieving pediatric preoperative anxiety.

Conclusions

This is the first feasibility study on the use of *Doc*VR to ease preoperative anxiety in pediatric patients and one of a few studies ever to use VR to address preoperative anxiety in pediatric patients prior to surgery. These results demonstrate the potential utility of VR and, particularly, *Doc*VR in the preoperative space. The present study capitalized on the fusion of familiar and lovable characters with immersive VR gameplay to transform the patient preoperative experience from unpleasant and potentially frightening to fun. Given that health care institutions continue to use patient and family satisfaction as a metric of success [52], digital therapeutic solutions that patients find enjoyable and distracting prove to be worthwhile investments. Furthermore, developers in pediatric health care would benefit from collaborating with children's media companies in order to capitalize upon pre-established characters and the emotional experience or relationship between children and best-loved characters. Continued research on emerging technologies and VR experiences is essential to ensure that science and an evidence base drive clinical interventions for pain and stress management in a pediatric environment.

Acknowledgments

The authors are grateful for all the patients and families who agreed to participate in the study and would also like to acknowledge the leadership at both Disney Junior and CHLA who made this collaboration possible. The authors would also like to thank the generous donors who continue to support VR research at the CHLA Biobehavioral Pain Laboratory, including Beatrice and Paul Bennett and Cancer Free Generation and the Board of Tower Cancer Research Foundation. A special thank you must go to the CHLA Child Life specialists and the CHLA Biobehavioral Pain Laboratory volunteers.

Abstract

Background: eHealth literacy can potentially facilitate web-based information seeking and taking informed measures.

Objective: This study aimed to evaluate socioeconomic disparities in eHealth literacy and seeking of web-based information on COVID-19, and their associations with COVID-19 preventive behaviors.

Methods: The COVID-19 Health Information Survey (CoVHIns), using telephonic (n=500) and web-based surveys (n=1001), was conducted among adults in Hong Kong in April 2020. The Chinese eHealth literacy scale (eHEALS; score range 8-40) was used to measure eHealth literacy. COVID-19 preventive behaviors included wearing surgical masks, wearing fabric masks, washing hands, social distancing, and adding water or bleach to the household drainage system. Adjusted beta coefficients and the slope indices of inequality for the eHEALS score by socioeconomic status, adjusted odds ratios (aORs) for seeking of web-based information on COVID-19 by socioeconomic status, and aORs for the high adherence to preventive behaviors by the eHEALS score and seeking of web-based information on COVID-19 were calculated.

Results: The mean eHEALS score was 26.10 (SD 7.70). Age was inversely associated with the eHEALS score, but education and personal income were positively associated with the eHEALS score and seeking of web-based information on COVID-19 (for all, *P* for trend<.05). Participants who sought web-based information on COVID-19 showed high adherence to the practice of wearing surgical masks (aOR 1.56, 95% CI 1.15-2.13), washing hands (aOR 1.33, 95% CI 1.05-1.71), social distancing (aOR 1.48, 95% CI 1.14-1.93), and adding water or bleach to the household drainage system (aOR 1.67, 95% CI 1.28-2.18). Those with the highest eHEALS score displayed high adherence to the practice of wearing surgical masks (aOR 3.84, 95% CI 1.63-9.05), washing hands (aOR 4.14, 95% CI 2.46-6.96), social distancing (aOR 2.25, 95% CI 1.39-3.65), and adding water or bleach to the household drainage system (aOR 1.94, 95% CI 1.19-3.16), compared to those with the lowest eHEALS score.

Conclusions: Chinese adults with a higher socioeconomic status had higher eHealth literacy and sought more web-based information on COVID-19; both these factors were associated with a high adherence to the guidelines for preventive behaviors during the COVID-19 pandemic.

KEYWORDS

COVID-19; eHealth literacy; preventive behaviors; socioeconomic disparities; web-based information seeking

Introduction

Curbing of the spread of COVID-19 depends on the timely adoption of appropriate preventive behaviors by the public. Web-based health information is important in affecting preventive behaviors, particularly when physical distancing and stay-at-home orders during the pandemic have reduced face-to-face health communication [1]. A recent study reported that seeking of web-based information on COVID-19 from social networking apps and internet-based news media are associated with preventive behaviors [2]. A breadth of information and misinformation has been disseminated on the internet and rapidly propagated and evolved on social media platforms [3]. Exposure to misinformation on the internet or conspiracy theories regarding COVID-19 are associated with decreased adherence to prevention guidelines and worse physical and mental health outcomes [4,5]. The ability to seek, understand, and appraise health information on the internet and ultimately take well-informed action to handle health problems can be assessed on the basis of eHealth literacy [6]. A higher eHealth literacy is associated with more active information seeking and scrutiny [7,8]. Lack of access or capacity to understand health information on the internet, in contrast, is associated with negligence toward health warnings and difficulty in making health decisions [9].

Appropriate processing and utilization of health information is complex during the COVID-19 pandemic, given the novel outbreak patterns and evolving information regarding the disease [10]. It is important to identify the characteristics of individuals at the risk of lower eHealth literacy for effective health promotion, including the provision of limited literacy resources [11]. Previous studies have suggested that eHealth literacy is affected by sociodemographic, environmental, and contextual factors [12]. Disparities in eHealth literacy by education and income have been previously reported [13], but incongruent correlations between socioeconomic status and eHealth literacy have been found across populations with different characteristics [8,14,15]. The COVID-19 pandemic has disproportionately affected the lower socioeconomic status (SES) group and has limited access to health care, overcrowded living conditions with a higher risk of disease transmission, and inconvenienced individuals who are in occupations that do not allow working from home [16], which have further accentuated existing socioeconomic inequalities. Since eHealth literacy skill is not static and evolves with changes in new social contexts [6], little is known about the disparities in eHealth literacy in the unique context of widening socioeconomic inequalities and the overwhelming influx of COVID-19–related information (and misinformation) being disseminated.

Hong Kong, the most developed and westernized city of China, has a larger income gap (Gini index 0.539 in 2016) compared to other developed countries [17], but internet use is prevalent across individuals of different SES because of the advanced cyber infrastructure and the low cost of internet access [18]. Nearly all individuals have sought web-based information during the COVID-19 pandemic [19]. Our previous study in 2009-2012 reported that disparities in SES groups affected web-based health information seeking behavior [20]. Considering that the context of COVID-19 may stimulate universal web-based information seeking behavior by triggering effective responses such as fear and anxiety [21], it remains unknown whether SES disparities in web-based health information seeking existed during the COVID-19 pandemic. Our study's research questions were as follows: (1) Are there socioeconomic disparities in seeking web-based information on COVID-19 during the pandemic? (2) Are there socioeconomic disparities in eHealth literacy among these web-based information seekers? (3) Is seeking of web-based information and eHealth literacy associated with preventive behaviors during the COVID-19 pandemic? In a random cohort of adults in Hong Kong, we examined socioeconomic disparities in seeking web-based information on COVID-19 and eHealth literacy, and their associations with personal preventive behaviors during the COVID-19 pandemic.

Methods

Design and Participants

This study was part of the COVID-19 Health Information Survey (CoVHIns)—which is a cross-sectional survey among adults in Hong Kong who are aged ≥18 years—which investigated COVID-19–related information use, preventive behaviors, and well-being. The survey was conducted on April 9-23, 2020, after the peak of the second wave of the outbreak, and when social distancing measures were implemented. Data were collected using telephonic and web-based surveys. All interviews were conducted by trained interviewers of Social Policy Research Limited through the Web-based Computer Assisted Telephone Interview system.

The details of CoVHIns have been reported previously [22,23]. Briefly, a 2-stage sampling method was adopted for the telephonic survey. First, telephone numbers were retrieved from the residential telephone directories and randomly listed for interview. Invalid numbers, lack of responses (after being called for a maximum of 5 times), and ineligible households (including individuals aged <18 years or those who are unable to communicate in Cantonese or Mandarin) were excluded. Second, once a household was successfully contacted, the eligible family member whose birth date was closest to the interview date was invited to complete the interview. Each interview lasted approximately 20 minutes. A total of 816 landline telephone numbers were successfully sampled, and 500 participants consented to and completed the interview (response rate=61.3%).

In addition, web-based surveys randomly sampled participants from a representative panel of >100,000 mobile phone users, which was generated by sending text messages to a random list of mobile phone numbers provided by the Numbering Plan for Telecommunication Services (prefixes 5, 6, 9). Stratified random sampling by sex and age was adopted. Text messages with an invitation were sent to the randomly selected members in the panel. Among 1623 eligible individuals contacted, 1001 participants consented to and completed the questionnaire on the internet (response rate=61.7%). Ethics approval was granted by the Institutional Review Board of the University of Hong Kong/Hospital Authority Hong Kong West Cluster (approval# UW-20-238).

Measurements

Seeking of web-based information on COVID-19 was self-reported (sought or no-sought). eHealth literacy was assessed among individuals who had sought web-based information on COVID-19, considering that eHealth literacy is based on the experience of access to web-based information [24]. We used the Chinese version of the eHealth literacy scale (eHEALS) to measure eHealth literacy levels by asking participants' about their past experience in seeking web-based information on COVID-19 (Multimedia Appendix 1). The eHEALS contains 8 items scored with a 5-point Likert scale (ranging from "strongly disagree" to "strongly agree"). The total score ranged from 8 to 40, with a higher score indicating higher eHealth literacy [25]. A Cronbach α of .95 was used in our study. Consistent with the Chinese version of eHEALS [25], we observed a unidimensional structure of the Chinese eHEALS with adequate model fitness (comparative fit index 0.974 [>0.95, acceptable], root mean square error of approximation 0.097 [close to 0.06, acceptable], and Tucker-Lewis index 0.964 [>0.95 acceptable]) [26]. We divided the eHEALS score into 4 categories (Q1-Q4) based on quartile values (median 28, IQR 22-32) in accordance with previous studies, using the median as the cutoff [7,27]. Specifically, Q1 was the interval of the overall eHEALS score ranging from the lowest value (ie, 8) to a score of 22; Q2, from 22 to 28; Q3, from 28 to 32; and Q4, from 32 to the highest value (ie, 40).

Based on World Health Organization guidelines for COVID-19 prevention [28], we assessed personal preventive behaviors in the past 7 days, including the following: "wearing surgical masks when going out," "wearing fabric masks when going out," "washing hands with alcohol-based sanitizer," "adding water/bleach to the household drainage system," and "keeping a social distance from people in public areas (eg, 1.5 meters)," with responses of "never," "occasionally," "sometimes," and "often" (Multimedia Appendix 2). Adherence to personal preventive behavior was dichotomized (low or high adherence) on the basis of previous studies on the association between eHealth literacy and health behaviors [14,24]. Responses of "never," "occasionally," and "sometimes" were together considered as low adherence and "often" was considered as high adherence.

Education levels and income were considered as indicators of SES. Education levels were measured as categorical variables ("primary or below," "secondary," and "tertiary or above") on the basis of the highest education level attained. We measured monthly personal income in accordance with 6 predefined categories (from ≤HK $10,000-$50,001 [US $1=HK $7.8]). Since few participants had an income of HK $40,001-$50,000 and ≥HK $50,001, the data were recoded in 4 categories including ≤HK $10,000, HK $10,001-$20,000, HK $20,001-$30,000, and >HK $30,000 to obtain robust outcomes on regression analyses.

Other demographic data included sex, age, and marital status (never been married, married or cohabitating, and divorced or separated or widowed). Employment status was categorized as economically active (full-time work or part-time work) and economically inactive (student, homemaker, unemployed, and retiree) [29]. Any chronic diseases were self-reported (any or none).

Statistical Analysis

All data were weighted by sex, age, and education levels in accordance with the 2016 population by census to improve the representativeness of the sample.

First, disparities in seeking web-based information on COVID-19 (dichotomized variable) by SES were assessed through multivariable logistic regression, which yielded adjusted odds ratios (aOR) for seeking web-based information on COVID-19. Second, socioeconomic disparities in eHealth literacy, being a continuous variable, were assessed through linear regression, which yielded unstandardized regression coefficients to reflect the change in the eHEALS score for a unit change in the independent variable. Third, we used the slope index of inequality (SII) to estimate the absolute difference in the eHEALS score between the most advantaged and most disadvantaged groups. The SII has been recommended by the World Health Organization, and a high SII indicates severe inequality [30]. Income categories were first ranked from the lowest to highest, and the cumulative proportion of participants were assigned to each category on the basis of the midpoint of range as the code for each category. The eHEALS score was then regressed against the cumulative proportion of each income category [30]. A similar analysis was performed for education-related SII. As each personal preventive behavior was dichotomized as low and high adherence, the associations (determined with aOR and 95% CI values) of seeking web-based information on COVID-19 and the eHEALS score with each personal preventive behavior were estimated through multivariable logistic regression adjusted for demographic variables, SES, and chronic disease. All analyses were performed using Stata (version 15.1, Stata Corp).

Results

Table 1 shows the weighted sample (N=1501; females: n=829, 52.6%), with 495 (27.7%) participants aged ≥60 years. Approximately two-third (66.1%) participants were married or cohabitating, and 981 (62.9%) were economically active. Most participants had attained secondary or tertiary and above education. In total, 519 (37.5%) participants' monthly personal income was HK ≤$10,000, and 1040 (67.8%) participants self-reported seeking web-based information on COVID-19. The mean eHEALS score was 26.10 (SD 7.70).

[g]Self-reported by participants if having been diagnosed with a chronic disease (eg, hypertension, diabetes, or cancer).

Table 3 shows the inverse correlation between age and the eHEALS score (*P* for trend<.001). Education (secondary education: adjusted β 3.58, 95% CI 1.98-5.18; tertiary or above education: adjusted β 6.22, 95% CI 4.39-8.06; *P* for trend<.001) and income (*P* for trend<.001) were associated with the eHEALS score. The estimated difference in the eHEALS score between participants of the highest and the lowest SES was higher by education than by income (SII 13.27 vs 7.30). Sex, marital status, employment status, and chronic diseases were not associated with the eHEALS score after adjusting for age and SES.

Table 3. Associations among demographic variables, socioeconomic status, and chronic diseases with the eHealth literacy score[a] among participants seeking web-based information on COVID-19 (N=1040).

[f]*P*<.001.

[g]US $1=HK $7.8.

Table 4 shows that participants who had sought web-based information on COVID-19 displayed higher adherence to the practice of wearing surgical masks (aOR 1.56, 95% CI 1.15-2.13), washing hands with alcohol-based sanitizers (aOR 1.33, 95% CI 1.05-1.71), adding water or bleach to the household drainage system (aOR 1.67, 95% CI 1.28-2.18), and social distancing (aOR 1.48, 95% CI 1.14-1.93) than those who did not seek web-based information on COVID-19. Seeking of web-based information on COVID-19 was not associated with the adherence to the practice of wearing a fabric mask. Among those who sought web-based information on COVID-19, the eHEALS score was associated with the adherence to the practice of wearing surgical masks (Q2: aOR 1.44, 95% CI 0.91-2.30; Q3: aOR 2.05, 95% CI 1.26-3.35; Q4: aOR 3.84, 95% CI

1.63-9.05; *P* for trend<.001; overall score: aOR 1.04, 95% CI 1.01-1.07). Regarding the adherence to washing hands with alcohol-based sanitizers, the aOR was 1.77 (95% CI 1.25-2.53) for Q2, 2.16 (95% CI 1.52-3.09) for Q3, 4.14 (95% CI 2.46-6.96) for Q4 (*P* for trend<.001), and 1.06 (95% CI 1.04-1.08) for the overall eHEALS score. Similarly, the eHEALS score was associated with the adherence to adding water or bleach to the household drainage system (Q2: aOR 1.47, 95% CI 1.02-2.15; Q3: aOR 1.89, 95% CI 1.30-2.75; Q4: aOR 1.94, 95% CI 1.19-3.16; *P* for trend=.001; overall score: aOR 1.04, 95% CI 1.02-1.06) and social distancing (Q2: aOR 1.68, 95% CI 1.16-2.44; Q3: aOR 1.58, 95% CI 1.09-2.30; Q4: aOR 2.25, 95% CI 1.39-3.65; *P* for trend=.002; overall score: aOR 1.03, 95% CI 1.01-1.05). We observed no association between the eHEALS score and the practice of wearing fabric masks.

Table 4. Association between the adherence to preventive behaviors by seeking web-based information on COVID-19 and the eHealth literacy score.

[g]The eHealth literacy score was divided into 4 categories (Q1-Q4) on the basis of the quartile values (median 28, IQR 22-32); a higher score indicated higher eHealth literacy.

Discussion

Principal Findings

This study is the first to report socioeconomic disparities in seeking web-based information on COVID-19 and eHealth literacy during the COVID-19 pandemic and their association with a high adherence to COVID-19–related preventive behaviors, including wearing surgical masks, washing hands, adding water or bleach to the household drainage system, and social distancing.

Seeking of web-based information on COVID-19 was observed among younger participants in our study, concurrent with previous studies on web-based health information seeking behaviors [31]. A recent study also indicated that younger family members sought web-based information for the elderly during the pandemic [32]. Such an age disparity in information seeking can be attributed to the higher penetration rate of internet devices such as personal computers and smartphones among younger rather than older individuals [18]. Small font sizes, crowded visual presentations, and distracting flashes on most web-based information sources could be barriers to web-based information seeking among the elderly [33]. More frequent health information seeking from traditional media such as the radio and newspapers were observed among the elderly in our previous population-based study [20]. Our finding that higher SES including education levels and income is associated with seeking web-based information on COVID-19 is consistent with that of previous studies on seeking of web-based health information conducted before the COVID-19 pandemic [13,31]. Compared to our previous study, which measured SES disparities in seeking of web-based health information in 2009-2012, the ORs of web-based information seeking were found to decrease (eg, tertiary or above education: 2.98 in 2020 vs 8.00 in 2009-2012) [20]. Such a reduction in the effect size could result from the increased popularity of internet-accessible devices in the general population in Hong Kong [34]. Alternatively, the decreased ORs could be attributed to increased information seeking behaviors in crisis events, which were suggested as a means of reducing situation uncertainty and controlling risk [35].

Furthermore, we found age and SES disparities in eHealth literacy, thus revealing disparities in locating, understanding, and the utility of web-based information among those who sought web-based information on COVID-19. The associations between sociodemographic characteristics (eg, age and SES) and eHealth literacy observed in our study were concurrent with previous findings on health literacy [36,37]. Our study focused on eHealth literacy because the Internet has been the major platform for disseminating health information during the COVID-19 pandemic, since it is easily available and can instantly update information on, for example, preventive behaviors and access to social and health services. Considering that web-based information is complex and misinformation on the internet has led to inappropriate behaviors [38], those who used the internet for health information but with limited eHealth literacy skills to discern the quality of different information sources were the potential at-risk populations and require more attention. We observed stronger associations between eHealth literacy and education rather than income, which probably reflects the notion that knowledge and skills are more affected by cognitive function than by the available material. The education-related disparity in eHealth literacy was larger than the income-related disparity in our study, which suggest that education plays a more crucial role than income in affecting eHealth literacy. Other studies have also suggested that disparities in eHealth literacy were due to knowledge gaps rather than merely physical barriers to internet access [39]. Furthermore, we noticed that eHealth literacy and seeking of web-based information on COVID-19 have similar risk factors including an older age and a lower SES [13]. eHealth literacy enables seeking of web-based information [8]; further studies can explore the extent to which low eHealth literacy hinders seeking of web-based information among older and low-SES individuals.

Successful control of the COVID-19 pandemic would need universal adherence to preventive behaviors, which have proven very effective in reducing disease spread [40]. Seeking of web-based information on COVID-19 is associated with the adherence to preventive behaviors, suggesting the need to understand the barriers to the low SES group, including low eHealth literacy to use the internet to obtain health information. Our participants with higher eHealth literacy showed high adherence to personal preventive behaviors, which was consistent with the results of previous non–COVID-19 studies that eHealth literacy correlated with health behaviors such as regular physical exercise and balanced diets [24,41,42]. Our study extended those findings to COVID-19 preventive behaviors in the specific context of the COVID-19 pandemic, in which increasing misinformation has been disseminated through the internet. Low eHealth literacy could lead to difficulties in fact-checking and mistrust in peoples' beliefs in coronavirus conspiracies, which would impede the performance of preventive behaviors [43]. Such disparities in eHealth literacy have led to disparities in guidelines on preventive behaviors, their profound consequence being health inequality [44]. Web-based information should be better designed to address the eHealth literacy levels of target users, particularly those with a low SES, to bridge the existing knowledge gap. Further studies are needed to explore how to improve eHealth literacy effectively and the approach involving the use of eHealth literacy to facilitate better health behaviors.

Limitations

Our study has some limitations. First, the cross-sectional data cannot confirm the causal association, although it is unlikely that higher eHealth literacy or seeking of web-based information on COVID-19 would lead to higher education and income. Second, we measured the perceived eHealth literacy instead of actual performance on the internet. Some studies have measured performed eHealth literacy and reported a weak or moderate correlation between perceived and performed eHealth literacy [15,45]. Third, eHEALS, the most commonly used validated scale, was developed at the early stage of internet technology; its fit with Web 2.0-related technologies (social media) was not clear because of the considerable changes on the internet (more participatory and interactive web) [46]. Future studies are needed

to improve the model of eHealth literacy with the evolution of the internet and the COVID-19 pandemic [46,47]. Fourth, we did not collect data on channels of web-based information on COVID-19; hence, further studies should include details of the frequency and channels on the internet for seeking information on COVID-19.

Conclusions

This study provides the first evidence that Chinese adults with a higher SES had higher eHealth literacy and sought web-based information on COVID-19, and that both these factors are associated with high adherence to the guidelines on preventive behaviors during the COVID-19 pandemic. Effective interventions are needed to enhance the low eHealth literacy skills of low-SES individuals to combat the COVID-19 pandemic.

Acknowledgments

We thank the Social Policy Research for conducting the survey and the participants for their responses in the study.

Authors' Contributions

SZZ, JYHW, and MPW conceived and designed the study. ZG, YW, and MPW analyzed the data. ZG, NG, and MPW drafted the manuscript. All authors interpreted the data, critically reviewed the manuscript, and provided their final approval for submission of the manuscript for publication.

Abstract

Background: The United States is in an opioid epidemic. Passive decision support in the electronic health record (EHR) through opioid prescription presets may aid in curbing opioid dependence.

Objective: The objective of this study is to determine whether modification of opioid prescribing presets in the EHR could change prescribing patterns for an entire hospital system.

Methods: We performed a quasi-experimental retrospective pre–post analysis of a 24-month period before and after modifications to our EHR's opioid prescription presets to match Centers for Disease Control and Prevention guidelines. We included all opioid prescriptions prescribed at our institution for nonchronic pain. Our modifications to the EHR include (1) making duration of treatment for an opioid prescription mandatory, (2) adding a quick button for 3 days' duration while removing others, and (3) setting the default quantity of all oral opioid formulations to 10 tablets. We examined the quantity in tablets, duration in days, and proportion of prescriptions greater than 90 morphine milligram equivalents/day for our hospital system, and compared these values before and after our intervention for effect.

Results: There were 78,246 prescriptions included in our study written on 30,975 unique patients. There was a significant reduction for all opioid prescriptions pre versus post in (1) the overall median quantity of tablets dispensed (54 [IQR 40-120] vs 42 [IQR 18-90]; $P<.001$), (2) median duration of treatment (10.5 days [IQR 5.0-30] vs 7.5 days [IQR 3.0-30]; $P<.001$), and (3) proportion of prescriptions greater than 90 morphine milligram equivalents/day (27.46% [10,704/38,976; 95% CI 27.02%-27.91%] vs 22.86% [8979/39,270; 95% CI 22.45%-23.28%]; $P<.001$).

Conclusions: Modifications of opioid prescribing presets in the EHR can improve prescribing practice patterns. Reducing duration and quantity of opioid prescriptions could reduce the risk of dependence and overdose.

KEYWORDS

informatics; electronic health record; opioids; prescriptions; oxycodone

Introduction

The opioid epidemic is a public health emergency unlike any other [1-3]. The roots of this crisis are founded in over 30 years of influential guidelines, marketing campaigns, and advertising that led to an increase in opioid prescriptions [4-8]. Overprescribing has increased since the early 1990s [9]. In 2016, there were 66.5 opioid prescriptions written for every 100 persons in the United States [10]. Prescription opioid abuse has been associated with progression to use of heroin [11], and the increased availability of both prescription and illicit opioids has led to a rise in the rate of death [12]. Opioids caused over 67% of drug-related deaths in 2017 and are responsible for nearly 400,000 deaths overall since 1999 [12].

Reductions in prescribing rates have become paramount to combating the opioid epidemic. Higher doses and longer durations of opioid therapy have been associated with an increased risk of chronic opioid use, with a significant increase in risk on treatment days 5 and 31 [13-15]. Therefore, the Centers for Disease Control and Prevention (CDC) recommends that caution be exercised when increasing doses to greater than 50 morphine milligram equivalents (MME) per day, and doses greater than 90 MME/day should be avoided. The CDC also states that 3 days or less is often sufficient for acute pain, and more than 7 days is “rarely needed” [16,17].

The HITECH act of 2009 made electronic health records (EHRs) ubiquitous. By 2017, 95% of hospitals in the United States are using EHRs [18]. EHRs and the technologies associated with them have been successfully utilized to combat the opioid epidemic. Electronic prescribing of controlled substances can improve medication safety, with a 2017 study demonstrating that an increasing number of prescribers are prescribing electronically [19]. Prescription drug monitoring programs, which require prescribers to review prior controlled substance prescriptions prior to prescribing, have shown reductions in opioid prescribing rates [20]. Computerized provider order entry (CPOE) systems are components of modern EHRs, and allow for reduction in practice variation and medical error by simplifying the prescribing of medications to an electronic process [21].

In order to curb overprescribing and reduce quantities of tablets, CPOE-linked interventions focus on preset defaulted prescription settings [22-24]. Previous studies have shown that the introduction or modification of opioid prescription presets has demonstrated reductions of tablet quantities and prescription MME for postsurgical patients [22], as well as significant reductions in the number of tablet quantities dispensed in the emergency department (ED) [23,25]. These studies suggest that modification of EHR-linked CPOE settings is a simple, inexpensive, and effective method of reducing the number of tablets associated with opioid prescriptions. However, all previous studies have focused on isolated emergency [23-27] or surgery departments [22]. We are unaware of any research examining the effects of modifications to opioid presets across an entire hospital system.

Slovis et al [27] previously demonstrated a reduction in duration of therapy and number of tablets dispensed when modifying the opioid prescription presets in our ED [27]. The success of this project prompted an enterprise-wide intervention to modify opioid prescription settings in our EHR’s CPOE.

Our institution’s CPOE consists of 4 fields for oral tablet prescription entry: (1) dose (number of tablets or milligrams per dose), (2) frequency (doses per day), (3) duration (number of days), and (4) quantity (number of tablets per prescription). Prior to our intervention dose, frequency and quantity were required for prescribing, but duration was not.

In August 2018, we implemented a number of interventions in our EHR’s CPOE: (1) we made the duration of treatment for an opioid prescription mandatory, (2) we provided a quick button for 3 days’ duration on all opioid prescriptions while removing all other quick buttons, and (3) we set the default quantity to 10 tablets for all oral opioid formulations, and removed any departmental variations. Prior to our intervention there was variability in durations and quantity dispensed for opioids (Multimedia Appendix 1). All interventions were passive in nature, no decision support alerts were part of the design, and there were no provider re-education measures nor large-scale announcement as part of the implementation design.

The purpose of this study was to assess the effects of modifications of opioid prescription default settings across an entire institution. We hypothesize that modifications of these settings can lead to reductions in duration of treatment, tablets dispensed, and proportion of prescriptions greater than 90 MME/day for a hospital system for patients with nonchronic pain. By demonstrating a reduction in prescribing at the hospital system level we have the potential to reduce risk of dependence, overdose, and possibly death.

Methods

Design, Setting, and Participants

In this quasi-experimental retrospective pre–post analysis, we examined the effects on prescribing patterns at our institution before and after modifications of opioid prescription settings. Thomas Jefferson University Hospitals, as an enterprise, has 908 acute care beds and over 2700 physicians and practitioners caring for more than 1.4 million people throughout the inpatient, outpatient, and ED settings [28]. This study was performed at the Center City Division, our urban academic institution comprising a large tertiary-care hospital, a community hospital, and multiple ambulatory clinics. Our study encompasses all outpatient prescriptions for opioids written between September 1, 2017, and August 31, 2019, in our EHR (Epic Systems Corporation) and the patients who received them. We did not include prescriptions for buprenorphine or methadone as these medications are used in medical assisted treatment (MAT) for opioid use disorder [29]. We limited our analysis to only oral capsule and tablet formulations (excluding oral liquid, buccal films, patches, etc.).

Our interest was in the effect of our intervention on opioids prescribed for acute pain. To this end, we excluded patients with chronic pain from our analysis via a modified approach to a validated algorithm [30]. Tian et al [30] achieved an accuracy of 95% for the identification of patients with chronic diseases

via (1) a single International Classification of Diseases, 9th Revision (ICD-9) code [31] "highly likely" to represent chronic pain OR (2) 2 or more ICD-9 codes "likely" to represent chronic pain separated by at least 30 days OR (3) receipt of at least 90 days of opioids OR (4) an ICD-9 code "likely" to represent chronic pain AND 2 or more pain scores greater than or equal to 4.

We mapped ICD-9 codes utilized in the algorithm to the 10th Revision (ICD-10) [32] using the Centers for Medicare and Medicaid Services General Equivalence Mappings [33] via the R package "touch" [34]. ICD code mappings were also manually reviewed. There were 9476 prescriptions in our cohort that did not include an ICD-10 and remained in our analysis as if they did not meet criteria for exclusion. Our data set included unreliable pain score documentation, so we eliminated this step in the algorithm. Pain scores held the lowest positive predictive value for identifying patients with chronic pain in the initial study [30], and we presumed that excluding these patients would only bias our results against our objective, as patients with chronic pain are presumed to have long-term prescriptions. Finally, we excluded all prescriptions written in the ED given the results of our previous intervention.

Variables

Using our analytics software Qlik Sense (QlikTech International), we identified all prescriptions for non-MAT opioid medications written during the study period and extracted a number of variables for each individual prescription and the associated patient.

At the prescription level these variables were medication, number of tablets, dosage unit (ie, mg), route of administration (oral vs rectal), and frequency of administration. Using our previously described method, we also included the calculated duration of therapy [35]. We utilized this value to represent the duration of the prescription as our prior work demonstrated that what is documented in the prescription is at times unreliable [35]. We also extracted precalculated MME/day for each prescription. At the patient level we extracted demographic data including age and sex.

Data Cleaning, Outcomes, and Statistical Analysis

In order to mitigate bias, all information was obtained through the same data query, and all participants were selected in the same way (eg, a script for an opioid medication). Participants were retrospectively recruited from a continuous 24 months.

Participants were divided into 2 cohorts (12 months before and after the intervention). The intervention was introduced on August 24, 2018, so the month of August 2018 was included in the preintervention cohort to avoid influencing postintervention results.

We calculated and compared frequencies of missing values for metrics of interest before and after the intervention. Demographic information was compared to assess similarity between the 2 cohorts.

The total number of prescriptions and unique patients were evaluated before and after the intervention. To ensure our intervention did not inadvertently cause an increase in the frequency of opioid prescribing, we compared the median number of prescriptions per patient per month as well as the odds of a patient receiving more than 1 prescription or refills.

The proportion of prescriptions was calculated for each class of opioid medication. Opioid class was determined by the active ingredient in the compound. We chose not to separate by schedule class as these can change [36,37]. We compared the proportions of opioid classes before and after the intervention and then measured if our intervention changed the quantity, duration, or proportion of prescriptions greater than 90 MME/day for all prescriptions, as well as for each opioid class.

For statistical analysis, Wilcoxon rank-sum test was utilized for nonparametric data, and *t* test for parametric data. Chi-square and Fisher exact test were performed for comparison of categorical values. Confidence intervals were included for all appropriate analysis. Statistics were performed in R statistical software (R Core Team).

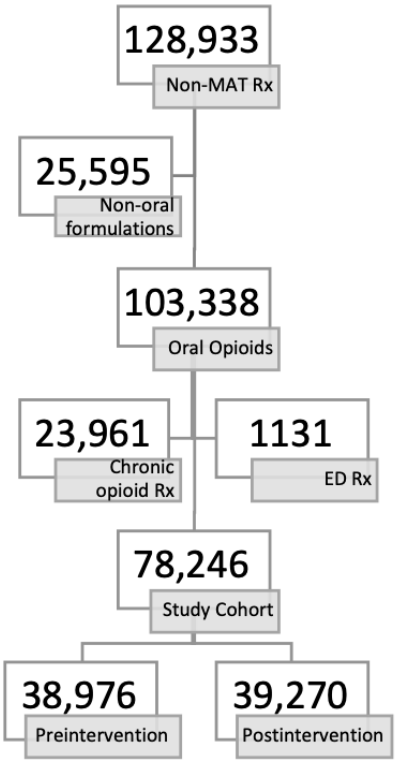
Results

Overview of Prescriptions

There were 128,933 non-MAT opioid prescriptions written during our study period. Of these, 103,338/128,933 (80.15%) were written for oral tablet or capsule formulations. We excluded 23,961/103,338 (23.19%) prescriptions that were written for patients with chronic pain. Of the remaining 79,377, we excluded 1131/79,377 prescriptions (1.42%) that were written by the ED. The median duration for these ED prescriptions was 2.7 days (IQR 2.5-3.3) with a median dispensed quantity of 9 tablets (IQR 9-31).

The remaining 78,246 prescriptions were for 30,975 unique patients. There were 38,976/78,246 (49.81%) prescriptions written for 16,464/30,975 (53.15%) patients in the preintervention period and 39,270/78,246 (50.19%) prescriptions written for 17,399/30,975 (56.17%) patients in the postintervention period. Figure 1 demonstrates the inclusion and exclusion criteria leading to our study cohorts.

Figure 1. Breakdown of our study cohort included excluded groups. ED: emergency department; MAT: medical assisted treatment.



Missing Data

Of the 78,246 prescriptions, 7167 (9.16%; 95% CI 8.96-9.36) were missing a calculated duration. The proportion of missing calculated durations decreased from 9.91% (7758/78,246; (95% CI 9.62-1.02) to 8.41% (6578/78,246; 95% CI 8.14-8.70; *P*<.001) before and after the intervention. In addition, 7156/78,246 (9.15%; 95% CI 8.94-9.35) prescriptions were missing documented quantity dispensed with a reduction from 9.90% (7750/78,246; 95% CI 9.60-10.20) to 8.40% (6570/78,246; 95% CI 8.13-8.68; *P*<.001) before versus after the intervention. Finally, 1139/78,246 (1.46%; 95% CI 1.37-1.54) prescriptions were missing the MME/day field with a significant increase in this proportion before versus after the intervention (915/78,246 [1.17%; 95% CI 1.07-1.28] to 1358/78,246 [1.74%; 95% CI 1.61-1.87]; *P*<.001). Missing values were excluded from their respective analysis.

Patient Demographics

Overall, 17,344/30,975 (55.99%; 95% CI 55.44%-56.55%) of all unique patients were female. There was no significant difference in patient sex before and after the intervention (17,300/30,975 [55.85%; 95% CI 55.10%-56.61%] vs 17,237/30,975 [56.65%; 95% CI 55.91%-57.39%] female; *P*=.14). The median age was 59, which did not change.

Rate of Prescribing

There was no significant change in the median number of prescriptions written per month, before and after the intervention (3254.5 [IQR 3176.25-3331.25] vs 3338 [3157.0-3391.5]; *P*=.59). The median monthly prescriptions per person remained 1 (IQR 1-2). The odds of getting more than 1 opioid prescription after the intervention did not significantly increase (1.003, 95% CI 0.967-1.04) and the odds of being prescribed a refill decreased (0.801, 95% CI 0.747-0.858).

Types of Opioids Prescribed

The majority (48,261/78,246, 61.68%; 95% CI 61.34%-62.02%) of prescriptions during the study period were for oxycodone. Table 1 demonstrates the proportion of individual opioids.

There were small but significant reductions in the proportion of prescriptions for morphine—6.30% (2456/38,976; 95% CI 6.06%-6.55%) to 5.95% (2335/39,270; 95% CI 5.72%-6.19%); *P*=.04)—and oxymorphone—0.37% (143/38,976; 95% CI 0.31%-0.43%) to 0.24% (96/39,270; 95% CI 0.20%-0.30%; *P*=.002). There was no change in the proportion of the other opioids.

Table 1. Proportion of each opioid during the study period with 95% confidence intervals.

Medication	Proportion[a] (N=78,246), n (%)	95% CI
Codeine	379 (0.48)	0.44-0.54
Hydrocodone	13 (0.02)	0.009-0.03
Hydromorphone	3995 (5.11)	4.95-5.26
Meperidine	40 (0.05)	0.04-0.07
Morphine	4791 (6.12)	5.96-6.29
Oxycodone	48,261 (61.68)	61.34-62.02
Oxymorphone	239 (0.31)	0.27-0.35
Tapentadol	172 (0.22)	0.19-0.26
Tramadol	20,356 (26.02)	25.71-26.32

[a]Proportion of the number of that individual opioid prescriptions from the total 78,246 opioid prescriptions.

Dispensing and Duration

There was a significant reduction in the overall median quantity of opioid tablets dispensed before versus after the intervention (54 [IQR 40-120] vs 42 [IQR 18-90]; *P*<.001). There was also a reduction in median duration of treatment before and after the intervention (10.5 days [IQR 5.0-30] vs 7.5 days [IQR 3.0-30]; *P*<.001). Finally, there was a significant reduction in the proportion of prescriptions greater than 90 MME/day (27.46% [10,704/38,976; 95% CI 27.02%-27.91%] vs 22.86% [8979/39,270; 95% CI 22.45%-23.28%]; *P*<.001), despite no change in the median of 45 MME/day per prescription before and after the intervention. These results are displayed in Figure 2.

There was a significant reduction in all metrics for oxycodone. Tramadol and codeine demonstrated a reduction in tablets dispensed, while codeine also had a reduction in the duration of treatment (*P*<.001 for all three metrics). Hydromorphone had a significant reduction (*P*<.001) in MME greater than 90/day despite no change in the other metrics. Table 2 demonstrates the effect of our intervention overall, and on each type of opioid medication before and after the intervention.

Given the majority of prescriptions were for oxycodone, Figure 3 demonstrates monthly numbers of tablets dispensed, median duration of treatment, and proportion of prescriptions greater than 90 MME/day for oxycodone.

Figure 2. Monthly median tablets prescribed pre and post-intervention, monthly median duration (days) pre and post-intervention and proportion of prescriptions >90 MME/day pre and post-intervention for all opioids. MME: morphine milligram equivalents.

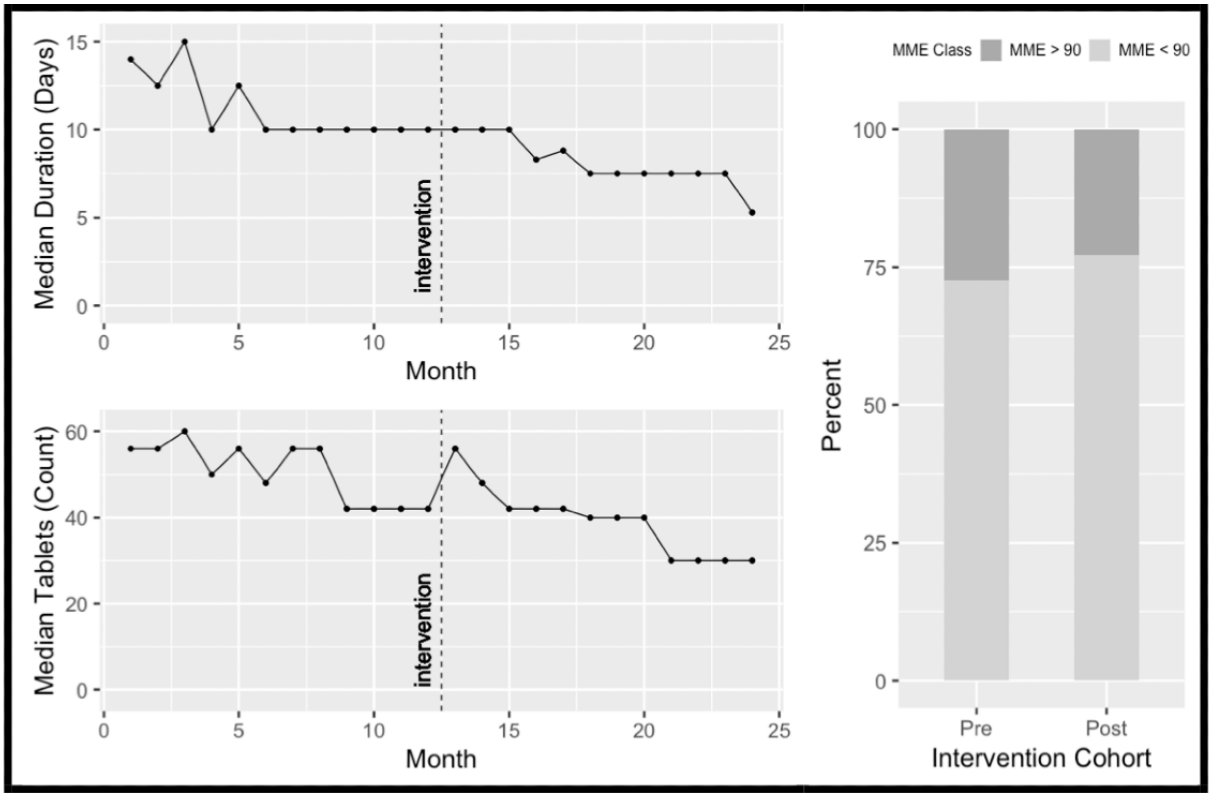


Table 2. Quantity, duration of treatment, and proportion of MME[a]/day >90 for all opioids and each individual opioid before and after the intervention.

Discussion

Principal Findings

In this quasi-experimental pre–post study our intervention resulted in a significant reduction (P<.001) in the duration of treatment, quantity of tablets dispensed, and proportion of prescriptions greater than 90 MME/day for all opioid prescriptions written for patients with acute pain without an increase in the rate of prescribing or MME/day per prescription, while maintaining clinician autonomy. Our postintervention median duration of treatment for all opioids was 7.5 days, which is slightly longer than the CDC's recommendations of 7 days [16], but an improvement over our preintervention duration of 10 days. In addition, we improved compliance with CDC recommendations that opioid dosing should not exceed 90 MME/day [16].

Oxycodone accounted for more than 60% (48,261/78,246, 61.68%) of our institutions prescriptions and was the only opioid to demonstrate reductions in all metrics, while tramadol, codeine, and hydromorphone had reductions in at least one metric. Our results show an improved median duration of treatment for oxycodone of 6 days, which is within CDC's recommendations for acute pain.

Modifications to prescription presets is a relatively simple and effective way to combat the opioid epidemic. Our results are similar to other studies of single departments. Delgado et al [23] studied 2 EDs prescribing oxycodone. They examined the difference in prescribing patterns before and after the implementation of a new EHR, where they previously had no prescribing presets and the new EHR was preset to 10 tablets per prescription demonstrating a decrease in the median number of tablets from 11.3 and 12.6 to 10 and 10.9, respectively, in the 2 departments [23].

Chiu et al [22] looked at opioid prescribing in the outpatient surgical setting. Their study included 3 hospitals examining changes in preset opioid prescription quantities from 30 to 12 tablets. The intervention reduced the median number of tablets prescribed from 30 to 20, with a decrease of 5.22 tablets and 34.41 MME per prescription, and no difference in refill rates [22].

Despite their expectation of decreased tablets dispensed, Zwank et al [26] showed an increase from 15.31 to 15.77 in the mean number of tablets dispensed for hydrocodone and oxycodone in the ED after they removed a 15-tablet preset and required manual entry of a dispense quantity [26]. This may suggest that presets are vital to reduce prescribing quantities; however, this is contradicted by Santistevan et al [24] who demonstrated that removal of a default of 20 tablets for hydrocodone and oxycodone reduced the median number of tablets prescribed from 20 to 15, although their preintervention presets were higher than Zwank et al's.

Montoy et al [25] implemented a block-randomization study at 2 EDs. They examined 6 possible opioid tablet quantity presets: "status quo" 12 and 20, as well as "null," 5, 10, and 15. They

demonstrated that each tablet increase in preset yielded an increase of 0.19 tablets prescribed, and lower default quantities were associated with lower number of pills in 8 of 15 pairwise comparisons [25]. These results support our approach that modifications to prescription presets are an effective way to enact change in opioid prescribing.

Despite a number of publications demonstrating reductions in opioid prescribing through presets [22,23,25], to our knowledge this research is the first to demonstrate reduction in overall opioid prescribing and prescribing of multiple individual opioids for an entire hospital system. Our hospitals and ambulatory clinics are located in one of the most lethal counties in one of the most lethal states associated with the opioid epidemic [38-40]. The CDC estimates that the risk of chronic use of opioids is 13.5% after 8 days of treatment [15] and the World Health Organization estimates the annual rate for opioid-dependent individuals overdosing at 45% and death at 0.65% [41]. We reduced our median duration of treatment from 10.5 to 7.5 (6 days for oxycodone), thus potentially bringing more than half of our institutions' opioid prescriptions below this high-risk threshold.

Examining our hospital's nearly 3300 prescriptions per month and postintervention median reduction of 12 tablets per prescription, we can estimate that our hospital system has reduced nearly 39,600 opioid tablets from being prescribed per month, or 475,200 tablets per year. Extrapolate this to the over 168 million prescriptions written in the United States in 2018 [42], and our simple intervention could potentially reduce the number of tablets being prescribed each year by over 2 billion. Our intervention excluded prescriptions for chronic pain, thus these approximations are likely extreme, but even a small percentage of these estimates is a net large and clinically important reduction in opioid tablets. Significant reductions in the number of opioid tablets prescribed, durations of treatment, and doses greater than 90 MME/day can play an important role in curbing the epidemic, improving quality of care, and ultimately saving lives.

Limitations

Our findings have a number of limitations. First, although a validated algorithm, we did not complete Tian et al's [30] algorithmic approach to identifying patients with chronic pain with EHR data. We believe this is unlikely to significantly bias our results as this was the least sensitive element in the original study and exclusion of this step, if anything, biases our results away from our objective (ie, including more patients with chronic pain with presumably higher doses and longer prescription durations in our data set). In addition, this algorithm was designed for use with ICD-9 codes. We mapped ICD-9 to ICD-10 codes and performed a manual review, but errors may still have persisted. Second, with regard to our results, we did demonstrate that morphine and oxymorphone had slight reductions in proportion prescribed after the intervention; however, this was unlikely to have biased our results. We also should acknowledge that 9.16% (7167/78,246) of our study cohort were missing calculated durations and quantity of tablets dispensed and the percentage of these missing values decreased after the intervention, while 1.46% (1139/78,246) of prescriptions were missing MME/day and this increased after the intervention. We believe the majority of missing calculated durations are likely due to the missing dispense quantities, which are required for the computation of this metric. Missing MME/day is likely due to missing concentrations, doses, or conversion factors of some formulations. Some of these missing values may be due to prescriptions being refilled and bypassing some of the new requirements we implemented. We excluded missing data from our analysis, but it is possible this exclusion influenced our results.

For our MME/day threshold we chose to use the CDC guidelines for opioid prescribing as the CDC is a federal agency that upholds "the health of the people of the United States." [43] It should be noted that individual states may have opioid prescribing guidelines that deviate from those presented by the CDC [44].

It should also be noted that our research was a quasi-experimental pre–post study, and we cannot infer causality with our intervention and the results observed. It is possible that other influential factors could have played a role in the reduction of opioid prescribing at out institution during this 2-year period, as the opioid epidemic has come to the forefront of modern medicine. However, we believe our results are encouraging, and other studies have demonstrated similar outcomes to suggest our intervention likely played at least a role in the reduction of prescribing patterns at our institution. Finally, our region has one of the highest opioid overdose and death rates in the nation, making our results of high value to curbing the epidemic; however, our results may not be generalizable to the rest of the country.

Conclusions

In this quasi-experimental retrospective pre–post analysis, we demonstrated that modifications of the opioid prescribing presets in our hospital system's EHR can improve prescribing practice patterns and reduce the number of pills dispensed, duration of treatment, and proportion of prescriptions greater than 90 MME/day. We have identified a simple and effective way to reduce opioid prescribing, and to our knowledge, we are the first to perform this kind of an intervention throughout an entire hospital system, and not just at the department level. Reduction in opioid prescribing may aid in curbing the opioid epidemic, thus improving quality of care and potentially saving lives.

Abstract

Background: Electronic health records (EHRs) are a central feature of care delivery in acute care hospitals; however, the financial and quality outcomes associated with system performance remain unclear.

Objective: In this study, we aimed to evaluate the association between the top 3 EHR vendors and measures of hospital financial and quality performance.

Methods: This study evaluated 2667 hospitals with Cerner, Epic, or Meditech as their primary EHR and considered their performance with regard to net income, Hospital Value–Based Purchasing Total Performance Score (TPS), and the unweighted subdomains of efficiency and cost reduction; clinical care; patient- and caregiver-centered experience; and patient safety. We hypothesized that there would be a difference among the 3 vendors for each measure.

Results: None of the EHR systems were associated with a statistically significant financial relationship in our study. Epic was positively associated with TPS outcomes (R^2=23.6%; β=.0159, SE 0.0079; *P*=.04) and higher patient perceptions of quality (R^2=29.3%; β=.0292, SE 0.0099; *P*=.003) but was negatively associated with patient safety quality scores (R^2=24.3%; β=−.0221, SE 0.0102; *P*=.03). Cerner and Epic were positively associated with improved efficiency (R^2=31.9%; Cerner: β=.0330, SE 0.0135, *P*=.01; Epic: β=.0465, SE 0.0133, *P*<.001). Finally, all 3 vendors were associated with positive performance in the clinical care domain (Epic: β=.0388, SE 0.0122, *P*=.002; Cerner: β=.0283, SE 0.0124, *P*=.02; Meditech: β=.0273, SE 0.0123, *P*=.03) but with low explanatory power (R^2=4.2%).

Conclusions: The results of this study provide evidence of a difference in clinical outcome performance among the top 3 EHR vendors and may serve as supportive evidence for health care leaders to target future capital investments to improve health care delivery.

electronic health records; medical informatics; hospitals; delivery of health care; financial management; quality of health care; treatment outcome

Introduction

Background

In the first part of the 20th century, health care predominantly revolved around a single health care provider, diagnosing and treating patients within the confines of their office or in the patient's home, and patient medical histories were recorded on paper. However, as the US health care industry has progressed and modernized, the proliferation of information technology has accelerated. In 2013, US health information technology investment totaled US $2.8 billion; however, by 2017, it had reached a staggering US $7.1 billion [1]. However, some reports indicate that hospitals have struggled to remain profitable during this same time frame [2]. Many health care executives are questioning the return on investment in hospital technology and wondering whether their capital outlay will result in improved financial outcomes [3].

Numerous studies have noted the high expense of care delivery yet low health care information technology proliferation in the United States. Citing the advancement of similar technology in other developed countries, researchers have indicated that through increased investment in health information technology, the United States can lower overall health care spending and simultaneously improve quality of care and patient outcomes [4,5]. As a result, the federal government has been heavily involved in the modernization of health information technology. As early as 2004, President George W Bush called for computerized health records in his State of the Union address and offered a strategy to provide Americans access to electronic health records (EHRs); unfortunately, he did not earn sufficient funding to change provider behavior [6]. In 2009, President Barack Obama signed the Health Information Technology for Economic and Clinical Health (HITECH) Act as part of the American Recovery and Reinvestment Act (ARRA) and originally set aside US $27 billion for an incentive program that encouraged hospitals and providers to adopt EHR systems [7,8]. This legislation prompted the adoption of EHRs in 2014 and established time frames for mandated EHR adoption. Furthermore, with the passage of the Medicare Access and CHIP Reauthorization Act, Medicare introduced the Medicare EHR Incentive Program, and the Merit-Based Incentive Payment System to advance the meaningful use of EHRs. As a result, by 2015, 96% of hospitals and 87% of physician practices implemented EHRs [9]. By mid-2016, the total federal government investment in EHR rose to US $35 billion and continued to rise [10].

One could argue that the proliferation of health care technology spending did not occur organically. The hospital and health care industry shifted to the use of EHR systems primarily because of the financial incentives incorporated within the ARRA and HITECH legislation [11]. HITECH provided eligible professionals who demonstrated the meaningful use of an EHR qualified for payments of US $18,000 in the first year; US $12,000 for the second year; US $8000 for the third year; US $4000 for the fourth year; and US $2000 for the fifth year [12]. An eligible professional was generally considered to be a physician. After 2015, physicians who failed to meaningfully use EHRs were subject to reductions in Medicare and Medicaid reimbursement. Meaningful use of an EHR includes 3 components: (1) the EHR must be certified and include e-prescribing capabilities; (2) the technology must provide for the electronic exchange of personal health information with other EHR systems (interoperability); and (3) the system must produce reports utilizing various clinical and quality metrics.

Beginning in 2011, incentive payments were also available for eligible hospitals that showed meaningful use of EHR and that submitted quality metrics based on criteria identified by the US Department of Health and Human Services. Incentive amounts were phased out in 2015 for hospitals that had not implemented a meaningful EHR. In addition, incentive payments were not available for hospitals that were not meaningful EHR users [13]. Despite the robust startup incentives offered by the federal government and continuing support provided via increased Medicare reimbursement, questions remain if the investment in health care information technology is sustainable. The adoption of a comprehensive EHR system can surpass several billion dollars for a large health care system [14]. The sustainability of these systems can approach several hundred million dollars annually, and numerous health care systems report significant implementation and sustainment cost overages [15,16]. Furthermore, despite the prevalent adoption of EHR systems since the passage of the HITECH Act, sharing of health care data and interoperability of information technology remains to be elusive. There remains to be little financial incentive to share and use data to reduce costs or improve the quality of care [17].

Thus, we seek to assess the association between investment in information technology and the dominant EHR platforms each have on the financial and quality outcomes of hospitals in the United States. We hypothesize that there is a difference in outcomes among the 3 vendors for each measure. Although extensive research has focused on the perceived and actual benefits of information technology in health care, this is an area of research that has not been fully evaluated. The body of literature predating the passage of the HITECH and Affordable Care Acts is fairly robust; however, with the passage of these legislative acts and the rate of change in technology, many of these studies are now outdated, particularly with respect to the direct impact of specific EHR vendors [18-20].

Literature Review

Two recent studies examined the relationships between health information technology capital expenditure and both financial and quality outcomes and aligned very closely with our work. Wang et al [21] examined the impact of investment in health information technology on hospital financial performance and productivity. In a later study, Wang and Gibbs [22] offered a framework to compare the performance of EHR systems. We intend to build on these studies in a few key areas [21,22].

First, in the 2018 and 2019 studies, the key financial outcome variable examined was return on assets (ROA). Net revenue per staffed bed was also considered in the 2018 study. Broadly speaking, financial performance can be assessed in 4 main areas: (1) profitability or return on investment, (2) liquidity, (3) leverage, and (4) operating efficiency. Within each category,

there are several variables to consider. Although ROA and revenue per bed are important, we believe that greater operational clarity can be achieved with a specific focus on the income statement and net income.

Second, quality was evaluated in the 2019 study via the Hospital Value–Based Purchasing (HVBP) Total Performance Score (TPS). These quality measures are all important to the field; however, we view the level of utilization of beds as a suboptimal measure of quality that is not well supported in the literature. The number of times a bed turns over speaks more to the volume of services demanded but offers little insight with respect to the quality of those services. We intend to focus more on the dimensions of HVBP and its subdomains. The contributory factors that are evaluated to produce the TPS include patient perceptions of care and measures of patient safety, process of clinical care delivery, and efficiency and cost reduction.

Third, both the 2018 and 2019 studies included important market characteristic variables as controls. These included hospital size, market concentration index (MCI), payer mix (Medicare and Medicaid; ie, the percentage of revenue coming from each of those programs), uncompensated care cost, ownership (governmental, proprietary, and nonprofit), teaching status, geographic classification, and year fixed effects. We suggest that additional variables may be insightful, as several other factors have been shown to influence both financial and quality outcomes [23-25]. Additional control variables worth considering are the level of outpatient services rendered, urban versus rural location, average length of stay, case mix index, wage index, sole community provider status, system membership, and geographic region [26]. These variables can further clarify the strength of the association between the independent variable of interest and our targeted dependent variables, while also serving to diminish any possible omitted variable bias.

Fourth, the 2019 study considers various EHR systems but does not clearly identify which vendors perform better or worse based on the available data. To the authors' credit, they did not want the research to be construed as the promotion of a particular vendor. However, in our view, the health care industry is in an era of evidence-based medicine and management. Thus, we believe that it is appropriate to identify the system in question. This more transparent approach, coupled with more specific outcome data that clearly identifies practitioner actionable evidence, should provide greater practical insight and facilitate improved organizational decision making.

In the following sections, we integrate and broaden the investigation of previous research efforts and evaluate the impact of 3 of the largest EHR providers' performance on measures of finance and quality. Quite simply, we would like to determine which EHR system performs the best and seek to provide health care leaders with an additional evidentiary basis for making EHR adoption decisions. Given the variation in EHR system cost, options, ease of use, training requirements, and on-site and follow-up support, we recognize that this can be a highly complex decision. Although we hypothesize that there is a difference in performance among the 3 EHR vendors in terms of financial and quality performance, we are uncertain a priori where each system will perform the best on the evaluation measures we have selected.

Methods

Data and Sample

The data for this study were extracted from two primary sources: the Definitive Health Care database and the American Hospital Association (AHA) Annual Survey database for 2018. The Definitive Health Care database provided the dependent and independent variables of interest, in addition to most of the control variables for this study. The Definitive Health Care database compiles US hospital data sources including Medicare Cost Reports, commercial claims data, Medicare Standard Analytics Files, Centers for Medicare and Medicaid Services (CMS) Hospital Compare, and many other data elements [27]. The cost report contains provider information such as facility characteristics, utilization data, cost and charges by cost center (in total and for Medicare), Medicare settlement data, and financial statement data. The AHA Annual Survey database provided the remaining data for the geographic region control variables [28]. All variables were linked with the 2 contributing data sources based on the Medicare provider number. Data on a total of 2667 short-term acute care hospitals were accumulated for analysis.

Measures—Dependent Variables

Table 1 shows the full complement of the study variables. Our study included 2 types of dependent variables drawn from the Definitive Health Care data set. The first set of data comes from the hospital income statement: net income scaled in millions of dollars. The second set of dependent variables is drawn from the hospitals' 2018 value-based purchasing scores and includes (1) the TPS, (2) patient experience score, (3) clinical process score, (4) efficiency score, and (5) the safety score. Each hospital's TPS is a weighted measure of performance based on each of the other areas listed, while each subordinate measure is an aggregation of several commonly tracked clinical and administrative criteria, as shown in Figure 1.

Under the CMS HVBP Program, Medicare makes incentive payments to hospitals based on how well they perform on each measure compared with other hospitals' performance during a baseline period and how much they improve their performance on each measure compared with the baseline reporting period [29]. All value-based purchasing variables are unweighted and based on a scale of 0 to 100, with higher scores being better, and have been validated by CMS for validity and reliability [30]. The total number of value-based purchasing participating hospitals provided a size limit to the study. A missingness map using Amelia, a program for missing data developed by Honaker et al [31], revealed approximately 1% missing from 2667 observations and 32 variables (k). The maximum proportion missing from any column was 12.5% and from any row was 10.1%; therefore, these values were conservatively imputed with the median using R Statistical Software [32].

Table 1. Variables and operational definitions.

Variable	Original source	Definition
Cerner	Definitive Health Care	Hospital using the Cerner EHR[a] as its primary EHR platform
Epic	Definitive Health Care	Hospital using the Epic EHR as its primary EHR platform
Meditech	Definitive Health Care	Hospital using the Meditech EHR as its primary EHR platform
TPS[b]	CMS[c]	The TPS is derived from 4 equally weighted domains in financial year 2018: • Clinical care • Patient experience of care • Safety • Efficiency and cost reduction
Patient experience score	CMS	Composite of 9 measures extracted from the hospital consumer assessment of health care providers and systems survey
Clinical care score	CMS	Composite of 3 mortality measures: acute myocardial infarction, heart failure, and pneumonia
Efficiency and cost reduction score	CMS	Medicare Spending Per Beneficiary
Safety score	CMS	Composite of 7 safety related rates: catheter-associated urinary tract infections, central line-associated blood stream infection, clostridium difficile infection, methicillin-resistant staphylococcus aureus, patient safety for selected indicators composite, elective delivery before 39 completed weeks gestation, and surgical site infections
For-profit status	Definitive Health Care	Hospitals operated by investor-owned organizations
Number of beds	Definitive Health Care	Number of staffed beds
Rural status	Definitive Health Care	Hospital located in a nonmetropolitan county or a hospital within a metropolitan county that is far away from the urban center, as defined by the Health Resource Services Administration
Government status	Definitive Health Care	Hospitals operated by local, county, or state government
Teaching status	Definitive Health Care	Hospitals affiliated with universities, colleges, medical schools, or nursing schools
Outpatient service mix	Definitive Health Care	Percent of care delivered in an outpatient setting
Average length of stay	Definitive Health Care	The average number of days that patients spend in hospital, measured by dividing the total number of days stayed by all inpatients during a year by the number of admissions or discharges
Case mix	Definitive Health Care	The case mix index is the average relative diagnosis related group weight of a hospital's inpatient discharges, calculated by summing the Medicare Severity-Diagnosis Related Group weight for each discharge and dividing the total by the number of discharges
Government payer mix	Definitive Health Care	The proportion of hospital reimbursement from governmental sources (Medicare, Medicaid, TRICARE, etc)
Wage Index	Definitive Health Care	A labor market area's wage index value is the ratio of the area's average hourly wage to the national average hourly wage
Sole community hospital	Definitive Health Care	A sole community hospital classified by specific criteria from CMS (distance from other like hospitals, rural, travel time, number of beds, etc)
System member	Definitive Health Care	An entity that owns or has owned 2 or more hospitals. In addition, health systems may also maintain ownership of other postacute or ambulatory sites of care
Market concentration	Definitive Health Care	The Herfindahl-Hirschman Index measure of market concentration was used to determine market competitiveness. It is calculated by squaring the market share of each firm competing in a market and then summing the resulting numbers
Average age of facility	Definitive Health Care	Average age of facility is calculated using the accumulated depreciation (total depreciation) and the depreciation expense (depreciation over a single period)
Occupancy rate	Definitive Health Care	Measure of utilization calculated as (inpatient days of care or bed days available)×100

Variable	Original source	Definition
Region	American Hospital Association	Regions of the United States as defined by the American Hospital Association

[a]EHR: electronic health record.

[b]TPS: total performance score.

[c]CMS: Centers for Medicare and Medicaid Services.

Figure 1. Financial year 2018 Hospital Value–Based Purchasing program measures.

Total Performance Score Domain	Measure Description
Safety	Catheter-Associated Urinary Tract Infections
Safety	Central Line Associated Blood Stream Infection
Safety	Clostridium difficile infection (C. difficile)
Safety	Methicillin-Resistant Staphylococcus aureus bacteremia
Safety	Patient Safety for Selected Indicators (composite)
Safety	Elective Surgery Priot to 39 Completed Weeks Gestation
Safety	Surgical Site Infection
Clinical care	Acute Myocardial Infarction (AMI) 30-day mortality rate
Clinical care	Heart Failure (HF) 30-day mortality rate
Clinical care	Pneumonia (PN) 30-day mortality rate
Efficiency and cost reduction	Medicare Spending per Beneficiary (MSPB)
Experience of care	Hospital Consumer Assessemnt of Healthcare Providers and Systems Survey

Measures—Independent and Control Variables

Our independent variables of interest included the top EHR systems used by hospitals in the United States (ie, Cerner, Epic, Meditech, or other), as reported in the Definitive Health Care database. These variables were included in our analysis as a dichotomous variable for each EHR system of interest ("1" if the system was used, "0" if not). Consistent with previous research, we also included several organizational-level control variables to account for other explanatory factors that could influence financial and quality outcomes. These variables included for-profit ownership status, number of beds, rural or urban geographic location, government ownership, teaching status, outpatient service mix, average length of stay, case mix, government payer percentage, wage index, sole community provider designation, system membership, MCI, occupancy rate, and geographic location by the AHA region. All analyses were performed using collinearity diagnostics. The variance inflation factor exceeded 10 in our analyses. Table 1 shows the data sources and operational definitions of the variables used in this study.

Results

Overview

Descriptive statistics and pairwise correlations were also calculated. The distributions of most of the dependent variables (income, TPS, experience score, clinical score, and safety) were relatively normal; however, the HVBP efficiency score was skewed to the right. Box-Cox analysis of the variable suggested a negative square root transformation, but for interpretability, it was not transformed. All dependent variables were min-max scaled between 0 and 1 for easier interpretation as percentile scores (eg, income percentile). All statistical analyses were performed using the R Statistical Software [32]. In all the analyses, a two-tailed *P* value <.05 was considered statistically significant.

Table 2 provides detailed descriptive statistics for each variable. Participating hospitals had a mean net income of US $15.01 million (SD US $109.04 million); TPS mean of 37.26 (SD 11.16); patient experience mean of 33.36 (SD 18.07); clinical process score mean of 59.45 (SD 19.24); efficiency score mean of 19.39 (SD 24.75); and safety score mean of 53.01 (SD 17.74). In all cases, higher scores on the HVBP variables were better. EHR vendors are represented in the following proportions in our sample: Epic: 39.85% (1063/2667; SD 0.48); Cerner: 23.39% (624/2667; SD 0.42); Meditech: 19.98% (533/2667; SD 0.39); and "other": 16.78% (447/2667; SD 0.39).

Among the numerous organizational characteristics included in our analysis as control variables, we observe 18.00% (480/2667) of the hospitals in the study population are for-profit facilities (SD 0.38), 22.98% (613/2667) are in rural locations (SD 0.42), 45.97% (1226/2667) are teaching facilities (SD 0.49), 72.97% (1946/2667) are affiliated with a health care system (SD 0.45), and that the hospitals are widely distributed across each of the AHA geographic regions.

Table 2. Descriptive statistics.

Variable	Values, mean (SD)
Net income (in millions; US $)	15.01 (109.04)
Total performance score	37.26 (11.17)
Patient experience score (unweighted)	33.36 (18.07)
Clinical process score (unweighted)	59.45 (19.24)
Efficiency score (unweighted)	19.39 (24.75)
Safety score (unweighted)	53.01 (17.74)
EHR[a]-Cerner	0.23 (0.42)
EHR-Epic	0.40 (0.48)
EHR-Meditech	0.20 (0.40)
EHR-other	0.17 (0.39)
For-profit	0.18 (0.40)
Beds	214.75 (185.47)
Rural	0.23 (0.42)
Government	0.13 (0.34)
Teaching	0.47 (0.50)
Outpatient service mix	0.53 (0.15)
Average length of stay	4.30 (0.92)
Case mix index	1.61 (0.28)
Government payer percent	0.71 (0.11)
Wage index	1.00 (0.20)
Sole community provider	0.08 (0.28)
System member	0.73 (0.45)
Market concentration index	0.34 (0.330)
Occupancy rate	0.57 (0.17)
Average age of facility	12.95 (9.23)
Region 1[b] (Connecticut, Maine, New Hampshire, Rhode Island, and Vermont)	0.04 (0.20)
Region 2 (New Jersey, New York, and Pennsylvania)	0.12 (0.32)
Region 3 (Delaware, Kentucky, Maryland, North Carolina, Virginia, West Virginia, and Washington, DC)	0.08 (0.28)
Region 4 (Alabama, Florida, Georgia, Mississippi, South Carolina, Tennessee, and Puerto Rico)	0.17 (0.37)
Region 5 (Illinois, Michigan, Indiana, Ohio, and Wisconsin)	0.17 (0.37)
Region 6 (Iowa, Kansas, Minnesota, Missouri, Nebraska, North Dakota, South Dakota)	0.08 (0.27)
Region 7 (Arkansas, Louisiana, and Texas)	0.13 (0.35)
Region 8 (Arizona, Colorado, Idaho, Montana, New Mexico, Utah, and Wyoming)	0.07 (0.260)
Region 9 (Alaska, California, Hawaii, Nevada, Oregon, and Washington)	0.13 (0.34)

[a]EHR: electronic health record.

[b]The representative geographical region is American Hospital Association Region 1 (Connecticut, Maine, New Hampshire, Rhode Island, and Vermont).

Net Income

Table 3 reflects the results of our regression analyses of hospitals' utilization of the top 3 EHR vendors and the associated hospital financial performance as measured by net income. On the basis of our analysis of net income regressed on EHR vendors (R^2=10.6%), we see no significant results for any of the vendors, when compared with facilities that fall into the "other" category. Thus, we can say, on average, and when controlling for the numerous organizational factors as controls, none of the EHRs are associated with favorable or unfavorable financial outcomes as measured by net income.

Table 3 also shows additional significant variables in our analysis that are associated with hospital net income, including

the number of hospital beds (β=.0001, SE 0.0000; *P*<.001), hospital case mix (β=.0067, SE 0.0032; *P*=.04), hospital wage index (β=−.0200, SE 0.0059; *P*<.001), and several geographic variables. These findings indicate that with a point increase in hospital case mix, net income increases by 0.67%, and with each point increase in the hospital wage index, net income falls by 2%.

Table 3. Analysis results for net income and total performance score.

[a]Not significant.

[b]Referent geographical region is Region 1 (Connecticut, Maine, New Hampshire, Rhode Island, and Vermont); referent electronic health record is "other."

Total Performance Score

Table 3 also shows the results of our regression analyses of the association of EHRs with HVBP quality measures. On the basis of our analysis of TPS regressed on EHR vendors (R^2=23.6%), Epic reflects only statistically significant results (β=.0159, SE 0.0079; *P*=.04). These results indicate that the Epic EHR is associated with a 1.6% higher performance score when compared with facilities that fall into the "other" category. Neither Meditech nor Cerner were associated with significant results.

Table 3 further indicates several control variables that are significantly associated with TPS performance score. These variables include for-profit ownership (β=−.0176, SE 0.6203; *P*=.02), number of hospital beds (β=−.0045, SE 0.0019; *P*<.001), rural designation (β=.0556, SE 0.0084; *P*<.001), teaching designation (β=.0129, SE 0.0055; *P*=.02), outpatient service mix (β=.2137, SE 0.0254; *P*<.001), average length of stay (β=−.0215, SE 0.0033; *P*<.001), case mix (β=.0254, SE 0.0111; *P*=.02), wage index (β=.0523, SE 0.0204; *P*=.01), sole community provider designation (β=.0345, SE 0.0095; *P*<.001), and the MCI (β=−.0380, SE 0.0098; *P*<.001).

Among other findings, these results imply, on average, for-profit facilities perform 1.7% lower on the TPS measure. In addition, with each day increase in average length of stay, we observed a 2.2% decrease in TPS, and with each point increase in market concentration, we see an associated 3.8% decrease in TPS performance. However, with each point increase in the case mix index, wage index, and outpatient service mix, we observed a 2.5%, 5.2%, and 21.4% increase in TPS outcomes, respectively. Teaching hospitals are also associated with a 1.2% higher level of performance than nonteaching facilities.

Efficiency Score

In Table 4, we also show the evaluation of efficiency performance scores regressed on EHR vendors (R^2=31.9%). Cerner (β=.0330, SE 0.0135; *P*=.01) and Epic (β=.0465, SE 0.0133; *P*<.001) were positively associated with improved efficiency quality scores approximately 3.3% higher (Cerner) and 4.7% higher (Epic) than hospitals in the "other" category. Meditech was not associated with any significant results.

Table 4 also indicates several variables that are significantly associated with hospital efficiency. These variables include the number of hospital beds (β=−.0001, SE 0.0000; *P*=.002), rural designation (β=.0723, SE 0.0142; *P*<.001), outpatient service mix (β=.4831, SE 0.0429; *P*<.001), average length of stay (β=−.0233, SE 0.0055; *P*<.001), case mix (β=−.0698, SE 0.0188; *P*<.001), government payer percent (β=−.2486, SE 0.0375; *P*<.001), wage index (β=.1145, SE 0.0344; *P*<.001), sole community provider designation (β=.0888, SE 0.0160; *P*<.001), occupancy rate (β=.0656, SE 0.0310; *P*=.03), and several regional variables. This implies, on average, there is a statistically significant 2.3% decrease in efficiency score with each day increase in average length of stay, a 6.9% decrease with each point increase in the case mix index, and a 24.9% decrease in efficiency is associated with each point increase in government payer percentage.

[a]Not significant.

[b]Referent geographical region is Region 1 (Connecticut, Maine, New Hampshire, Rhode Island, and Vermont); referent electronic health record is "other."

Patient Experience Score

Table 4 provides the final analysis results of our evaluation of hospitals' patient experience performance scores regressed on EHR vendors. Epic was positively associated with higher patient perceptions of quality scores 2.9% higher than hospitals in the "other" category (R^2=29.3%; β=.0292, SE 0.0099; *P*=.003).

Table 4 provides additional insight pertaining to the significant association between the control variables included in our study and patient experience scores. These variables include for-profit ownership (β=−.0542, SE 0.0093; *P*<.001), number of beds (β=−.0001, SE 0.0000; *P*<.001), rural status (β=.0517, SE 0.0105; *P*<.001), teaching (β=.0270, SE 0.0069; *P*<.001), outpatient service mix (β=.3091, SE 0.0320; *P*<.001), average length of stay (β=−.0251, SE 0.0041; *P*<.001), case mix

(β=.0100, SE 0.0140; *P*<.001), government payer percent (β=.0044, SE 0.0095; *P*<.001), market concentration (β=−.0586, SE 0.0123; *P*<.001), occupancy rate (β=−.0618, SE 0.0230; *P*=.007), and several geographic regions.

These results imply that, on average, the for-profit hospitals in our study scored 5.4% lower on the HVBP patient experience scores. In addition, for each additional day in the hospital, the patient experience scores decreased by 2.5%. Each point increase in market concentration and occupancy rate also reduces patient experience by 5.9% and 6.2%, respectively. Conversely, rural and teaching hospitals are associated with higher patient experience, with associated increased scores of 5.2% and 2.7%, respectively.

Patient Safety Score

Table 5 provides insight into our research on patient safety performance scores regressed on EHR vendors (R^2=24.3%). Epic (β=−.0221, SE 0.0102; *P*=.03) was negatively associated with patient safety quality scores of 2.2% lower than hospitals in the "other" category. Meditech and Cerner scores were not associated with significant results.

Table 5 also provides details regarding the significant associations between the control variables included in our study and patient safety scores. These variables include the number of hospital beds (β=−.0002, SE 0.0000; *P*<.001), rural status (β=.0420, SE 0.0109; *P*<.001), teaching (β=.0168, SE 0.0071; *P*=.02), outpatient service mix (β=.0965, SE 0.0330; *P*=.003), average length of stay (β=−.0143, SE 0.0042; *P*<.001), case mix (β=−.0812, SE 0.0144; *P*<.001), government payer percent (β=.0746, SE 0.0288; *P*=.009), and occupancy rate (β=−.0919, SE 0.0238; *P*<.001). These results indicate that patient safety is negatively impacted by 1.4% for every day increase in average length of stay and also declines by 8.1% for every point increase in the case mix index. Furthermore, with each percent increase in the hospital occupancy rate, patient safety scores declined by 9.2%. Conversely, patient safety scores were positively associated with rural and teaching hospitals by 4.2% and 1.7%, respectively. In addition, with each percentage increase in government payments, patient safety scores improved by 7.5%.

[a]Not significant.

[b]Referent geographical region is Region 1 (Connecticut, Maine, New Hampshire, Rhode Island, and Vermont); referent electronic health record is "other."

Clinical Care Performance Score

Finally, Table 5 shows the results of our evaluation of clinical care performance scores regressed on EHR vendors. All 3 vendors were associated with positive performance with Epic (β=.0388, SE 0.0122; *P*=.002), Cerner (β=.0283, SE 0.0124; *P*=.02), and Meditech (β=.0273, SE 0.0123; *P*=.03), reflecting positively associated higher clinical care performance scores between 2.7% (Meditech) and 3.8% (Epic) higher than hospitals in the "other" category. However, on this dependent variable,

we recognize that the explanatory power of the regressors is very low (R^2=4.2%).

Table 5 also provides insight into the association between the control variables in our study and clinical process outcomes. The statistically significant variables in our analysis included for-profit status (β=.0512, SE 0.0116; *P*<.001), number of hospital beds (β=−.0001, SE 0.0000; *P*=.02), government operated (β=−.0264, SE 0.0118; *P*=.03), teaching (β=.0167, SE 0.0086; *P*=.05), government payer percentage (β=−.0839, SE 0.0346; *P*=.02), system membership (β=.0329, SE 0.0095; *P*<.001), market concentration (β=.0323, SE 0.0152; *P*=.03), and the average age of the facility (β=.0009, SE 0.0004; *P*=.04). These results indicate that government-operated hospitals are associated with 2.6% lower clinical process scores, and for each point increase in government payer percentage, there is also an 8.3% lower score. However, for-profit, teaching, and system-owned hospitals appear to perform better on this measure by 5.1%, 1.6%, and 3.3%, respectively. Hospitals in concentrated markets also appear to perform better than those in less concentrated markets. With each point increase in market concentration, we observed an increase of 3.2%.

Discussion

Principal Findings

In general, our findings were insightful regarding the performance of individual EHR vendors. We did not expect to see a clearly obvious choice of EHR vendor with respect to performance as defined by our financial and quality-focused dependent variables. To this end, we did not ascertain that there is a single EHR that outperforms all other competitors across all of our study measures.

Our findings pertaining to financial outcomes were somewhat interesting in that no single EHR demonstrated a significant and positive association with net income. In most instances, the capital allocation process is predicated on reasonable assurance that there will be some tangible return on investment over a reasonable amount of time. As EHR adoption is a major capital investment and requires a major organizational change and extensive training, some have argued that it may take the organization a few years to see its effect on financial performance. For instance, Collum et al [20] found a statistically significant improvement in the total margin 2 years after EHR adoption in hospitals. However, the authors attributed the observed effect more to HITECH Act incentive payments than operational improvements, primarily because the authors found no significant association with operating margin. Thus, these previous authors' observations, coupled with our own, continue to indicate that EHR return on investment remains an unsettled matter.

In our evaluation of TPS as a dependent variable, we note that Epic was the singular EHR with a positive and significant association with improved scoring. Given that the TPS is a composite of the other variables in our analysis, it prompted us to examine each of the subdomains' performance scores more closely. Although we did not see a positive association for Epic in improved financial performance, this EHR recorded positive and significant associations in clinical care, patient experience, and efficiency scoring. Thus, when considered together, this combination of scores across these 3 quality subdomains appears to provide a performance advantage to Epic and a positive association with TPS scoring.

However, Epic also demonstrated a statistically significant and negative association with patient safety, which was not observed in our other vendors' performance. Although we did not expect to observe a significant and negative association between any EHR vendors and patient safety scoring, upon further research on this topic, we note that our findings appear to be consistent with several previous researchers' results. Bowman [33] captures these areas of concern very well in her synthesis of 64 studies and papers highlighting numerous areas where EHRs can impose undue burdens on health care providers and introduce the possibility of errors. These include the potential for recording erroneous data entry leading to patient safety hazards, system design flaws, improper system use, inappropriate document capture, erroneous application of copy and paste functions within the medical record, rigid application of prepopulated templates, and errors related to clinical decision support systems such as alert fatigue [33]. In recent years, others have pointed to potential problems with EHRs as a vector for increased risk to patient safety with respect to incorrect use [34,35], malfunctions [36,37], interoperability or system interaction [38], and health information technology blackouts or downtime [36,39]. On the basis of our findings, we can reasonably assume that many of these issues persist.

Our research group discussed the possible reasons for these results. In many ways, our results are supported by independent research. The top vendors that we studied are often highlighted in the KLAS, LLC Research for best in class, most user friendly, and holding buyers' attention [40]. It is a user-friendly variable that could contribute to the software's success in efficiency measures. It is possible that all 3 vendors are equally capable of achieving similar efficiency scores, but the fact that users are more familiar with their function and more willing to explore beyond the basic user training that renders Epic more effective in the areas of TPS. One could reasonably assume that the number of years since the hospital adopted the EHR system, and also the stage of adoption, might have had an effect. Hospitals that have adopted the EHR over several years may be more efficient than hospitals that only recently adopted or changed their EHR system. This could have an impact on levels of customer service, capability to integrate modules together, onboarding processes relating to the EHR, and the organization's capacity to facilitate initial and ongoing training.

Finally, another factor contributing to the success of one vendor over the others could be ownership. Epic and Meditech have proudly and defiantly maintained their private status. This factor could make a vendor more agile in its software development life cycle, enabling them to customize to order or correct flaws rapidly.

Practice Implications

Those involved in purchasing decisions surrounding EHR should carefully consider areas of focus in the facility, capital expenditure cycles, strategic direction, and willingness of the

organization to change EHR vendors. The significant decision to switch EHR vendors is a complex process, and many factors need to be aligned to set up the organization for success. Our research may provide an evidentiary basis for vendor selection. For example, an organization that struggles with improving clinical care performance might consider Epic or Meditech with an understanding that there are numerous other factors that might influence outcomes. A similar choice might be considered for facilities desiring to improve patient experience. However, if patient experience or efficiency—in terms of Medicare Spending Per Beneficiary—is an area of weakness, Epic might be a preferred choice. Ultimately, an organization using a vendor other than these 3 might look at the features that these vendors offer that their vendor does not. Is there something their current vendor could offer and increase measures of efficiency? Regrettably, our research does not extend to the module level of the EHR, so we cannot make any recommendations in that regard.

Limitations and Recommendations for Future Research

Our study had several limitations. First, this is a single year of data drawn from the 2018 data pertaining to performance within only short-term acute care HVBP participating facilities. Future studies should consider examining the growth or decline of EHR influence on these outcomes over time. Furthermore, as a single-year study, our analysis also does not account for any changes in EHR systems during the delay between baseline and performance reporting periods from which HVBP scores were determined, nor do we include the length of time the EHR has been in place within the hospitals studied. A more in-depth paired analysis could be considered to match the EHR system with the exact time frame of performance. Additional financial and quality outcome variables might also be considered, which could broaden the study unit of observations beyond the HVBP constraint. Finally, as more granular data becomes available pertaining to the specific modules in use at the hospital level, future studies might examine how specific module use is associated with specific clinical outcomes.

Beyond the extensive implementation of EHRs, health care providers, hospitals, and health care facilities invest heavily in other forms of information technology to provide and enhance care delivery. As the industry progresses toward value-based care, organizations are increasingly investing in imaging, telehealth, precision medicine, artificial intelligence, cloud-based computing or data storage, consumer-facing technologies, and disease management technologies. Furthermore, in the days since the start of the COVID-19 pandemic, telemedicine has been showcased as an indispensable capability of the EHR. Another aspect that should be evaluated in the future is the telemedicine capabilities of these vendors. Future research should carefully examine care delivered through this modality and compare the outcomes across the top vendors.

Conclusions

The return on investment and outcomes associated with EHRs have been a topic of intense focus and debate over the past 2 decades. Up to this point, a research gap has persisted pertaining to the study and transparent disclosure of comparative studies of major EHR vendors. In our analysis of the big 3 vendors—Epic, Cerner, and Meditech—we endeavored to fill that gap. Yet, we can see that clearly answering which system performs the best is complex. The implementation of any of these products can take years, and success is not guaranteed. However, our findings may provide some clarity to health care leaders seeking to develop an evidence base to support future capital investment in EHR systems. If an organization is already considering a switch to a new EHR vendor, the organization can devote sufficient funding for such an undertaking, and if the leadership is willing to lead such a large organizational change, then our study may provide some points of clarity pertaining to the big 3 vendors that might be apt for consideration.

Abstract

Background: Mobile health (mHealth) apps are considered to be potentially powerful tools for improving lifestyles and preventing cardiovascular disease (CVD), although only few have undergone large, well-designed epidemiological research. "kencom" is a novel mHealth app with integrated functions for healthy lifestyles such as monitoring daily health/step data, providing tailored health information, or facilitating physical activity through group-based game events. The app is linked to large-scale Japanese insurance claims databases and annual health check-up databases, thus comprising a large longitudinal cohort.

Objective: We aimed to assess the effects of kencom on physical activity levels and CVD risk factors such as obesity, hypertension, dyslipidemia, and diabetes mellitus in a large population in Japan.

Methods: Daily step count, annual health check-up data, and insurance claim data of the kencom users were integrated within the kencom system. Step analysis was conducted by comparing the 1-year average daily step count before and after kencom registration. In the CVD risk analysis, changes in CVD biomarkers following kencom registration were evaluated among the users grouped into the quintile according to their change in step count.

Results: A total of 12,602 kencom users were included for the step analysis and 5473 for the CVD risk analysis. The participants were generally healthy and their mean age was 44.1 (SD 10.2) years. The daily step count significantly increased following kencom registration by a mean of 510 steps/day (P<.001). In particular, participation in "Arukatsu" events held twice a year within the app was associated with a remarkable increase in step counts. In the CVD risk analysis, the users of the highest quintile in daily step change had, compared with those of the lowest quartile, a significant reduction in weight (–0.92 kg, P<.001), low-density lipoprotein cholesterol (–2.78 mg/dL, P=.004), hemoglobin A_{1c} (HbA_{1c}; –0.04%, P=.004), and increase in high-density lipoprotein cholesterol (+1.91 mg/dL, P<.001) after adjustment of confounders.

Conclusions: The framework of kencom successfully integrated the Japanese health data from multiple data sources to generate a large, longitudinal data set. The use of the kencom app was significantly associated with enhanced physical activity, which might lead to weight loss and improvement in lipid profile.

KEYWORDS

mHealth; app; cardiovascular disease; physical activity; smartphone; mobile phone

Introduction

Reducing the burden of cardiovascular disease (CVD) is an urgent public health issue. The major aspect of primordial prevention is self-care behavior for the prevention of CVD, such as healthy diet and exercise [1]. Long-term success in lifestyle modification is multifactorial and needs cost-effective, innovative approaches. With the widespread use of smartphones in the last decade, numerous mobile health (mHealth) apps have been developed and considered as potentially powerful tools for this purpose because of their convenience and practicality [2]. The core functions of mHealth apps are self-monitoring, providing tailored information or feedback, and exercise goal setting/reviewing [3,4]. Several apps have undergone scientific evaluation for health effects, and meta-analyses have implicated the favorable effects of mHealth apps on physical activity [5], behavioral change [6], and multiple CVD risk factors [3]. However, previous studies generally targeted small populations and may also have serious selection bias, warranting the need for well-designed epidemiological research [3].

Furthermore, although mHealth apps may positively influence the user's lifestyle on a short-term basis, the attrition rates are commonly high in long-term condition management [7]. Apps must be optimized to increase the adherence to the app-guided healthy lifestyles in order to practically reduce the user's CVD risk factors. For example, avoidance of manual data entry increases app usage [8]. Providing immediate rewards in the form of incentives may be effective to motivate individuals to enhance physical activity [9]. A game-based design or positive peer influence may also be effective to increase user engagement, as is well shown in the Pokémon Go app [10]. To date, only few mHealth apps could demonstrate the positive impact of the user's objective health status as represented by CVD biomarkers, such as blood pressure (BP), lipid profile, and glucose metabolism.

'kencom' is an mHealth app with integrated functions that include providing tailored health information, automatically gathered annual health check-up results, self-monitoring, and feedback service to the users. It is also synchronized to smartphone pedometers to count daily steps. The app is optimized to keep a low attrition rate through the easy-to-use user interface, incentive system, and regularly held events. Most importantly, the app data can be linked to a large-scale Japanese insurance database with detailed prescription information and to Japanese annual health check-up data, thus making a large longitudinal data set. In this study, we aimed to assess the effects of kencom on physical activity levels and CVD risk factors such as obesity, hypertension, dyslipidemia, and diabetes mellitus in a large Japanese population. We then discussed the plausible mechanisms of kencom from the perspectives of behavioral economics.

Methods

Overview and Functions of Kencom

kencom is a service developed by DeSC Healthcare, Inc. that is available as an app on iOS and Android platforms as well as through a web service. The kencom app is free to use and over 90% of the active users (ie, those who logged into kencom at least one time a month) are app users. Individuals can use the app for free if they live in Japan, are at least 19 years of age, and have joined an affiliated society-managed, employment-based health insurance association, one of the major insurers of Japanese universal health coverage. The affiliated society-managed, employment-based health insurance associations pay a subscription fee to DeSC Healthcare Inc. There are 5 core functions of kencom (Textbox 1; also see Figure 1).

Textbox 1. Core functions of kencom.

1. **Displaying annual health check-up data**

   Users can check their own longitudinal, detailed health data based on the government-led annual health check-ups without manual input (Figure 1A).

2. **Monitoring daily health data and goal setting**

   Steps are counted by each smartphone's built-in pedometer and the data can be synchronized to the kencom app with the user's agreement. Users may set the daily goals of physical activity and the kencom app gives feedback to them according to self-checked achievements. Users may also manually input weight, blood pressure, and blood sugar levels in the app (Figure 1B).

3. **Providing tailored health information**

   Users receive tailored health information according to their lifestyle or disease risks, which is aimed to improve their health literacy. Every original article is peer-reviewed by medical doctors or nutrition professionals.

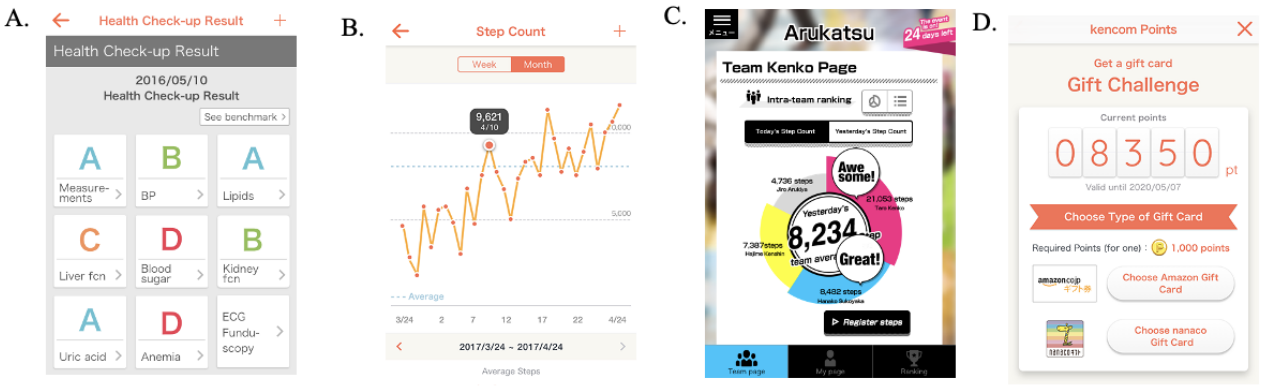
4. **Facilitating physical activity through team-based events**

   kencom regularly runs "Arukatsu" events to facilitate users' physical activity. Up to 10 users form a team and the teams compete with each other in the total step counts for 1 month. Individual step counts are shared with the team members, encouraging each member's physical activity. Game design elements were utilized in the event (Figure 1C).

5. **Incentive system**

   kencom points are awarded for daily logging-in and engaging in various services including Arukatsu. Points were not basically rewarded for daily activities or achieving goals. Users can get gift vouchers from kencom points that can be spent in the market place (Figure 1D).

Figure 1. Sample images of kencom app. A. Annual health check-up results; B. Trends of daily step counts; C. Arukatsu (a game event) team page where individual step counts are shared with the team members, encouraging each member's physical activity; D. Incentive system (kencom point).



Data

This cohort study was based on 3 data sources: Japanese health check-up database, Japanese health insurance claims database, and kencom database. These data were integrated, anonymized, and stored in the affiliated local society-managed, employment-based health insurance associations. DeSC Healthcare Inc. then combined data from different society-managed, employment-based health insurance associations, making it a large, longitudinal database for research purposes. Multimedia Appendix 1 summarizes the variables from each data source. In brief, the Japanese health check-up database consists of the results of questionnaires, physical examinations, measurement of biomarkers, and imaging examinations, which are conducted annually for the majority of adults living in Japan. Japanese health insurance claims database records monthly information about the patient demographics, diagnoses according to the International Classification of Diseases and Related Health Problems, 10th Revision (ICD-10), medical procedures, and medications. The kencom database is mainly about daily physical activity data and the app usage.

The data anonymization was conducted under the "opt-out agreement" between the users and the society-managed, employment-based health insurance associations, in which the users were notified of their data usage and they can propose the deletion of their data. The study complied with the International Society for Pharmacoepidemiology Guidelines for Good Pharmacoepidemiology Practices. This study design was approved by the institutional review board of Juntendo University (approval number 2020045).

Study Population

This analysis targeted previously healthy adults living in Japan. The inclusion criteria were the registration of kencom between April 2016 and June 2018, and the availability of the baseline insurance claims data, health check-up data, and step data before and after kencom registration (12 months each) for the step analysis; and further availability of the follow-up annual health check-ups data for the CVD risk analysis. The baseline health

check-up was defined as the check-up within 1 year before the kencom registration, and the follow-up corresponds to the first check-up conducted after 1-year usage of kencom (Figure 2). These criteria were applied only to iOS users in whom the step data prior to the app installation were automatically transferred into the app. The exclusion criteria included previous medical history of any cancer, end-stage renal disease requiring hemodialysis, and those with too high variance in baseline steps (top one percentile SD: over 7680 steps/day). From 15,363 kencom users with baseline information, 12,602 users met the criteria for the step analysis and 5473 for the CVD risk analysis (Figure 3).

Figure 2. Data collection timelines.

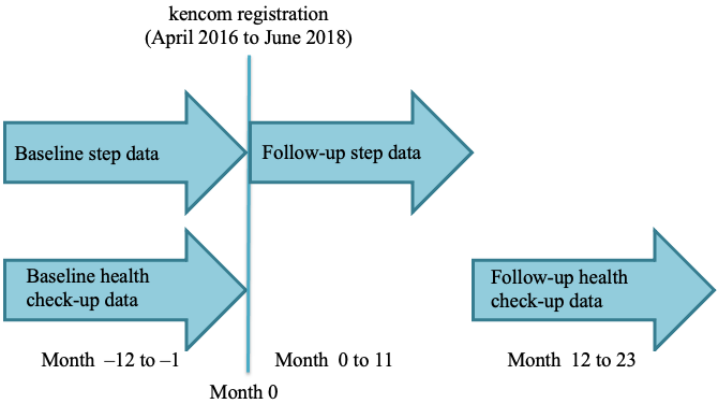


Figure 3. Study flow. CVD: cardiovascular disease.

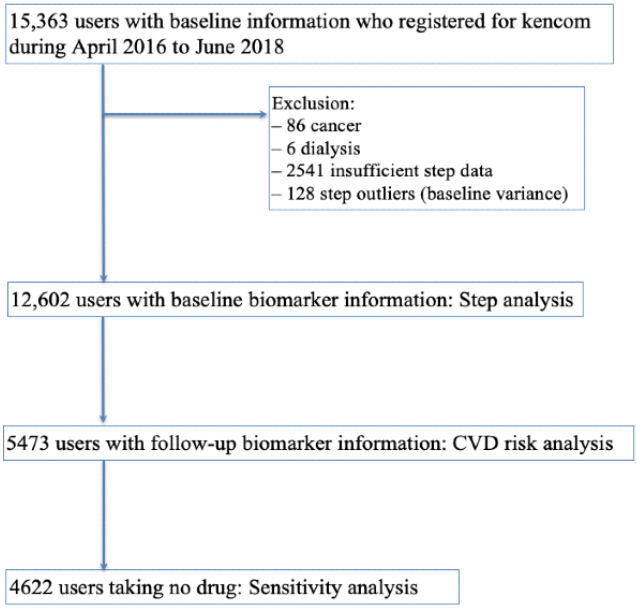

Step Analysis

Pre- and post-registration daily step counts were defined as the 1-year average step count before and after kencom registration (Figure 2). This definition allowed us to evaluate the change in step (post- minus pre-registration daily step count), minimizing the seasonal variation of step count [11]. The changes in average daily steps following kencom registration (ie, the mean of each user's averaged steps over a year) were assessed for weekdays and the weekend. Furthermore, we compared the average daily step counts over each Arukatsu period, 1 month after the event, 1-2 months after the event, and 2-3 months after the event between the Arukatsu participants and nonparticipants.

CVD Risk Analysis

The changes in CVD biomarkers (weight, systolic/diastolic BP, low-density lipoprotein [LDL]/high-density lipoprotein [HDL] cholesterol, triglyceride, and hemoglobin A_{1c} [HbA_{1c}]) over at least 1-year usage of the app were assessed. Participants were divided according to the quintile of the changes in daily steps after kencom registration, and the changes in CVD biomarkers (follow-up minus baseline check-up data) were evaluated with the lowest quintile as the reference.

Statistical Analysis

Depending on the normality of variables, continuous data were expressed as mean (SD) or median (IQR). The changes in daily step count or biomarker levels following kencom app registration were assessed by unpaired *t* test. We estimated the associations between the changes in CVD biomarkers and the

changes in step count following kencom registration by multiple linear models with the biomarkers as the dependent variables. Multivariable model 1 was adjusted for age (continuous), sex (male/female), BMI (continuous), current smoking (yes/no), and alcohol drinking (yes/no) at baseline health check-up. Intention to improve lifestyle ("not interested," "considering," and "working on") was further adjusted in multivariable model 2, because this question in the Japanese annual health check-ups has not been well scientifically validated. The linear trends in relation to the changes in CVD biomarkers' levels were assessed with the use of quintiles of changes in daily steps following kencom registration as continuous variables in which the median change in the corresponding quintile groups was assigned. Sensitivity analysis was performed among 4622 users not taking any medications for hypertension, dyslipidemia, and diabetes mellitus. All analyses were performed using R 3.6.1 (The R Foundation). Statistical significance was set at a two-tailed $P<.05$ and multiple comparisons were adjusted by the Bonferroni method.

Results

Baseline Characteristics

Baseline cohort characteristics for the step and CVD risk analyses are summarized in Table 1. Among 12,602 users for the step analysis, the mean age was 44.1 (SD 10.2), and 52.25% (6584/12,602) were male. Distribution of age is illustrated in Multimedia Appendix 2. For the intention to improve their lifestyles, 22.9% (1225/5339), 44.6% (2380/5339), and 32.5% (1734/5339) of the users answered "not interested," "considering," and "working on," respectively. The median (IQR) levels of BMI, systolic BP, LDL cholesterol, HDL cholesterol, triglyceride, and HbA_{1c} at baseline were 22.4 (20.4-24.7) kg/m^2, 117 (107-128) mmHg, 119 (100-142) mg/dL, 63 (53-75) mg/dL, 80 (57-119) mg/dL, and 5.4 (5.2-5.6) %, respectively. The users accessed the kencom app for a median of 6.8 (IQR 2.6-14.1) days per month. The characteristics were similar to those of the population for the CVD risk analysis except for the male proportion (63.1% [3451/5473] in the CVD risk analysis).

Table 1. Cohort characteristics.

Characteristics	Step analysis (n=12,602)	CVD[a] risk analysis (n=5473)
Age, year, mean (SD)	44.1 (10.2)	43.8 (10.2)
Male, n (%)	6584 (52.2)	3451 (63.1)
BMI (kg/m^2), median (IQR)	22.4 (20.4-24.7)	22.5 (20.5-24.7)
Current smoking, n/N (%)	2724/12,389 (22.0)	1060/5463 (19.4)
Alcohol drink, n/N (%)	6408/8673 (73.9)	3473/4589 (75.7)
Intention to improve the lifestyle, n/N (%)

Effects of Kencom on Step Count

Mean step counts before and after kencom registration were 5642 (SD 2686) steps/day and 6152 (SD 2723) steps/day, respectively. The daily step count was significantly increased following kencom registration by a mean of 510 steps/day ($P<.001$). Figure 4A visualizes the change in averaged daily step count in each month before and after kencom registration. The increase in step counts persisted for a year after kencom registration. Physical activity levels were generally higher on

weekdays than on the weekend, and the kencom app positively influenced both step counts (step change: 534 steps/day, $P<.001$ for weekdays; 463 steps/day, $P<.001$ for the weekends; Figure 4B). The spikes in month 1 and month 7 might reflect the Arukatsu event, in which users form teams and each team competes in step counts over a month, thereby exerting a positive peer influence on the participants to improve their physical activity levels. The company promoted kencom when the event was held, which led to increases in the number of users, highlighting the first spike at month 1. The event has been held almost 6 months apart; therefore, the users who experienced Arukatsu at month 1 were likely to experience the next event at month 7, represented as the next spike.

Table 2 describes the average daily step counts during and after each Arukatsu event comparing participants and nonparticipants. On average, the step counts were 1000-2000 steps higher in Arukatsu participants than in the nonparticipants during the event period. The differences in steps became smaller after the event, while generally the participants had higher daily steps than nonparticipants 3 months after the event.

Figure 4. Changes in average daily step count following kencom registration. Dots indicate the mean daily step count of 12,602 users according to the months before/after kencom registration, and bars indicate the standard errors. In total cohort, the 1-year mean daily step count was increased from 5,642 steps/day to 6,152 steps/day following the registration (A). While the average step count was higher on weekdays compared with weekends, the increase in step counts was documented similarly for weekdays and weekends (B).

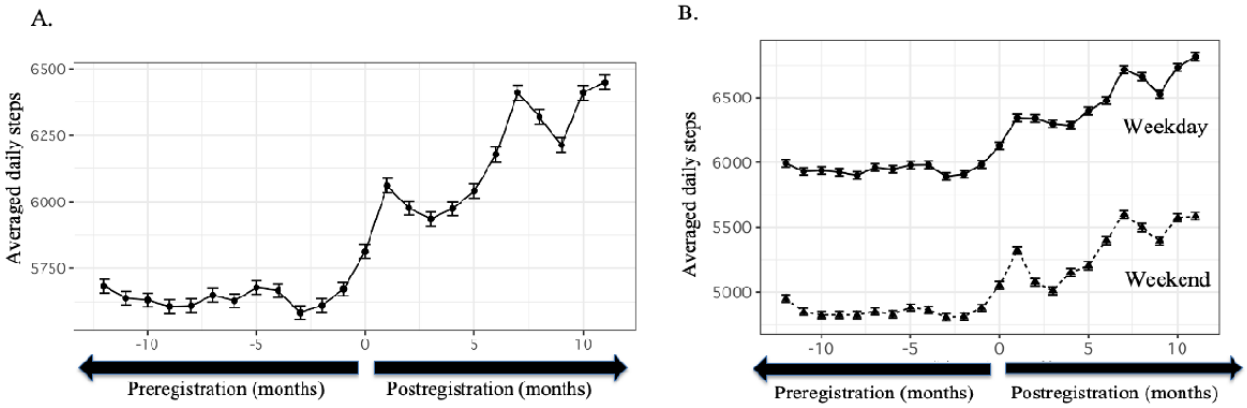

Table 2. Association of Arukatsu event participation and average daily steps.

[a]Month X refers to the X month after the corresponding Arukatsu event.

CVD Risk Analysis

Baseline/follow-up CVD biomarkers were available for 5473 users. They were classified according to the quintile of the change in daily steps (<–578, <–122, <248, <864, and ≥864) and the changes in CVD biomarkers following kencom registration were assessed. Baseline characteristics were similar across the quintile groups except for “intention to improve the

lifestyle" (Multimedia Appendix 3). Higher increase in daily step count was associated with a higher prevalence of users already working on improving their lifestyles and higher average frequency of access to kencom.

Increase in step counts was significantly associated with the improvement in weight, HDL cholesterol, and HbA_{1c} (Figure 5; $P<.001$ for all 3; the adjusted threshold for the P value was .007). In adjusted linear regression models, compared with the lowest quintile, the highest quintile in daily step change was associated with a significant reduction in weight (–0.92 kg, $P<.001$), LDL cholesterol (–2.78 mg/dL, $P=.004$), HbA_{1c} (–0.04%, $P=.004$), and increase in HDL cholesterol (+1.91 mg/dL, $P<.001$; Table 3). Further consideration of "intention to improve lifestyle" attenuated the improvement in LDL cholesterol and HbA_{1c} ($P=.10$ and .49, respectively), but changes in weight and HDL cholesterol remained significant ($P<.001$ each, respectively). The adjusted threshold for the P value was .007.

Figure 5. Changes in CVD biomarkers among users according to the changes in daily step count. Changes in CVD biomarkers following kencom registration (follow-up data minus baseline data) were compared according to the quintile of the changes in the user's step count (corresponding to Q1 to Q5 in the x-axis). Bars represent the average changes in the biomarker in each unit and the error bars indicate the standard errors. P values are for the linear trend. BP: blood pressure; CVD: cardiovascular disease; HbA_{1c}: hemoglobin A_{1c}; HDL: high-density lipoprotein; LDL: low-density lipoprotein.

Sensitivity Analysis

Sensitivity analyses were performed among 4622 healthy participants who did not take any medications for hypertension, dyslipidemia, and diabetes mellitus. They were divided into 5 groups according to their changes in step counts following kencom registration (Table 4). After full adjustment for the confounders, the highest quintile was associated with a significant reduction in weight (–0.75 kg, *P*<.001) and increase in HDL cholesterol (+1.84 mg/dL, *P*=.002) compared with the lowest quintile.

Table 4. Association between the changes in step count and the changes in cardiovascular disease risk biomarkers among 4622 users not taking any drugs for hypertension, dyslipidemia, and diabetes mellitus[a,b]

Discussion

Principal Findings

This is the first study to evaluate the effects of kencom, an mHealth app with integrated functions for healthy lifestyles, on physical activity levels and CVD biomarkers. The use of the kencom app was associated with increased daily step counts by a mean of 510 steps/day, and the higher increase in step counts was related to subsequent weight loss and improvement of lipid profile, in particular HDL cholesterol. The participations in Arukatsu events consistently had increased daily steps. Therefore, commitment to the kencom app might be associated with improved CVD risks through increased physical activity. Notably, this cohort study was conducted within the framework of kencom, in which the Japanese health data from multiple data sources were integrated; it may potentially become a much larger platform of anonymized health data where various epidemiological studies could be implemented.

Association of Kencom and Steps

The present result of an averaged increase of 510 steps/day was not outstanding among incentive-based interventions, as a recent meta-analysis of 12 randomized controlled trials (RCTs) demonstrated an average increase of 607 steps/day by such interventions [11]. However, the observed changes in the activity level were after just registration of the app, unlike after the interventions of the RCTs. Furthermore, the meta-analysis had high heterogeneity due to the constituent small-sized RCTs and was also likely to be confounded by publication bias [11]. The present association of kencom registration and increase in daily step counts was robust because the analysis based on almost all-comers was the comparison of the average step counts over a year, separately in weekdays and weekends, thus accounting

for the selection bias and well-established confounding by holiday period [4,12] and by seasons [13]. Although mHealth apps have typically high attrition rate that attenuates the effects [14], we observed that the increase in daily step counts after the registration of the kencom app was sustained at least one year, supporting the long-term efficacy of this app.

Insight of Behavioral Economics Into the Mechanisms

Theories of behavioral economics may offer the mechanistic explanation as to why the kencom app can positively influence the user's behavior [15]. The dual process theory describes 2 different systems that trigger human behavior: intuition or emotion-linked unconscious reasoning (System 1) and rule-based, analytic conscious reasoning (System 2) [16]. System 1 is susceptible to cognitive biases that can lead to "irrationality" dictated by the subjective reality, often precluding people's health-oriented behaviors. The kencom app has been designed to modify the behaviors of individuals in contemplation stage in which status quo bias (preference for the current state) [17], present bias (tendency toward a small present reward compared with a big future reward), and overoptimism (unrealistic belief that one will less likely encounter negative events) play major roles in their decision makings. The app leverages functions that can work on System 1 and preclude the biases toward sedentary behaviors while accelerating positive biases such as peer bias. This characteristic satisfies the NUDGES framework as summarized in Table 5 [18].

Table 5. NUDGES framework of kencom.[a,b]

Framework components	Explanation	Corresponding features of kencom (examples)
i**N**centives	Incentives encourage the action	kencom points for daily logging-in and entry/winning of Arukatsu events; users can get gift vouchers from kencom points that can be spent in the market place
Understanding mappings	Understandings of the relations between choice and welfare prevent dropouts	Easy and detailed description of Arukatsu events to prevent dropouts; tailored articles and visualization of physical activity may appeal to the users' emotion that healthy behaviors may lead to mental, physical, and financial benefit
Defaults	Better default settings improve the usability	Positive, big images like savory dishes or beautiful landscapes are displayed in the initial screen after logging-in (priming effect); no need to input step or health data by users
Giving feedbacks	Positive feedback keep one's motivation	Setting of the daily goals of physical activity (declaration of commitment) and positive feedback according to the self-checked achievements; comment function in Arukatsu to encourage the team members with each other
Expecting errors	Prevention of expecting errors enhances one's commitment	One-click entry for Arukatsu to avoid procrastination; synchronization with smartphone accelerometers to keep daily record and minimize measurement errors
Structure complex choices	Avoidance of complex options and optimization of the structures lead to less stressful experiences	The simple design allows anyone including those not familiar with a smartphone to use the app immediately; optimized user experience according to the frequency of user's decision

[a]The features of kencom that satisfy NUDGES framework are summarized [18].

[b]The adherence to the NUDGES framework may lead to a better chance of altering one's behaviors.

Some nudges have only short-term effects that inevitably limit the health benefits. The structure of kencom aimed to overcome this limitation by (1) providing multiple interventions in appropriate timings and (2) offering health education that may work on System 2 simultaneously with the nudge interventions. The following points illustrate the detailed interventions, potential effects, and the mechanisms of kencom:

- Incentives are offered for each daily login to kencom, aiming at habituating the behavior.
- Positive, big images such as savory dishes or beautiful landscapes are displayed on the initial screen after login, consistent with priming effects. The user's positive feeling activated by the stimulus may sustain during the exploration of the app.
- The tailored health information is designed to be read like a newsfeed during commute or lunch time, when the users are not yet exhausted in a day and maintain their self-control. The contents generally focus on the "feasible action (plan)," with the intention to shifting the user's fixed mindset into a growth mindset.
- The tailored health information is evidence based, which may improve the user's health literacy.
- Arukatsu events are announced through the app and workplace. The participation may be prompted by the user's fostered growth mindset, incentives, and peer influence from the colleagues.
- Arukatsu events leverage the use of game design elements in nongame contexts (competition of total step counts of the teams) [19], sharing of the step counts with team members, and comment function. These features may facilitate the participants' physical activity through positive peer influence.

Comparison With Other mHealth Apps

Other interventions leveraging cognitive biases have been evaluated for their efficacies in improving physical activities, including the Shape Up Rhode Island state-wide campaign [20], the SHAPE-UP program at a Northeastern university [21], and more recently, the CARADA app [22]. The concept of an event in the CARADA app was similar to Arukatsu, while the evaluation was conducted in much fewer participants (n=175)

by one-time intervention, without any analysis on the postintervention periods [22]. Arukatsu events have been repeatedly conducted almost by half a year, which could foster the users' participation and commitment to the events and apps, eventually contributing to the consistently increasing trend of steps after kencom registration.

The structure of kencom systematically differs from that of popular, scientifically evaluated mHealth apps such as Sweatcoin [4] and Carrot Rewards [23,24], in which incentive systems are leveraged as the main mechanism to stimulate the users' physical activity; in Sweatcoin, digital currency was provided according to how many steps the users take; and in Carrot Rewards, users can earn loyalty points by achieving daily step goals. The "direct" incentives of these apps may efficiently enhance daily activity levels as the observational studies demonstrated an increase of over 1000 steps/day by using these apps. However, caution is needed to interpret these findings; the study on Sweatcoin could have serious selection bias because only 5892 out of more than 30 million committed users were analyzed [4]; and that of Carrot Rewards defined baseline steps based on the steps taken by the users during the 2-week induction period, potentially sensitive to the daily or seasonal variation [23], compared with the 1-year baseline evaluation in our study. In comparison, our analyses robustly support the association of kencom usage and enhanced physical activity with less bias, indicative of a novel mHealth approach toward population immobility without "direct" incentives.

Implications on CVD Risks

The enhanced activity following kencom app registration was associated with improvement in CVD biomarkers, especially in weight and HDL cholesterol. This observation is in accordance with previous studies showing the positive relationship between walking exercise and HDL cholesterol [25,26]. Such an objective improvement in CVD risk factors further underscores the effectiveness of the use of the kencom app. Although the associations were consistent even after controlling for the semiquantitative intention to improve their lifestyles, the effect sizes were not clinically remarkable; this may highlight the characteristics of generally healthy, young participants and the variations in the users' commitment on the app. Longitudinal analyses with longer follow-up data from multiple perspectives may confer the more precise and detailed effects and public health implications of the kencom app usage.

Limitations

The strengths of our study are the large sample size, minimum exclusion criteria, rigorous definitions of baseline/follow-up step counts by averaging over 1-year data, and assessments of serial CVD biomarkers. Our study does have several important limitations. Study participants were mainly healthy Japanese and as such, our results may not be generalizable to other populations. Step data could be biased because the data solely from iPhone users were used, whereas there may be little difference in demographics between iPhone and Android users [27]. We cannot entirely rule out the possibility of unmeasured confounding factors, whereas the homogeneity of this study population minimized them. Finally, the current analysis was among users of the kencom app and a comparison with controls was not conducted. An RCT is warranted to infer causal effects of kencom app use on health outcomes.

Conclusions

The use of an mHealth app "kencom" was associated with enhanced physical activity, which was related to the weight loss and increase of HDL cholesterol. This cohort study was conducted within the framework of kencom, in which health data from multiple data sources were anonymized and integrated, implicating the future usage to build a much larger database to provide reliable evidence.

Acknowledgments

We thank Akiko Tanaka, MSc, for assisting with the handling and interpretation of the health insurance claims data. This study was funded by DeSC Inc.

Conflicts of Interest

RH and HF received consultancy fees from DeSC Inc., including fees for this study. MT received consultancy fees from DeSC Inc. outside of this project. MM, RM, KN, and YT are employees of DeSC Inc. KM is a representative director (medical doctor) of DeSC Inc.

Abstract

Despite the growing popularity of digital health interventions, limitations of traditional behavior change theories and a lack of theory integration hinder theory-driven behavior change applications. In this paper, we aim to review theories relevant to lifestyle behavior change from the broader psychology literature and then integrate these theories into a new theoretical framework called adaptive decision-making to address two specific problems. First, our framework represents lifestyle behaviors at two levels—one of individual daily decisions (action level) and one of larger behavioral episodes (reflection level)—to more closely match the temporal characteristics of lifestyle behaviors and their associated digital data. Second, the framework connects decision-making theories and learning theories to explain how behaviors and cognitive constructs dynamically influence each other, making it a suitable scaffold for building computational models. We map common digital intervention techniques onto the behavioral and cognitive processes in the framework and discuss possible contributions of the framework to both theory development and digital intervention design.

Introduction

Background

Digital intervention systems have been considered as promising tools to change people's unhealthy lifestyle behaviors, such as eating fast food, not exercising, or having suboptimal dental routines [1-4]. In realizing the potential of such systems, many researchers have advocated the role of behavior change theories, especially their translation to digital lifestyle interventions [3,5-8]. Ideally, behavior change theories and digital lifestyle interventions should inform each other. Good theories, when applied appropriately, are generally expected to increase the effectiveness of interventions. They can be used to identify behavioral determinants as intervention targets, translate general behavior change techniques (BCTs) to fine-tuned features in digital systems, and predict intervention outcomes. On the other hand, the vast amount of behavioral data collected by digital systems could potentially contribute to theory evaluation [9-11]. Compared with data from traditional behavioral experiments, digital behavioral data can have larger and more diverse samples, greater ecological validity, and higher temporal resolution.

Despite these expectations, the synergy between theory development and intervention practice is far from ideal [9]. The role of behavior change theories in digital interventions is not as prominent as hoped. Several surveys indicate that the

application rate of theories in digital intervention trials and commercial eHealth apps ranges between 19% and 52% [6,12-19], and when theories are applied, only 3-5 classical theories dominate the applications [15,17,19-21]. Moreover, although some reviews and meta-analyses have suggested that applying theories has benefits [22,23], other reviews found no clear evidence [24-26] and questioned the value of applying theories in real-world applications [27]. Finally, as for theory development, data collected by digital systems are commonly used to evaluate the effectiveness of specific interventions but are rarely used to examine predictions derived from theoretical models [25].

One factor contributing to this *theory-interventiongap* is the lack of theory integration in the field of behavior change research [28], especially integrations that are tailored to digital lifestyle interventions. Even for a phenomenon as complex as behavior change, the large number of individual theories pertaining to behavior change (83 according to a systematic review [20]) clearly suggests that some integration and unification is probably beneficial for theory development in the field. The sheer number of behavior change theories can be overwhelming for intervention designers who want to grasp the literature and selectively apply theories to their designs. Perhaps the difficulty of orienting oneself with respect to the literature can explain why only a limited set of theories are applied [20]. Many basic theoretical ideas in psychology, despite being highly relevant, are underrepresented in applied research, such as decision-making, reinforcement learning, self-control, and habit formation.

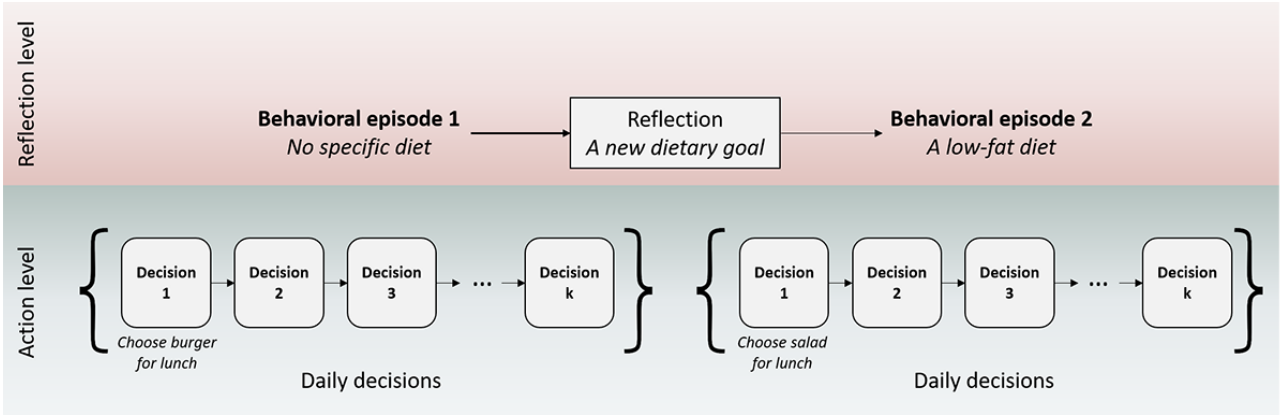
The lack of impact of theories on interventions also raises the question whether the current knowledge about lifestyle behavior change is too limited to be fully useful. Two specific reasons have been proposed to explain why traditional behavior change theories are inadequate in the digital age [6]. First, many prominent traditional theories are static rather than dynamic, in the sense that they provide *snapshot* explanations of what factors determine behavior. Temporal aspects are not taken into consideration. Second, even when time is included in the theories, there is often a mismatch between traditional theories and digital interventions in terms of at what temporal scale behaviors are represented. These two limitations are evident in three of the most applied theories [15,17,19-21]. In the Theory of Planned Behavior (TPB) [29], neither temporal dynamics of the behavioral determinants in the model nor any mechanisms to account for the reciprocal influences of behavior on its determinants are specified. The influential Transtheoretical Model (TTM) includes the temporal aspect of behavior change stages [30]. However, although a healthy-eating app may intervene in its users' daily dietary choices, the TTM only describes the stages of behavior change in terms of months. If a theory represents behavior at a coarse temporal scale, processes at finer scales are overlooked and time-intensive digital interventions cannot be informed. Other theories, such as the Social Cognitive Theory (SCT) [31], consider more rapid interactions between behavior and behavior determinants (eg, self-efficacy); however, the dynamic interaction is theorized only at a very abstract conceptual level without explicitly modeling the role of time or how the interaction works [32]. Both criticisms also coincide with the recent advocates of paying more attention to temporal aspects in health psychology to improve theories and their translation into practice [32,33].

The two aforementioned points should not be considered as criticism of the original theories. Although these theories have been applied in the context of lifestyle behavior change and digital intervention, they were either not meant to explain lifestyle behaviors initially (eg, TPB) or developed at a time when technologies for continuously monitoring lifestyle behaviors were unavailable (eg, TTM or SCT). To advance theories, it is useful to consider some of the often-overlooked characteristics of lifestyle behaviors through the lens of modern digital technologies. Lifestyle behaviors, such as eating, exercising, or toothbrushing, are performed very frequently, as part of everyday habits and routines, and on each occasion, they are fast decisions that are not extensively deliberated. This type of decisions (eg, choosing what to eat for dinner) may be relatively inconsequential; however, they can form larger behavioral *episodes* (eg, following a diet), which may affect one's health significantly over time. This characteristic of hierarchical organization sets lifestyle behaviors apart from single-time health behaviors or decisions, such as cancer screening or vaccination. Moreover, unlike single-time decisions, as lifestyle behaviors are repeated frequently, learning and adaptation through repetitions plays a very significant role in lifestyle changes and interventions. This requires the inclusion of temporal dynamics in behavior change theories.

Objectives

On the basis of the aforementioned rationale, we propose a new integrative theoretical framework, called *adaptive decision-making*, which specifically focuses on lifestyle behaviors and incorporates temporal dynamics. In doing so, the new framework represents lifestyle behaviors at two temporal levels: a lower level (*action level*) that matches the daily individual decisions and the time-intensive interventions realized by digital systems and a higher level (*reflection level*) that matches the episodes of repeated decisions (Figure 1). In addition, both decision-making processes (how behaviors are determined or decisions are made) and learning processes (how earlier behaviors or decisions influence later ones through cognitive variables) at each level will be included in the framework. The goal is to incorporate both traditional and more recent theoretical ideas about behavior change in a single framework and reinterpret these ideas in light of a fine-grained temporal perspective. We hope this effort will facilitate a more integrated approach for developing more precise theories (eg, computational models) and intelligent intervention systems.

Figure 1. A two-level representation of lifestyle behavior (change).



In the remainder of this paper, we first review important theoretical ideas relevant to lifestyle behavior changes from a broad psychology literature. To facilitate theory integration, individual theories are compared in terms of their temporal scales and their emphasis on learning or decision-making. Next, the adaptive decision-making framework is introduced by integrating the relevant but disparate theoretical ideas into a 2-level representation of lifestyle behavior changes presented earlier (Figure 1). Afterward, we relate the framework to intervention practice by mapping common BCTs used in digital systems to the behavioral processes in the framework. The paper concludes with a general discussion on the added value of the framework to behavior change theorists and digital intervention designers.

Review of Individual Theories Relating to Lifestyle Behavior Change

Overview

There are two distinct and complementary traditions for explaining human behavior—a learning tradition and a decision-making tradition [34]. The learning tradition, as its name suggests, focuses on the time course of learning a behavior—in particular, the interdependence among behavioral occasions in a sequence rather than the exact determinants of each occasion. In contrast, researchers in the decision-making tradition care more about what factors determine a behavior on specific occasions and what information is processed at such moments but much less on how repeated decisions are interrelated. As both learning and decision-making aspects are crucial for developing a dynamic framework, this review is organized based on the roots of theories in either tradition. After the review, we briefly discuss whether each theory focuses primarily on explaining individual daily decisions (action level) or episodic behavioral processes (reflection level).

Theories in the Learning Tradition

Reinforcement Learning Theory

Reinforcement learning, or learning by outcomes, is a fundamental form of learning discovered in the early years of modern psychology [35] and is still influential in today's behavioral and brain sciences [36] and artificial intelligence research [37]. Humans and other organisms are theorized to adapt their behaviors through their interactions with changing environments to survive and thrive. If a behavior results in goodness to an organism, the frequency of performing the same behavior increases; conversely, if a bad outcome follows, the behavior will be performed less often in the future. This is summarized as the *law of effect* [38].

Reinforcement theory becomes more complex when one also considers the *law of exercise* [38]. The aforementioned response-outcome learning, or goal-directed learning, is accompanied by stimulus-response learning, also known as a process of habit learning [36]. The distinction between goal-directed learning and habit learning has been demonstrated in instrumental learning experiments where animals or humans are trained to acquire reward-generating responses (eg, pressing a lever to receive food): when a response is overly trained, it persists to be triggered by the corresponding stimulus even when the reward becomes goal irrelevant (eg, when a rodent is satiated) [39]. The recent resurgence of interest in habit formation in social and health psychology also follows the theory of defining habits as mental associations between behaviors and environmental cues [40-42]. When a behavior becomes strongly habitual, goal-related determinants of behavior, such as attitude and intention, cease to influence behavior [43].

Control Theory of Self-regulation

The classical reinforcement learning theory focuses on the role of external immediate rewards in controlling behavior but neglects the role of distal behavioral outcomes that may be cognitively represented. Following criticism of this limitation [44], the control theory of self-regulation assumes that people can mentally represent distal outcomes of goals, and the regulation of behavior is generally toward reducing the discrepancies between the goals and people's current status [45,46]. When a behavior leads to a reduced discrepancy, the reduction itself becomes a reinforcer of the behavior, similar to external rewards. This discrepancy-reduction mechanism is analogous to feedback control systems in engineering, where discrepancies between perceived states and a reference value are constantly monitored to maintain homeostasis.

The control theory also hierarchically represents goals and self-regulation. A 9-level hierarchical control system was proposed by Carver and Scheier [45], in which a behavior output from a higher level serves as the goal reference to the next lower

level. For lifestyle behaviors, it is sufficient to consider three levels: long-term goals (eg, improving health), short-term goals (eg, walking 10,000 steps a day), and actions (eg, taking a specific walk). Taking actions leads to the fulfillment of short-term goals, which in turn brings a person closer to the long-term objectives. Self-regulation operates most frequently at the action level (ie, making daily decisions); however, people's attention can be shifted to higher or lower levels. Downward shifting occurs when lower-level motor control, which is normally highly automated, becomes temporarily impeded during action executions (eg, when learning a new motor skill or when a dysfunctional action has to be inhibited [47]). Upward shifting can be understood as self-reflective moments when a person reconsiders the attainability of a higher-level goal, which is more difficult to predict (Psarra [48]).

Social Cognitive Theory

SCT, proposed by Albert Bandura, is one of the most cited and applied theories in behavior change research [20,21]. The theory encompasses three key concepts: *social learning* [49], *self-efficacy* [50], and *proactive control* [31]. First, based on research on children's learning behaviors [51], *Social Learning Theory* posits that behaviors or attitudes are acquired not only through direct reinforcement but also by observing the behaviors and their corresponding consequences to others [49]. For many health-related behaviors, long-term health consequences are often learned by observing other people's behavioral outcomes. Second, based on organizational decision-making research [52], it was found that subjective belief in one's ability to perform a behavior was closely related to actual performance. According to the control theory mentioned earlier, this self-efficacy belief can be understood as a cognitive mechanism that simulates a series of future actions (eg, dinner choices every day) in an extended episode of goal pursuit (eg, adherence to a diet). If the mentally simulated actions fail to bring sufficient progress, a person may decide to abandon the goal pursuit altogether. Third, Bandura [31] was among the earliest scholars to discuss a discrepancy-production process called proactive control, in which a person sets higher goals to further motivate behavior. Thus, it complements the discrepancy-reduction mechanism at the core of the control theory. The idea that goals are susceptible to changes also allows the possibility of adjusting an unattainable goal downward to reduce its discrepancy to the current status. Altogether, the three concepts contribute to extending reinforcement learning and control theory by incorporating flexibilities in complex human behaviors.

Theories in the Decision-Making Tradition

Expected Utility Theory

Across behavioral sciences (eg, psychology and economics), many mathematical models have been developed to describe how people make choices, given a fixed set of alternatives (options, eg, fries or salad) and attributes (eg, healthiness or tastiness). A fundamental theoretical idea behind many models is the expected utility theory. The theory assumes that people integrate multiple attributes of choice alternatives (their potential for satisfying different personal goals) into a unidimensional construct called expected utility and then choose the alternative with the highest utility [53]. Formally, the expected utility is computed as  , where $V(x_{jn})$ is the subjective value function for the nth possible value of attribute j, and $P(x_{jn})$ is the probabilistic belief that attribute j takes that value [54,55]. The equation implies that the expected utility of one choice alternative increases when choosing the alternative is likely to produce certain outcomes (large $P(x_{jn})$) and when the outcomes are highly valuable (large $V(x_{jn})$). For example, whether people choose salad over fries depends on both their beliefs about their respective benefits for health and their valuations of good health. The theory does not imply that people always consciously follow the equation to compute utilities but rather reflects key neural mechanisms that underlie decision-making [56]. In reality, conscious and deliberative computations are more common for single-time important decisions (eg, comparing different health insurance policies) than for fast daily lifestyle decisions.

Sequential Sampling Models

Empirical data from choice experiments have repeatedly shown that people are less rational than those suggested by classical choice models [57]. People are prone to be influenced by information that is seemingly irrelevant, for example, the addition of an inferior choice option [58] or framing of losses versus gains [59]. To account for these anomalies, a sequential sampling approach has been developed to dynamically model the cognitive process of decision-making, such as the *multialternative decision field theory* [60] and the *associative accumulation model* [57]. The new models share the idea that preferences for different choice alternatives are accumulated over time (eg, a few seconds) and the choice that is made is the choice whose preference signal is first to exceed a decision threshold. At each time step, the preference signals of choice alternatives fluctuate according to a process of utility comparison based on one [57] or multiple attributes (as in drift diffusion models [61]). The stochastic property of sequential sampling models enables them to explain the sensitivity of choices to subtle changes in choice sets and to predict decision time [56]. Finally, sequential sampling models suggest a mechanism for habitual choices, where repeatedly choosing an alternative may shift its starting position of preference accumulation toward a decision threshold at the baseline ([60], Zhang et al, unpublished data, 2021).

Reasoned Action Approach

Influenced by the expected utility theory [62] but with a strong focus on application, the reasoned action approach [63] has produced some of the most applied theories in behavior change research, such as the TPB [29,64] and the Health Belief Model [65]. From a decision-making perspective, this approach categorizes attributes in certain choice situations into a smaller set of behavioral determinants that are generalizable to a wide range of behaviors and measurable by self-report. For example, in the TPB, regardless of the specific alternatives and attributes considered, factors affecting choices are categorized into three determinants, namely attitude, social norm, and perceived behavioral control [64]. When a specific behavior is considered (eg, dinner choice), attitude toward a choice alternative is further determined by many attributes [29], such as taste, nutrition, and

price, whereas social norms are influenced by the perceived social consequences of choosing an alternative (eg, presenting oneself to be environmentally friendly). Perceived behavioral control, similar to self-efficacy, measures one's confidence in maintaining certain choices in the future. TPB was explicitly considered by Prochaska and DiClemente [29] as a model for behavioral prediction rather than for explaining the processes underlying overt behaviors or decisions or how such processes can be influenced.

The reasoned action approach also makes a strong assumption on the intentionality of behavior [66]. For example, behavioral intention is a prerequisite for actual behavior in the TPB [64]. Thus, this approach considers behaviors as *planned* or *intended*, resulting from careful deliberations on the pros and cons of certain behaviors. Such a theoretical position is reasonable because the reasoned action approach was developed to mainly deal with single-time decisions or the planning of behavioral episodes, rather than *small* daily decisions. When applied to lifestyle behaviors, this approach relies on aggregated behavior representations over a substantive period [67].

Dual-Processing Models

A recurrent idea in psychology is that humans possess two distinct modes or systems for processing information and making decisions. Although different dual-system models use different terminologies [68], it is widely accepted that one system is fast, impulsive, and largely automatic, and the other system is slow, reflective, and deliberate [69].

The Reflective-Impulsive Model [70] is a representative of this approach, and it has been explicitly applied to health-related behaviors [71,72]. The reflective system hosts various higher-order mental operations that rely on controlled processes and symbolic representations, including deliberate judgments, planning for goal pursuit, and inhibition of prepotent responses. In contrast, the impulsive system operates fast on associative clusters in long-term memory that group stimuli, affective states, and behavioral responses together. At the moment of a specific decision, the success of self-control depends on the relative ability of the processes in the two systems to activate the corresponding behavioral schemas. Several boundary conditions have been proposed to moderate the relative strengths of the two systems [72]. For example, people are believed to behave more impulsively when their behaviors are highly habitual, when their cognitive loads are high, and when their moods are positive.

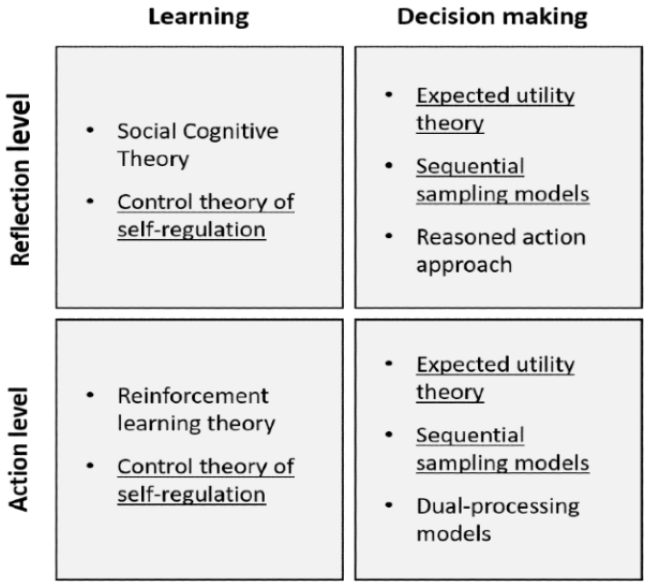
Temporal Scales Used in the Aforementioned Theories

Figure 2 summarizes the learning and decision-making theories based on the temporal scales of behavior representation. A similar distinction was made by Karoly [66], where theories at the action level were called *online* theories and theories at the reflection level were called *offline* theories.

In the learning tradition, the reinforcement learning theory clearly represents behavior at the action level, as the outcome of each specific action or decision is modeled to have concrete impacts on the frequency of repeating the same action in the future. Reinforcement learning experiments also involve repeated trials within a relatively short period (eg, a few hours). The control theory of self-regulation, because of its hierarchical structure, covers both behavioral processes at the reflection level and the action level. SCT and its processes of self-efficacy and proactive control apply mainly to behaviors at the reflection level. Although the two processes may have counterparts at a lower level, as in the control theory, Bandura's [31] focus was clearly on voluntary and deliberative human behaviors.

In the decision-making tradition, mathematical models as part of the expected utility theory and the sequential sampling approach can be equally applied to decisions at both temporal scales, as long as decisions with clearly defined choice sets are considered. As discussed earlier, theories in the reasoned action approach deal mainly with decisions at the reflection level because of its assumption of intentionality. In contrast, dual-process models are mainly intended to account for *small* daily decisions, for which both reflective and impulsive processes play a role. There is a difference between *reflective* used in dual-processing theories and what we mean by *reflection level*, which will become clear after theory integration.

Figure 2. Categorization of reviewed theories based on their theoretical traditions and temporal scales (theories that apply to both temporal scales are underlined).



Theory Integration: An Adaptive Decision-Making Framework

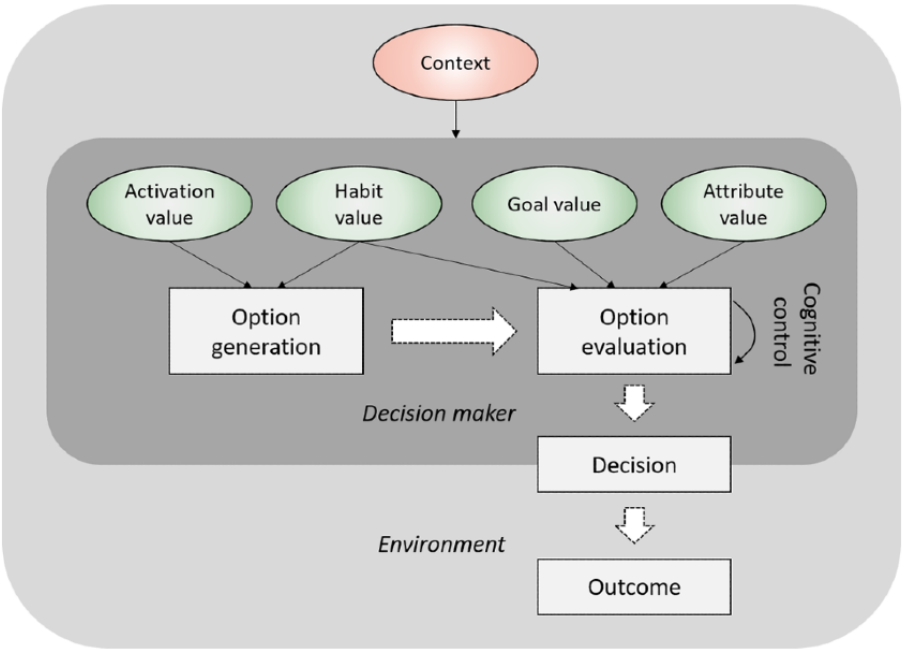
Overview

To reiterate, our goal of theory integration is to develop a unified framework that identifies and connects all relevant decision-making and learning processes at both the action and reflection levels of lifestyle behavior change. Most processes in the framework came directly from the theories reviewed earlier, but efforts were made to unify different terminologies from different theories to form a coherent framework and to tailor the framework to lifestyle behaviors. Taking dietary behavior as a primary example, the framework should explain not only how daily meal choices are made and how each decision outcome influences future choices but also how the goal of adhering to a specific diet is made and how such goals are evaluated. The following sections introduce the adaptive decision-making framework in four parts: action-level decision-making, action-level learning, reflection-level decision-making, and reflection-level adaptation.

Action-Level Decision-Making: Daily Meal Choices

Daily lifestyle decisions, such as daily meal choices, can be modeled as a two-step process—*option generation* and *option evaluation* (Figure 3). The framework assumes that when choosing a meal, different meal options must be generated or recalled by a decision maker first, before evaluations of a few options can be made to inform a final choice [73,74]. The notion of option generation has not been examined in any of the decision-making theories reviewed, probably because most of the theories are based on laboratory choice experiments, where options are simply provided by the experimenters. For lifestyle behaviors in daily environments, how choice alternatives are generated is an important question.

Figure 3. A two-step model of daily lifestyle decision making.



In general, behavioral options can be generated using three different methods. First, if an option is habitual, it will be activated when the associated cues are encountered, such as location and time (eg, lunch at the office) or a combination of contextual cues (eg, a busy Wednesday evening). Second, options may be remembered at the right moments because people intentionally try to maintain them in their prospective memory (ie, not to forget to do something in the future [74,75]). This usually happens when there is a salient goal guiding daily decisions, such as the goal of adhering to a low-carb diet. People may also intentionally associate important options with external cues so that encountering cues is likely to trigger the options [76]. Third, options can be triggered by direct external suggestions at the decision moments, for example, a coaching message from a mobile health app that recommends healthy foods [73]. Through these means, behavioral options that are sufficiently activated (eg, by passing an activation threshold) will be evaluated.

Option evaluation can be modeled as a process of comparing several options and then choosing the one with the highest goal-satisfying value. The exact computation of utilities can follow either classical expected utility models or more dynamic sequential sampling models. Here, it is sufficient to identify three main cognitive variables in the evaluation process. First, when multiple personal goals are relevant for a daily decision, these goals can be regarded as more or less important by a decision maker, thus entailing higher or lower *goal values*. For example, between the goals of living a healthy life and enjoying delicious food, a person who regards the former goal as more valuable would be more likely to choose food options for meals that satisfy their health goals.

Second, for each personal goal, a behavioral option has its *perceived attribute value* relating to that goal, which determines the total utility of the option. These attribute values are subjective beliefs held by people about the causal relationships or contingencies between choosing certain behavioral options and the realizations of personal goals. Although goal values are relatively more stable within-person, attribute values are more context-dependent and prone to changes through learning and experience. For example, the perceived taste of a particular meal option may depend on a person's momentary appetite, and it may change over time through repeated tasting of the food (ie, habituation [77]).

There is a particular challenge for making healthy decisions, as usually two distinct types of attributes are considered: an immediate hedonic aspect such as tastiness and a long-term consideration of health consequences. From a decision-making perspective, this challenge is essentially a problem of self-control [78]. According to the idea of temporal discounting in decision-making theories [79,80], as any reward from potential health improvements is delayed in time when compared with the immediate hedonic aspects, the value of the attribute healthiness is discounted before it is integrated in option evaluation [81,82]. Another reason why health aspects are often weighted less than hedonic aspects in actual decisions is that the former are more abstract concepts so they might be more difficult or take longer to be processed [83-86]. Finally, from a dual-processing perspective (eg, [54]), dietary self-control may sometimes succeed because people can voluntarily exert top-down cognitive control on the option evaluation process, especially if a momentary preference for a meal option conflicts strongly with a diet goal. It has been shown experimentally that cognitive control may either modulate the valuation process to be more in favor of healthiness rather than tastiness [87] or filter people's attention away from hedonic attributes in the early stage of option evaluation [88]. Effective top-down control depends on many contextual variables, such as motivation [89], mental fatigue [90], stress level [91], and daily affective states [92].

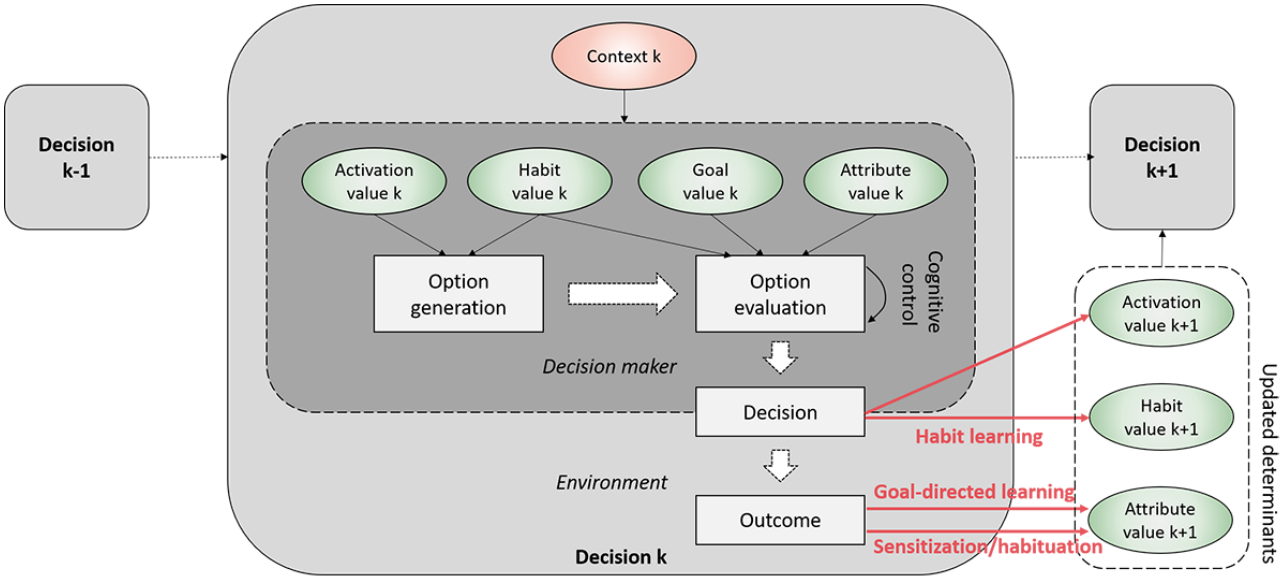
Third, *habit values* or habit strengths, which represent the history of choosing certain behavioral options, may influence the evaluation of options. As mentioned earlier, learning

experiments have shown convincingly that even when two options are provided to decision makers, habitual options are more likely to be chosen than nonhabitual options [36,39]. In sequential sampling models, the influence of habits on the dynamic process of option evaluation can be understood as positively biasing the baseline preferences for habitual options ([60], Zhang et al, unpublished data, 2021). As an intuitive example, if someone often chose fast food in the past, fast food is by default more favorable than other options when no additional deliberations are made.

Action-Level Learning and Adaptation: Developments of Eating Habits

Action-level learning processes can be added to the framework by integrating the ideas of goal-directed learning and habit learning from the reinforcement learning theory to the two-step decision-making model proposed earlier (Figure 4). First, feedback from decision outcomes to perceived attribute values represents goal-directed learning. For example, when a new canteen is opened at a workplace, employees may have initial but very uncertain beliefs about the tastes and calories of different lunch options; however, after a few weeks of trying them out, they gradually form more accurate perceptions about the options. Computationally, the updates of perceived attribute values can be done through model-based and model-free reinforcement learning algorithms (eg, temporal difference learning [37]) or Bayesian belief update [93]. For health-related attributes, because concrete decision outcomes are infrequent except for extreme cases (eg, food poisoning), it is less clear how direct learning from experience works, if it is possible at all (Gershman and Daw [94]). People's beliefs about the health consequences of different foods are more susceptible to social learning and education.

Figure 4. Action-level learning processes added to the decision-making model.



Second, there is direct feedback from decisions to habit values, as in the process of habit formation or habit learning. Although daily lunch decisions in a new canteen are driven primarily by goal-related attribute values, through repeated decisions, mental associations between frequently chosen food options and environmental cues (eg, the physical setting of the canteen or lunchtime) are gradually strengthened. These associations, as habit values, influence future decisions through both the option generation and option evaluation processes, as discussed earlier. The exact mechanism of habit learning is beyond the scope of this paper; however, it has been modeled in the literature [48,72,95,96].

Third, there is also a direct link between decisions and the activation values of options, which has been discussed much less in the learning literature. When a decision is made and the corresponding behavior is executed, the behavior execution increases the activation level of the behavioral option in memory, although such an increase has been shown to be very small empirically [72]. As discussed earlier, the dynamics of activation values are primarily memory processes and are mostly affected by physical and social stimuli in the environment.

Fourth, with repeated daily actions and exposure to the sensory outcomes of the actions, people's neurological responses to the same sensory stimuli, depending on the parameters, may either intensify (sensitization) or fade away (habituation) [97]. This action-level adaptation is especially important for eating behavior, for which the exact same food becomes less palatable over time and accordingly its consumption will decrease [77]. This explains why the large variety in the modern food industry is considered a contributor to obesity [98]. In our framework, sensitization or habituation can be represented as an additional mechanism of sensory feedback from decision outcome to attribute value, in addition to the more cognitive process of goal-directed learning.

Reflection-Level Decision-Making: Dietary Goal Setting

Action-level decision-making and learning processes cover a substantial part of what people do in their daily lives. They depict lifestyle behaviors as repeated decisions without much purpose. However, people also have moments when they reflect on their health status, contemplate possible improvements, and make concrete plans. According to the control theory [45], these

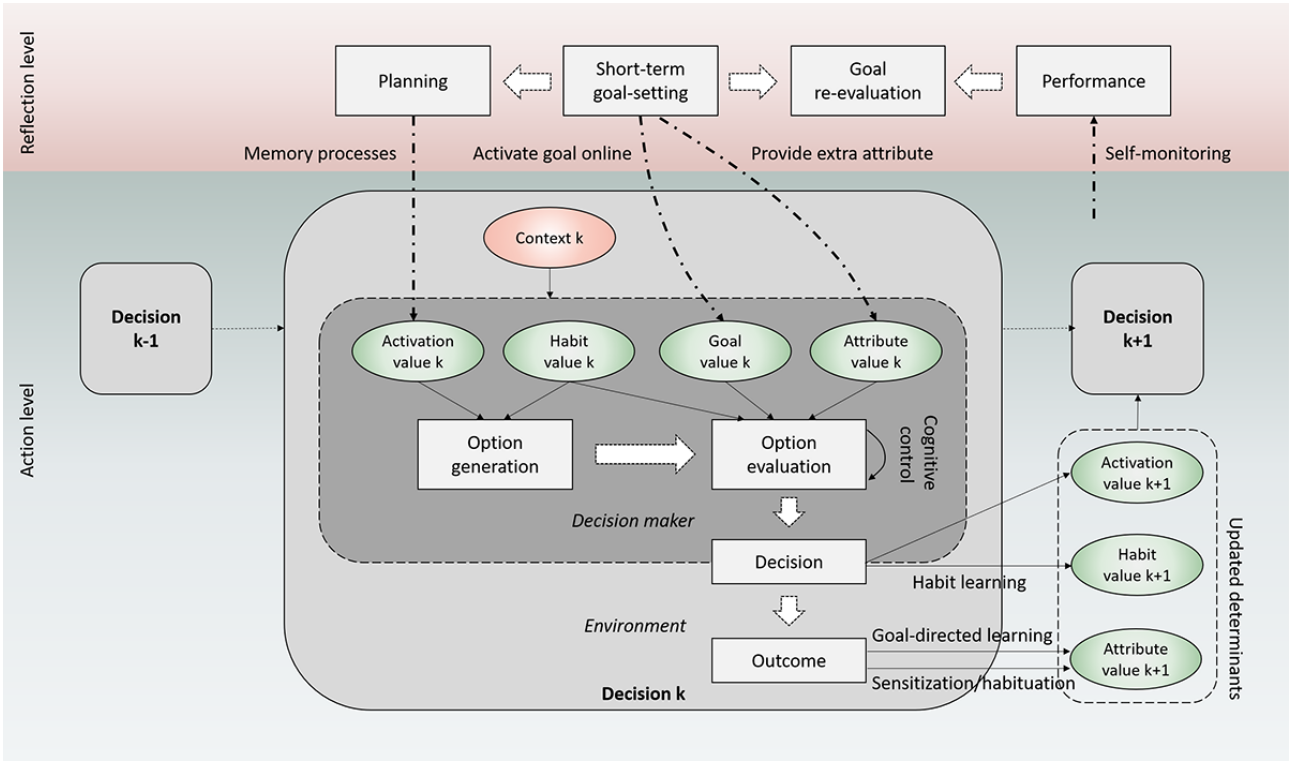
reflective processes require short-term goals that bridge people's abstract long-term goals (ie, what they pursue in their lives) and action-level daily decisions. Short-term goal setting can also be understood as a process of decision-making, albeit at the reflection level rather than the action level. The decisions made are commitments to goals that guide future daily decisions rather than overt behaviors that trigger motor programs.

Therefore, the two-step model of action-level decisions also applies to the setting of short-term goals. In selecting a dietary plan, for example, people first search for diet options that serve their long-term goals and then evaluate the options on relevant attributes, such as taste, ease of preparation, and expenses. At the reflection level, these attributes are often categorized into a few determinants, such as attitude, social norm, and perceived behavior control [29]. Nonetheless, goal setting differs from action-level decisions in some respects. First, because goal setting is less frequent than daily decisions, strong habits are unlikely to be formed to influence decision-making processes. Potential biases by habits are further reduced because people are more careful and take more time to generate goal options and evaluate them. Second, because people set goals for an extensive period of time in the future, they may form a more abstract mental construal [99], which is detached from direct sensory information and visceral attributes, such as effort and tastiness. Thus, the self-control problem for daily lifestyle decisions is less prevalent in goal setting. Third, self-efficacy plays an important role in goal setting [50]. People may carefully consider the feasibility of different diet goals by mentally simulating a series of daily dietary choices in the future.

Motivating Functions of Short-Term Goals

When short-term goals are generated, they can influence daily lifestyle decisions through both option generation and option evaluation (Figure 5). First, setting up a short-term goal can increase the activation values of desirable behavioral options through a process termed *planning*. Planning can be done through two mechanisms discussed earlier: an effortful prospective memory process (eg, rehearsing eating salads [75]) or an *implementation intention* process, that is, mentally associating a behavioral option with certain environmental cues (eg, eating an apple when watching television [76]). Second, compared with long-term goals, short-term goals are more concrete; therefore, complying with these goals brings immediate satisfaction [100]. Goal-compliance satisfaction functions as an additional attribute that competes with other hedonic attributes in the option evaluation.

Figure 5. A full representation of the adaptive decision-making framework (reflection-level processes and interactions between the 2 levels added to the previous decision-making model).



Reflection-Level Learning and Adaptation: Self-monitoring and Re-evaluation of Dietary Goals

Short-term goals must be re-evaluated in reflection moments periodically to change the goals that are too difficult, too easy, or no longer relevant. Such reflection-level adaptation processes are well described by the control theory [45] and SCT [31]. Goal re-evaluation first requires inputs from action-level processes through *self-monitoring*. Through repeated daily dietary choices, past choices and their outcomes are stored in episodic memory and are later retrieved and integrated into a mental representation of overall past performance (Figure 5). Next, discrepancy between a goal reference (eg, a dietary plan) and a performance representation is computed and used to inform the reflection-level adaptation. Depending on the size of discrepancies and other contextual factors, people may motivate themselves further to make healthy daily dietary choices to reduce the goal performance discrepancies. However,

when discrepancies are deemed too large, people may instead lower their goal standards (eg, be less strict on calorie intake) or abandon their goals altogether (eg, give up a diet). Instead, when performance matches or even exceeds current goal standards, they may proactively adjust their goal standards upward to further improve their health [31].

Mapping Digital Intervention Techniques to the Framework

We define *digital intervention techniques* as BCTs or behavior change methods that target lifestyle behaviors and are implemented in digital systems (eg, web, mobile, or wearable systems). BCTs, in turn, are generally defined as the active ingredients of interventions that can influence behaviors in desirable ways [34,101,102]. Mapping BCTs to theoretical constructs is an important exercise when trying to evaluate and enhance the effectiveness of the techniques; such mappings have been carried out previously [102,103]. Focusing on their implementations in digital intervention systems, our mapping exercise is the first to connect BCTs to theoretical constructs in a single unified framework. Specifically, we categorize and interpret digital BCTs according to targeted behavioral processes and cognitive variables in the framework. The strengths and limitations of some techniques are discussed based on the implications of the framework.

Digital Intervention Techniques Targeting Action-Level Decision-Making

As digital systems are prevalent in people's daily lives, they are well positioned to influence people's daily lifestyle decisions at the time of the decision. The ability to target action-level decisions is considered by many as a promising direction for digital lifestyle interventions, as reflected in research on *ecological momentary interventions* [1] and *just-in-time adaptive interventions* (JITAIs) [104-108]. According to our framework, there are many different ways in which digital intervention systems can influence online decision-making processes, depending on whether the techniques target option generation or option evaluation and which cognitive variables are targeted; four main categories can be distinguished.

Option-Based Techniques

Option-based techniques make certain desirable behavioral options salient but leave the evaluation of options to users themselves. When a desirable behavior is obvious but may not be constantly salient to users, digital systems can simply prompt users to actively make decisions to engage in that behavior, for example, to take breaks when overly sedentary behaviors are detected by the system [109,110]. Otherwise, it might be possible to provide users with new options that are better than those known by users themselves [73]. Finding such *attractive* options relies on a system's sensor network and smart algorithms, which potentially make it more knowledgeable than its users in a given behavioral domain or context. For example, a smart system was developed to recommend new commuting routes to users in situ to increase physical activities, based on automatic detection of users' habitual routes and Google Maps data [111].

Attribute-Based Techniques

Attribute-based techniques aim to change users' beliefs about the attribute values of options by providing health-related knowledge or facts. They are referred to as *providing information about behavior-health links* or *providing information about consequences* in the taxonomy of BCTs [101]. Given the common assumption that humans are rational decision makers, providing information about attribute values is a logical approach to behavior change and has been used extensively in traditional health education campaigns. However, attribute-based techniques alone do not guarantee successful behavior change, as attribute value is only one of many factors that influence decision-making. It is also questionable whether digital systems are better tools for providing such information when compared with human experts (eg, lifestyle coaches). Nonetheless, information about attribute values can be provided to justify the recommendations of behavioral options whenever appropriate in digital systems (eg, calorie information for different meal choices).

Goal-Based Techniques

As goal values modulate attribute values in option evaluation, activating health-related goals in the decision moments provides yet another type of intervention technique. When implemented in digital systems, they link the suggestions of concrete behavioral options with the reminder of associated short-term or long-term goals. For example, when a mobile app prompts a user to take a lunch walk, the user's goal of walking 10,000 steps a day (and the achieved steps) can be presented along with the option of taking a lunch walk.

Structure-Based Techniques

Structure-based techniques differ from previous types because they neither change the availability of options nor alter users' existing beliefs about attribute values. As they require less processing effort and are less susceptible to reactance from users than other techniques, structure-based techniques have attracted significant research interest [112,113], usually under the name of *nudging* or *choice architecture* [114,115]. For example, people can become more likely to choose the desirable options when they are presented as default options [116] or an additional option is introduced to change their perceptions of choice sets (context effects [57]). Lee et al [117] adopted the default technique to promote healthy snacking in an online environment by making healthier options the default choices. Zhang et al [118] built on a context effect called the *compromise effect* to promote physical exercise at work using a mobile app. Intensive exercise options were added to make moderate exercise options appear more achievable and thus more attractive [118].

A challenge for all JITAIs is that most lifestyle behaviors are *physical* rather than *digital* in nature. When making decisions about snacking, exercising, or toothbrushing, people do not naturally come to digital applications. In contrast, in e-commerce, for example, people are accustomed to shopping online; therefore, e-commerce sites such as Amazon never miss the opportunity to influence consumers in their decision moments. To influence lifestyle decisions at critical moments, interfaces between the information in digital systems and

people's spontaneous behaviors in the physical world need to be created. Current approaches include predicting users' spontaneous decision-making moments using sensor networks (eg, predicting *about-to-eat* moments [119]) and initiating decisions when interventions are predicted by the system to be most valuable (eg, predicting stressful moments [120]). This challenge will continue to stimulate new intelligent digital solutions and at the same time debates on the associated ethical implications [121].

Digital Intervention Techniques Targeting Action-Level Learning

Digital intervention techniques targeting action-level learning processes operate in between rather than at decision moments. The goal is to support either goal-directed learning or the formation of healthy habits. If these techniques are effective, the cognitive variables that influence decision-making will be in a health-promoting state, so that users are expected to maintain the learned healthy behaviors without continuous intervention by digital systems.

A main challenge for lifestyle behavior change is learning the causal relationships between one's behaviors and health consequences, as these consequences are usually delayed. As discussed, researchers have speculated on the role of episodic memory in tracking internal and external events to support this type of learning [94]. In this regard, the self-tracking function of many digital systems can support learning by externalizing the user's memory systems [98]. Behavioral and contextual data can be objectively recorded and reviewed later by users when consequential health events occur. As self-tracking studies mostly focus on the effectiveness of the technology as a whole, evidence regarding its specific role in supporting goal-directed learning is lacking [122]. Some interview data indicated that users of self-tracking systems believed that they acquired knowledge about behavior-health links through self-tracking technology [123,124].

Instead of directly supporting the learning of health consequences, another popular approach is to provide extra rewards that may reinforce desirable behaviors. In the so-called gamification systems, the most common extra rewards are virtual rewards, such as points, badges, or rankings in leaderboards [125-127]. These virtual rewards are expected to steer users to healthy behavioral options by competing with the inherent hedonic values of many unhealthy behaviors.

Despite its popularity, the effectiveness of virtual rewards in their simplest forms is questionable, as empirical studies found no positive effects in several health domains, such as physical activity [128] and sexual protection behavior [129]. Moreover, users in one study perceived such virtual rewards implemented in an exercise-promoting app as *not motivating* or even *unnecessary* [130]. Our framework implies that the problem with virtual rewards is not in the learning of the contingencies between behavioral responses and rewards but in the corresponding goal values of these rewards: the goal values of virtual rewards are often low, when compared with other hedonic attributes, such as tastiness and reduced effort. Future research on gamification should focus on making virtual rewards more goal relevant and meaningful [131], for example, by embedding them as a game mechanic that users care about [132], using tangible rather than intangible rewards [133,134], or making the rewards socially meaningful [135,136].

Another technique in this category is habit formation support, usually by reminding users about a new and desirable behavioral option. This is especially valuable at the beginning of habit formation when new options are not always remembered by users themselves. Unlike the technique of suggesting options at decision moments, reminders that support habit formation are sent offline and according to time-based schedule (eg, once every morning). They do not persuade users to act immediately but to increase the activation values of certain options so that they are more likely to be generated when decision moments arrive. Reminders have been widely used and have been shown to be effective in domains where forgetting is the main obstacle for behavior change [137,138]. More research is warranted to understand its value in changing more complex lifestyle behaviors when the activation value is one of several cognitive variables.

Digital Intervention Techniques Targeting Reflection-Level Decision-Making

Setting up a short-term goal as a reflection-level decision-making process is often the starting point of self-directed behavior change [139]. Without external interventions, goal setting can be triggered under specific conditions, for example, when someone has learned new health-related knowledge (eg, become aware of the risk of smoking) or has experienced a sudden change in their health status (eg, being diagnosed with diabetes). Thus, a straightforward intervention technique is to proactively prompt users to set up new goals to improve their lifestyles. In many digital systems, following a goal-setting prompt, a user can choose a goal and then record it in the system, which allows the system to remind the user of the goal when needed.

As goal setting is a decision-making process, most techniques discussed in the section on targeting action-level decision-making also apply to goal setting, including option-, attribute-, and structure-based techniques. As a particularly promising direction, digital systems may use their data-gathering power and artificial intelligence to recommend novel and attractive options for short-term goals [73]. To address the subtlety and complexity of goal setting in the health domain, the systems need to personalize options based on users' abilities [140] and based on their unique life experiences and personal context [141-144]. In the future, the difficult task of setting up challenging, motivating, yet realistic goals may indeed be transferred from people to intelligent intervention systems, at least in part.

After the goal-setting step, digital systems can go further to support the planning phase that connects short-term goals to daily decisions in the future. A simple technique is to prompt users to make concrete plans in the system, for example, by adding activities to a calendar. Data provided by users allow digital systems to check user adherence and send reminders when necessary. In addition to this time-based planning technique, digital systems may encourage users to use the event-based planning technique of implementation intention

[76]. Implementation intention has been shown to be effective in the health domain [145,146], and it has also been implemented in digital interventions where no human instructions are required [147,148]. A recent system even uses sensor data to automatically generate *if-then* rules adapted to the living contexts of individual users [149].

Digital Intervention Techniques Targeting Reflection-Level Adaptation

At the level of reflection-based adaptation, providing behavioral feedback to users to support self-monitoring is the most commonly used BCT in digital systems [19,150-153]. Technically, with the development of increasingly powerful sensors, digital systems are able to track lifestyle behaviors and related variables more accurately and in greater detail than people's own memories. Moreover, these systems can transform the rich raw data into numerical or visual information (eg, weekly summary of step count) to facilitate better comparison with short-term goal references [122].

Although self-monitoring as a general BCT has been identified as effective [154], the evaluation of this technique in digital systems has yielded mixed results [153,155]. The evaluation is also impeded by the lack of high-quality studies and a lack of focus on self-monitoring per se [122]. It is evident that the abundance of self-tracking devices has not solved the problem of lifestyle behavior changes. From an evolutionary perspective, as people's natural self-monitoring function has existed long before the existence of digital systems and quantitative data, it is not self-evident that technology-enhanced information would lead to better functioning. A recent study indicates that some self-tracking users may have an exaggerated focus on numeric feedback as the replacement of bodily experience as feedback, potentially leading to negative consequences such as rumination [156]. The bottom line is that even if technology-enhanced self-monitoring is beneficial to some extent, our framework implies that it is only one step in reflection-level adaptation. Future research should investigate how digital systems can also support reflective processes that immediately follow self-monitoring, including the comparison between goal references and monitored performance and the adjustments of goals and behaviors.

Discussion

Overview

Understanding and changing lifestyle behaviors in the digital age require a theoretical perspective that combines decision-making and learning and a representation of behavior at the level of both daily decisions and episodic reflections. These two requirements have guided our review of individual theories and their integration, and the outcome is temporally fine-grained, dynamic, and process-oriented theoretical framework of lifestyle behavior change. Through a mapping exercise, we also linked common digital intervention techniques to behavioral processes and cognitive constructs in the framework.

Theoretical Contributions and Comparisons With Previous Integration Works

The primary objective of developing an adaptive decision-making framework is to address the mismatch between theory and digital intervention in terms of temporal granularity [6]. This was done by considering lifestyle behaviors at two different timescales, one representing the individual daily decisions or actions and one grouping the repeated daily decisions into a larger episode and incorporating self-regulatory processes. This 2-level representation adds value over previous integration attempts that were based on the stage model of change [30], such as the computerized behavior intervention (COMBI) model [157,158] and the i-Change Model [159]. Although the COMBI and i-Change Model postulate a more general process of behavior change (eg, through contemplation, preparation, action, and maintenance), our framework allows one to zoom to a finer level of granularity to explain how repeated daily actions, with the help of reflection-level regulatory processes, lead to maintenance. With time-intensive behavioral monitoring becoming more accessible, our framework compliments earlier work by motivating future intelligent systems that update users' behavioral and cognitive states after every daily lifestyle decision (eg, computing self-efficacy [160]). In our own work, we proposed a system that computes users' habit strengths of toothbrushing based on sensor-measured behaviors [161].

There are previous frameworks that are more similar to our adaptive decision-making framework when it comes to behavior representation. Both PRIME (Plan, Responses, Impulses, Motives, and Evaluations) theory [162] and Temporal Self-Regulation Theory [163] model behavior change as a continuous process rather than a series of discrete stages. However, our framework explicitly distinguishes between the two distinct levels of lifestyle behaviors and the different timescales involved. Note that similar to many other dichotomies used in psychology (eg, impulsive vs reflective, unconscious vs conscious), although our 2-level dichotomy is a simplification of a potential continuum of processes, it is still useful for developing new theories, empirical research, and applications. The conceptual distinction is important because it enables our framework to represent lifestyle behaviors at the same temporal granularity with time-intensive behavioral data while incorporating cognitive processes that are detached from daily decisions (eg, goal setting or planning).

A second limitation in the current literature is the lack of dynamic processes in traditional behavior change theories [6]. By integrating theories from both learning and decision-making tradition, our framework depicts a dynamic bidirectional relationship between behaviors and cognitive variables that influence behaviors. The framework complements previous frameworks that focused exclusively on learning processes, such as the framework of evolutionary learning processes [97] and Action Change Theory [164]. More broadly, we believe that the need to capture the complexities of lifestyle behaviors for designing better digital interventions provides a strong and timely motivation to integrate decision-making and learning theories in basic psychological research [165].

Furthermore, this study may stimulate some rethinking about the popular dual-processing models, in which health behaviors are assumed to be driven by two distinct forces, one reflective and one impulsive [72]. In our view, such dichotomous categorization of diverse processes and constructs might be too coarse for a full understanding of the dynamic lifestyle behavior change process. The adaptive decision-making framework suggests several dualities. First, there is a contrast between long-term health benefits and immediate hedonic rewards in option evaluation, where effortful cognitive control is required to battle impulses. Second, goal-directed evaluation based on attributes (both long-term and short-term) competes with the influences of habits. This has been discussed extensively in the learning literature as a dual action control by goals and habits [166]. Third, the faster processes at the action level can certainly be contrasted with the more deliberative processes at the reflection level, which also operate on a much slower timescale. Note that this distinction between action and reflection levels certainly reminisces the classical distinction between motivation and volition [167] and the related Rubicon model of action phases [168].

Finally, the process-oriented nature of our framework makes it an ideal scaffold for developing new dynamic computational models envisioned by many researchers [6,104,169,170]. The processes and mechanisms in the framework are described at a level of specificity that allows their transformation into computational models by introducing additional assumptions and formal algorithms. For example, key cognitive variables are defined for option evaluation, but the exact computational process of how these variables are integrated to produce decisions is left open to different modeling possibilities [44,171]. Similarly, although the framework acknowledges the joint influence of habit and goal-directed control, the exact arbitration between the two is subjected to different computational accounts [96,172,173].

Added Value to the Synergy Between Theory and Digital Intervention

The adaptive decision-making framework was developed with the aim of narrowing the gap between behavior change theories and digital intervention applications. As a first step, the framework provides a summary of the main theoretical ideas in psychology relevant to applied behavior change research. As such, it can be used as a reference if practitioners want to read more about specific theories and computational models. The integration of both traditional and more cutting-edge theories in the framework should help practitioners to see familiar theories (eg, self-efficacy and goal setting) in a new light and hopefully motivate them to experiment with new ideas (eg, habit formation or sequential sampling models of decision-making). What is especially promising is the prospect of designing intelligent close-loop intervention systems based on computational models informed by our framework. In the current best practice, behavior change determinants and corresponding BCTs are identified and then carefully translated into functions in digital applications; however, their effects on behavior are simply speculated (open loop). By relying on computational models, intelligent systems can monitor behaviors that are targeted and use behavioral data to update the cognitive variables of users to deliver JITAIs for each individual user [107,174]. Examples of such close-loop systems can be found in recent works by other researchers [160] and ourselves [161].

Moreover, our framework's emphasis on behavioral processes and their corresponding digital intervention techniques should contribute to the identification, implementation, and evaluation of intervention techniques. First, similar to an intervention mapping approach [102], our framework makes a clear distinction between people's behavioral processes and the techniques that may influence these processes, which is not always made in other coding taxonomies. For example, *habit formation* has been considered a BCT [101]; however, it is essentially a behavioral process that also operates without interventions and is driven by multiple lower-level processes. It is more informative and actionable for system designers if they are informed about the specific processes underlying habit formation and how they can be changed rather than simply implementing a technique called habit formation. Second, by mapping digital intervention techniques to behavioral processes in our framework, it should become clear that a technically well-defined function often targets multiple distinct behavior processes. For example, self-tracking may increase users' knowledge about behavior-health links but may also support self-monitoring [122]. We argue that evaluation research (eg, review and meta-analysis) should focus more on the effects that specific intervention techniques have on individual processes rather than the effectiveness of broadly defined categories of technologies (eg, *feedback system* [155]), to gain a better understanding of how and why certain intervention techniques work. Third, when combining multiple intervention techniques within a single digital system, our framework can inform designers about whether the techniques target complimentary processes and constructs or the same process and construct. In the latter case, the combination of techniques as a package may not necessarily be more effective than its components, and more careful analysis is needed. For example, as implementation intention and *just-in-time* reminder both increase the activation values of desirable options, it is questionable whether combining them would yield better results (Luszczynska et al [147]).

The adaptive decision-making framework may also help to encourage the use of digital lifestyle intervention systems to advance basic human behavior sciences. We have emphasized in this paper the unique opportunities of *bringing psychology laboratories to the real world* [175,176] and exploiting the time-intensive and ecologically valid behavior data generated by digital systems [9-11]. The integration of fundamental psychological processes in the framework, such as reinforcement learning and sequential sampling models of decision-making, can increase the awareness of scientists in these fields to the practical value of their research and the great potential value of using digital systems in the field as data collection tools for *fundamental* social science research. We also hope that by summarizing and structuring the theoretical landscape for digital system designers, they can find their potential collaborations with behavioral scientists more efficiently. Finally, the clear mapping between intervention techniques and the processes and constructs in the framework makes it easier to search for the required data and manipulations to be used for theory testing.

Scope and Limitation of the Framework

Given the ambitious goal of the framework to incorporate a wide range of theoretical traditions and to connect to the full gamut of digital intervention techniques, it is important to discuss the scope and limitations of our framework. First, the adaptive decision-making framework is not a new theory in itself or a model to be directly tested or falsified in a strong empirical sense. It is a framework that integrates existing theoretical ideas into a novel representation of lifestyle behaviors. In other words, it identifies relevant explananda in the course of lifestyle behavior change and provides explanations based on the most recent theoretical advances available. The usefulness of the framework should be judged by whether it succeeds in informing new computational models and intelligent intervention systems in the future, and predictions derived from the framework and its associated computational models should be rigorously tested using empirical data.

Second, proposing an integrated framework is not meant to discourage the use of individual theories in digital interventions. The adaptive decision-making framework is a framework of basic behavioral and cognitive processes in lifestyle behavior changes that are generalizable to a wide range of behavioral domains. However, there is also large heterogeneity across different behavioral domains and target populations, in terms of which processes in the framework are more critical and which variables or parameters are more changeable. For this reason, specialized theories are always needed, even if future theoretical advances might allow a single unified theory of basic psychological mechanisms. Therefore, it makes perfect sense for digital intervention systems to focus on one or a few processes or to target only a small set of variables for change based on domain-specific theories. The theoretical scope of the framework itself is focused on explaining individual lifestyle behaviors. It does not address interactions between individuals or larger socioeconomic processes.

Third, the adaptive decision-making framework is a theoretical framework of behavior change but not a framework of digital intervention systems. We have discussed the educational and heuristic value of the framework for digital intervention designers to help them understand and apply theories. It can potentially also motivate and facilitate the development of intelligent intervention systems that model user behaviors and cognitive states [161,174]. However, the framework should not be considered as a *cookbook* in the sense of prescribing specific design choices or requirements in specific interventions.

Conclusions

We developed an adaptive decision-making framework in the hope that it will benefit behavior change theorists and digital system designers and, most importantly, facilitate better communication between the two communities. A stronger synergy will potentially help bring us closer to a future where digital systems live up to their potential to promote healthy lifestyles at scale. In the meantime, a wider adoption of more effective and theory-driven digital interventions will offer ample opportunities for building and testing new theories of human behavior.

Abstract

Background: Machine learning algorithms have been drawing attention at the joining of pathology and radiology in prostate cancer research. However, due to their algorithmic learning complexity and the variability of their architecture, there is an ongoing need to analyze their performance.

Objective: This study assesses the source of heterogeneity and the performance of machine learning applied to radiomic, genomic, and clinical biomarkers for the diagnosis of prostate cancer. One research focus of this study was on clearly identifying problems and issues related to the implementation of machine learning in clinical studies.

Methods: Following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) protocol, 816 titles were identified from the PubMed, Scopus, and OvidSP databases. Studies that used machine learning to detect prostate cancer and provided performance measures were included in our analysis. The quality of the eligible studies was assessed using the QUADAS-2 (quality assessment of diagnostic accuracy studies–version 2) tool. The hierarchical multivariate model was applied to the pooled data in a meta-analysis. To investigate the heterogeneity among studies, I^2 statistics were performed along with visual evaluation of coupled forest plots. Due to the internal heterogeneity among machine learning algorithms, subgroup analysis was carried out to investigate the diagnostic capability of machine learning systems in clinical practice.

Results: In the final analysis, 37 studies were included, of which 29 entered the meta-analysis pooling. The analysis of machine learning methods to detect prostate cancer reveals the limited usage of the methods and the lack of standards that hinder the implementation of machine learning in clinical applications.

Conclusions: The performance of machine learning for diagnosis of prostate cancer was considered satisfactory for several studies investigating the multiparametric magnetic resonance imaging and urine biomarkers; however, given the limitations indicated in our study, further studies are warranted to extend the potential use of machine learning to clinical settings. Recommendations on the use of machine learning techniques were also provided to help researchers to design robust studies to facilitate evidence generation from the use of radiomic and genomic biomarkers.

prostate cancer; machine learning; systematic review; meta-analysis; diagnosis; imaging; radiomics; genomics; clinical; biomarkers

Introduction

Prostate cancer (PCa) is the second most diagnosed cancer worldwide in men [1,2]. To guarantee cancer-specific survival, early detection of PCa is essential at a treatable stage. The most common method to diagnose PCa is via transrectal ultrasonography (TRUS) [3]. The rapid development of medical imaging techniques and modalities has demonstrated great value

in the screening, diagnosis, treatment response measurement, and prognosis evaluation of PCa. In particular, radiomic investigation, defined as computationally extracting quantitative image features for the characterization of disease patterns [4], has been intensively applied to tumor detection, localization, staging, aggressiveness assessment, treatment decision-making assistance, and patient follow-up in PCa [5] .

More recently, multiparametric magnetic resonance imaging (mpMRI) has been demonstrated to be a better radiomic biomarker than systematic TRUS biopsy, achieving high diagnostic accuracy and becoming a clinical routine investigation for suspected PCa patients [6,7]. The second version of the Prostate Imaging Reporting and Data System (PI-RADS-V2) was updated in regard to minimum technical acquisition parameters and image interpretation [8]. It describes a standard prostate mpMRI protocol that combines anatomical T2-weighted images with functional sequences, that is, diffusion-weighted imaging (DWI) or dynamic contrast-enhanced (DCE) sequences.

Alongside radiomic investigation, there are numerous Food and Drug Administration–approved genomic biomarkers underlying the biomolecular functions most strongly associated with clinical outcomes. In fact, a major focus of personalized medicine has been the biomolecular characterization of tumors by integrating genomics into clinical oncology to identify unique druggable targets and generate higher-order tumor classification methods that can support clinical treatment decisions [9]. They are mainly used to decide whether biopsy screening is necessary and whether patients require primary treatment (such as radical prostatectomy or radiation therapy) [10]. The combination of biopsy screening and evaluation of the Gleason score still remains the most widely accepted grading system in the evaluation of prostatic adenocarcinoma [11]. The Gleason grading system is based on a morphologic continuum of architectural dedifferentiation and is directly correlated with response to therapy and mortality rate. However, novel biomarker tests that can potentially detect PCa from blood, urine, tissue, and semen samples continue to be investigated. Prostate-specific antigen (PSA) is the most commonly used biomarker for the management of PCa [12]. Increased PSA density has been shown to be associated with increased risk of PCa compared to healthy or benign prostatic hyperplasia patients [13]. The Prostate Health Index and 4Kscore utilize isoforms of PSA and its precursors to help risk-stratify patients with an abnormal PSA level. In addition, microRNAs have an important role during tumor progression, and their combination with PSA serum can improve prediction of PCa status [14-16]. Other proposed biomarkers that belong to various classes of biological compounds, including proteins and metabolites, have shown to be noninvasive methods with high diagnostic potential [17].

Over the last decade, the landscape for PCa detection tools has expanded to include novel biomarkers, clinical information, genomic assays, and noninvasive imaging tests. The prospect of detecting PCa using readily available clinical and demographic health information is a potentially innovative part of improving screening practices [18].

In this scenario, machine learning (ML) is helping researchers in identifying and discovering new biomarkers to detect PCa. ML is a branch of artificial intelligence (AI) techniques based on the development and training of algorithms by learning from data and the performance of predictions. ML methods are able to improve and learn over time in a more efficient way than classical statistical approaches [19]. Therefore, ML has been widely used in radiology and recently in the field of bioinformatics [6,20]. A recent field of ML, deep learning (DL), is based on artificial neural networks, which offer superior problem-solving capabilities applied to large heterogenous data sets [20,21]. Specifically, ML allows the integration or combination of different layers of data, such as those from medical images, laboratory results, clinical outcomes, biomarkers, and other biological features, for better prognostication and stratification of patients toward personalized medicine [22,23]. However, the accuracy of such algorithms can be highly impacted by the complex workflows adopted to develop and generalize such ML algorithms [24,25]. High heterogeneity is expected, as ML problems are usually regarded as black boxes, and the consideration of all possible risk factors and transformation is tremendously difficult [26,27]. Moreover, there are no clear guidelines on how to develop ML approaches for medical studies.

Therefore, this study aimed to suggest an integrated estimate of the accuracy for use of ML algorithms in detecting PCa through a systematic review and meta-analysis of the available studies. Due to the internal heterogeneity of ML algorithms, subgroup analyses helped in investigating the diagnostic capability of ML systems and highlighting the sources of bias and common pitfalls to avoid in order to assure reproducibility among studies. Subgroup analyses were mainly based on the model choice, model development, and validation methods to identify potential covariates that could influence the diagnostic performance of ML.

This review helps to support ML studies in rising up the pyramid of evidence. In fact, we identify and discuss recurrent factors that hinder the uptake of these studies in clinical settings.

To the best of the authors' knowledge, there are no systematic review and meta-analysis studies evaluating the performance and estimating the current status of existing approaches on PCa detection. Therefore, this study aims to fill the gap in the existing literature and gather recommendations on ML model development to achieve robust results to automatically detect PCa.

Methods

We conducted and reported this meta-analysis in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [28]. Two researchers (RC and MF), who were blinded to the articles' author information, conducted the study inclusion, data extraction, and assessment of the risk of bias independently. A third author (CC) was consulted in case of disagreements.

Search Strategy

The PubMed, Scopus, and OvidSP (ie, Embase) databases were searched to identify studies evaluating the accuracy of radiomic, clinical, and genomic biomarkers in the diagnosis of PCa. The following criteria were used to limit the research: papers published in the last 5 years (from 2015 to 2020) to guarantee homogeneity among radiomic studies, as the new protocol (PI-RADS) for mpMRI was updated in 2015 [8]; study on adult humans (ie, not animals); language (English); and full-text publications. The search took place on February 24, 2020. The reference lists of the included studies were checked, and the authors were contacted if required. The search strategy and queries for each search database are presented in Table S1 in Multimedia Appendix 1.

An author (RC) retrieved the initial search results and removed duplicates via Excel (Microsoft). Subsequently, another author (MF) manually searched for and removed any remaining duplicates. Finally, RC and MF independently screened the studies by title, abstract, and keywords, after which the full texts of the selected studies were assessed by inclusion and exclusion criteria. The main considerations for study inclusion were if machine learning was fully applied in distinguishing individuals or lesions with clinically diagnosed PCa from controls and if the study assessed the accuracy of such applications. Detailed inclusion and exclusion criteria are reported in Table S2 in Multimedia Appendix 1.

Data Extraction and Outcomes of Interest

After the evaluation was completed, two authors extracted the following information from the selected literature: literature data—the first author, publication date, study population, number of patients, study design, and data collection; basic research information—age, Gleason score, and PSA level, where possible; information regarding the reference standard used in individual studies; definitions of positive and negative PCa (PCa positive and control) and methodologies to distinguish individuals or lesions with PCa from the control group; specific methodologies to process and classify data for use in machine learning algorithms; and the sensitivity, specificity, and, if available, true-positive (TP), true-negative (TN), false-positive (FP), and false-negative (FN) rates.

The authors independently graded the quality of the eligible studies using the quality assessment of diagnostic accuracy studies–version 2 (QUADAS-2) tool [29]. The full process is provided in the supplementary materials in Multimedia Appendix 1.

Meta-analysis Paper Inclusion Criteria and Subgroup Analysis

For radiomic analysis, due to the very low number of included studies investigating central gland and transition zone (TZ) prostate tumors, only studies investigating the peripheral zone were included in the meta-analysis. This was also due to the fact that central gland and TZ prostate tumors have significantly different quantitative imaging signatures [30], and they could have highly biased the final results.

Due to the low number of studies employing 3D volumes of interest (VOIs) to extract quantitative features, only studies delineating 2D regions of interest (ROIs) were included in the meta-analysis to reduce the risk of bias. This was mainly due to the fact that significant differences were found between prediction performance when using 3D VOIs and that when using 2D ROIs [31]. If studies investigated several diagnostic imaging techniques via ML, only classification models using mpMRI sequences were included in the meta-analysis.

To reduce heterogeneity among the selected studies, subgroup analyses were carried out for radiomic and genomic studies due to their intrinsic differences in data acquisition, analysis, and feature extraction. Radiomic subgroup analyses helped to investigate the role of the mpMRI biomarker in detecting PCa via ML, whereas genomic subgroup analyses were carried out to understand the role of genomic biomarkers in detecting PCa via ML.

Several covariates suitable for subgroup analysis were identified during the review process where the individual peculiarities of the studies, which may affect the outcome, were investigated.

The included studies were investigated if they explored a patient- or lesion-based model, validation approaches (cross-validation, hold-out approach or external validation, or no validation), ML algorithms (regression-based model, tree-based model, or deep learning algorithms), whether the studies used a DL or ML approach, or whether the employed data set was balanced or unbalanced. For genomic studies, the use of different specimens (ie, urine, serum, semen, and tissue) was also investigated in a subgroup analysis. One study [17] investigated both urine and serum specimens separately; therefore, ML performance was included for both predictors in the meta-analysis.

In case a study investigated multiple ML algorithms, only the method achieving the highest area under the curve (AUC) was included in the meta-analysis, as AUC is a good estimator of ML performance.

Statistical Analysis and Software Tools

This meta-analysis was conducted via the Open Meta-Analyst Software tool, and statistical significance was expressed with 95% CIs. Pooled estimates for sensitivity and specificity with the corresponding 95% CIs were used to determine the accuracy of machine learning for detecting PCa in radiomic and genomic studies. From these data, we generated a hierarchical summary receiver operating characteristic curve (HSROC) and coupled forest plots by random-effects model. Heterogeneity among studies was assessed by calculation of the inconsistency index (I^2) and evaluation of the Cochran χ^2 test (Q test). An I^2 of ≥50% and P<.001 indicated substantial between-study heterogeneity. The TP/FP/TN/FN values were extracted or calculated from each independent study. A correction factor of 0.5 was added if any of the TP/FP/TN/FN rates reported a value of 0, in order to prevent zero cell count problem [32].

In our meta-analysis, a multivariate random-effects model was used to consider both within- and between-subject variability and threshold effects [33]. The HSROC curve was specified by pooled sensitivity and specificity point. Attempts were made

to resolve the heterogeneity by performing a subgroup analysis [34].

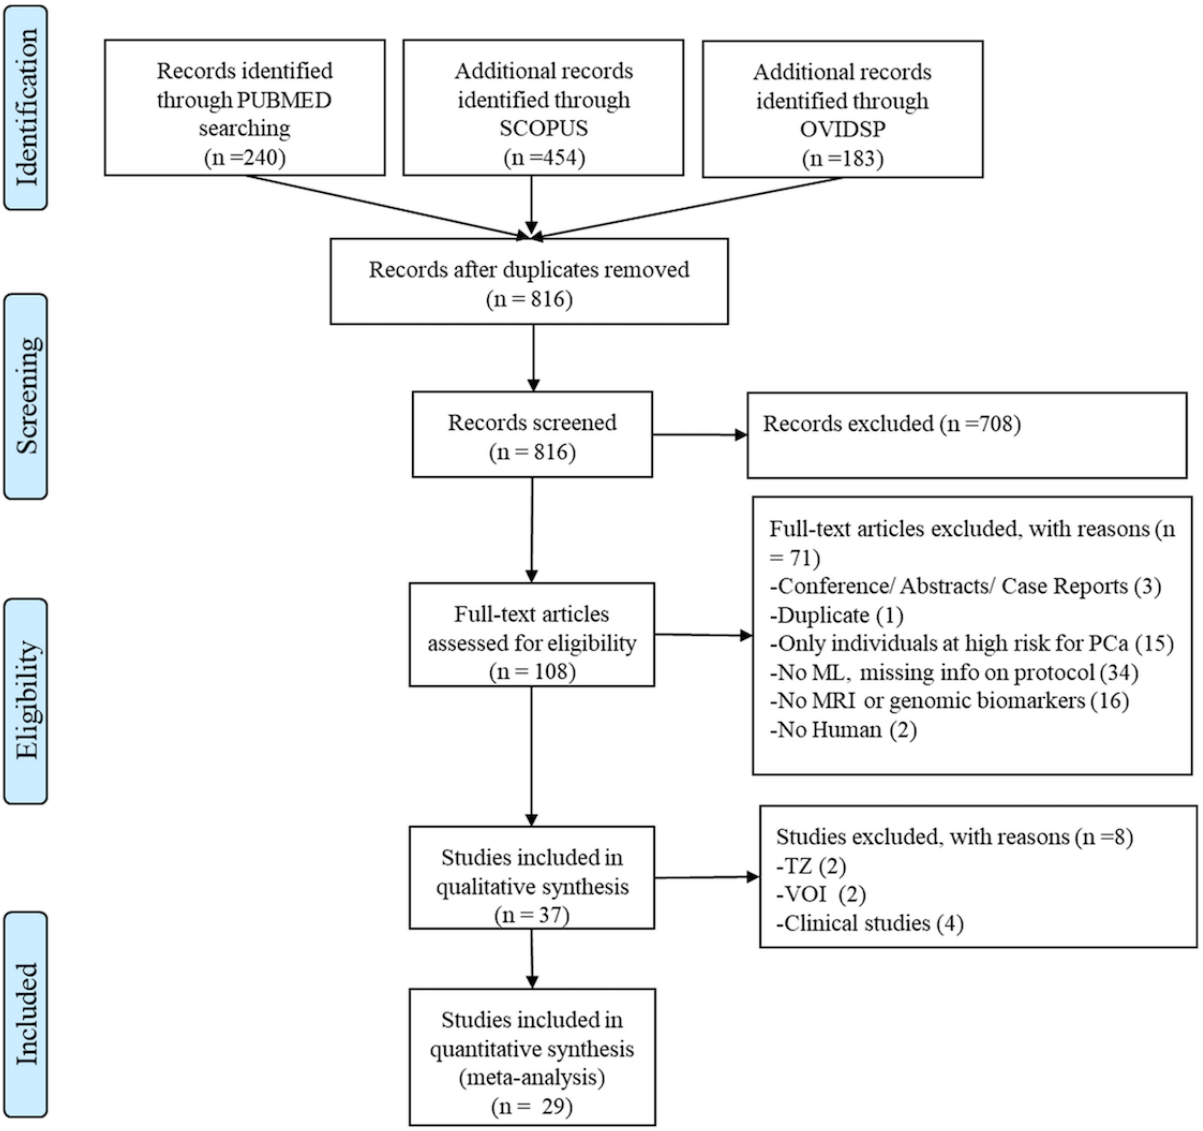
Results

Literature Search

According to the search strategy described above, 877 titles were identified in PubMed, Scopus, and OvidSP. After removing duplicates, 816 titles were considered. Of these, 708 were excluded after reading of the abstracts because they did not meet the inclusion criteria. From the remaining 108 full-text articles, 71 were removed due to the exclusion criteria. Finally, 37 full texts were included in the qualitative analysis, and 29 studies were considered appropriate for inclusion in the meta-analysis. A flowchart of the literature search is shown in Figure 1.

The distribution of the risk of bias evaluated via the QUADAS-2 tool for the included studies is presented in the supplementary materials (Figure S1 in Multimedia Appendix 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of literature search: included/excluded titles, abstracts, and full papers. ML: machine learning; MRI: magnetic resonance imaging; PCa: prostate cancer; TZ: transition zone; VOI: volume of interest.



Characteristics of the Included Studies

The publication years ranged from 2015 to 2020 to guarantee homogeneity among radiomic studies, as the new PI-RADS was updated in 2015 [8]. All patients were diagnosed with PCa by biopsy. The main characteristics of the studies are reported in Table 1. The extracted raw data are presented in Tables S3 and S4 in Multimedia Appendix 1.

Table 1. Characteristics of 37 studies included in the systematic review.

Characteristics	Studies, n	Patients (average over the number of studies), n
Study type		
Prospective	8	2210 (276.25)
Retrospective	29	6414 (221.17)
Data set type		
Private data set	33	7760 (235.15)
Public database (SPIE-AAPM-NCI[a] PROSTATEx challenge)	2	399 (199.5)
Mixed (private and public) data set	2	465 (232.5)
Classification algorithms		
Random forest	4	1621(405.25)
Regression-based models	20	4678 (233.9)
Partial least squares discriminant analysis (PLS-DA)	2	180 (90)
Linear discriminant analysis (LDA)	1	53
Support vector machine (SVM)	2	65 (32.5)
Classification and regression tree (CART)	1	67
Artificial neural networks (ANNs)	2	1012 (506)

[b]SNCSAE: stacked nonnegativity constraint sparse autoencoders.

[c]MRI: magnetic resonance imaging.

Quantitative Analysis (Meta-analysis)

Of the final 37 papers, 29 were considered for the meta-analysis. Eight studies were excluded to reduce heterogeneity among the studies. Of those, 2 studies were excluded because they extracted radiomic features from VOIs [35,36], and 2 studies [37,38] were excluded because they only focused on detecting TZ tumors. Due to the low number of studies investigating TZ tumors, a comparative assessment of the results for the peripheral zone, central gland, and TZ was not possible.

Studies [18,39-41] employing only clinical information were excluded because a minimum sample of 5 studies is recommended for a meta-analysis [34,42]. In fact, 5 or more studies are needed to reasonably achieve power from random-effects meta-analyses [43].

Radiomic

All the included studies for the radiomic analysis are reported in Table 2. A total of 4438 independent samples were inspected

from 16 studies with sensitivity and specificity ranging from 0.62 to 0.99 and 0.51 to 0.98, respectively.

Multivariate meta-analysis via the HSROC model was assessed for all the studies (Figure S2 in Multimedia Appendix 1). The pooled sensitivity and specificity were 0.815 (95% CI 0.410-0.999) and 0.828 (95% CI 0.424-0.999), respectively.

The calculated heterogeneity values for pooled sensitivity and specificity were 84% and 79% (P<.001), respectively; therefore, a random-effects model was adopted to generate coupled forest plots (Figure S3 in Multimedia Appendix 1).

Subgroup Analysis

To resolve the heterogeneity, subgroup analysis was conducted for different covariates. The subgroup analysis per model-based covariate is shown in Figure 2. Subgroup 1 included the studies that employed a lesion-based ML approach. Those studies [44-54] employed multiple lesions for each patient enrolled in the study. Subgroup 2 gathered those studies [55-59] that enrolled two distinct groups (PCa and controls) and employed a patient-based ML approach. The heterogeneity in the subgroups was greater than 70% (subgroup 1: P<.001, subgroup 2: P=.002).

[j]Sen: sensitivity.

[k]Spe: specificity.

Figure 3 shows the subgroup analysis among studies that employed internal cross-validation techniques (subgroup 1) [46-49,51,54,55,59], split validation approaches (subgroup 2) [44,50,52,53,56,57], and no validation (subgroup 3) [45,58]. The heterogeneity for subgroups 1 and 2 was around 80% (P<.001).

Figure 2. Subgroup analysis for the model-based covariate in radiomic studies. Subgroup 1: lesion-based models; subgroup 2: patient-based models. FN: false-negative; FP: false-positive; TN: true-negative; TP: true-positive.

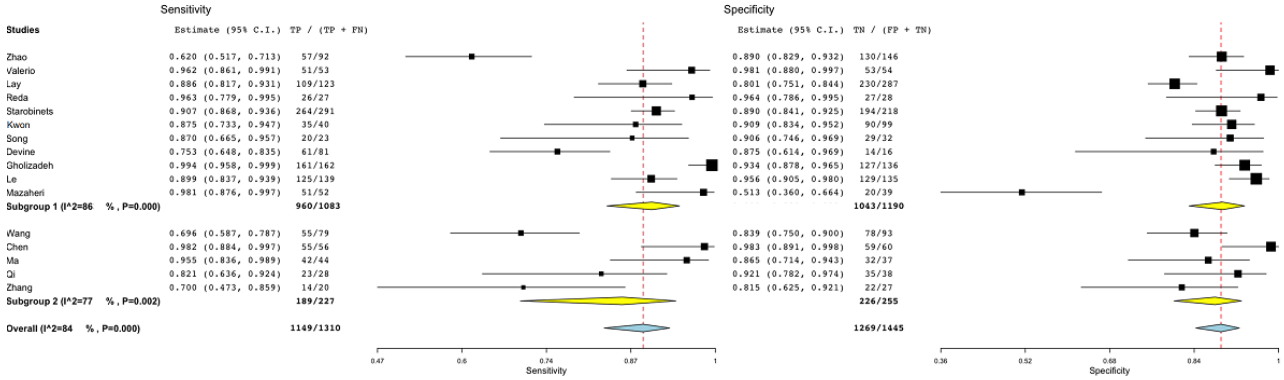

Figure 3. Subgroup analysis for the validation covariate in radiomic studies. Subgroup 1: internal cross-validation; subgroup 2: hold-out approach or external validation; subgroup 3: no validation. FN: false-negative; FP: false-positive; TN: true-negative; TP: true-positive.

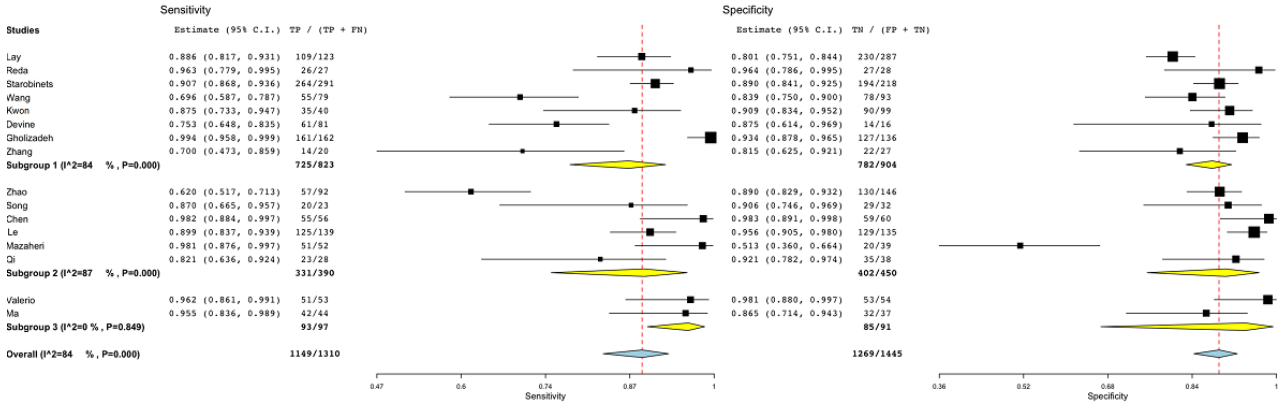

Figure 4 shows the subgroup analysis for regression-based models (subgroup 1) [45,48,49,51,56-58], tree-based models (subgroup 2) [46,53,59], and DL methods (subgroup 3) [44,47,50,52,55]. One study was not included [54], as it was the only study employing a support vector machine model. The heterogeneity among groups oscillated between 74% and 86% (subgroup 1: P=.001, subgroup 2: P=.01, subgroup 3: P<.001).

The results of the subgroup analysis to discriminate among machine and deep learning methods are reported in Figure 5. Subgroup 1 included the studies [45,46,48,49,51,53,56-59] employing ML methods, whereas subgroup 2 comprised the studies [44,47,50,52,55] employing DL methods (based on artificial neural networks) such as convolutional neural networks and deep neural networks. The I^2 statistics for subgroups 1 and 2 were 76% and 86% (P<.001), respectively.

Figure 6 shows the subgroup analysis based on whether the studies employed a balanced or unbalanced data set. A data set was defined as unbalanced if it had more than 30% of the total observations in one specific class rather than the other (PCa and controls) and did not apply any correction on performance (eg, synthetic minority oversampling technique [SMOTE] or voting techniques). The heterogeneity of subgroup 1 [36,44,51,53] was around 58% (P=.005). As a result, among the several covariates, the imbalance covariate was the only one by which the heterogeneity could be partially resolved.

Therefore, Devine et al [51], Wang et al [36], Mazaheri et al [53], and Zhao et al [44] were excluded from the coupled forest plot (Figure 7).

Figure 8 shows the HSROC curve for the studies employing balanced data sets to automatically detect PCa. The pooled sensitivity and specificity were 0.808 (95% CI 0.38-0.999) and 0.831 (95% CI 0.41-0.999), respectively.

Figure 4. Subgroup analysis for the machine learning algorithm covariate in radiomic studies. Subgroup 1: regression-based models; subgroup 2: tree-based models; subgroup 3: deep learning methods. FN: false-negative; FP: false-positive; TN: true-negative; TP: true-positive.

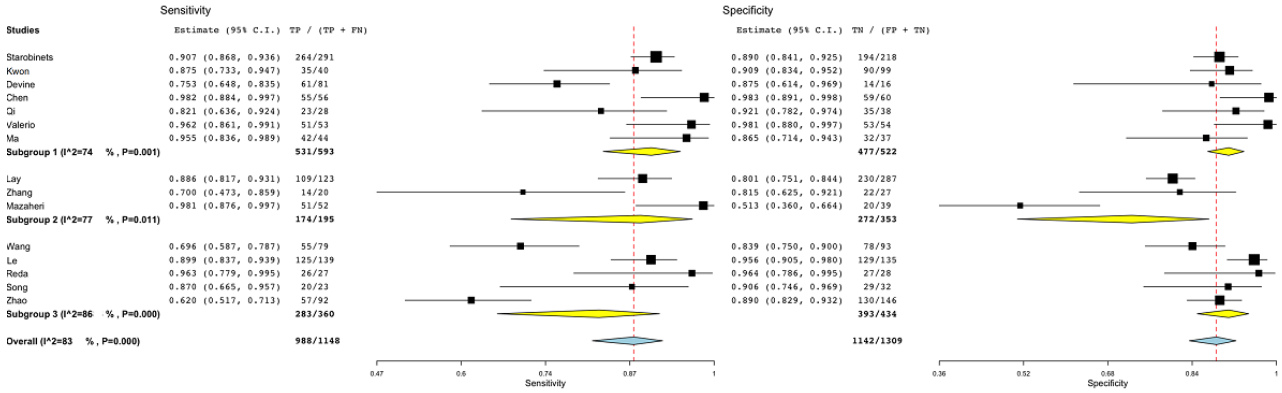

Figure 5. Subgroup analysis for the machine learning or deep learning covariate in radiomic studies. Subgroup 1: machine learning–based models; subgroup 2: deep learning methods. FN: false-negative; FP: false-positive; TN: true-negative; TP: true-positive.

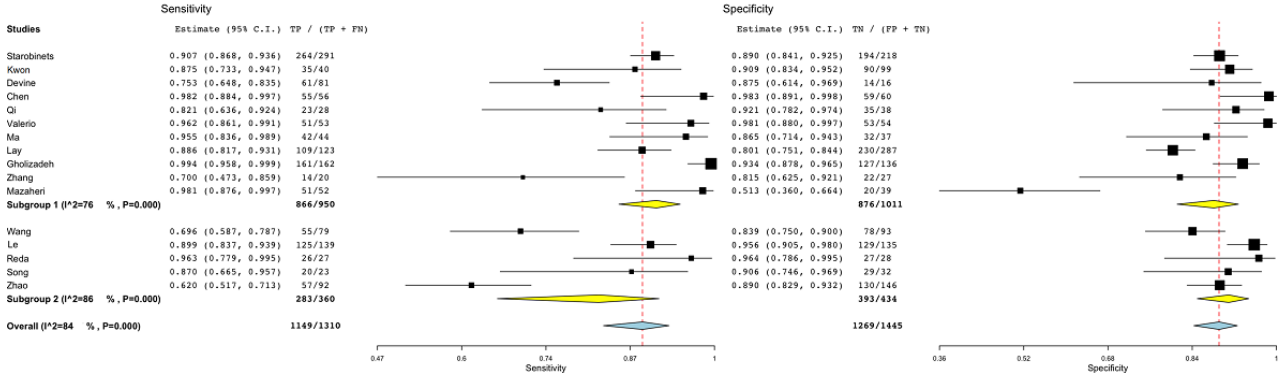

Figure 6. Subgroup analysis for the imbalance covariate in radiomic studies. Subgroup 1: balanced data sets; subgroup 2: unbalanced data sets. FN: false-negative; FP: false-positive; TN: true-negative; TP: true-positive.

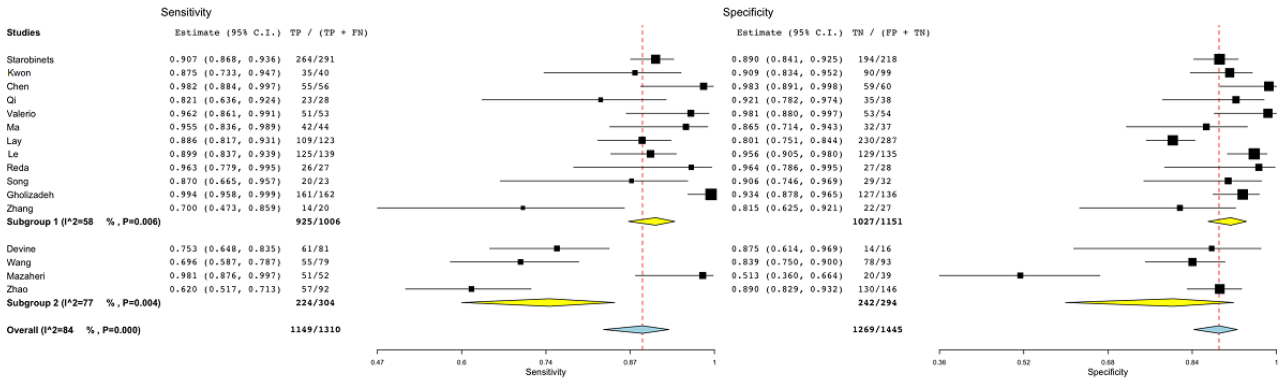

Figure 7. Subgroup analysis for the model-based covariate in a subset of radiomic studies. Subgroup 1: lesion-based models; subgroup 2: patient-based models. FN: false-negative; FP: false-positive; TN: true-negative; TP: true-positive.

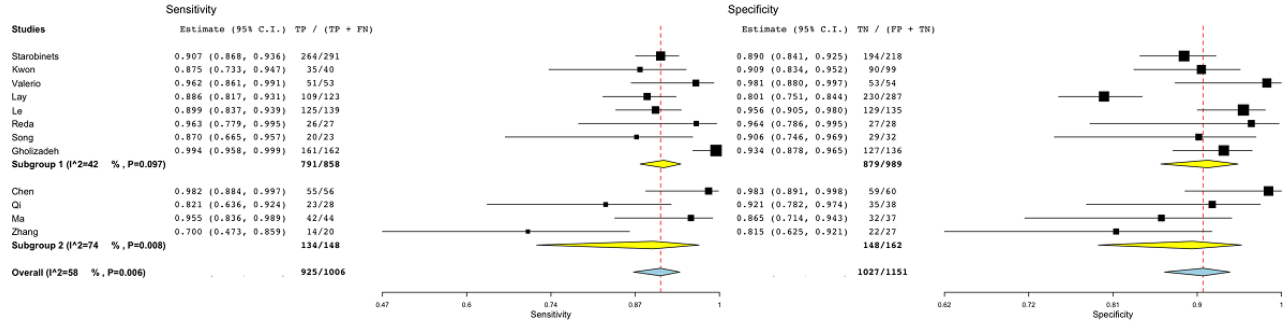

Figure 8. Overall hierarchical summary receiver operating characteristic curve (HSROC) for a subset of radiomic studies. HSROC was calculated for radiomic studies with low heterogeneity, excluding 4 studies [36,44,51,53].

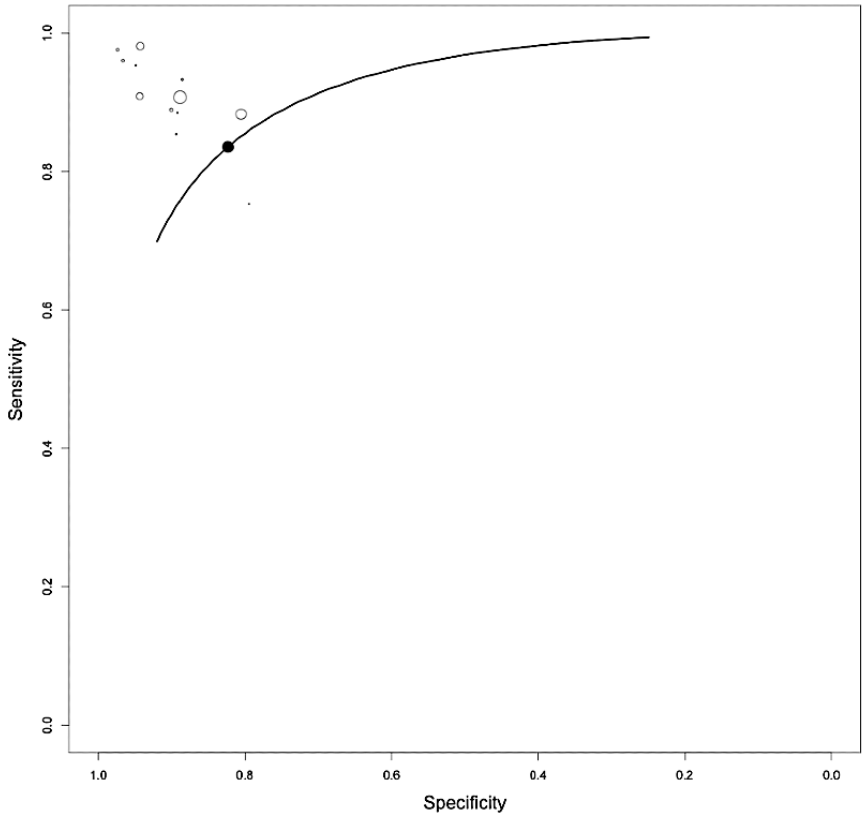

Genomic

All the included studies for the genomic analysis are reported in Table 3. A total of 3221 independent samples were inspected from 14 studies and included in the meta-analysis, with sensitivity and specificity ranging from 0.67 to 0.95 and 0.15 to 0.97, respectively.

An HSROC model was assessed for all genomic studies (Figure S4 in Multimedia Appendix 1). The pooled sensitivity and specificity were 0.883 (95% CI 0.541-0.999) and 0.734 (95% CI 0.330-0.999), respectively.

The calculated heterogeneity values for the pooled sensitivity and specificity were 73% and 92% (P<.001), respectively; therefore, a random-effects model was adopted to generate the coupled forest plots (Figure S5 in Multimedia Appendix 1).

Subgroup Analysis

To resolve this heterogeneity, subgroup analyses were conducted for several covariates. The subgroup analysis for model-based covariates is shown in Figure 9. Subgroup 1 included the studies [60,61] that used malignant lesions and benign-adjacent tissue from PCa patients. Subgroup 2 gathered those studies [15-17,62-69] that enrolled two distinct groups (PCa and controls) and employed a patient-based ML approach. The heterogeneity for subgroup 1 was greater than 80%, whereas for subgroup 2 it was around 60%. However, subgroup 2 only included 2 studies.

[a]All studies employed regression-based models.

[b]LB: lesion-based model; PB: patient-based model.

[c]PCa: prostate cancer.

[d]Crossval: cross-validation techniques.

[e]TP: true-positive.

[f]FN: false-negative.

[g]FP: false-positive.

[h]TN: true-negative.

[i]Sen: sensitivity.

[j]Spe: specificity.

The subgroup analysis among studies that employed internal cross-validation techniques (subgroup 1) [16,64,66], split validation approaches (subgroup 2) [17,60,61,63,67,69], and no validation (subgroup 3) [15,62,65,68] is shown in Figure 10. For subgroups 1 and 2, the heterogeneity was greater than 50%. In subgroup 3, the heterogeneity was around 20%.

Figure 9. Subgroup analysis for the model-based covariate in genomic studies. Subgroup 1: lesion-based models; subgroup 2: patient-based models. FN: false-negative; FP: false-positive; TN: true-negative; TP: true-positive.

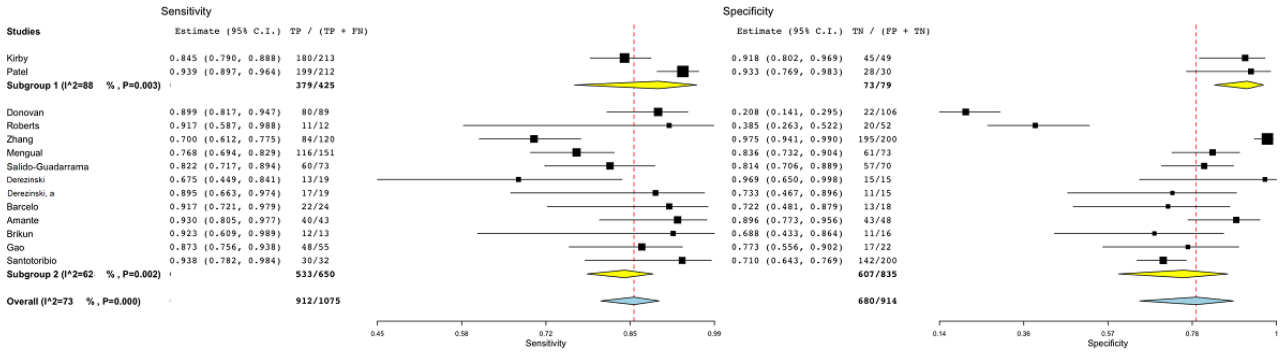

Figure 10. Subgroup analysis for the validation covariate in genomic studies. Subgroup 1: internal cross-validation; subgroup 2: hold-out approach or external validation; subgroup 3: no validation. FN: false-negative; FP: false-positive; TN: true-negative; TP: true-positive.

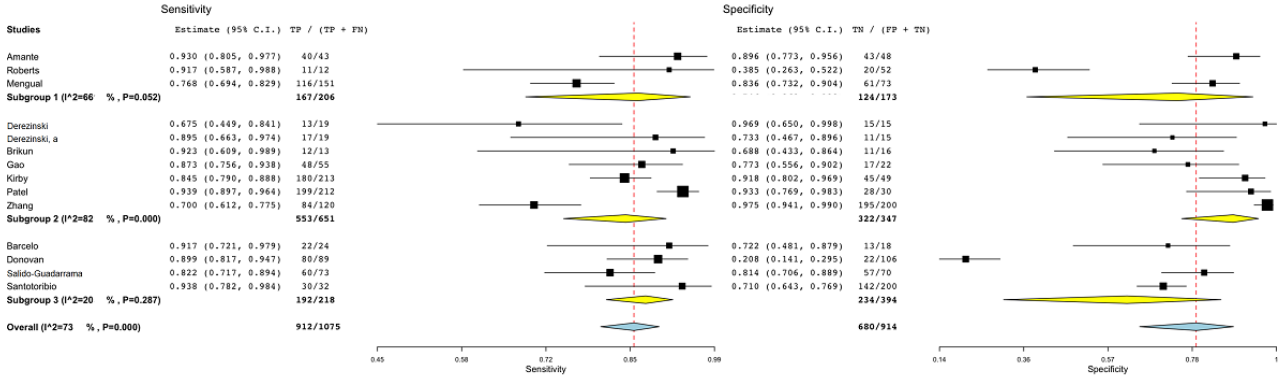

A subgroup analysis was also carried out based on the specimen used by the genomic studies (ie, urine [15,17,62,64,66,67,69], semen [16,65], serum [17,63,68], and tissue [60,61] biomarkers). The subgroup of studies investigating urine biomarkers to automatically detect PCa presented a lower heterogeneity than studies employing tissue and serum biomarkers and included more than 5 studies (Figure 11).

An inspection of ML algorithms among genomic studies was not possible because all the included studies employed a regression-based model (Table S4 in Multimedia Appendix 1).

Finally, the effect of using balanced or highly unbalanced data sets in ML approaches was investigated (Figure 12). Seven studies were included in subgroup 2, as they employed highly unbalanced data sets. The heterogeneity of subgroup 1 was around 36%, whereas subgroup 2 showed a high heterogeneity (I^2=84%, P<.001).

As a result, among several covariates, the imbalance covariate was the only one by which the heterogeneity could be partially resolved for more than 5 studies.

By inspecting Figure 12, Donovan et al [62] presented a very low value for specificity; this was due to the fact that they fixed the sensitivity threshold value at 90%.

Five studies employing urine specimens and balanced data sets showed a very low heterogeneity (Figure 13) [15,17,66,67,69].

The HSROC curve for the studies employing balanced data sets to automatically detect PCa via urine biomarkers is shown in Figure 14. The pooled sensitivity and specificity were 0.812 (95% CI 0.577-0.999) and 0.8101 (95% CI 0.544-0.999), respectively.

Figure 11. Subgroup analysis for the predictor covariate in genomic studies. FN: false-negative; FP: false-positive; TN: true-negative; TP: true-positive.

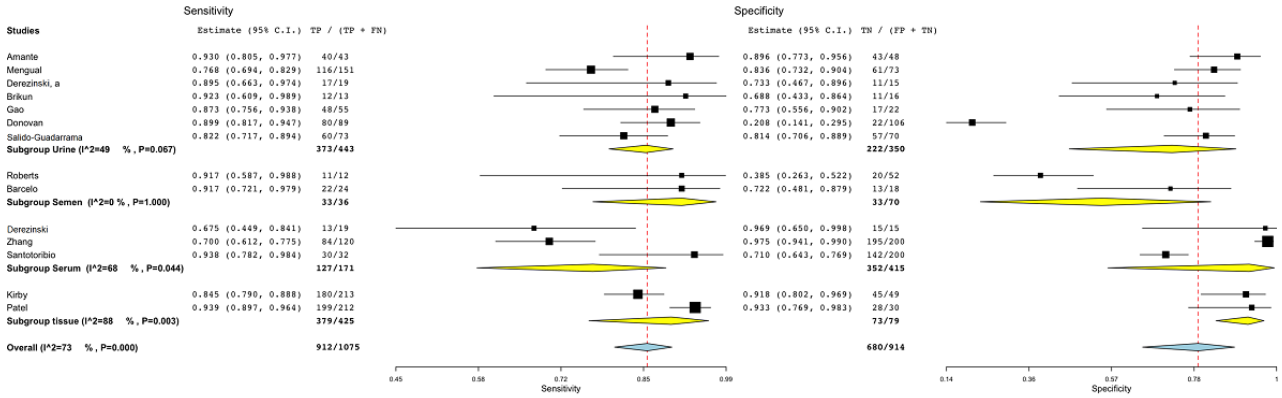

Figure 12. Subgroup analysis for the imbalance covariate in genomic studies. Subgroup 1: balanced data sets; subgroup 2: unbalanced data sets. FN: false-negative; FP: false-positive; TN: true-negative; TP: true-positive.

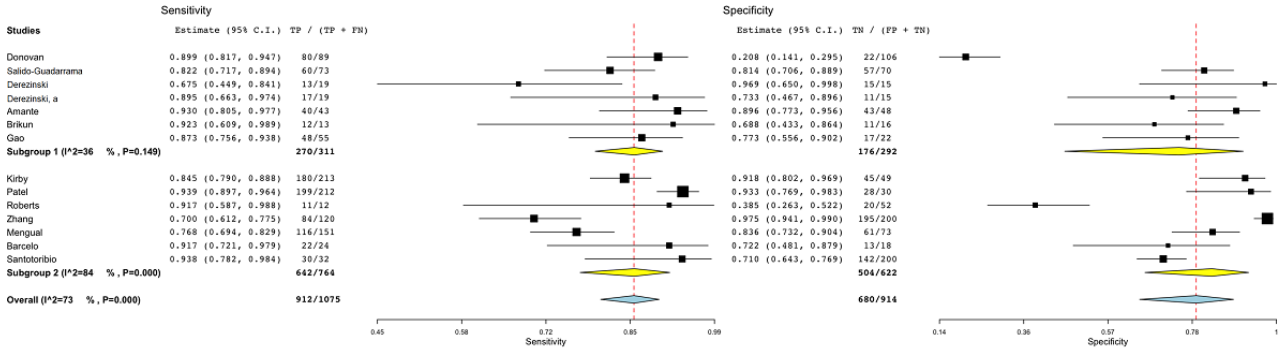

Figure 13. Coupled forest plots for balanced studies. The included studies investigated urine specimens. FN: false-negative; FP: false-positive; TN: true-negative; TP: true-positive.

Discussion

Principal Findings

This paper presents the results of a systematic literature review with meta-analysis of articles investigating machine learning algorithms to detect PCa via radiomic or genomic analysis. One research focus of this study was on clearly evaluating how the implementation of different ML approaches impacts the clinical results. At this stage, due to the high heterogeneity of methods and tools employed in the existing literature, no clear clinical relevance on the use of ML for PCa can be drawn from this study. This review shows that ML has helped to improve the diagnostic performance of the detection of PCa, but challenges still remain for clinical applicability of such methods, and more research is needed. The presented literature aims to help in building an ML system that is robust and computationally efficient to assist clinicians in the diagnosis of PCa via radiomic and genomic biomarkers.

In this review, 37 studies were shortlisted, and 29 studies were included in a meta-analysis. All patients were diagnosed with PCa by biopsy. However, not all the included studies reported full information on the methods used to carry out biopsy (eg, direct MRI-guided, cognitive fusion, or MRI-TRUS fusion biopsy).

In the radiomic and genomic meta-analysis, 16 and 14 studies were included, respectively. Heterogeneity among radiomic and genomic studies was 84% and 73%, respectively. This was expected, as ML methods are usually regarded as black boxes, and the consideration of all possible transformations is onerous. Moreover, there are no clear guidelines on how to develop AI approaches for medical studies, even though a few recommendations have been summarized by Foster et al [24] and Chen et al [25]. Another font of heterogeneity in radiomic studies may be due to the inclusion of PI-RADS score 3 and Gleason score 3+3 lesions, which are equivocal and should be disregarded in classification processes.

To partially solve the heterogeneity for the included studies, subgroup analyses were conducted based on several covariates. In the field of ML, applications where repeated measures or records have been captured on each subject can affect the overall performance. In most studies, the main aim is to predict if a given subject is “sick” or a “control” subject. In these applications, each subject has a single label type (eg, “sick” or control case). Nonetheless, there are other classification problems where each subject can have multiple labels. For instance, multiple lesions can be extracted from the same subject, and the control part can be represented by the benign-adjacent prostate lesion. It has been demonstrated that this phenomenon, known as identity confounding, can cause discrepancy in classification performance [70,71]. Therefore, the studies included in the meta-analysis were investigated to determine whether they explored patient- or lesion-based models. A patient-based model could be defined as a model that is developed and assessed in a “subject-wise” fashion, where all the records of each subject are considered as a group in the training and testing set and when assessing the model performance; conversely, a lesion-based model could be defined as a model that is developed and assessed in a “record-wise” fashion, where each measurement or record contributes to both

the training and test sets and when assessing the model performance [70].

In both radiomic and genomic studies, patient-based models presented lower heterogeneity and performance than lesion-based models; this could be due to the fact that lesion-based models employed a bigger size sample, but the models may be overfit due to repeated measures.

A second important covariate to examine in ML problems is the data set construction. In particular, the data set is usually divided into training and testing sets in order to reduce overfitting problems [70,71]. The training set is often further split into a training set and a validation set, which is used to update model parameters. At least one procedure of internal or external validation is required in ML approaches. Cross-validation techniques are preferred if availability of data is not a problem. It is also strongly suggested to retrain on a subset of data or use an independent data set for external testing. Therefore, "validation approach" was used as a covariate in subgroup analysis. Validation approaches were divided into cross-validation, hold-out approach (split) or external validation, and no validation. In both radiomic and genomic analysis, studies employing cross-validation techniques and hold-out approaches had very high heterogeneity and similar performances among them. High heterogeneity may be due to the different cross-validation techniques used (eg, bootstrapping [16,40,52], Monte Carlo cross-validation [17]) or the choice of number of folders used in cross-validation methods; if an external data set was used [52,60,61,63], differences in the study protocols may have increased the bias among studies. Moreover, few studies in radiomic [50,53,57,59] and genomic [17,67] analysis employed both cross-validation and external testing. Studies employing no validation showed very low heterogeneity (only 2 studies in radiomic analysis), which may be due to the absence of other confounding variables, and high performances may be due to overfitting problems. A lower specificity was only noted in genomic analysis; this was due to Donovan et al [62], which used a fixed threshold for sensitivity at 90%.

Different ML approaches were also investigated among radiomic studies as a possible covariate factor. There were no relevant differences in heterogeneity or performance among subgroups (Figure 4). All genomic studies employed regression-based models. In fact, one limitation of the genomic studies was that none of the selected studies explored the potential of ML techniques at full capacity. Subgroup analysis was also conducted among radiomic studies employing ML or DL (ie, based on artificial neural networks) approaches. As expected, heterogeneity among DL studies was higher than among the studies employing other ML approaches to detect PCa. This could be mainly due to the high complexity of DL methods and hyperparameters. Moreover, DL approaches showed lower performance due to the small sample sizes used; they need large volumes of data to automatically identify patterns and achieve high performance.

The imbalance covariate was crucial in this study. Unbalanced and small data sets are very common in the medical field, and ML algorithms tend to produce unsatisfactory classifiers when handled with imbalanced data sets. Therefore, several techniques to overcome this problem have been proposed over time [72]. In this review, none of the studies included in the subgroup of unbalanced data sets had used any techniques to overcome the problem. Only one study [56] used SMOTE, but it did not employ a highly unbalanced data set.

For radiomic studies, after excluding studies that employed highly unbalanced data sets, the heterogeneity was less than 50%. The final pooled sensitivity and specificity for the use of mpMRI were 0.808 (95% CI 0.38-0.999) and 0.831 (95% CI 0.41-0.999), respectively.

For genomic studies, the heterogeneity dropped to 36% and reached a value close to zero when Donovan et al [62] was excluded because they fixed a threshold of 90% for sensitivity. The final pooled sensitivity and specificity were 0.812 (95% CI 0.577-0.999) and 0.8101 (95% CI 0.544-0.999), respectively. The predictor used to estimate the final pooled sensitivity and specificity was urine specimen.

Only 4 studies [18,39-41] investigating clinically based models were identified through the search. All the included studies adopted internal validation techniques (3 cross-validation [39-41] and 1 internal split validation [18]). Two studies [40,41] employed regression-based models, one [39] employed a tree-based model, and lastly, one employed a DL approach [18]. Heterogeneity was very high among them (I^2=96%, P=.01) due to different sample sizes and diversity of predictors. However, contributions from genomic and imaging biomarkers should be considered to improve the overall performance of the clinically based diagnostic models.

Comparison among genomic and radiomic studies was not possible because they describe two different but complementary prospective approaches to the disease. However, the pooled sensitivity and specificity for both mpMRI and urine biomarkers were around 80%, showing them to be promising biomarkers in the detection of PCa via ML in clinical practice. The use of mpMRI has shown great diagnostic potential [73]; however, its analysis and interpretation are quite challenging, and there is not a consensus on how to optimally extract significant information. On the other side, genomic analyses have significantly increased our understanding of PCa and greatly improved patient risk classification, thus impacting treatment decision making. Therefore, a new prospective approach is the integration of radiomic and genomic signatures, commonly known as radiogenomics [74-76], in order to improve the overall performance of diagnostic tools to automatically detect PCa. In the existing literature, only a few studies have investigated "radiophenotypes" to complement existing validated clinical and genomic risk stratification biomarkers [77-79].

In this scenario, a typical ML postprocessing pipeline for radiomic and genomic analysis to automatically detect PCa may be constituted of a few crucial steps. In the case of radiomic studies, a common pipeline may be constituted of (1) examination of mpMRI; (2) image segmentation through the delineation of ROIs or VOIs, which can include whole gland volume, a specific zone, and one or multiple lesions, which should be explicitly specified in the manuscript; (3) image preprocessing; (4) filtering; (5) feature extraction; (6) integration

of radiomic data with clinical data, genomic data, or both; (7) feature selection in relation to the target class; and (8) algorithm training, validation, and testing. Alternatively, a DL approach would only require the examination of the images and annotation of the ROIs or VOIs of the whole image, according to the desired classification output.

The image processing pipeline should be carefully described in the manuscripts, and the spatial coregistration of DWIs is a critical factor in the correct analysis of diffusion tensor imaging data, which has often been used as a predictor of PCa diagnosis. Moreover, the use of endorectal coil can cause high deformation of the prostate compared with other coils and may not provide adequate MR image quality [80]. Therefore, further processing of the images should also be considered, especially when the study is multicenter and different protocols have been adopted.

Due to the high heterogeneity of genomic studies, a standard pipeline configuration could be structured into (1) missing value management; (2) filtering to remove low-variance features; (3) data normalization due to data coming from heterogeneous formats; (4) a feature selection step to remove irrelevant features due to the high dimension of data; (5) dealing with class imbalance distribution present in this type of large-scale data set; and (6) algorithm training, validation, and testing. Alternatively, a DL approach would handle filtering and feature selection to generate handcrafted features. Deep learning is a powerful tool to integrate different "omics" and increase the computational power of diagnostic tools.

Further general recommendations on how to avoid bias and pitfalls in applying ML to medical problems are as follows: (1) in the case of multicenter studies, it is recommended to use batch effect approaches to prevent any bias due to different study protocols and feature normalization procedures to reduce within-subject bias [81]; and (2) for classifier performance, it is necessary to report if any threshold has been used to identify sensitivity and specificity and whether the performance was reported on patient-based or lesion-based data sets.

Limitations

Our study presents several limitations. Some variability still remains due to the actual thresholds between studies. However, the multiple hierarchical model accounts for between- and within-subject variability among studies, including threshold effects. Another factor that could have affected the heterogeneity among studies is the use of different predictors among radiomic and genomic studies. Moreover, several studies reported little or incomplete information on the parameters used to develop ML models. Therefore, the number of parameters that are estimated by each technique was not investigated as a possible source of heterogeneity among studies. Additional heterogeneity in the observed results is due to the variability of calibration differences between equipment and differences between readers or observers, as well as variation in the implementation of tests. Another possible bias may be due to the preprocessing techniques on the extracted data and feature selection and feature normalization methods.

We limited the search to English-only studies; although this is common in systematic reviews, this exclusion criterion could have reduced the generalizability of the findings. However, the extent and effects of language bias have recently diminished because of a shift toward publication of studies in English [82]. At this stage, we also excluded PCa risk stratification studies to reduce bias and heterogeneity among studies, but further investigation on the use of ML methods to assess risk stratification biomarkers could give a comparative perspective on the treatment selection.

Finally, publication bias was not assessed in our analysis, as there are currently no statistically adequate models in the field of meta-analysis of diagnostic test accuracy [29].

Conclusion

ML has shown its potential to empower clinicians in the detection of prostate cancer. The accuracy of ML algorithms for diagnosis of PCa was considered acceptable, in terms of heterogeneity, for 12 radiomic studies investigating mpMRI and 5 genomic studies using urine biomarkers.

However, given the limitations indicated in our study, further well-designed studies are warranted to extend the potential use of ML algorithms to clinical settings. Recommendations on the use of these techniques were also provided to help researchers to design robust studies aiming to identify radiomic and genomic biomarkers to detect cancer.

Abstract

Background: In a previous study, we examined the use of deep learning models to classify the invasion depth (mucosa-confined versus submucosa-invaded) of gastric neoplasms using endoscopic images. The external test accuracy reached 77.3%. However, model establishment is labor intense, requiring high performance. Automated deep learning (AutoDL) models, which enable fast searching of optimal neural architectures and hyperparameters without complex coding, have been developed.

Objective: The objective of this study was to establish AutoDL models to classify the invasion depth of gastric neoplasms. Additionally, endoscopist–artificial intelligence interactions were explored.

Methods: The same 2899 endoscopic images that were employed to establish the previous model were used. A prospective multicenter validation using 206 and 1597 novel images was conducted. The primary outcome was external test accuracy. Neuro-T, Create ML Image Classifier, and AutoML Vision were used in establishing the models. Three doctors with different levels of endoscopy expertise were asked to classify the invasion depth of gastric neoplasms for each image without AutoDL support, with faulty AutoDL support, and with best performance AutoDL support in sequence.

Results: The Neuro-T–based model reached 89.3% (95% CI 85.1%-93.5%) external test accuracy. For the model establishment time, Create ML Image Classifier showed the fastest time of 13 minutes while reaching 82.0% (95% CI 76.8%-87.2%) external test accuracy. While the expert endoscopist's decisions were not influenced by AutoDL, the faulty AutoDL misled the endoscopy trainee and the general physician. However, this was corrected by the support of the best performance AutoDL model. The trainee gained the most benefit from the AutoDL support.

Conclusions: AutoDL is deemed useful for the on-site establishment of customized deep learning models. An inexperienced endoscopist with at least a certain level of expertise can benefit from AutoDL support.

Introduction

Artificial intelligence (AI) using deep learning (DL), which mimics the intellectual function of humans, has been increasingly adopted in clinical medicine, especially for cognitive function in computer vision [1-3], including automated image recognition, classification, and segmentation tasks [4-6]. Application of AI to endoscopic examination is noninvasive and can further help in detecting hidden or hard-to-detect lesions in real time. Moreover, automated determination of the optimum classification—providing delineation of the lesions—may be helpful to endoscopists, especially for inexperienced physicians. Optimizing classification facilitates the appropriate selection of high-risk patients who need additional workup or treatment [4,7]. Current established AI models are in the research-based format, which tend to have limited value in real-world clinical practice. However, AI models can potentially be used as add-on testing as a secondary assistant observer for endoscopists.

The accurate prediction of invasion depth for gastric neoplasms is an essential skill of endoscopists [8,9]. Gastric neoplasms confined to the mucosa or superficial submucosa are potential candidates for endoscopic resection [9]. Thus, precisely predicting the invasion depth is essential for determining the therapeutic strategy. Prediction of the invasion depth is based on the gross morphology of the lesions, and there are no standard criteria for classifying invasion depth. Therefore, current practice is limited by the inevitable interobserver variability and inaccurate determination of the invasion depth in gastric neoplasms [9].

The authors previously established DL models for classifying the invasion depth (mucosa-confined versus submucosa-invaded) of gastric neoplasms from endoscopic images using transfer learning of pretrained convolutional neural networks (CNNs) based on the PyTorch platform [10]. The external test accuracy was able to reach 77.3% [9]. However, the establishment of a DL model requires substantial time, and high performance is needed before applying these models to real-world clinical practice.

Automated deep learning (AutoDL) techniques, which enable fast searching of optimal neural architectures and hyperparameters without complex coding, have been widely developed. This “off-the-shelf” software or platform can be used without professional AI expertise and can easily be applied to clinical practice with simple inference structures [11]. However, the performance of AI models established by data scientists in the traditional manner and AutoDL models established by health care researchers for the gastrointestinal endoscopy field have not been directly compared. Moreover, there are scarce data in terms of human-AI interactions. For example, the reaction of endoscopists (ie, approval, indolence, or disregard) to diagnoses made using an AI model remains unknown [12]. This study aimed to establish AutoDL models classifying invasion depth of gastric neoplasms using endoscopic images and compare the diagnostic performance of the AutoDL models with previous CNN models established in the traditional way. Additionally, endoscopist-AI interactions using the newly established model were further examined.

Methods

Construction of the Data Set

This study extends the previous research on this topic [9] by constructing (Figure 1) and evaluating (Figure 2) experimental DL models with AutoDL tools. In order to compare the diagnostic performance of AutoDL–based models to the previous CNN models, the same input images (2899 white-light imaging endoscopic images) that were used to establish the previous model were used again. The detailed data collection process was described previously [9]. Briefly, between 2010 and 2017 in the Chuncheon Sacred Heart Hospital (Republic of Korea), we enrolled consecutive patients with any type of gastric neoplasms discovered during upper gastrointestinal endoscopy and histologically confirmed. Endoscopic images were collected from the in-hospital database in JPEG format, with a minimum resolution of 640×480 pixels [9]. The same previously used external test data set (206 white-light imaging endoscopic images) was also used in classifying the performance of the AutoDL models. This external test data set was constructed by collecting images from consecutive patients who underwent upper gastrointestinal endoscopy between 2019 and 2020, and all the images were mutually exclusive from those of the training and internal validation data set (Table 1) [9].

To guarantee the generalizability of the performance of the newly developed AutoDL model, an additional performance verification (prospective validation) test with another external test data set was conducted. This second external test data set, including 1597 images, was collected from consecutive patients who underwent upper gastrointestinal endoscopy at the Hallym University Sacred Heart Hospital from 2018 to 2020 (Table 1).

Figure 1. Schematic flow for the establishment of automated deep learning models in data construction.

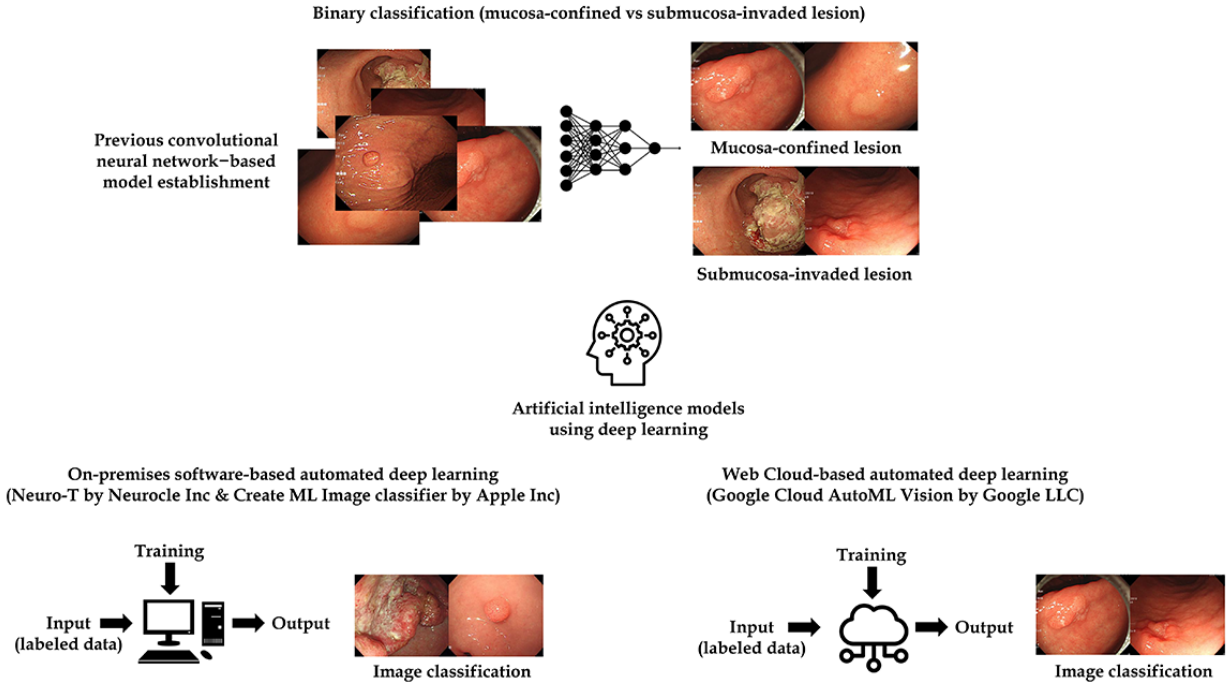

Figure 2. Schematic flow for the establishment of automated deep learning models in performance evaluation.

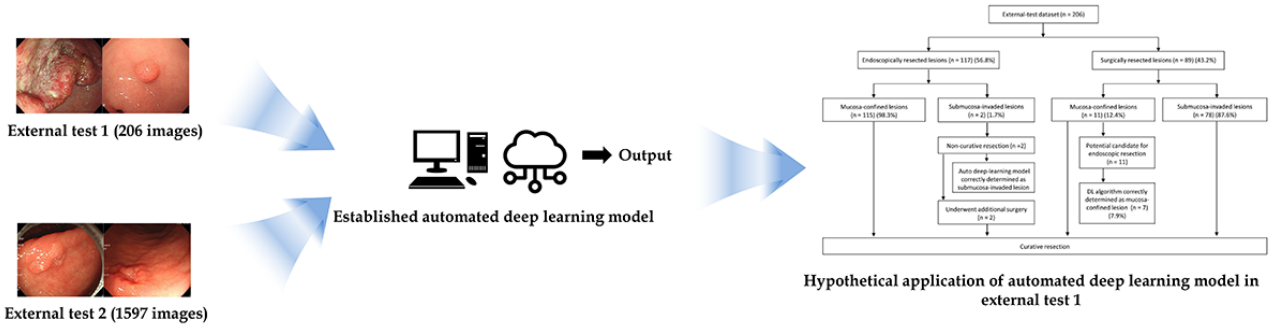

Table 1. Summary of images in each data set.

	Number of images		
Invasion depth of gastric neoplasms	Training and internal validation data set	External test data set 1	External test data set 2
Overall	2899	206	1597
Mucosa-confined lesions	1900	126	1344
Low-grade dysplasia	727	68	734
High-grade dysplasia	421	21	110
Early gastric cancer	752	37	500
Submucosa-invaded lesions	999	80	253
Early gastric cancer	282	23	155
Advanced gastric cancer	717	57	98

AutoDL Tools Used in the Study

AutoDL tools including Neuro-T (version 2.0.2; Neurocle Inc), Create ML Image Classifier (Apple Inc), and Google Cloud AutoML Vision (Google LLC) were used in this study.

Neuro-T has been defined as an AutoDL software that can establish DL algorithms on its own for image recognition and classification based on a graphical user interface (GUI). The software's algorithm analyzes the features of the data set and self-discovers optimal hyperparameters, thus making it easy for

non-AI experts to build the best models. Neuro-T also offers a platform to establish anomaly detection models (supervised anomaly detection based on the clustering algorithm with deep neural networks). Anomaly detection is the identification of observations that raise suspicions by differing significantly from the majority of the training data. The neural network clustering algorithm clusters each training sample and makes its own cluster decision boundary for classifying the test sample into normal class or abnormal class. Meanwhile, Create ML is defined as a framework used to establish customized DL models on the Mac operating system (Apple Inc); Image Classifier can be accessed by GUI or Swift language code. DL models can be established using image data sets through the self-learning process of specific features. Google Cloud AutoML Vision is a web-based service to build customized DL models with automatic neural architecture searching and feature extraction. These 3 AutoDL tools were used based on the manner of the GUI (ie, no coding tool required) to build the DL models.

Preprocessing of Images

The authors used data augmentation methods—such as rotation, and horizontal or vertical flipping of included images—and image normalization with linear transformation in terms of 3 RGB channels in order to build the previous DL model [9]. However, AutoDL tools are determined to have data preprocessing functions. Neuro-T has an automated image normalization process with a resizing function for input images. All of the included images were resized with a resolution of 512×480 pixels while building the Neuro-T–based models. Create ML Image Classifier offers GUI–based data augmentation options. These include 6 image data augmentation methods, such as “add noise,” “blur,” “crop,” “expose,” “flip,” or “rotate” functions. In order to identify the best models, we conducted multiple experiments (with or without data augmentation and single or combination data augmentation options) in Create ML. In terms of AutoML Vision, no GUI-based data augmentation option was determined. Developers can add image augmentation codes using a Python application programming interface. However, considering that the aim of this study was to develop AutoDL models without complex coding or AI expertise, we only selected the GUI-based function without data augmentation while building the AutoML Vision–based models.

Training of AutoDL Models

The 2899 input images were uploaded to each AutoDL tool. Neuro-T and Create ML were considered on-premise software; however, AutoML Vision is a cloud-based service. The input images were uploaded to Neuro-T and Create ML, and a bucket in Google Cloud Storage system was used for data uploading in the AutoML Vision. After selecting data preprocessing options (as described above, including resizing/normalization in Neuro-T and image augmentation in Create ML), AutoDL models were trained in each specified way of self-learning. Images were then randomly split into training and internal validation sets. The Neuro-T variable options—such as 9:1, 8:2, or 7:3—were set as per the user’s preference. Multiple experiments were further conducted to determine the model with the best performance with variable splitting ratios. However, Create ML Image Classifier automatically sets an internal validation set using approximately 5.1% of the images; thus, 149 images were allocated in the internal validation data set. In AutoML Vision, the ratio of training, internal validation, and internal test sets was 8:1:1. For the training of the anomaly detection model in Neuro-T, only images with mucosa-confined lesions could be used. Therefore, 1714 mucosa-confined images were used for training, and 186 mucosa-confined images and 999 submucosa-invaded images were used for the internal validation set. The number of iterations in training can be set for Create ML. Experiments for the different iteration numbers were conducted to prevent overfitting (ie, model learns too much about training images, and predictions are not well generalized to new images) [3].

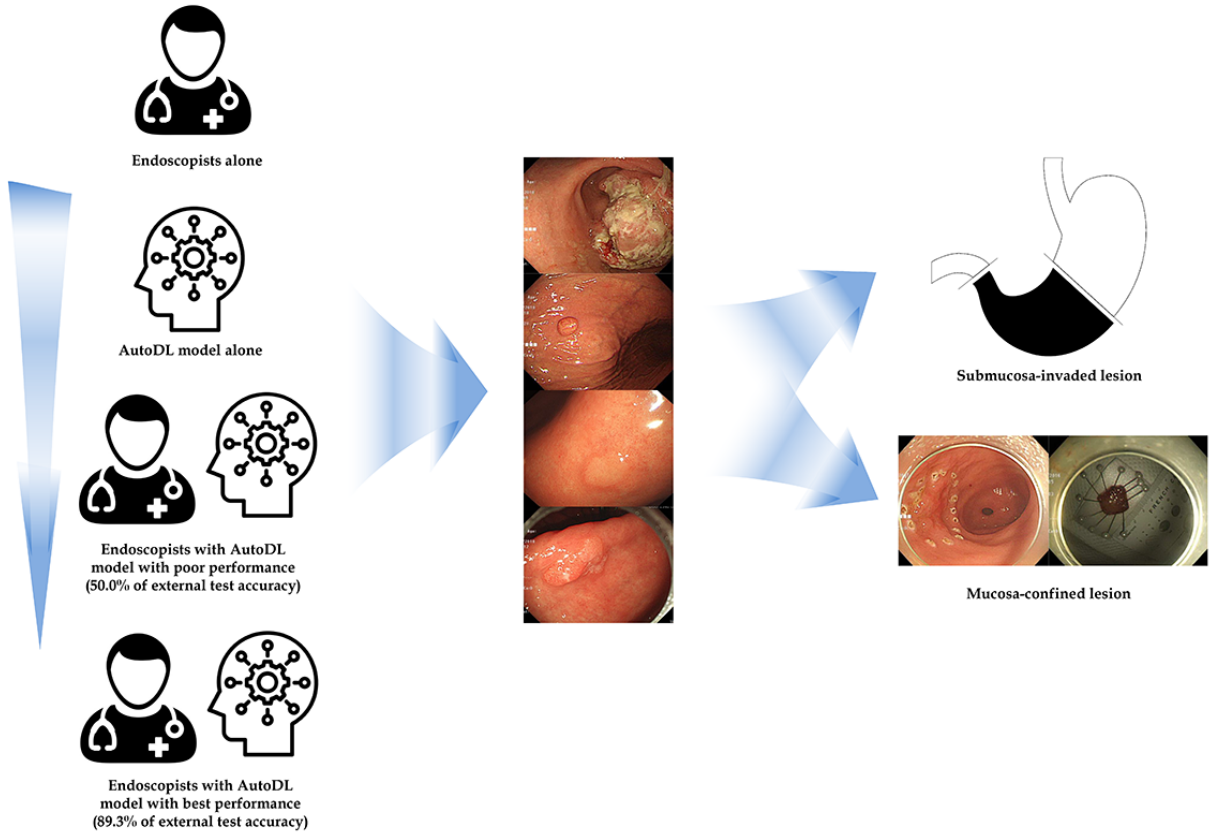
The hardware system used for the training included NVIDIA GeForce RTX 2080 Ti graphics processing units (GPUs), dual Intel Xeon central processing units (CPUs), and 256 GB RAM for the Neuro-T–based AutoDL models. Create ML–based models were established on both the MacBook Pro laptop (2019 version, AMD Radeon Pro 5500M GPU, Intel Core i9 CPU, and 32 GB RAM) and the Mac Pro workstation (2019 version, AMD Radeon Pro Vega II GPU, Intel Xeon W CPU, and 192 GB RAM) environments in order to compare the training time according to the hardware system.

Endoscopist-AI Interactions

Three doctors with different levels of endoscopy expertise were asked to classify the invasion depth of gastric neoplasms for each endoscopic image without AutoDL support, with faulty AutoDL support, and with the support of the best performance AutoDL in sequence (Figure 3). A board-certified endoscopist with more than 7 years of endoscopic submucosal dissection experience, an endoscopy trainee, and a general physician with minimal endoscopy expertise participated in the blind test. Endoscopic images (206 images from the external test data set) without information about invasion depth were used. The first test was conducted without AI support. To find the interaction between endoscopists and poor-quality AI, blind testing was conducted while providing the poor-quality model’s (faulty AI) answers with only 50.0% external test accuracy. Another round of blind testing was performed while providing the answers from the best performance AutoDL model (89.3% external test accuracy). The confidence of the raters in their answers was recorded for each test.

A detailed description of the primary outcome and statistics are described in Multimedia Appendix 1.

Figure 3. Schematic flow for the establishment of automated deep learning (AutoDL) models in endoscopist–artificial intelligence interaction test.



Results

Characteristics of the Included Images

The detailed characteristics of the images included in this study were described in the previous report [9]. In brief, 65.5% of the images were mucosa-confined lesions and 34.5% were determined to be submucosa-invaded lesions (2899 images for the training and internal validation set). For the first external test (206 images), 61.2% and 38.8% of the images were determined to be mucosa-confined lesions and submucosa-invaded lesions, respectively. For the second external test (1597 images), 84.2% and 15.8% were identified to be mucosa-confined lesions and submucosa-invaded lesions, respectively. Table 1 shows a summary of the images used in this study.

Diagnostic Performance of AutoDL Models for the First External Test

The Neuro-T–based classification model reached 89.3% (95% CI 85.1%-93.5%) accuracy, 89.1% (95% CI 84.8%-93.4%) average precision, 88.4% (95% CI 84.0%-92.8%) average recall, and 88.7% (95% CI 84.4%-93.0%) F1 score in the external test. The total training time was approximately 13 hours. The external test accuracy of the Neuro-T–based model was significantly higher than that of the previous CNN model with the best performance (ie, 77.3%, 95% CI 75.4%-79.3%; *P*=.005). The confusion matrix for the Neuro-T–based model in the external test is illustrated in Multimedia Appendix 2A. The detailed information of the established model is as follows: batch size, 80; epochs, 84; number of layers, 53; optimizer, Adam; and input height and width, 480×512 pixels. All images were resized with interlinear interpolation, and the initial learning rate was 0.002.

The anomaly detection model established by Neuro-T was able to reach 49.5% (95% CI 42.7%-56.3%) accuracy, 51.0% (95% CI 44.2%-57.8%) average precision, 51.0% (95% CI 44.2%-57.8%) average recall, and 51.0% (95% CI 44.2%-57.8%) F1 score in the external test. The training time was approximately 20 minutes. The confusion matrix for the anomaly detection model is illustrated in Multimedia Appendix 2B.

For the Create ML Image Classifier, data augmentation options combining “blur” and “rotate” provided the best performance after 25 iterations. The external test accuracy reached 83.5% (95% CI 78.4%-88.6%). The training time was approximately 76 minutes in the laptop environment, which was determined to be not significantly different from the training time in the workstation environment. Furthermore, the external test accuracy of the Create ML–based model was not statistically different from that of the previous model (*P*=.26). The confusion matrix for the Create ML–based AutoDL model with the best performance is presented in Multimedia Appendix 2C.

The fastest model establishment with high performance was achieved by data augmentation options combining “add noise” and “blur” after 25 iterations. The external test accuracy reached 82.0% (95% CI 76.8%-87.2%). The training time was determined to be only about 13 minutes in the laptop

environment, which was not different from the training time in the workstation environment. Also, the external test accuracy of the Create ML–based model was not statistically different from that of the previously established CNN model (*P*=.45). The confusion matrix for the Create ML–based AutoDL model with the fastest building time and high performance is illustrated in Multimedia Appendix 2D.

For the Google Cloud AutoML Vision model, external test accuracy reached 83.0% (95% CI 77.9%-88.1%). The training time was only 25 minutes (web cloud–based environment). The external test accuracy for the AutoML Vision–based model was not statistically different from that of the previous CNN model (*P*=.31). The confusion matrix for the AutoML Vision–based model is illustrated in Multimedia Appendix 2E.

The summary statistics of external test accuracy with internal validation accuracy are shown in Table 2.

Table 2. Summary of external test accuracy with internal validation accuracy for each automated deep learning (AutoDL) model.

AutoDL model	Accuracy, % (95% CI)	Precision, % (95% CI)	Recall, % (95% CI)	F1 score, % (95% CI)	Training time (minutes)
Neuro-T–based model					826

[a]M: mucosa-confined lesions.

[b]SM: submucosa-invaded lesions.

Additional Performance Verification to Gain Generalization Potential in the Second External Test

For the 1597 images in the second external test, the AutoDL model was determined to perform the best (Neuro-T–based), reaching 88.6% (95% CI 87.0%-90.2%) accuracy, 83.7% (95% CI 81.9%-85.5%) average precision, 68.5% (95% CI 66.2%-70.8%) average recall, and 75.4% (95% CI 73.3%-77.5%) F1 score.

Hypothetical Application of AutoDL Model

Hypothetical clinical application of the established AutoDL model with the best performance was conducted using the first external test data set, assuming that the AutoDL was applied in order to determine the treatment (ie, endoscopic resection or surgical resection), based on the invasion depth of the lesion. Among the lesions with endoscopic resection (n=117), 2 lesions (1.7%) were found to invade the submucosa and were resected with additional surgery after endoscopic resection. The AutoDL model correctly determined that these were submucosa-invaded lesions. Thus, the model has the potential to prevent unnecessary endoscopic procedures. Among the lesions with surgical resection (n=89), 11 lesions (12.4%) were identified to be mucosa-confined, having the potential for endoscopic resection. The AutoDL model correctly determined the mucosa-confined lesions in 7 of the 11 patients (7.9%). Thus, the model has the potential to prevent unnecessary surgeries (Multimedia Appendix 3).

Endoscopist-AI Interactions

Figure 4 and Table 3 show the external test accuracy of the 3 raters. The expert endoscopist's decision was determined to have not been influenced by the support of the AutoDL in the consecutive tests. The faulty AutoDL model misled the decisions of the endoscopy trainee and general physician, but the difference was not statistically significant. However, support from the best performance AutoDL model corrected this misdirection. The endoscopy trainee benefited the most from the support of the AutoDL model (P=.002). In the analysis of whether the raters were sure of their answers, confident answers showed a similar pattern to that of the overall results. In the "unconfident answers" subgroup, the expert endoscopist's decisions were not influenced, and the trainee gained a statistically significant benefit, even with the support of the poor performance AutoDL model (P<.05). However, the general physician did not benefit from the support of the AutoDL models.

Figure 4. Endoscopist–artificial intelligence interactions. AutoDL: automated deep learning.

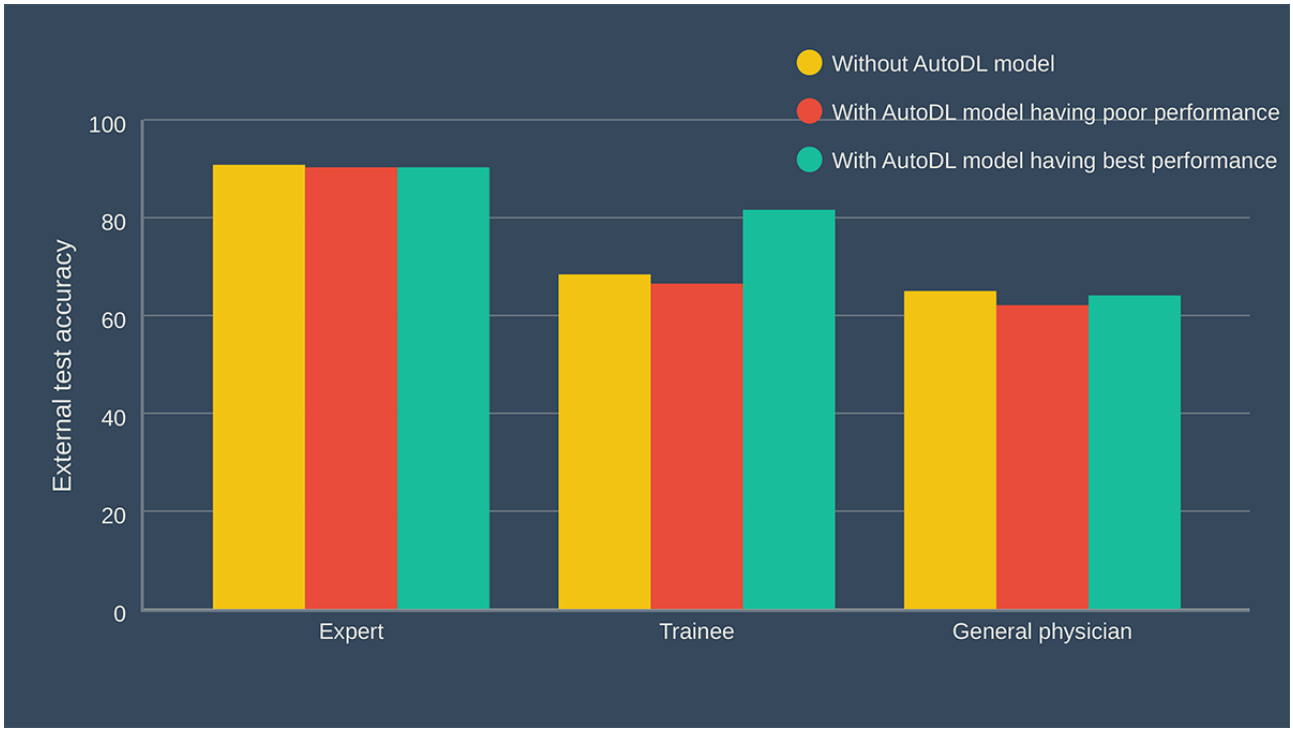

Table 3. Summary of external test accuracy in endoscopist–artificial intelligence (AI) interactions.

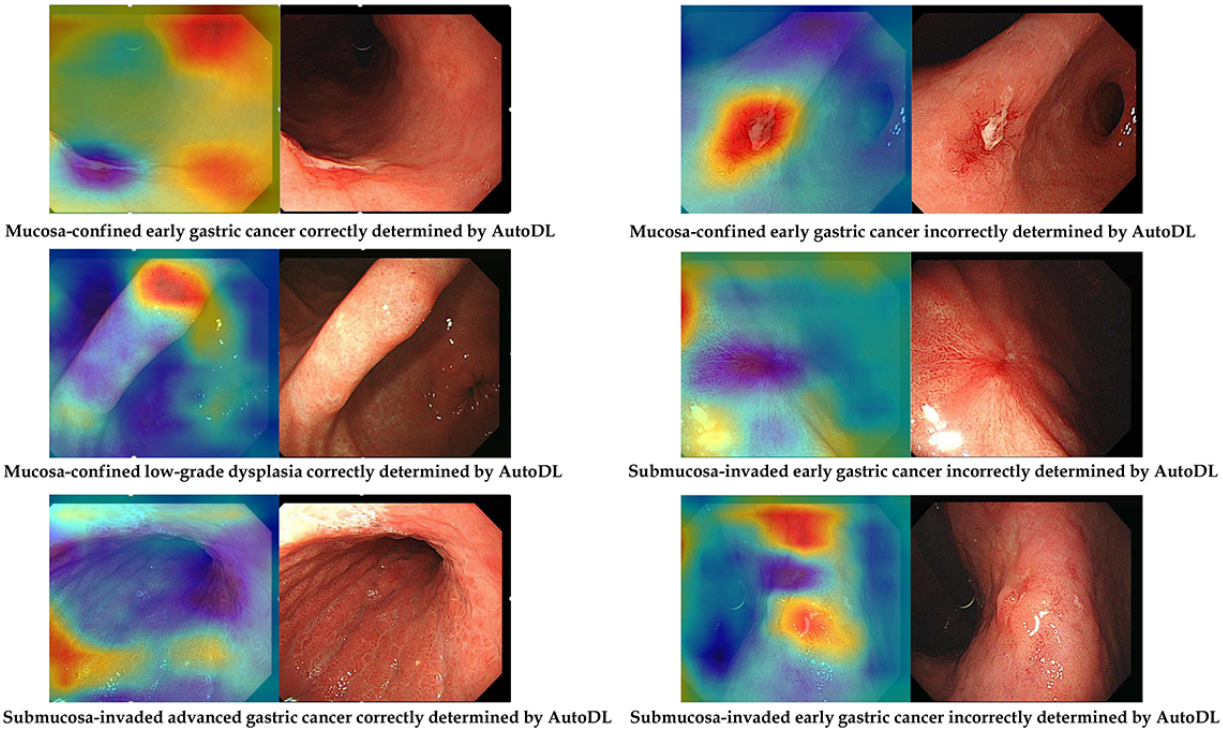
Rater	External test accuracy, % (95% CI)			*P* values	
	First test: endoscopist alone	Second test: endoscopist with faulty AI	Third test: endoscopist with best performance AI	First test vs second test	First test vs third test
Expert endoscopist					
All answers	90.8 (86.8-94.8), (187/206)	90.3 (86.3-94.3), (186/206)	90.3 (86.3-94.3), (186/206)	.87	.87
Confident answer	93.8 (91.7-95.9), (181/193)	90.6 (86.6-94.6), (182/201)	90.6 (86.6-94.6), (184/203)	.23	.24
Unconfident answer	46.2 (19.1-73.3), (6/13)	80.0 (44.9-99.9), (4/5)	66.7 (13.4-99.9), (2/3)	.20	.52
Endoscopy trainee					
All answers	68.4 (62.1-74.7), (141/206)	66.5 (60.1-72.9), (137/206)	81.6 (76.3-86.9), (168/206)	.67	.002
Confident answer	80.6 (74.4-86.8), (125/155)	71.1 (63.2-79.0), (91/128)	92.2 (87.8-96.6), (130/141)	.06	.004
Unconfident answer	31.4 (18.7-44.1), (16/51)	59.0 (48.1-69.9), (46/78)	58.5 (46.5-70.5), (38/65)	.002	.004
General physician					
All answers	65.0 (58.5-71.5), (134/206)	62.1 (55.5-68.7), (128/206)	64.1 (57.5-70.7), (132/206)	.38	.84
Confident answer	77.4 (70.0-84.8), (96/124)	71.6 (64.5-78.7), (111/155)	74.2 (67.5-80.9), (121/163)	.27	.53
Unconfident answer	46.3 (35.5-57.1), (38/82)	33.3 (20.4-46.2), (17/51)	25.6 (12.6-38.6), (11/43)	.14	.02

Attention Map for Explainability

A class activation map to localize the discriminative regions used by the AutoDL model to determine a specific class in the image is presented for the Neuro-T model. Figure 5 shows the correctly and incorrectly determined samples in the external test using the Neuro-T–based AutoDL model.

Figure 5. Representative samples of the attention map (Neuro-T–based model). AutoDL: automated deep learning.



Discussion

AutoDL models were established using only GUI-based systems, which surpassed or had a similar accuracy to that of the previous model for the determination of the invasion depth of gastric neoplasms using endoscopic images. The best performance model showed an external test accuracy of 89.3%, which is deemed much higher than the previous CNN model built in the traditional manner. Furthermore, the authors performed an external test to determine the generalizability, and the external test was found to exhibit robust performance. As far as the authors know, this is the highest performance achieved by an AutoDL model in the context of gastric neoplasms. In previous studies, the internal validation accuracy was 64.7% to 94.5%

for the discrimination of invasion depth in gastric cancers [13-16]. However, these models can only be applied after a definite diagnosis of gastric cancer, which has limited value due to various types of gastric neoplasms in real-world clinical practice [9]. Moreover, no single study evaluated the external test accuracy; thus, the previous tests lacked generalizability.

Creating a classification model using medical images through transfer learning based on high performance CNNs is a representative establishment method for AI models. However, health care researchers often lack the AI expertise to directly apply the models to clinical data to create the AI model [17]. Data scientists and endoscopists can collaborate to create AI models. However, this process usually takes a substantial amount of time and does not immediately reflect the unmet needs of clinical practice.

AutoDL technology makes it possible for nonexperts to create high-quality DL models even without AI expertise. These tools are easy-to-use and only require data uploading to the on-premise software or web cloud platform and simple labeling for the correct classification [18]. After self-learning and model fitting, AutoDL tools provide models ready for direct inference or deployment in real-world practice. Establishing a model requires considerably less time than traditional platform-based model generation. In this study, the fastest establishment time was only 13 minutes and provided an external test accuracy (82.0%) that was similar to that of the previous CNN models based on the laptop environment. In addition, Apple's Create ML and Google Cloud AutoML Vision are publicly available platforms that anyone can download from the App Store or access from the web cloud platform.

Endoscopists produce an enormous amount of image data in their daily practice; often, they are forced to make instantaneous medical judgments even during endoscopic procedures. However, the burnout phenomenon of endoscopists is a serious concern that needs to be addressed, as it affects concentration and, possibly, medical judgment [19]. A previous study on human-AI interactions suggested that applying a high-quality DL model to clinical decision making improves diagnostic performance compared with either DL models or physicians alone; thus, it was deemed particularly beneficial for less-experienced doctors [7].

Although AI is potentially efficacious in clinical practice, data regarding endoscopist-AI interactions remain to be scarce. Based on the findings in this study, inexperienced endoscopists with at least a certain level of expertise can benefit from AutoDL support. The endoscopy trainee—but not the general physician or expert endoscopist—benefited from AI support in this study. Most of the answers by the expert endoscopist were rated as confident and were not influenced by the AI support (ie, possible disagreement with or disregard for the AI answers). The proportion of unconfident answers in the first test was the highest for the general physician, and this proportion was markedly decreased with the support of the faulty AI in the second test. In the third test, the general physician appeared to be confused by changes in the AI answers (from the faulty AI answers to the best performance AI answers). The sequential support by the faulty AI and then the best performance AI confused the general physicians because of their minimal endoscopy expertise. This highlights not only the importance of robust answers provided by the AI but also the importance of the baseline level of experience of AI users. Therefore, the conclusion from the previous study [6] that inexperienced doctors would benefit the most from AI support was not reproduced in this study. Rather, endoscopists having at least a certain level of expertise benefited from AI support.

Although this study established a high performance AutoDL model and rigorously validated the model's performance, this analysis has several inevitable limitations originating from potential bias in data sets. First, the training images were retrieved from a single institution, which might infer a selection or spectrum bias. Because of the unique characteristics of patients in each institution, medical AI models developed from a single institution usually have limitations for widespread implementation, indicating the importance of the external test [5]. To compensate for this pitfall, we performed two rounds of prospective validations and included images from another institution. Second, the efficacy of inference for each established model was not measured in clinical practice. Each established AutoDL model employs a specified inference method, such as website-based inference or edge computing–based application inference. The efficacy of inference includes inference speed, accuracy, easy applicability, simple control flow, energy efficiency, and model size. Because inference is a different field from that of this study, another comparative study will have to be conducted for the best inference AutoDL model. Recently developed machine learning or DL models in gastrointestinal endoscopy are focused on improving the effectiveness rather than the interpretability or efficiency. The most accurate model in our study also showed longer establishment time than the other models. There have been efficiency-effectiveness trade-offs in the field of DL models. Although real-world clinical application or inference time was not the primary outcome in this study, efficiency-effectiveness trade-offs should be considered in the context of real-world settings. Third, a relatively small number of raters were included in the endoscopist-AI interaction test. We only included one representative physician in each endoscopy expertise level. Large-scale studies evaluating more discrete expertise levels would elucidate the future perspectives for the implementation of AutoDL models in the clinical setting.

AutoDL has been considered as a useful tool for the on-site establishment of customized DL models, and anyone can create an AI model with the help of AutoDL. An inexperienced endoscopist with at least a certain level of expertise can benefit from AutoDL support.

Abstract

Background: Undifferentiated type of early gastric cancer (U-EGC) is included among the expanded indications of endoscopic submucosal dissection (ESD); however, the rate of curative resection remains unsatisfactory. Endoscopists predict the probability of curative resection by considering the size and shape of the lesion and whether ulcers are present or not. The location of the lesion, indicating the likely technical difficulty, is also considered.

Objective: The aim of this study was to establish machine learning (ML) models to better predict the possibility of curative resection in U-EGC prior to ESD.

Methods: A nationwide cohort of 2703 U-EGCs treated by ESD or surgery were adopted for the training and internal validation cohorts. Separately, an independent data set of the Korean ESD registry (n=275) and an Asan medical center data set (n=127) treated by ESD were chosen for external validation. Eighteen ML classifiers were selected to establish prediction models of curative resection with the following variables: age; sex; location, size, and shape of the lesion; and whether ulcers were present or not.

Results: Among the 18 models, the extreme gradient boosting classifier showed the best performance (internal validation accuracy 93.4%, 95% CI 90.4%-96.4%; precision 92.6%, 95% CI 89.5%-95.7%; recall 99.0%, 95% CI 97.8%-99.9%; and F1 score 95.7%, 95% CI 93.3%-98.1%). Attempts at external validation showed substantial accuracy (first external validation 81.5%, 95% CI 76.9%-86.1% and second external validation 89.8%, 95% CI 84.5%-95.1%). Lesion size was the most important feature in each explainable artificial intelligence analysis.

Conclusions: We established an ML model capable of accurately predicting the curative resection of U-EGC before ESD by considering the morphological and ecological characteristics of the lesions.

Introduction

Endoscopic submucosal dissection (ESD) is indicated for the treatment of patients with early gastric cancer (EGC) satisfying prespecified criteria, including histology, according to the differentiation, specific lesion size, morphology, and whether ulcers are present or not in the target lesion. The long-term prognosis following ESD for cases of EGC meeting the ESD criteria (achievement of curative resection) is comparable to that achieved with surgical resection [1,2]. In the context of histology, the undifferentiated type of EGC (U-EGC) generally refers to poorly differentiated adenocarcinoma, signet-ring cell carcinoma, or mucinous adenocarcinoma [3,4]. Although U-EGC is included among the expanded indications of ESD (mucosal U-EGC<2 cm without ulceration and without evidence of lymphovascular invasion), the rate of curative resection in U-EGC has remained very low—reported previously as 61.4% in a meta-analysis and 36.4% in a nationwide cohort study in Korea [5,6]. This implies that an unmet need persists regarding the accurate prediction of curative resection in U-EGC (ie, difficulty in adopting a precise ESD indication). Therefore, proper candidate selection prior to ESD is important.

Endoscopists predict the probability of curative resection by considering the size and shape of the lesion and whether ulcers are present or not. These components together compose the indications of ESD. In addition, lesion location, which can suggest the expected technical difficulty during the procedure and hint at the general condition of the patient, is also considered prior to conducting ESD. However, U-EGC has distinctive growth patterns relative to differentiated-type EGC [3,4,6,7]. U-EGC is known to extend laterally along the proliferative zone in the intermediate layer of the mucosa (subepithelial spreading), and the development pattern from the intermediate layer could lead to nonexposure to the surface mucosa, limiting the precise measurement of lesion size [5,8]. Subepithelial-spreading signet-ring cell carcinoma is more prevalent than the epithelial-spreading type in cases with background atrophy or intestinal metaplasia of the gastric mucosa [9,10]. Further, ESD of poorly differentiated adenocarcinoma presents a stronger association with submucosal invasion relative to that of signet-ring cell carcinoma [6]. Although adopting a precise indication is a key ability of endoscopists, U-EGC itself is a risk factor for a greater out-of-indication rate, leading to noncurative resection [11,12].

With the extensive production and collection of ongoing medical data, the application of artificial intelligence has been attempted in clinical practice [13]. Machine learning (ML) is a mathematical artificial intelligence algorithm automatically built from given data to predict precise outcomes in uncertain conditions without being explicitly programmed [14]. Examples of ML include Bayesian inferences, decision trees, support vector machines, deep neural networks, or ensemble methods (bagging or boosting) [14]. In short, ML is a type of applied statistical technique and is characterized by high accuracy. We aimed to establish an ML model to better predict the possibility of curative resection in U-EGC prior to ESD.

Methods

Ethical Statement

This study was approved by the Institutional Review Board of the Chuncheon Sacred Heart Hospital, Korea (no. 2020-07-019). It adhered to the principles expressed in the Declaration of Helsinki.

Data Sets

A nationwide cohort of 2703 U-EGCs treated by ESD (n=967) or surgery (n=1736) from 2006 to 2015 composed the training and internal validation groups. Eligible subjects were retrospectively enrolled from 18 university hospitals in Korea. Separately, an independent data set involving the Korean ESD registry with 275 U-EGCs and an Asan medical center data set with 127 U-EGCs treated by ESD were used for external validation. Subjects in the Korean ESD registry data set were retrospectively identified from 8 institutions of Korea [6], having been treated with ESD from 2006 to 2015, while subjects in the Asan medical center data set were treated by ESD from 2007 to 2013. All these data sets were mutually exclusive.

ML Models

All the currently available types of supervised ML classifiers were tested for the establishment of a curative resection prediction model in U-EGC. In total, 18 ML classifiers were assessed, including naïve Bayes in Bayesian inferences, linear-discriminant analysis, logistic regression in generalized linear modeling, linear support vector machine, stochastic gradient descent, decision tree, k-nearest neighbors, deep neural networks, bagging ensemble methods (bagging classifier, random forest, and voting classifier), boosting ensemble methods (gradient boosting, adaptive boosting, categorical Boosting, extreme gradient boosting [XGBoost], light gradient boosting machine, histogram-based gradient boosting), and a stacking ensemble method (stacking classifier). The Gaussian Naïve Bayes classifier is a model based on the Bayes' theorem encompassing the assumption that there is independence between the features. A generalized linear model is the extension of a linear model set up to include cases where the dependent variable is not normally distributed. We adopted the logistic regression classifier for this study. The support vector machine is a model that defines a decision boundary (hyperplane), that is, a reference line for classification. The stochastic gradient descent is a model for linear classifiers under convex loss functions such as support vector machine and logistic regression [15]. The decision tree is an algorithm that automatically finds rules in the data and creates tree-based classification rules.

k-nearest neighbors is a classification or clustering algorithm that relies on distance metrics measures for similarity. Deep neural networks refer to an artificial neural network with multiple hidden layers between the input and output layers that learns from input data and optimizes the output classification with mathematical calculations. Ensemble algorithms combine multiple classification models to achieve better performance and can be classified as either bagging, boosting, or stacking methods. Bagging is a parallel ensemble method that fits individual random samples of the data set and aggregates the predictions of each model for the final classification (bootstrap aggregation) [15]. This meta-estimator can reduce the variance of each classification model by introducing randomization for the model establishment and then creating an ensemble out of it. As such, bagging reduces overfitting of the ML model [15]. Separately, boosting algorithms attempt to conduct ensemble modeling sequentially by learning from the errors of the previous model and updating the weight of subsequent models to optimize the loss functions and reduce the overall bias. In contrast with learning from homogenous weak models in the bagging and boosting algorithms, stacking algorithms learn from heterogeneous models, creating a meta-model for the final classification. For the current ML analysis of this study, we used bagging classification, random forest, and voting classification for the bagging ensemble methods and gradient boosting, adaptive boosting, categorical boosting, XGBoost, light gradient boosting machine, and histogram-based gradient boosting for the boosting methods. For the stacking algorithm, we chose stacking classification. All the ML classifiers were imported from the scikit-learn package version 0.23.2 using the Python programming language (version 3.8.5, Python Software Foundation). Figure 1 shows the types of ML classifiers examined in this study.

Figure 1. Machine learning classifiers used in this study. Variables, Primary Outcome, and Data Splitting

A total of 18 ML classifiers were used for the establishment of prediction models of curative resection with the following variables: age; sex; location, size, and shape of the lesion; and whether ulcers were present or not. The primary outcome was the accuracy of the established ML models for the prediction of curative resection with the given variables of the lesions. Thus, the main metric was the classifying accuracy. Each data set was prepared in the .csv file format. After uploading .csv files to the Google Colaboratory analysis platform, 2703 U-EGC data points were randomly split into training and internal validation sets according to a ratio of 9:1.

Definitions of the Variables

Among the variables used in this study, patient age and the size of the lesion were the continuous variables and the others were considered as categorical variables. The location of the lesion was categorized by both longitudinal location (lower-third, mid-third, and upper-third) and circular location (lesser curvature, greater curvature, posterior wall, and anterior wall). The shape of the lesion was defined in accordance with the Japanese classification: elevated, flat, or depressed according to the morphological characteristics. According to this system, type I (protruded) and type IIa (superficial elevated) were considered as elevated, type IIb (flat) and type IIc (superficial depressed) were considered as flat, and type III (excavated) was considered as depressed [4]. Curative resection was defined as complete resection of U-EGC with a diameter of 2 cm or less and a lesion confined to the mucosa, with negative lateral and deep resection margins and lymphovascular invasion. Noncurative resection referred to cases in which the resected lesion did not fulfill these criteria.

Statistical Analysis and Explainable Artificial Intelligence

Continuous variables were expressed as mean (SD) and categorical variables were expressed as numbers and percentages. Descriptive synthesis was conducted to reveal the baseline characteristics of the training and internal validation data set and external validation data set. To add to the interpretability of the established ML model, we performed an explainable artificial intelligence analysis. To elucidate the variables associated with lesions either accurately or inaccurately determined by the ML model, univariable analysis was conducted (Student *t* test and Fisher exact test for continuous and categorical variables, respectively). A two-tailed *P* value

of less than .05 was adopted as the threshold for statistical significance. These analyses were performed using SPSS version 24.0. (IBM Corporation). Additionally, a feature importance (or permutation importance) analysis was completed to reveal which variables primarily contributed to the model's decision process [16,17]. This assessment measures the predictive error when a certain feature value is randomly shuffled; therefore, insignificant features do not affect the performance of the model [15]. Feature importance is measured by the F-score, which represents the ratio between the explained and the unexplained variance [17]. A decision process tree was plotted to visualize the step-by-step process of the decision making of the established ML model using the Graphviz package (version 0.14.1; AT&T Labs Research). A partial-dependence plot tool box (version 0.2.0) in the scikit-learn package to visualize the important features for the ML model was adopted and the target plot and interaction plot were visualized [18,19]. A Shapley additive explanations (version 0.35.0) analysis is an approach used to explain the output of any ML model using Shapley values and the degree of independence between features. The Shapley value expresses how much each feature contributes to creating the overall performance and represents feature importance while maintaining consistent and locally accurate additive feature attribution for a particular prediction [20].

Results

Characteristics of the Training, Internal Validation, and External Validation Data Sets

The training and internal validation data sets contained not only endoscopically resected cases but also surgically removed cases of U-EGC. The first external validation data set was composed of a nationwide cohort of cases of ESD performed for U-EGC, while the second external validation data set consisted of cases of ESD performed for U-EGC from a single hospital with the largest degree of ESD experience to date in Korea. Therefore, the included data sets were marked by different clinical characteristics. Table 1 presents the detailed clinical characteristics of the included lesions in this study. A male sex predominance was consistently observed in all data sets. Patient age ranged from 64.1 (SD 13.0) years to 67.8 (SD 12.0) years. In the context of endoscopic findings, the lower-third part in the longitudinal location (2069/2703, 76.5% and 214/275, 77.8%) and lesser curvature in the circular location (97/275, 34.5% and 945/2703, 34.9%) were the most frequent lesion positions in the training and internal validation dataset and first external validation data set, respectively. Meanwhile, the mid-third part was the most frequent lesion location in the longitudinal location (61/127, 48.1%) for U-EGC in the second external validation data set. The mean endoscopic size of the included lesions ranged from 21.7 (SD 12.5) mm to 27.9 (SD 16.2) mm. Depressed lesions (type IIc) were observed as the most frequent morphological type in the training and internal validation data set and second external validation data set (1762/2703, 65.2% and 62/127, 48.8%, respectively), while the first external validation presented an even distribution of elevated, flat, and depressed lesion morphologies. Meanwhile, 63 (22.9%) and 16 (12.6%) cases had ulcers in the first and second external validation data sets, respectively. The overall rate of curative resection ranged from 36.4% (100/275) to 74.4% (2010/2703).

Table 1. Baseline characteristics of the included data sets.

Characteristics	Training and internal validation set (n=2703)	First external validation set (n=275)	Second external validation set (n=127)
Sex, n (%)			
Male	1427 (52.8)	165 (60.0)	80 (62.9)
Female	1276 (47.2)	110 (40.0)	47 (37.0)
Age (years), mean (SD)	65.9 (12.4)	67.8 (12.0)	64.1 (13.0)
Longitudinal location, n (%)			
Lower-third	2069 (76.5)	214 (77.8)	53 (41.7)
Mid-third	336 (12.4)	28 (10.2)	61 (48.1)
Upper-third	298 (11.0)	33 (12.0)	13 (10.2)
Circular location, n (%)			
Lesser curvature	945 (34.9)	95 (34.5)	49 (38.6)
Greater curvature	557 (20.6)	58 (21.1)	27 (21.3)
Posterior wall	585 (21.6)	68 (24.7)	22 (17.3)
Anterior wall	607 (22.5)	54 (19.6)	29 (22.8)
More than 2 areas involved	9 (0.3)	0 (0)	0 (0)
Endoscopic size of the lesion (mm), mean (SD)	21.7 (12.5)	27.9 (16.2)	21.7 (12.6)
Morphology, n (%)			
Elevated	375 (13.9)	101 (36.7)	28 (22.1)

Curative resection, n (%)			
Yes	2010 (74.4)	100 (36.4)	87 (68.5)
No	693 (25.6)	175 (63.6)	40 (31.5)

Internal Validation Performance

Table 2 shows the prediction performance of 18 ML classifiers for internal validation. The XGBoost classifier demonstrated the best performance as follows: internal validation accuracy 93.4%, 95% CI 90.4%-96.4%; precision 92.6%, 95% CI 89.5%–95.7%; recall 99.0%, 95% CI 97.8%-99.9%; and F1 score 95.7%, 95% CI 93.3%-98.1%. In detail, the XGBoost classifier required several parameter settings for the establishment of the ML model. The initial classifying performance of the XGBoost classifier established by us was as follows: internal validation accuracy 79.0%, 95% CI 74.1%-83.9%; precision 80.9%, 95% CI 76.2%-85.6%; recall 94.1%, 95% CI 91.3%-96.9%; and F1 score 87.0%, 95% CI 83.0%-91.0%. To discern the optimal hyperparameter setting for the establishment of the ML model, we relied on the GridSearchCV library (version 0.22) [15] to automatically search among multiple optimal parameter values to fit estimators of an ML model. By using the GridSearchCV analysis, we found the optimal hyperparameters for the best performance as follows: learning rate 0.4, maximum depth 6, and number of estimators 100. Figure 2 shows the confusion matrix for the XGBoost classifier in the internal validation data set.

Table 2. Internal validation performance for the prediction of curative resection of undifferentiated type of early gastric cancer by using 18 machine learning classifiers.

Machine learning classifier	Accuracy (%) (95% CI)	Precision (%) (95% CI)	Recall (%) (95% CI)	F1 score (%) (95% CI)
Gaussian Naïve Bayes	73.8 (68.6-79.0)	86.2 (82.1-90.3)	77.2 (72.2-82.2)	81.5 (76.9-86.1)

External Validation Performance in the XGBoost Classifier

For the first external validation data set, the XGBoost classifier demonstrated its performance as follows: external validation accuracy 81.5%, 95% CI 76.9%-86.1%; precision 83.6%, 95% CI 79.2%-88.0%; recall 61.0%, 95% CI 55.2%-66.8%; and F1 score 70.5%, 95% CI 65.1%-75.9%. Then, for the second external validation data set, the XGBoost classifier demonstrated its performance as follows: external validation accuracy 89.8%, 95% CI 84.5%-95.1%; precision 90.2%, 95% CI 85.0%-95.4%; recall 95.4%, 95% CI 91.8%-99.0%; and F1 score 92.7%, 95% CI 88.2%-97.2%. Figure 3 and Figure 4 show the confusion matrices for the XGBoost classifier in the first and second external validation data sets, respectively.

Figure 3. Confusion matrix for the extreme gradient boosting classifier in the first external validation cohort. XGBoost: extreme gradient boosting.

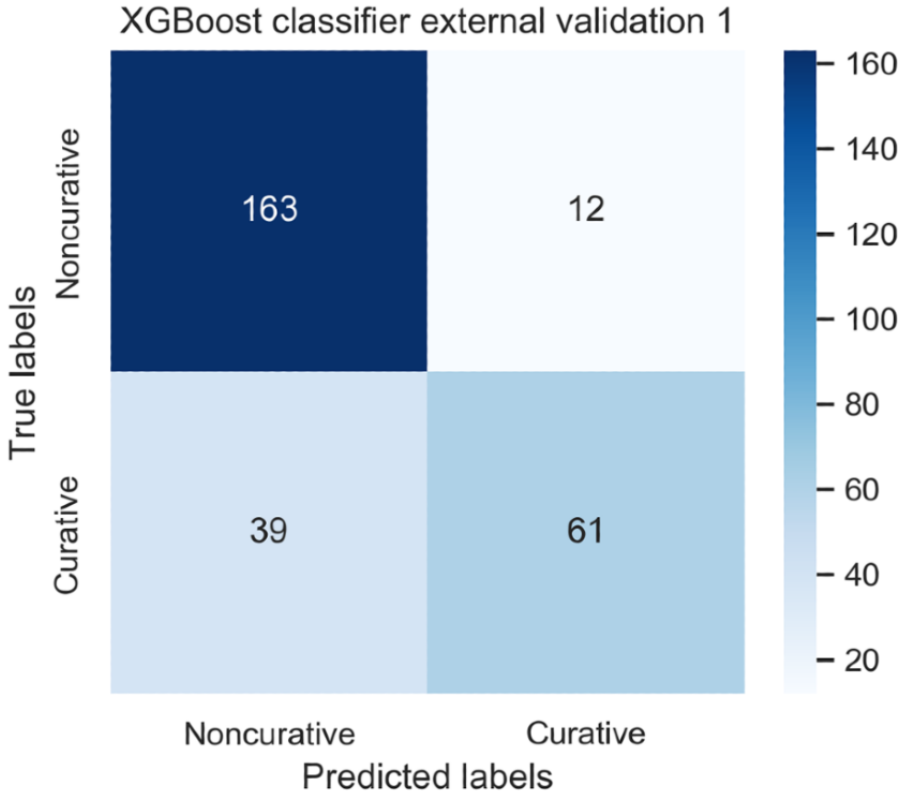

Figure 4. Confusion matrix for the extreme gradient boosting in the second external validation cohort. XGBoost: extreme gradient boosting.

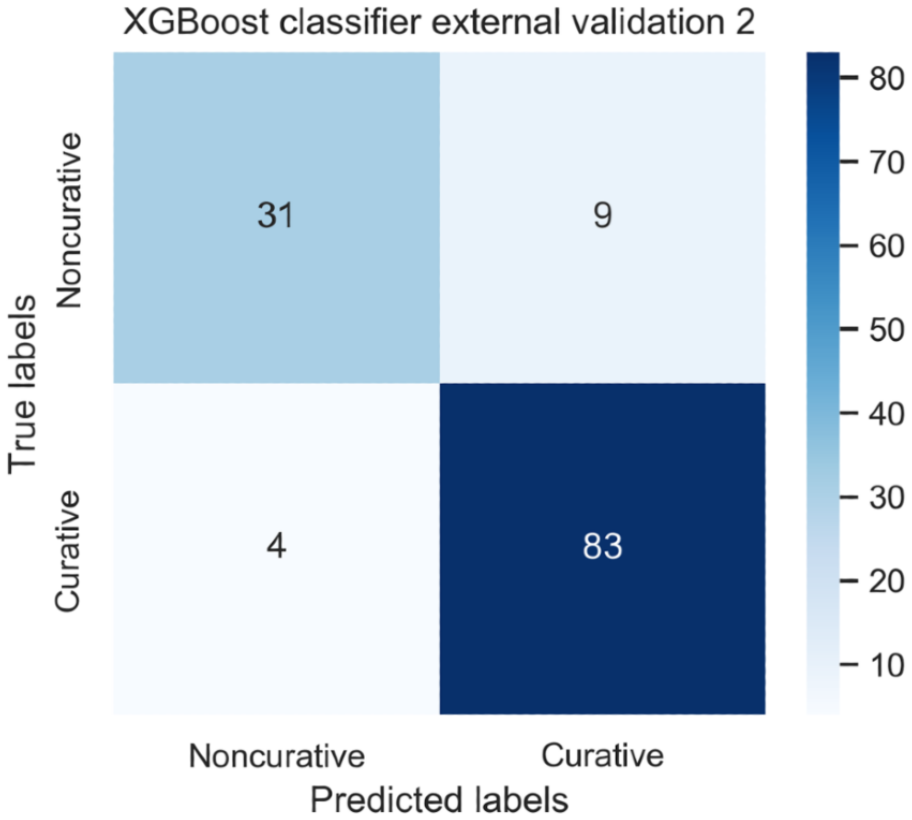

Explainable Artificial Intelligence

Table 3 shows the univariable analysis for the associated factors of lesions determined accurately or inaccurately in the curative resection of U-EGC by the XGBoost classifier. Notably, there was no single significant factor associated with lesions determined either accurately or inaccurately by the XGBoost classifier.

Table 3. Univariable analysis of the associated factors of lesions determined accurately or inaccurately in the curative resection of undifferentiated type of early gastric cancer by the extreme gradient boosting classifier.

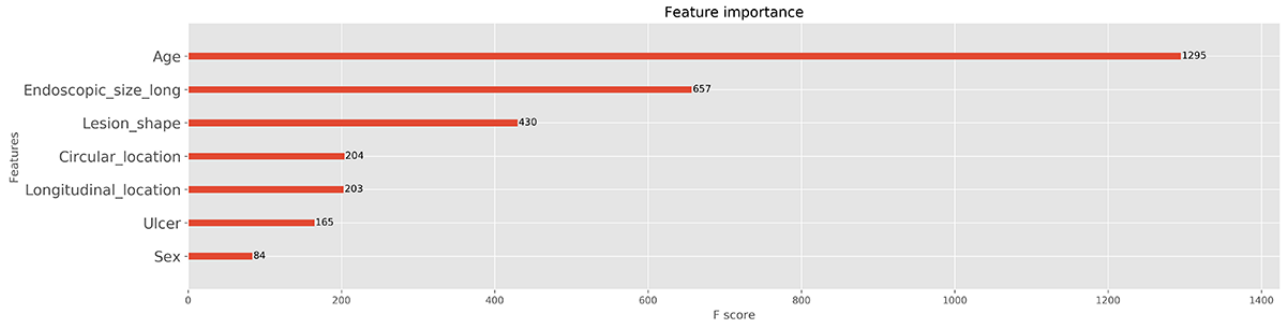
[a]XGBoost: extreme gradient boosting.

Figure 5 shows the feature importance plot for the XGBoost classifier. Age, endoscopic size, and morphology of the lesions were the three most significant factors for the establishment of the ML model, in sequence. Multimedia Appendix 1 illustrates the decision process tree for the XGBoost classifier prior to adopting the GridSearchCV library. This simplified tree shows the step-by-step determination process of the ML model. The final leaf score is inserted in the following equation: $p(x) = 1 / 1 + e^{-leaf\ score}$. Any value over 0.5 (50%) indicates curative resection and any value less than 0.5 indicates noncurative resection, as predicted by the XGBoost classifier [21]. Multimedia Appendix 2 shows the final decision process tree for the XGBoost classifier after adopting the GridSearchCV library, which presented the best performance in the internal validation. Endoscopic size of the lesion, patient age, and longitudinal location of the lesion were the important factors, in sequence. Multimedia Appendix 3 shows the partial-dependence target plot for the feature of endoscopic size of the lesion in the first external validation assessment. The probability of curative resection for the lesions with sizes ranging from 4 mm to 10 mm reached 80%. Meanwhile, U-EGC lesions with sizes ranging from 20.78 mm to 26.22 mm showed the lowest probability of curative resection at 16.1%. Multimedia Appendix 4 presents the two-way partial-dependence target plot for the features of endoscopic size of the lesion and patient age in the first external validation cohort. Given that the color of the circle above the imaginary line of Y=X is darker than that below the line, the endoscopic size and age are suggested to be correlated with curative resection of U-EGC. Multimedia Appendix 5 shows the partial-dependence interaction plot for the features of endoscopic size of the lesion and age in the first external validation group. Given that the contour lines are generally parallel to the Y-axis, the probability of curative resection is more dependent on the endoscopic size of the lesion. Since the feature importance analysis measures the prediction error after permutating the features' values, the results can be skewed when the said features exhibit dependency. However, the Shapley value considers the influence of the features on each other. Multimedia Appendix 6 and Multimedia Appendix 7 demonstrate the summary plot and bar plot of the Shapley additive explanations analysis, respectively, where endoscopic

size of the lesion and age are the important features for the model output.

Figure 5. Feature importance plot for the extreme gradient boosting classifier in the internal validation cohort. The average F-score was calculated through 50 repetitions of five-fold cross-validation in the training data set.



Discussion

This study introduces the good performance of an ML model applied to the prediction of curative resection of U-EGC prior to ESD, suggesting the possibility of a beneficial effect of ML modeling for decision making in this part of clinical practice [22]. Moreover, thorough external validations confirmed the higher rate of curative resection predicted by ML modeling as compared with curative resection rates reported by clinicians. To our knowledge, this is the first study to establish and confirm the predictive performance of an artificial intelligence model for the therapeutic outcomes of ESD for U-EGC. Indeed, ML is characterized as a computer-aided prediction method and its most important benefit in this context consists of the improvement in predictive accuracy for curative resection prior to ESD. The proper selection of candidates for ESD is essential before beginning ESD. The most fundamental hypothesis is that endoscopic resection can be performed with curative intent in cases of EGC without lymph node metastasis. Therefore, indications of ESD were established using a combination of factors associated with a negligible lymph-node metastasis rate from the retrospective analysis of surgically resected specimens [3]. These indications are categorized by differentiated-type EGC and U-EGC according to the differentiation, specific size, and morphological and histological conditions of the involved lesion. However, optical endoscopic determination of the factors stated above involves operator-dependent characteristics. In the study of a Korean multicenter registry of ESD for U-EGC, there was a discrepancy between pre-ESD indications and post-ESD criteria in 36.7% of all the lesions [6]. Underestimation of the size was the most common reason for noncurative resection (71.4%), followed by underestimation of the depth of invasion (32%) and unpredictability of lymphovascular invasion (14.9%) [6]. Although adopting a precise indication is important, U-EGC itself is a risk factor for an enhanced out-of-indication rate, leading to noncurative resection; therefore, more strict indications might be necessary for pursuing the ESD of U-EGC [11,12].

Another important finding of this study is the presentation of the determination reason or process of the ML model through the explainable artificial intelligence analysis. Notably, there is a tradeoff between accuracy and interpretability in the classification model of ML [14]. Although the ML approach exhibited high degrees of accuracy based on complex calculations, it is characterized by low interpretability (artificial intelligence is more generally characterized as being of a “black-box nature”) [14]. Conventional statistical analyses such as univariate or multivariate logistic regression analyses in previous studies have shown the reasons underlying the lower curative resection rate of ESD for U-EGC [5,6]. However, there is a limitation in the explanatory power of the overall model (low accuracy) in these studies. The XGBoost classifier used parallel-tree boosting analysis to provide highly efficient and accurate predictions. Through the ensemble model and extensive explainable artificial intelligence analysis, we identified the size of the lesion as being the most important feature for the successful prediction of curative resection in the ESD of U-EGC. Although a prospective trial of ESD for U-EGC that satisfied the expanded indication reported an excellent long-term survival rate [6,23,24], more cautious application or restriction of ESD indications has been recommended, especially regarding the size categorization [3,25]. Most recently published studies have also indicated that small intramucosal U-EGC lesions measuring less than 1.0 cm or 1.5 cm without lymphovascular invasion should be considered as the ESD candidate [26,27]. The explainable artificial intelligence analysis in our study also revealed that U-EGC lesions of less than 1 cm have the greatest probability of curative resection (Multimedia Appendix 3). Considering that the aim of this study was not the validation of current ESD criteria, further studies with robust analysis would elucidate the value of these findings.

In the context of ecological factors, age and gender have been tested with the endoscopic factors for the potential variable for the curative resection rate prediction. However, these variables were not consistently identified as important indicators for predicting curative resection [28-30]. Although feature importance analysis (Figure 5) or Shapley additive explanations analysis (Multimedia Appendix 6) in our study revealed that age is an important variable for the ML determination process, explainable artificial intelligence analysis is currently an experimental method to understand how ML judges. It is presumed that the reason ML shows higher accuracy than traditional statistics is that it performs a complex operation that considers all variables. It is true that age is an important factor influencing ML judgment, but further explainable artificial intelligence statistics can explain how much it affects the actual curative resection.

Although this study established and rigorously validated the predictive performance of the designed ML model, several inevitable limitations became apparent. First, there was some discrepancy in the validation performance between the first and second external data sets. The indications of ESD for U-EGC have not been approved by all endoscopists. Therefore, practice patterns adopting ESD indications for U-EGC have been heterogenous depending on the institution. The first external validation data set was more heterogenous with respect to the baseline characteristics and therapeutic outcomes. However, the second data set was collected from a single institution, thus providing a more discrete application pattern of the ESD indication for U-EGC. Second, patient age was an important feature in the explainable artificial intelligence analysis; however, this feature does not perfectly reflect the general condition of the patient. Further, there is no age factor for ESD indications. However, the general condition of the patients is frequently considered in the determination of whether to pursue ESD. Therefore, clinical factors that reliably reflect patients' health status other than age should be developed and considered so as to attain the most favorable therapeutic outcomes of ESD. Third, the training and internal validation data sets included cases that were surgically resected as well as endoscopically resected cases. Endoscopists decide whether to perform ESD or surgery when they detect U-EGC. In other words, it has not been determined which U-EGC is a candidate for ESD or surgery. All the U-EGCs resected with surgery or ESD were included as it was not always accurate and appropriate for the endoscopists to differentiate between ESD or surgery. If only U-EGCs that were resected by ESD were collected, a clear ESD candidate would have been collected, which in itself may be a selection bias. In conclusion, we established an ML model capable of accurately predicting the curative resection of U-EGC prior to ESD by considering the morphological and ecological characteristics of the lesions. A clinical application study in a randomized controlled manner would elucidate the real value of this ML model.

Acknowledgments

Funding for this research was provided by the Bio & Medical Technology Development Program of the National Research Foundation, the Korean government, Ministry of Science and ICT (grant number NRF2017M3A9E8033253), and the Korean College of Helicobacter and Upper Gastrointestinal Research Foundation Grant (2017-08). All investigators have access to the final data set. All the data are accessible and are available upon request by the corresponding author.

Authors' Contributions

CSB, WGS, JYA, JK, and IJC curated the data. CSB acquired the funds. CSB and WGS conceptualized this study, conducted the investigations, designed the methodology for this study, administered the project, performed the formal analysis, supervised the study, wrote the original draft, and reviewed and edited the manuscript. Abstract

Background: Artificial intelligence (AI) applications are growing at an unprecedented pace in health care, including disease diagnosis, triage or screening, risk analysis, surgical operations, and so forth. Despite a great deal of research in the development and validation of health care AI, only few applications have been actually implemented at the frontlines of clinical practice.

Objective: The objective of this study was to systematically review AI applications that have been implemented in real-life clinical practice.

Methods: We conducted a literature search in PubMed, Embase, Cochrane Central, and CINAHL to identify relevant articles published between January 2010 and May 2020. We also hand searched premier computer science journals and conferences as well as registered clinical trials. Studies were included if they reported AI applications that had been implemented in real-world clinical settings.

Results: We identified 51 relevant studies that reported the implementation and evaluation of AI applications in clinical practice, of which 13 adopted a randomized controlled trial design and eight adopted an experimental design. The AI applications targeted various clinical tasks, such as screening or triage (n=16), disease diagnosis (n=16), risk analysis (n=14), and treatment (n=7). The most commonly addressed diseases and conditions were sepsis (n=6), breast cancer (n=5), diabetic retinopathy (n=4), and polyp and adenoma (n=4). Regarding the evaluation outcomes, we found that 26 studies examined the performance of AI applications in clinical settings, 33 studies examined the effect of AI applications on clinician outcomes, 14 studies examined the effect on patient outcomes, and one study examined the economic impact associated with AI implementation.

Conclusions: This review indicates that research on the clinical implementation of AI applications is still at an early stage despite the great potential. More research needs to assess the benefits and challenges associated with clinical AI applications through a more rigorous methodology.

artificial intelligence; machine learning; deep learning; system implementation; clinical practice; review

Introduction

Background

Artificial intelligence (AI) has greatly expanded in health care in the past decade. In particular, AI applications have been applied to uncover information from clinical data and assist health care providers in a wide range of clinical tasks, such as disease diagnosis, triage or screening, risk analysis, and surgical operations [1-4]. According to Accenture analysis, the global health AI market is expected to reach US $6.6 billion by 2021

and has the potential to grow more than 10 times in the next 5 years [5].

The term "AI" was coined by McCarthy in the 1950s and refers to a branch of computer science wherein algorithms are developed to emulate human cognitive functions, such as learning, reasoning, and problem solving [6]. It is a broadly encompassing term that includes, but is not limited to, machine learning (ML), deep learning (DL), natural language processing (NLP), and computer vision (CV).

Researchers have devoted a great deal of effort to the development of health care AI applications. The number of related articles in the Google Scholar database has grown exponentially since 2000. However, their implementation in real-life clinical practice is not widespread [1,7]. Several reasons may account for this research-practice gap. Specifically, AI algorithms may be subject to technical issues, such as data set shift, overfitting, bias, and lack of generalizability [8], limiting the safe translation of AI research into clinical practice. Further, practical implementation of AI applications can be incredibly challenging. Examples of key challenges that need to be addressed include data sharing and privacy issues, lack of algorithm transparency, the changing nature of health care work, financial concerns, and the demanding regulatory environment [1,3,9-13]. However, the huge potential of health care AI applications can only be realized when they have been integrated into clinical routine workflows.

Research Gap

To the best of our knowledge, this review is the first to systematically examine the role of AI applications in real-life clinical environments. We note that many reviews have been carried out in the area of health care AI. One stream of reviews provided an overview of the current status of AI technology in specific clinical domains, such as breast cancer diagnosis [14], melanoma diagnosis [15], pulmonary tuberculosis diagnosis [16], stroke diagnosis and prediction [17], and diabetes management [18]. Another stream of reviews focused on comparing clinician performance and AI performance to provide the evidence base needed for AI implementation [19-21]. In contrast, our work differs from previous reviews in at least three aspects. First, we review clinical AI applications that provide decision support more broadly and hence do not restrict our scope to a specific clinical domain. Second, we focus on studies that reported the evaluation of clinical AI applications in the real world. We hence exclude studies that discussed the development and validation of clinical AI algorithms without actual implementation. Finally, we report a wide range of evaluation outcomes associated with AI implementation, such as performance comparison, clinician and patient outcomes, and economic impact.

On the other hand, we note that several viewpoint articles have provided a general outlook of health care AI [1-3,7,9,22]. These articles mainly provided insights into the current status of health care AI and selected a few clinical AI applications as illustrative examples. They might have also discussed the challenges associated with the practical implementation of AI. However, these articles did not discuss the progress of AI implementation that had been made in detail. In contrast, our work aims to provide a comprehensive map of the literature on the evaluation of AI applications in real-life clinical settings. By doing so, we summarize empirical evidence of the benefits and challenges associated with AI implementation and provide suggestions for future research in this important and promising area.

Objective

The objective of this systematic review was to identify and summarize the existing research on AI applications that have been implemented in real-life clinical practice. This helps us better understand the benefits and challenges associated with AI implementation in routine care settings, such as augmenting clinical decision-making capacity, improving care processes and patient outcomes, and reducing health care costs. Specifically, we synthesize relevant studies based on (1) study characteristics, (2) AI application characteristics, and (3) evaluation outcomes and key findings. Considering the research-practice gap, we also provide suggestions for future research that examines and assesses the implementation of AI in clinical practice.

Methods

Search Strategies

The systematic review was conducted following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines [23]. We searched PubMed, Embase, Cochrane Central, and CINAHL in June 2020 to identify relevant articles on AI applications that had been implemented in clinical practice. We limited our search to English-written peer-reviewed journal articles published between January 2010 and May 2020. We chose 2010 as the start period because health care AI research has since taken off.

We used two groups of keywords to identify terms in the titles, abstracts, and keywords of the publications. The first group of keywords had AI-related terms, including "artificial intelligence," "machine learning," and "deep learning." It is worth noting here that AI is a broadly encompassing term and also includes specific AI techniques, such as neural networks, support vector machines, decision trees, and NLP. However, studies using these techniques are highly likely to use "artificial intelligence" or "machine learning" in abstracts or keywords [24]. The second group of keywords had terms related to clinical implementation, including "clinical," "health," "healthcare," "medical," "implement," "implementation," "deploy," "deployment," and "adoption." Details of the search strategy can be found in Multimedia Appendix 1.

Eligibility Criteria

We downloaded and imported all of the identified articles using EndNote X9 (Thomson Reuters) for citation management. After removing duplicates, two researchers (JY and KYN) independently screened the titles and abstracts of the identified articles to determine their eligibility. Disagreements were resolved by discussion between the authors until consensus was reached. The inclusion criteria were as follows: (1) the study implemented an AI application with patients or health care providers in a real-life clinical setting and (2) the AI application provided decision support by emulating clinical decision-making

processes of health care providers (eg, medical image interpretation and clinical risk assessment). Medical hardware devices, such as X-ray machines, ultrasound machines, surgery robots, and rehabilitation robots, were outside our scope.

The exclusion criteria were as follows: (1) the study discussed the development and validation of clinical AI algorithms without actual implementation; (2) the AI application provided automation (eg, automated insulin delivery and monitoring) rather than decision support; and (3) the AI application targeted nonclinical tasks, such as biomedical research, operational tasks, and epidemiological tasks. We also excluded conference abstracts, reviews, commentaries, simulation papers, and ongoing studies.

Data Extraction and Charting

Following article selection, we created a data-charting form to extract information from the included articles in the following aspects: (1) study characteristics, (2) AI application characteristics, and (3) evaluation outcomes and key findings (Textbox 1).

Textbox 1. Components of the data-charting form.

Study characteristics

- Author, year
- Study design
- Involved patient(s) and health care provider(s)
- Involved hospital(s) and country of the study

Artificial intelligence (AI) application characteristics

- Application description
- AI techniques used (eg, neural networks, random forests, and natural language processing)
- Targeted clinical tasks
- Targeted disease domains and conditions

Evaluation outcomes and key findings

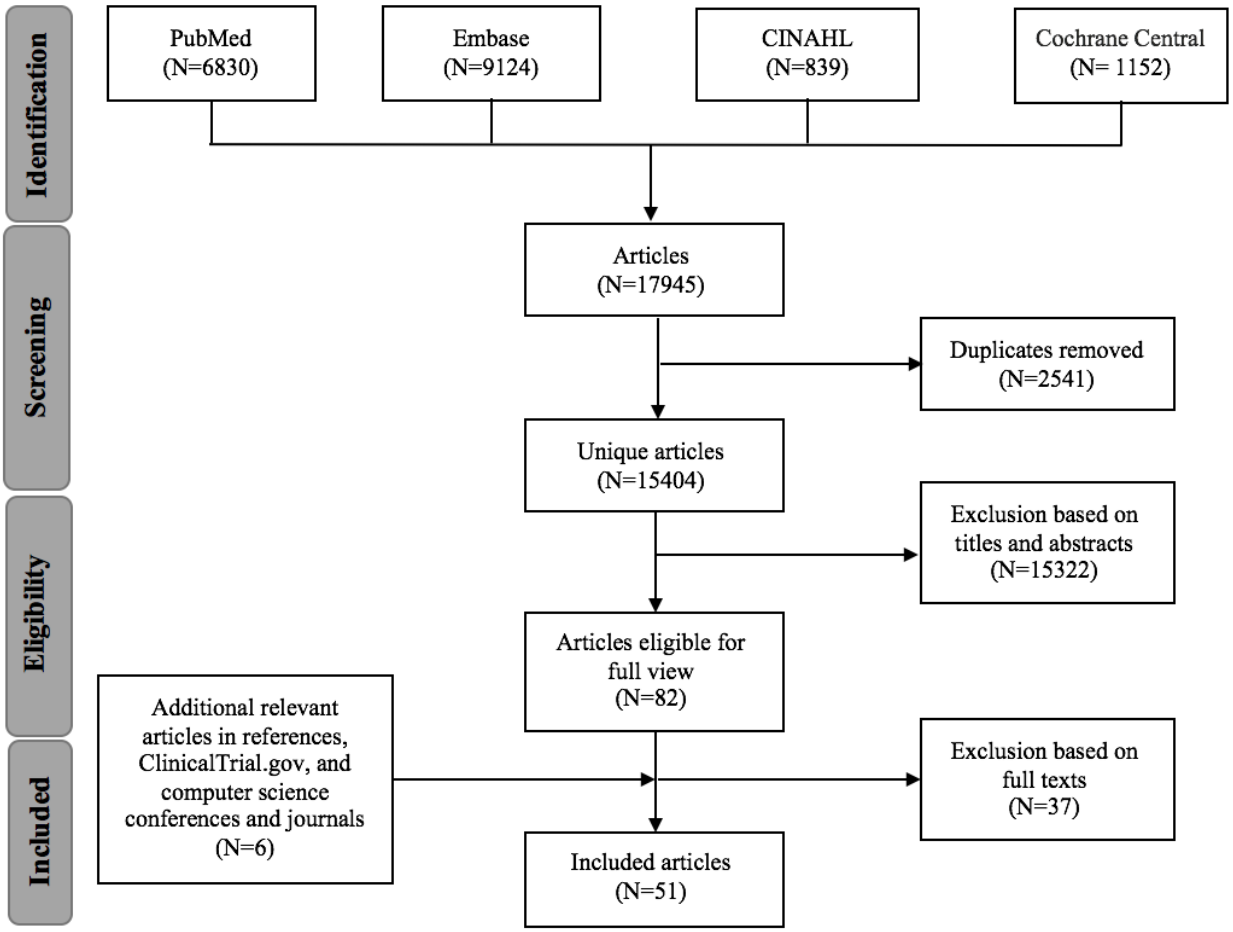
- Performance of AI applications
- Clinician outcomes
- Patient outcomes
- Cost-effectiveness

Results

Overview

Our initial search in June 2020 returned a total of 17,945 journal articles (6830 from PubMed, 9124 from Embase, 839 from CINAHL, and 1152 from Cochrane Central) (Figure 1). We first identified and excluded 2541 duplicates. After that, we excluded 15,322 articles after screening the titles and abstracts. Thus, 82 articles remained for full-text review, of which 45 were included in this review. Additionally, we identified six relevant articles by examining the references of the included articles, browsing through ClinicalTrial.gov using AI-related keywords, and hand searching premier computer science journals and conferences in AI (Multimedia Appendix 1). Finally, a total of 51 articles met our inclusion criteria.

Figure 1. Flow diagram of the literature search based on the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement.



Study Characteristics

Table 1 summarizes the authors, year of publication, study design, involved patients and health care providers, and involved hospitals [25-75]. As shown in Figure 2, there was a rising trend in the number of included studies in the last decade, with a recent peak in 2019, suggesting accelerated research activity in this area.

Regarding study design, the 51 studies included 20 observational studies (17 prospective studies and three retrospective studies), 13 randomized controlled trials (RCTs), eight experimental studies, four before-and-after studies, three surveys, one randomized crossover trial, one nonrandomized trial, and one structured interview. It is important to note that observational studies can be categorized into prospective and retrospective studies based on the timing of data collection. In prospective studies, researchers design the research and plan the data collection procedures before any of the subjects have the disease or develop other outcomes of interest. In retrospective studies, researchers collect existing data on current and past subjects, that is, subjects may have the disease or develop other outcomes of interest before researchers initiate research design and data collection.

Of the 51 studies, 29 (57%) explicitly mentioned the involved patients, two of which had a sample size smaller than 30. On the other hand, 28 (55%) studies provided information about the involved health care providers, of which 17 studies had 10 or fewer providers.

Additionally, 46 (90%) studies mentioned the involved hospitals or clinics (Figure 3). Of these, 36 studies were conducted in developed countries, with 20 conducted in the United States, five in the United Kingdom, two each in Australia, Canada, and Japan, one each in Germany, Israel, Spain, and the Netherlands, and one in the United States and South Korea. On the contrary, 10 studies were conducted in developing countries, with eight conducted in China, one in India, and one in India and Kenya.

Table 1. Characteristics of the included studies.

Author, year	Study design	Sample characteristics	Hospital (country)	Evaluation outcomes
Abràmoff et al, 2018 [25]	Observational study (prospective)	819 patients	10 primary care clinics (United States)	AP[a] (sensitivity, specificity, imageability rate)
Aoki et al, 2020 [26]	Experimental study (crossover design)	6 physicians	The University of Tokyo Hospital (Japan)	CO[b] (reading time, mucosal break detection rate)
Arbabshirani et al, 2018 [27]	Observational study (prospective)	347 routine head CT[c] scans of patients	Geisinger Health System (United States)	AP (AUC[d], accuracy, sensitivity, specificity) CO (time to diagnosis)
Bailey et al, 2013 [28]	Crossover RCT[e]	20,031 patients	Barnes-Jewish Hospital (United States)	PO[f] (ICU[g] transfer, hospital mortality, hospital LOS[h])
Barinov et al, 2019 [29]	Experiment (within subjects)	3 radiologists	NR[i]	AP (AUC) CO (diagnostic accuracy)
Beaudoin et al, 2016 [30]	Observational study (prospective)	350 patients (515 prescriptions)	Centre hospitalier universitaire de Sherbrooke (Canada)	AP (number of triggered recommendations, precision, recall, accuracy)
Bien et al, 2018 [31]	Experimental study (within subjects)	9 clinical experts	Stanford University Medical Center (United States)	AP (AUC) CO (specificity, sensitivity, accuracy)
Brennan et al, 2019 [32]	Nonrandomized trial	20 physicians	An academic quaternary care institution (United States)	AP (AUC) CO (risk assessment changes, AUC, usability)
Chen et al, 2020 [33]	RCT	437 patients	Renmin Hospital, Wuhan University (China)	CO (blind spot rate)
Connell et al, 2019 [34]	Before-after study	2642 patients	Royal Free Hospital, Barnet General Hospital (United Kingdom)	PO (renal recovery rate, other clinical outcomes, care process)
Eshel et al, 2017 [35]	Observational study (prospective)	6 expert microscopists	Apollo Hospital, Chennai (India); Aga Khan University Hospital (Kenya)	AP (sensitivity, specificity, species identification accuracy, device parasite count)
Giannini et al, 2019 [36]	Before-after study	22,280 patients in the silent period, 32,184 patients in the alert period	3 urban acute hospitals under University of Pennsylvania Health System (United States)	AP (sensitivity, specificity) PO (mortality, discharge disposition, ICU transfer, time to ICU transfer, clinical process measures)
Ginestra et al, 2019 [37]	Survey	43 nurses and 44 health care providers	A tertiary teaching hospital in Philadelphia (United States)	CO (nurse and provider perceptions)
Gómez-Vallejo et al, 2016 [38]	Observational study (retrospective)	1800 patients (2569 samples)	A Spanish National Health System hospital (Spain)	AP (accuracy) CO (system perceptions)
Grunwald et al, 2016 [39]	Observational study (retrospective)	15 patients, 3 neuroradiologists	A comprehensive stroke center (Germany)	AP (e-ASPECTS performance)
Kanagasingam et al, 2018 [40]	Observational study (prospective)	193 patients, 4 physicians	A primary care practice in Midland (Australia)	AP (sensitivity, specificity, PPV[j], NPV[k])
Keel et al, 2018 [41]	Survey	96 patients	St Vincent's Hospital, University Hospital Geelong (Australia)	AP (sensitivity and specificity, assessment time) PO (patient acceptability)
Kiani et al, 2020 [42]	Experimental study (within subjects)	11 pathologists	Stanford University Medical Center (United Kingdom)	AP (accuracy) CO (accuracy)
Lagani et al, 2015 [43]	Observational study (prospective)	2 health care providers	Chorleywood Health Centre (United Kingdom)	AP (system performance) CO (usability)

Author, year	Study design	Sample characteristics	Hospital (country)	Evaluation outcomes
Lin et al, 2019 [44]	RCT	350 patients	5 ophthalmic clinics (China)	AP (accuracy, PPV, NPV) CO (time to diagnosis) PO (patient satisfaction)
Lindsey et al, 2018 [45]	Experimental study (within subjects)	40 practicing emergency clinicians	Hospital for Special Surgery (United States)	AP (AUC) CO (sensitivity, specificity, misinterpretation rate)
Liu et al, 2020 [46]	RCT	1026 patients	No. 988 Hospital of Joint Logistic Support Force of PLA (China)	CO (ADR[l], PDR[m], number of detected adenomas and polyps)
Mango et al, 2020 [47]	Experimental study (within subjects)	15 physicians	13 different medical centers (United States)	AP (AUC, sensitivity, specificity) CO (AUC, interreliability, intrareliability)
Martin et al, 2012 [48]	Observational study (prospective)	214 patients	13 different medical centers (United States)	AP (sensitivity, PPV) PO (ACSC[n], care-supported activities)
McCoy and Das, 2017 [49]	Before-after study	1328 patients	Cape Regional Medical Center (United States)	PO (hospital mortality, hospital LOS, readmission rate)
McNamara et al, 2019 [50]	Observational study (prospective)	3 breast cancer experts	John Theurer Cancer Center (United States)	CO (decision making)
Mori et al, 2018 [51]	Observational study (prospective)	791 patients, 23 endoscopists	Showa University Northern Yokohama Hospital (Japan)	AP (NPV) CO (time to diagnosis)
Nagaratnam et al, 2020 [52]	Observational study (retrospective)	1 patient	Royal Berkshire Hospital (United Kingdom)	PO (patient care and clinical outcomes)
Natarajan et al, 2019 [53]	Observational study (prospective)	213 patients	Dispensaries under Municipal Corporation of Greater Mumbai (India)	AP (sensitivity, specificity)
Nicolae et al, 2020 [54]	RCT	41 patients	Sunnybrook Odette Cancer Centre (Canada)	AP (day 30 dosimetry) CO (planning time)
Park et al, 2019 [55]	Experimental study (within subjects)	8 clinicians	Stanford University Medical Center (United States)	CO (specificity, sensitivity, accuracy interrater agreement, time to diagnosis)
Romero-Brufau et al, 2020 [56]	Pre-post survey	81 clinical staff	3 primary-care clinics in Southwest Wisconsin (United States)	CO (attitudes about AI[o] in the workplace)
Rostill et al, 2018 [57]	RCT	204 patients, 204 caregivers	NHS, Surrey and Hampshire (United Kingdom)	CO (system evaluations) PO (early clinical interventions, patient evaluations)
Segal et al, 2014 [58]	Observational study (prospective)	16 pediatric neurologists	Boston Children's Hospital (United States)	CO (diagnostic errors, diagnosis relevance, number of workup items)
Segal et al, 2016 [59]	Observational study (prospective)	26 clinicians	Boston Children's Hospital (United States)	CO (diagnostic errors)
Segal et al, 2017 [60]	Structured interviews	10 medical specialists	Geisinger Health System and Intermountain Healthcare (United States)	CO (system perceptions)
Segal et al, 2019 [61]	Observational study (prospective)	3160 patients (315 prescription alerts)	Sheba Medical Center (Israel)	AP (accuracy, clinical validity, and usefulness) PO (changes in medical orders)
Shimabukuro et al, 2017 [62]	RCT	142 patients	University of California San Francisco Medical Center (United States)	PO (LOS, in-hospital mortality)

Author, year	Study design	Sample characteristics	Hospital (country)	Evaluation outcomes
Sim et al, 2020 [63]	Observational study (prospective)	12 radiologists	4 medical centers (United States and South Korea)	AP (sensitivity, FPPI[p]) CO (sensitivity, FPPI, decision change)
Steiner et al, 2018 [64]	Experimental study (within subjects)	6 anatomic pathologists	NR	CO (sensitivity, average review per image, interpretation difficulty)
Su et al, 2020 [65]	RCT	623 patients, 6 endoscopists	Qilu Hospital of Shandong University (China)	CO (ADR, PDR, number of adenomas and polyps, withdrawal time, adequate bowel preparation rate)
Titano et al, 2018 [66]	RCT	2 radiologists	NR	CO (time to diagnosis, queue of urgent cases)
Vandenberghe et al, 2017 [67]	Observational study (prospective)	1 pathologist and 2 HER2 raters	NR	CO (decision concordance, decision modification)
Voerman et al, 2019 [68]	Before-after study	NR	Five Rivers Medical Center, Pocahontas (United States)	CE[q] (average total costs per patient) PO (numbers of patients with clostridium difficile and antibiotic-resistant infections, LOS, antibiotic use)
Wang et al, 2019 [69]	RCT	1058 patients, 8 physicians	Sichuan Provincial People's Hospital (China)	CO (ADR, PDR, number of adenomas per patient)
Wang et al, 2019 [70]	RCT	75 patients	4 primary care clinics affiliated with Brigham and Women's Hospital (United States)	CO (anticoagulation prescriptions)
Wang et al, 2020 [71]	RCT	962 patients	Caotang branch hospital of Sichuan Provincial People's Hospital (China)	CO (ADR, PDR, number of adenomas and polyps per colonoscopy)
Wijnberge et al, 2020 [72]	RCT	68 patients	Amsterdam UMC (Netherlands)	PO (median time-weighted average of hypotension, median time of hypotension, treatment, time to intervention, adverse events)
Wu et al, 2019 [73]	Observational study (prospective)	3600 residents	3 ophthalmologists, community healthcare centers (China)	AP (AUC) CO (ophthalmologist-to-population service ratio)
Wu et al, 2019 [74]	RCT	303 patients, 6 endoscopists	Renmin hospital of Wuhan University (China)	AP (accuracy, completeness of photo documentation) CO (blind spot rate, number of ignored patients, inspection time) PO (adverse events)

Author, year	Study design	Sample characteristics	Hospital (country)	Evaluation outcomes
Yoo et al, 2018 [75]	Observational study (prospective)	50 patients, 1 radiologist	NR (Korea)	AP (sensitivity, specificity, PPV, NPV, accuracy) CO (sensitivity, specificity, PPV, NPV, accuracy)

[a]AP: application performance.
[b]CO: clinician outcomes.
[c]CT: computed tomography.
[d]AUC: area under the curve.
[e]RCT: randomized controlled trial.

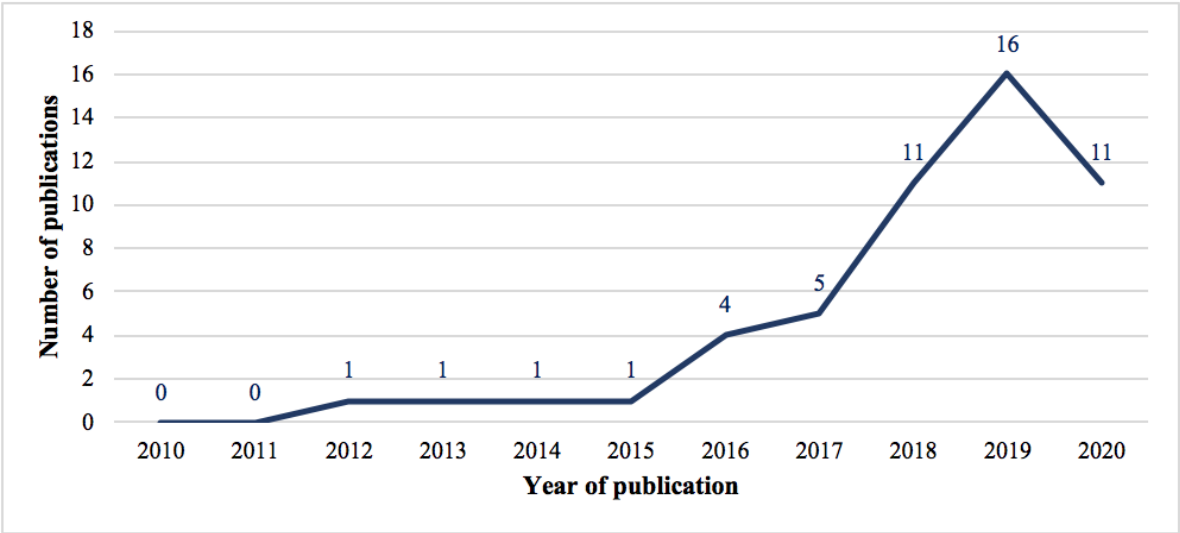

Figure 3. Country distribution of the involved hospitals.

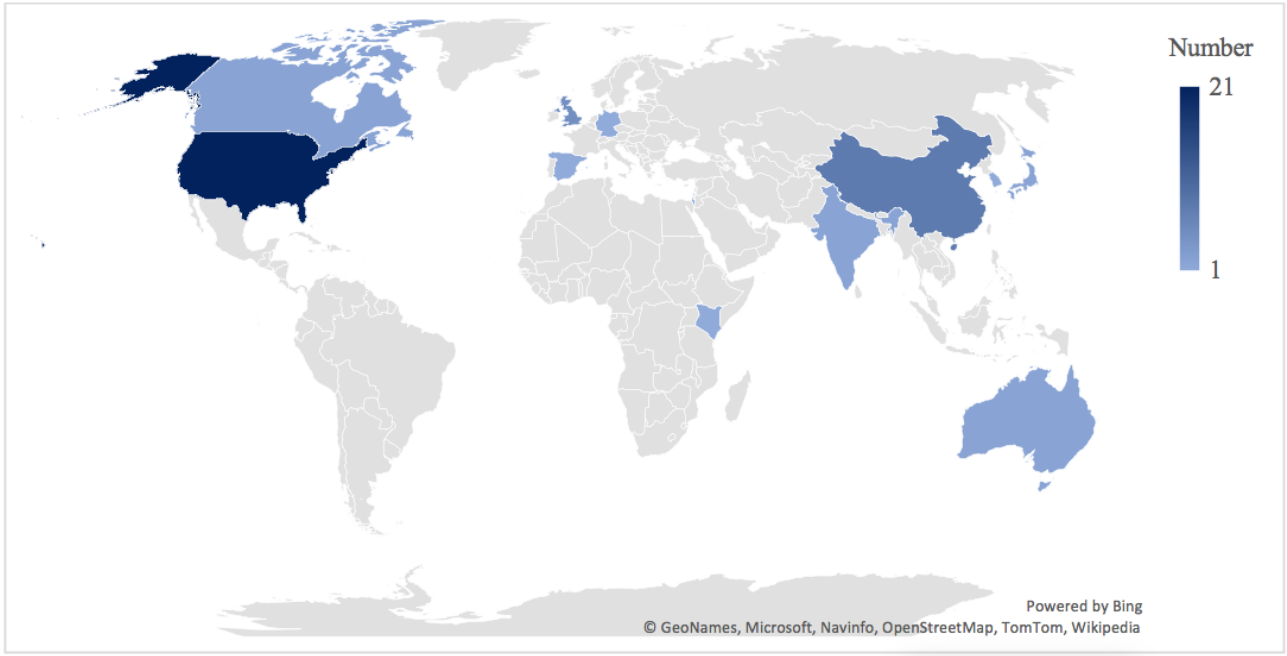

Quality Assessment

Considering the heterogeneity of study types included in the review, we only assessed the risk of bias of 13 RCTs using the Cochrane Collaboration Risk of Bias tool (Multimedia Appendix 2) [76]. Overall, the total score of the RCTs ranged from 0 [57] to 6 [44,65,69], with a mean value of 3.84. Specifically, eight studies reported random sequence generation [33,44,62,65,69,71,72], and three studies explicitly stated that the allocation was concealed [62,65,72]. Only two studies were double blinded [66,71]. Blinding of participants was unsuccessful in two studies [62,72] and was unclear in six studies [44,46,54,57,69,70]. Blinding of outcome assessment was unsuccessful in seven studies [33,46,62,65,69,70,74] and was unclear in one study [57]. Three studies did not clearly state whether they had complete data for the enrolled participants [57,66,77]. All of the 13 studies had a low risk of selective reporting bias. Other potential sources of bias included a small sample size [62,70,72], a short study period [62], and a lack of detailed information regarding RCTs and follow-ups [57,66].

AI Application Characteristics

Among the 51 studies, two did not disclose any information regarding the AI techniques used. Among the remaining 49 studies, the most popular ML technique was neural networks (n=22), followed by random forests (n=3), Bayesian pattern matching (n=3), support vector machine (n=2), decision tree (n=2), and deep reinforcement learning (n=2). We also found that the included AI applications mainly provided decision support in the following four categories of clinical tasks: disease screening or triage (n=16), disease diagnosis (n=16), risk analysis (n=14), and treatment (n=7). Further, AI applications in 46 (94%) studies targeted one or more specific diseases and conditions. The most prevalent diseases and conditions were sepsis (n=6), breast cancer (n=5), diabetic retinopathy (n=4), polyp and adenoma (n=4), cataracts (n=2), and stroke (n=2). Details of AI application characteristics are provided in Multimedia Appendix 3.

Evaluation Outcomes

We categorized the evaluation outcomes in our review studies into the following four types: performance of AI applications, clinician outcomes, patient outcomes, and cost-effectiveness, as can be seen in Table 1 and Multimedia Appendix 4.

Performance of AI Applications

Twenty-six studies evaluated the performance of AI applications in real-life clinical settings [25,27,29-32,35,36,38-43,45,47,48,51,52,54,61,63,73-75,78]. Commonly used performance metrics included accuracy, area under the curve (AUC), specificity, sensitivity, positive-predictive value (PPV), and negative-predictive value (NPV). Of these, 24 studies reported acceptable and satisfactory performance of AI applications in practice. For example, one study [25] conducted a pivotal trial of the IDx-DR diagnostic system (IDx, LLC) to detect diabetic retinopathy in 10 primary clinic offices in the United States. They reported that IDx-DR had a sensitivity of 87.2%, a specificity of 90.7%, and an imageability rate of 96.1%, exceeding prespecified endpoints. Based on the results, IDx-DR became the first Food and Drug Administration (FDA)–authorized AI diagnostic system, with the potential to improve early detection of diabetic retinopathy and prevent vision loss in thousands of patients with diabetes.

On the contrary, two studies found that AI applications failed to outperform health care providers and needed further improvement [40,44]. In particular, one RCT [44] examined the performance of CC-Cruiser, an AI-based platform for childhood cataracts, in five ophthalmic clinics in China. The authors found that CC-Cruiser had considerably lower accuracy, PPV, and NPV than senior consultants in diagnosing childhood congenital cataracts and making treatment decisions. Another study [40] evaluated the performance of an AI-based diabetic retinopathy grading system in a primary care office in Australia

and found that the AI system had a high false-positive rate with a PPV of 12%. Specifically, of the 193 patients who consented to the study, the AI system identified 17 patients with severe diabetic retinopathy that required referral. However, only two patients were correctly identified, and the remaining 15 patients were false positives.

Clinician Outcomes

Thirty-three studies examined the effect of AI applications on clinician outcomes, that is, clinician decision making, clinician workflow and efficiency, and clinician evaluations and acceptance of AI applications [26,27,29,31-33,37,38,42-47,50,51,54-60,64,65,67,69-71,73-75].

AI applications have the potential to provide clinical decision support. From our review, 16 studies demonstrated that AI applications could enhance clinical decision-making capacity [31-33,45-47,50,55,58,59,63,64,67,69,71,74,75]. For example, Brennan et al [32] found that clinicians gained knowledge after interacting with MySurgery, an algorithm for preoperative risk assessments, and improved their risk assessment performance as a result. On the contrary, two studies did not find any evidence for enhanced decision-making [26,42]. One possible explanation is that AI may provide misleading recommendations, offsetting the benefits of AI. Specifically, Kiani et al [42] evaluated the effect of a DL-based system for live cancer classification on the diagnostic performance of 11 pathologists and found that AI use did not greatly improve the diagnostic accuracy. They further noted that AI improved accuracy when it provided correct predictions and harmed accuracy when it provided wrong predictions. Aoki et al [26] examined the impact of a DL-based system for mucosal break detection on endoscopists in reading small bowel capsule endoscopy. They found that the system failed to improve the mucosal break detection performance of endoscopists, particularly trainees.

Seven studies were aimed at clinician workflow and efficiency [26,27,44,51,54,66,73]. Of these, six studies found that AI accelerated the time needed for clinical tasks and improved the existing workflow [26,27,44,51,54,66]. For example, Titano et al [66] found that a DL-based cranial image triage algorithm processed and interpreted images 150 times faster than human radiologists (1.2 seconds vs 177 seconds) and appropriately escalated urgent cases, enhancing the triage of cases in the radiology workflow. The only exception is the work of Wu et al [74], which assessed the quality improvement system WISENSE for blind-spot monitoring and procedure timing during esophagogastroduodenoscopy. This study found that WISENSE helped endoscopists monitor and control their time on each procedure and increased inspection time as a result.

Finally, clinician perceptions and acceptance of AI applications were examined in seven studies [32,37,38,43,56,57,60]. Particularly, five out of the seven studies reported overall positive perceptions of AI applications [32,38,43,57,60]. For example, Brennan et al [32] asked 20 surgical intensivists to use and evaluate MySurgeryRisk for preoperative risk prediction in a simulated clinical workflow. Most respondents indicated that MySurgeryRisk was useful and easy to use and believed that it would be helpful for decision making. On the other hand, the remaining two studies reported mixed or even negative evaluations of AI [37,56]. Specifically, Ginestra et al [37] assessed physician evaluations of an ML-based sepsis prediction system in a tertiary teaching hospital and found that only 16% of health care providers perceived system-generated sepsis alerts to be helpful. The negative evaluations could be attributed to providers' low confidence in alerts, low algorithm transparency, and a lack of established actions after alerts. Romero-Brufau et al [56] reported survey results from implementing an AI-based clinical decision support system in a regional health system practice and found that only 14% of clinical staff were willing to recommend the system. Staff feedback revealed that some system-recommended interventions were inadequate and inappropriate.

Patient Outcomes

Fourteen studies reported patient outcomes [28,34,36,41,44,48,49,52,57,61,62,68,72,74]. In 11 of the 14 studies, researchers examined the effect of AI on clinical processes and outcomes, such as hospital length of stay, in-hospital mortality, intensive care unit (ICU) transfer, readmission, and time to intervention [28,34,36, 48,49,52,57,61,62,68,72,74]. The results were inconsistent. Most studies reported improved clinical outcomes (n=8) [36,48,52,57,61,62,68,72,74]. For example, one RCT [62] implemented and assessed an ML-based severe sepsis prediction algorithm (Dascena) in two ICUs at the University of California San Francisco Medical Center. They found that the algorithm implementation greatly decreased the hospital length of stay from 13.0 days to 10.3 days and decreased the in-hospital mortality rate from 21.3% to 8.96%. However, three of the studies did not find evidence for improved clinical outcomes, indicating the limited applicability of the algorithms in their current form [28,34,36]. In particular, Bailey et al [28] examined the effect of an ML-based algorithm that generated real-time alerts for clinical deterioration in hospitalized patients. They found that providing alerts alone could not reduce the hospital length of stay and the in-hospital mortality. Connell et al [34] examined the effect of a novel digitally enabled care pathway for acute kidney injury management and found no step changes in the renal recovery rate and other secondary clinical outcomes following the intervention. Giannini et al [36] developed and implemented a sepsis prediction algorithm in a tertiary teaching hospital system. The results showed that the algorithm-generated alerts had a limited impact on clinical processes and could not reduce mortality, discharge dispositions, or transfer to the ICU. Future algorithm optimization is thus needed.

Three studies examined how patients evaluated AI applications, and all of them reported positive results [41,44,57]. Keel et al [41] evaluated patient acceptability of an AI-based diabetic retinopathy screening tool in an endocrinology outpatient setting. They found that 96% (92/96) of the screened patients were satisfied with the AI tool and 78% (43/55) of the patients in the follow-up survey preferred AI screening over manual screening, suggesting that the AI tool was well-accepted by patients. Lin et al [44] assessed patient satisfaction with CC-Cruiser for childhood cataracts and found that patients were slightly more satisfied with CC-Cruiser in comparison with senior consultants. One explanation is that childhood cataracts may cause

irreversible vision impairment and even blindness without early intervention. Therefore, parents of patients appreciated the faster diagnosis of CC-Cruiser. Rostill et al [57] assessed an Internet of Things (IoT) system for dementia care and found that dementia patients trusted the system and would like to recommend it.

Cost-Effectiveness

The economic impact of AI implementation in clinical practice was addressed in only one study [68]. This study reported that the implementation of an ML-based system for antibiotic stewardship reduced costs by US $25,611 for sepsis and US $3630 for lower respiratory tract infections compared with usual care.

Discussion

Principal Findings

AI applications have huge potential to augment clinician decision making, improve clinical care processes and patient outcomes, and reduce health care costs. Our review seeks to identify and summarize the existing studies on AI applications that have been implemented in real-life clinical practice. It yields the following interesting findings.

First, we note that the number of included studies was surprisingly small considering the tremendous number of studies on health care AI. In particular, most of the health care AI studies were proof-of-concept studies that focused on AI algorithm development and validation using retrospective clinical data sets. In contrast, only a handful of studies implemented and evaluated AI in a clinical environment. To ensure safe adoption, however, an AI application should provide solid scientific evidence for its effectiveness relative to the standard of care. Therefore, we urge the health care AI research community to work closely with health care providers and institutions to demonstrate the potential of AI in real-life clinical settings.

Second, more than two-thirds of the included articles were from developed economies, of which more than half were from the United States, suggesting that developed countries are at the forefront of health care AI development and deployment. This is consistent with the fact that top health AI companies and start-ups (eg, Google Health, IBM Watson Health, and Babylon Health) are mainly located in the United States and Europe. This finding should be interpreted with caution because we excluded non-English–written articles, even though our search had identified 890 non-English publications. We did not include these non-English articles because it is difficult to conduct an unbiased analysis owing to translation difficulty and variation. The imbalanced distribution of articles by country or economic development status could be attributed to the fact that researchers from low-income countries have a very low publication rate.

However, it is worth noting that 8 (16%) of our articles were from China, suggesting that China has been extensively applying health care AI and conducting health care AI research. Indeed, hospitals, technology companies, and the Chinese government have been driving clinical AI deployment with the aim to alleviate doctor shortages, relieve medical resource inequality, and reduce health care costs [79-82], and Chinese researchers have acquired the capability to publish in international English journals.

Third, the quality of research on clinical AI evaluation needs to be improved in the future. Our review revealed that only 13 (26%) studies were RCTs and most of them suffered from moderate to high risk of bias. Eight studies were experimental studies, and all of them adopted a cross-over design or within-subjects design and were hence susceptible to confounding effects. With respect to sample information, only 8 (16%) studies provided information on both patients and health care providers, and 14 (28%) studies used a sample size smaller than 20 (Table 1), limiting the generalizability of their results. Regarding the evaluation design, one-third of the studies (n=17, 33%) did not include a comparison group (Multimedia Appendix 4), limiting the ability to identify the added value of AI applications compared with the current best practice. Given that health care providers may hold different perceptions toward different AI systems of varying performance and reliability, it would be helpful if the studies provide a transparent description of the AI system's architecture, accuracy or reliability performance, and possible risks. Unfortunately, in our review, 21 studies did not provide adequate information about the architecture of the AI applications [25,29,32,34,37,44,46,50,52,54,56-62,65,68,70,75] and 22 studies did not reveal the performance and possible risks of AI under evaluation [26,29,34,37,39,46,48-50,52,54,56-62,64,65,68,69]. Further, considering that some self-evolving adaptive clinical AI applications continuously incorporate the latest clinical practice data and published evidence, it is important to undertake periodic monitoring and recalibration of AI applications to ensure that they are working as expected. Finally, we found that more than half of the studies (n=29, 57%) investigated only one aspect of evaluation outcome (Multimedia Appendix 4). We encourage future research to conduct a more comprehensive assessment of the quality of clinical AI applications as well as their impacts on clinicians, patients, and health care institutions. This will facilitate the comparison and selection of alternative AI solutions in the same clinical domain.

Fourth, our analysis indicated that AI applications could provide effective decision support, albeit in certain contexts. For instance, the augmenting role of AI in clinical decision-making capacity can be affected by the level of expertise. In particular, two studies suggested that junior physicians were more likely to benefit from AI than senior physicians because they had a higher tendency to reconsider and modify their clinical decisions when encountering disconfirming AI suggestions [38,47]. However, it is worth noting that AI can be misleading sometimes. For example, one study from our review speculated that trainee endoscopists may feel confused about false-positive results from an AI screening tool owing to limited reading experience and, as a result, ignore AI-marked lesions of small-bowel mucosal breaks [26]. It is therefore important for future research to examine under what circumstances physicians could benefit more from AI applications. However, we are sanguine that when AI technology is sufficiently mature and

accurate to become the evidence-based best practice, its use would become part of routine clinical care in the future.

With respect to AI acceptance, we observed that health care providers expressed negative feelings toward AI in two studies [37,56], indicating that barriers existed in the incorporation of AI into the routine workflow. However, an elaboration of AI implementation barriers will be lengthy and is beyond the scope of this work, and we refer interested readers to the reports by Kelly et al [8], Ngiam and Khor [83], Lysaght et al [84], Shaw et al [10], and Yu and Kohane [12] for more details.

Fifth, for most of the included studies on patient outcomes, we found that they did not examine the clinical processes and interventions in detail. However, AI applications without appropriate and useful interventions may be ineffective at improving patient outcomes. For example, Bailey et al [28] found that simply notifying the nursing staff of clinical deterioration risks was not able to improve the outcomes of high-risk patients. Effective patient-specific interventions are needed. Therefore, future research may design and evaluate patient-directed interventions to enhance the clinical effectiveness of AI applications.

Moreover, three of the included studies suggested that patients and their families were highly satisfied with health care AI owing to its convenience and efficiency [41,44,57]. However, this may not always be the case. Prior research has shown that patients preferred to receive primary care from a human provider than AI even if the care from the health provider entailed a higher misdiagnosis risk [85]. The reason is that they perceived AI to be less capable in considering their unique circumstances. Additionally, patients may disparage physicians aided by a clinical decision support system and perceive them as less capable and professional than their unaided counterparts [86]. Further studies to explore the possible patient concerns and resistance toward health AI applications should be considered.

Finally, according to an Accenture survey, more than half of health care institutions are optimistic that AI will reduce costs and improve revenue despite the high initial costs associated with AI implementation [87]. However, only one included study documented the economic outcomes of AI implementation. This highlights the need to conduct more cost-effectiveness analyses of AI applications in clinical practice.

Limitations

This review has several limitations. First, we only included peer-reviewed English-written journal articles. It is plausible that some relevant articles were written in other languages or published in conferences, workshops, and news reports. As noted earlier, this may partly explain the imbalanced country distribution of the reviewed articles. Moreover, we did not include articles that were published before 2010 because AI only started to make in-roads in the clinical field in the last decade, as evident in our search results. Moreover, we only reviewed premium computer science conferences and journals without comprehensively examining engineering and computer science databases. This should be less of a concern here because we found that computer science conferences and journals mainly focus on the training and validation of novel AI algorithms without actual deployment. Still, future research can expand the search scope to gain deeper insights into state-of-the-art clinical AI algorithms.

Another concern is that some AI applications may have been implemented in real-world clinical practice without any openly accessible publications. For example, IDx-DR, the first FDA-approved AI system, has been implemented in more than 20 health care institutions such as University of Iowa Health Care [88]. However, our search only identified one related published result [25]. Clinical practitioners should take a more active role in reporting AI evaluation and use results in their daily practice in the future.

Conclusions

AI applications have tremendous potential to improve patient outcomes and improve care processes. Based on the literature presented in this review, there is great interest to develop AI tools to support clinical workflows, with increasing high-quality evidence being generated. However, there is currently insufficient level 1 evidence to advocate the routine use of health care AI for decision support, hindering the growth of health care AI and presenting potential risks to patient safety. We thus conclude that it is important to conduct robust RCTs to benchmark AI-aided care processes and outcomes to the current best practice. A rigorous, robust, and comprehensive evaluation of health care AI will help move from theory to clinical practice.

Abstract

Background: Owing to the COVID-19 pandemic and the imminent collapse of health care systems following the exhaustion of financial, hospital, and medicinal resources, the World Health Organization changed the alert level of the COVID-19 pandemic from high to very high. Meanwhile, more cost-effective and precise COVID-19 detection methods are being preferred worldwide.

Objective: Machine vision–based COVID-19 detection methods, especially deep learning as a diagnostic method in the early stages of the pandemic, have been assigned great importance during the pandemic. This study aimed to design a highly efficient computer-aided detection (CAD) system for COVID-19 by using a neural search architecture network (NASNet)–based algorithm.

Methods: NASNet, a state-of-the-art pretrained convolutional neural network for image feature extraction, was adopted to identify patients with COVID-19 in their early stages of the disease. A local data set, comprising 10,153 computed tomography scans of 190 patients with and 59 without COVID-19 was used.

Results: After fitting on the training data set, hyperparameter tuning, and topological alterations of the classifier block, the proposed NASNet-based model was evaluated on the test data set and yielded remarkable results. The proposed model's performance achieved a detection sensitivity, specificity, and accuracy of 0.999, 0.986, and 0.996, respectively.

Conclusions: The proposed model achieved acceptable results in the categorization of 2 data classes. Therefore, a CAD system was designed on the basis of this model for COVID-19 detection using multiple lung computed tomography scans. The system differentiated all COVID-19 cases from non–COVID-19 ones without any error in the application phase. Overall, the proposed deep learning–based CAD system can greatly help radiologists detect COVID-19 in its early stages. During the COVID-19 pandemic, the use of a CAD system as a screening tool would accelerate disease detection and prevent the loss of health care resources.

Introduction

In 2020, the rapid global spread of COVID-19 made the World Health Organization declare the first pandemic of the 21st century, with the highest level of alert worldwide. Based on the WorldMeters statistics, until January 5, 2021, more than 86 million people worldwide contracted this disease, with more than 1,870,000 confirmed deaths due to COVID-19. Early detection of COVID-19 is essential not only for patient care but also for public health by ensuring patients' isolation and controlling disease spread [1,2]. The first and most important step to control this pandemic is the rapid detection of infected patients and monitoring of positive cases. Various diagnostic methods for the rapid detection of COVID-19 have been introduced by different studies and by the WHO, with the reverse transcription–polymerase chain reaction (RT–PCR) test being the most prominent diagnostic method. Although RT–PCR is the gold standard for COVID-19 detection, owing to its time-intensiveness and high cost, infected individuals, as a source of transmission, can transmit the virus to many people while they are waiting to receive the results of their RT–PCR test. Moreover, previous studies have reported that the RT–PCR test has a high false-negative rate; this is a major limitation of this diagnostic test and reduces its sensitivity. Furthermore, this leads to delayed detection, treatment, and—in advanced stages of the disease—an increased mortality rate [3-8]. A high influx of patients at diagnostic centers during the pandemic has led to excessive use of resources and a shortage of RT–PCR test kits. Regardless of the need of RT–PCR tests for suspected individuals, the multiple repeats of these tests for patients have imposed a heavy burden on health care sources. The time-consuming nature of laboratory tests, coupled with the molecular and nonspecific nature of serological tests, has necessitated the use of a cheaper test focusing on findings in the lung tissue. As major lung health monitoring tools, radiological tests have attracted the attention of clinical specialists. For COVID-19 evaluation, computed tomography (CT) is a more sensitive and specific detection method than chest X-ray imaging, and, in many cases, lung involvement and ground-glass opacities (GGO) can be viewed on CT even before the onset of clinical symptoms and before obtaining positive results on an RT–PCR test. This implies that, in many cases, before the emergence of the first clinical symptoms and a positive RT–PCR finding, the complications of COVID-19 can be detected in the lungs. Based on previous reports and the WHO's recommendations, chest CT has emerged as a valuable tool for the early detection and triaging of individuals suspected with COVID-19 [4,9,10]. In a study on 1014 patients with COVID-19, CT enabled more sensitive detection than RT–PCR [11]. Despite the success of this radiological modality in detecting COVID-19–related lung damage, certain problems are associated with its use. Despite the WHO's recommendations, chest CT findings are normal in some patients at the outset of the disease, and this lends a negative predictive value to CT alone. The low-specificity of CT can deter disease detection in non–COVID-19 cases. In addition, ionizing radiation from the CT scanner can cause problems to patients who require multiple CT scans during the course of their disease [12-16]. In the past decade, numerous computer-based methods have been employed for improving the efficiency of medical imaging techniques. One such method is the use of machine learning algorithms, which has had remarkable success in medical imaging. Among different types of machine learning methods, deep learning models have achieved high precision in machine vision tasks rapidly after the emergence of COVID-19. Convolutional neural networks (CNNs) have high potential for feature extraction and analysis. Upon the emergence of COVID-19, and owing to the limitations of diagnostic tests, numerous machine learning techniques have been adopted to improve the precision of diagnostic methods. Table 1 lists some relevant studies.

Methods

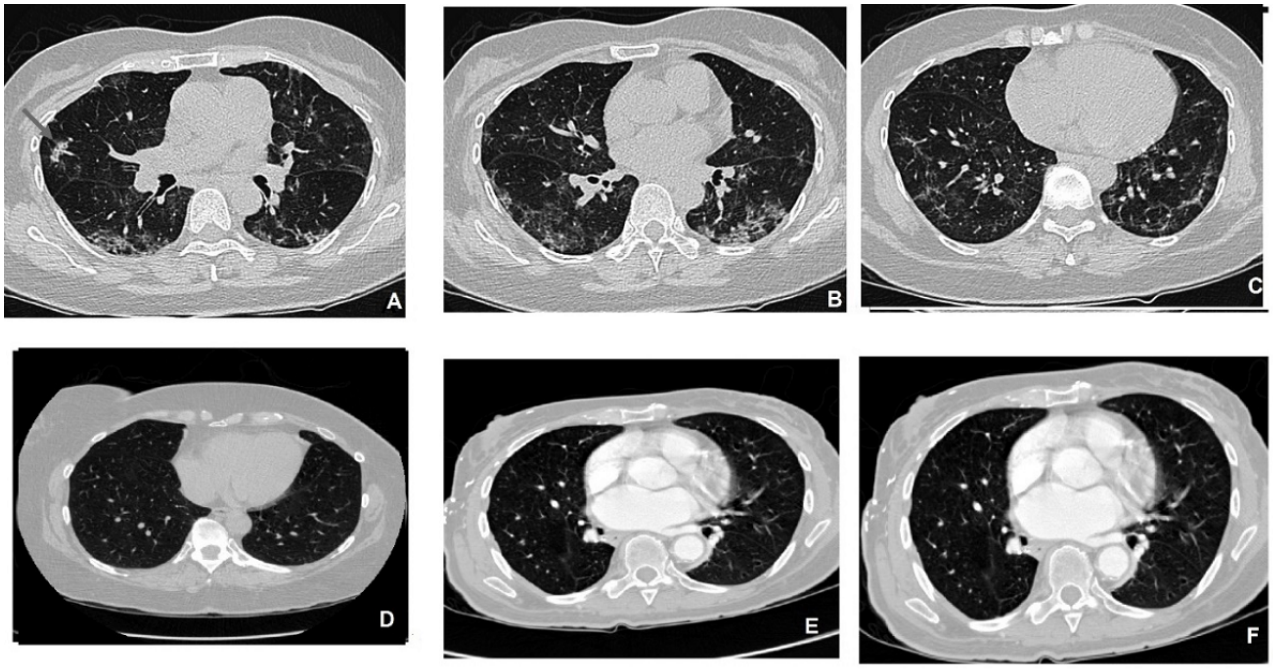
Study Overview

Based on the success of CNNs in machine vision tasks, we designed and implemented a model for the classification of CT images of individuals with and those without COVID-19 through a deep neural network based on a Neural Search Architecture Network (NASNet) [24] feature extractor.

Data Set

The data set comprised 10,153 CT scans, of which 7644 belong to 190 patients with COVID-19 and 2509 belong to 59 people without COVID-19, including those with pneumonia and otherwise healthy individuals who visited the hospital owing to a suspicion of COVID-19 [25]. All these images were collected from the radiology centers of teaching hospitals in Tehran, Iran. The disease status in suspected individuals was confirmed in this set after an RT–PCR test. Figure 1 shows the CT scans of some patients with COVID-19 and their counterparts with suspected disease.

Figure 1. Axial computed tomography scan slices of the lung. (A, B, C) Non–COVID-19 cases including those of pneumonia and healthy individuals; (D, E, F) infected lungs of patients with COVID-19.



Proposed Method

To detect COVID-19 in patients at an early stage of the disease from multiple lung CT scans, a state-of-the-art model based on a NASNet CNN feature extractor was proposed. Based on the proposed model, a computer-aided detection (CAD) system was designed.

Data Preparation and Preprocessing

For data preparation, lung CT scans were first received in the Digital Imaging and Communications in Medicine format as the output of the picture archiving and communications system of a diagnostic center. In the preprocessing stage, the images were converted to the commonly used JPG format, and the order of the color channels was changed from the default BGR to RGB to prepare the images for processing.

Based on the literature, the success of medical image visual tasks in deep learning is not merely attributed to CNN models; rather, a major part of this success results from image preprocessing [26]. Data normalization to maintain the integrity of the images was performed as the first step of preprocessing, which plays a key role in the analysis of CT scans [27]. To this end, first, the pixel-level global mean (SD) values were calculated for all the images; thereafter, the data were normalized using the following equation:

where  is the global mean of the image set X, σ is the SD, and ε=1e–10 is an insignificant value to prevent the denominator from becoming 0.

After normalization, for standardizing the images to achieve a unified scale for the input of the deep neural network, the values of the pixels of each image were scaled by transferring to (0,255) and then by transforming to the (0,1) interval, such that the images would be standard during training. Since CNNs depend on a large number of data to enhance their efficiency and prevent model over-fitting [28,29]; at this stage, data were augmented for the training data set through random rotation, contrast alteration, illumination alteration, and gamma correction.

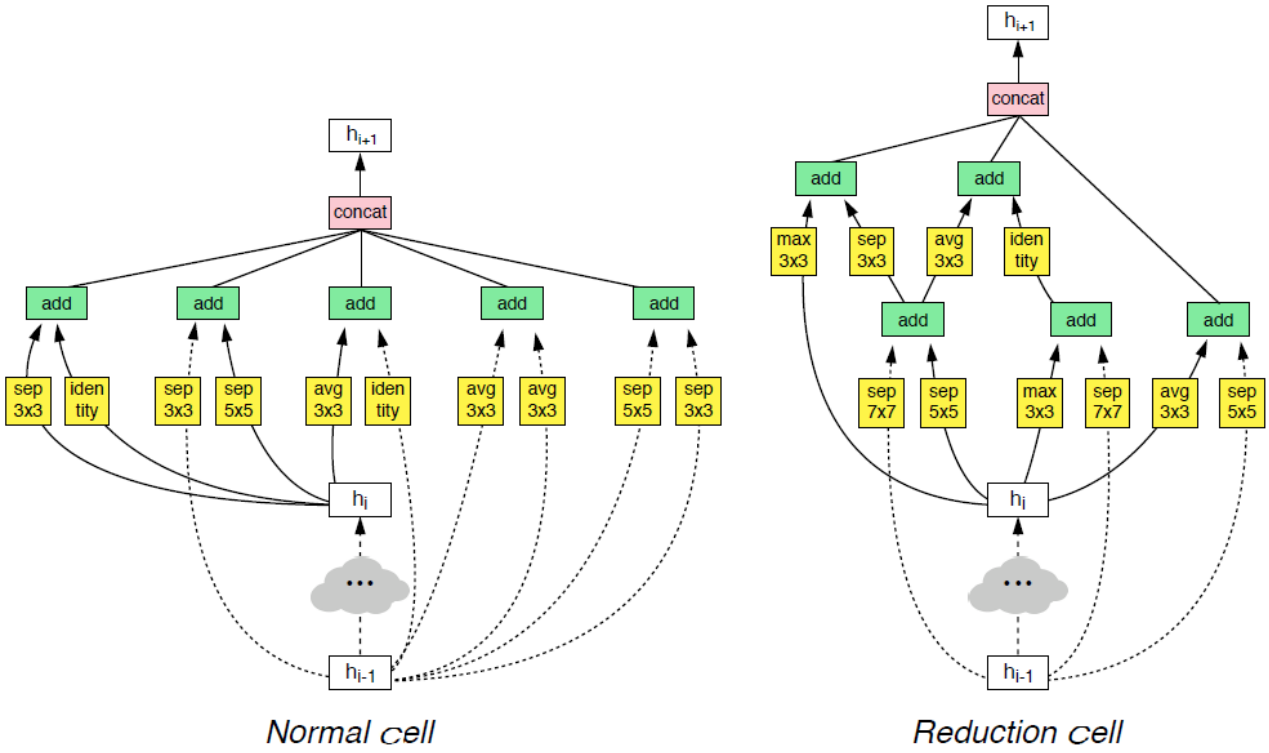
All the images of the sets were shuffled such that the network would not necessarily see the data of only a certain class during training, and each batch would include images with different labels belonging to both COVID-19 and non–COVID-19 classes. The dimensions of the input images were changed to 224×224×3; however, this method can be used on images with any other dimensions. The data set with the 64:16:20 ratio was randomly divided among the training, validation, and test sets, respectively, whereby 20% of the data were allocated to the test set, the remaining 80% to the training set, and 20% of the training set was assigned to the validation set.

Feature Extraction and Classification

Convolutional layers were used in the feature extraction block. Immediately after each Conv2D layer, the useful statistics were collected using the Max-Pooling module and, after normalizing them using batch normalization, passed to the next CNN block. To prevent model overfitting, in addition to batch normalization, weight regularization and dropout methods were also applied. For regularization, the Euclidean norm (L2) was used with different coefficient values in the (0.001-0.01) interval after activation using the LeakyReLU activation function and dropout of 20%-30% of the weights. Inspired by the transfer learning approach, for better feature extraction, the preliminary blocks of the pretrained NASNetLarge network were used. NASNet has a scalable architecture for image classification and consists of 2 repeated motifs termed the normal cell and the reduction cell. Figure 2 illustrates the architecture of these convolutional cells. All parameters were initialized using the weights obtained from fitting NASNetLarge on the ImageNet data set. After the

feature extraction block, the weights were transferred to 3 dense or fully connected layers by using a global average pooling flatten layer in the form of a 1-dimensional tensor.

Figure 2. Architecture of the NASNet's convolutional cells with B=5 blocks. The input (white) is the hidden state from previous activations (or input image). The output (pink) is the result of a concatenation operation across all resulting branches. Each convolutional cell is the result of B blocks. A single block corresponds to 2 primitive operations (yellow) and a combination operation (green) [23].



In these layers, batch normalization, regularization, and weight dropout were performed as well. The first dense layer used a ReLU activation function, the next layer utilized a LeakyReLU, and the last layer, which actually is the classifier layer, employed a Softmax multiclass activation function.

During the training process, in the first phase, the feature extraction block was frozen and contained nontrainable parameters, and Adam was used as the optimizer. In this phase, the initial learning rate of 1*e*–3 and the binary cross-entropy loss function were used. If validation loss remained stable in every 10 epochs, the learning rate would be reduced by 20% to a minimum of 1*e*–6 in case of no further improvement. If the validation loss remained stable up to 20 epochs, the process of training would stop. Eventually, only the best weights were saved. After training the dense layers, in the second phase the feature extraction block was unfreezed, and the network—this time fully trainable—was fitted once more on the same data; in this phase, the stochastic gradient descent optimizer with the initial learning rate of 1*e*–4 was utilized. The batch size was 32; the number of epochs in the first phase was assumed to be 200, and 1000 iterations were considered in the second phase.

CAD System Based on the Proposed Model

Many studies have recommended the use of CT scans for COVID-19 detection, many of which have used machine learning–based computer methods to enhance the results of chest CT. All machine learning methods have attempted to detect COVID-19 in the images with a single CT slice [10,12,30-33]; however, in real time, radiologists confirm or reject COVID-19 on the basis of overall slices of a patient's CT scan. This study aimed to design a computer-aided diagnostic system to detect COVID-19 with multiple CT images for each person. In the CAD system designed on the basis of the proposed model, 4 CT slices were obtained from a person suspected with COVID-19 and the system estimates the final result from the output average mean of classifying all the slices. However, the proposed system can receive a different number of slides and does not depend on the number of inputs. This increases the reliability of the results obtained from the proposed model. Figure 3 provides a schematic representation of the proposed model.

In the experiments, the proposed model successfully detected all the cases of COVID-19 with high accuracy and differentiated all the positive and negative cases without any discernible error. Figures 4 and 5 display the performance of the proposed model by presenting the results of detection on the first 25 samples and 25 random ones from the test set, respectively.

Figure 3. Proposed deep convolutional neural network–based CAD system for COVID-19 detection using multiple lung computed tomography scans. CT: computed tomography.

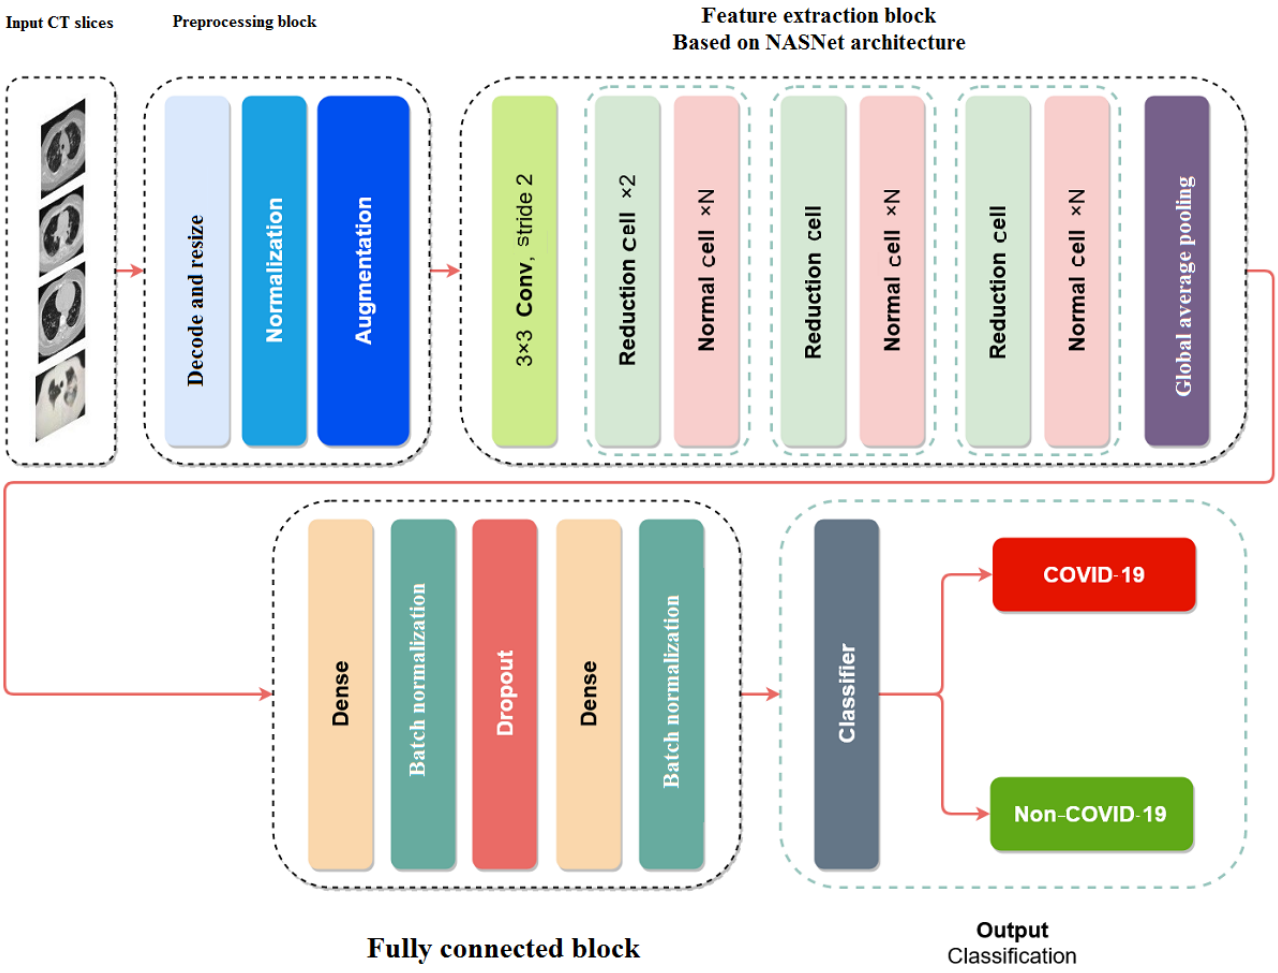


Figure 4. Results of the detection on the first 25 samples from the test set. “I” is the image index, “P” is the predicted value, and “L” is the grand truth label. Green indicates correct detection and red indicates incorrect detection.

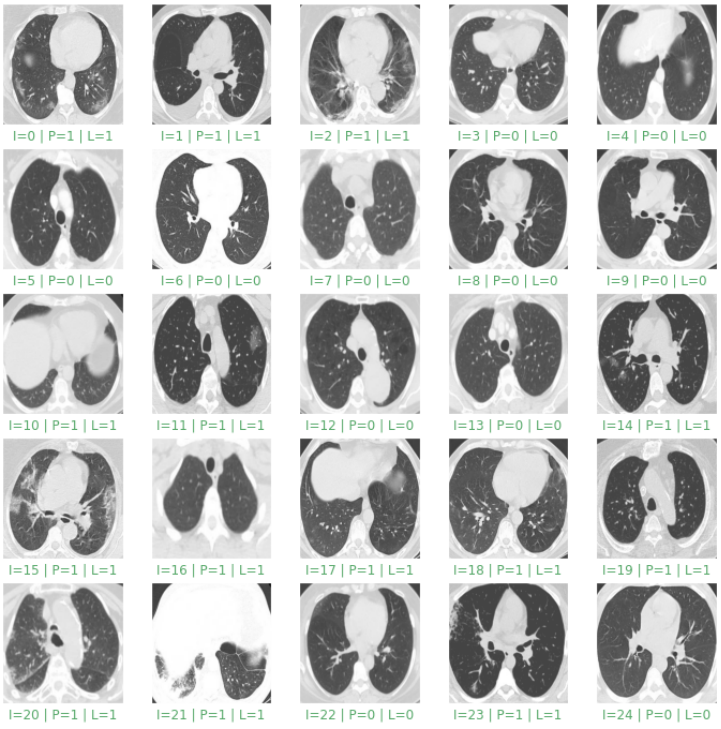

Figure 5. Results of detection on 25 random samples from the test set. “I” is the image index, “P” is the predicted value, and “L” is the grand truth label. Green indicates correct detection and red indicates incorrect detection.

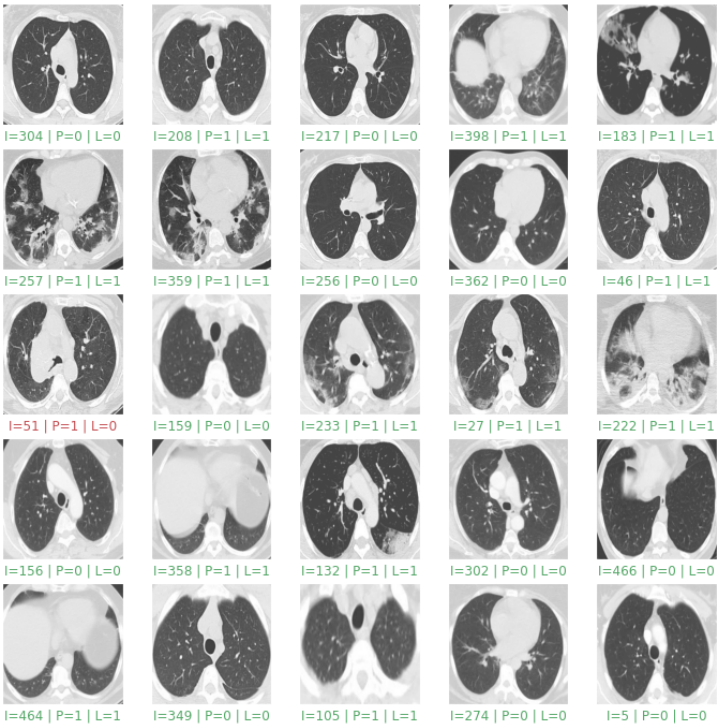

In the case of COVID-19, the lack of an early and accurate diagnosis leads to the spread of the disease among other individuals, which has irreversible effects on the control of the pandemic. The proposed CAD system, which detects cases of COVID-19 from multiple CT slices can perform more accurately because, owing to the error of not showing the area of the GGO in some CT slices, the data of many slices may have been missed. Moreover, in models that detect COVID-19 from a single slice, there is a risk of error in viewing the infected area of the lung or ROI owing to operator errors, the angle of the slices, or problems with the CT scanner tube. Thus, by using a multislice CAD system, the disease can be detected in its early stages, and the initial signs of lung involvement can be discovered with maximum precision.

Implementation

The proposed method was implemented using the Python programming language by Keras, which is a high-level library for TensorFlow machine learning framework which also utilized a Compute Unified Device Architecture deep learning network library for parallel processing on the graphics processing unit. The computer system had an Intel Core i7 7700K CPU, 32 GB RAM, and an Nvidia T4 GPU accelerator. Implementation codes and the pretrained model are available on GitHub [34].

Results

Metrics

To quantitatively evaluate the performance of the proposed method, the sensitivity, specificity, accuracy, and F_1 score evaluation criteria were determined on the basis of the model’s performance by using a confusion matrix. Here, sensitivity was defined as the ratio of COVID-19 cases correctly detected by the model to all the actual COVID-19 cases. Specificity was defined as the ratio of the non–COVID-19 cases correctly detected by the model to all the actual non–COVID-19 cases. Moreover, accuracy was defined as the rate of all the COVID-19 and non–COVID-19 cases accurately detected on the basis of the CT images.

Experimental Results and Evaluation

In this study, we used traditional measures to evaluate the performance of the proposed model, using a confusion matrix. Based on this confusion matrix, the specificity and sensitivity in measuring and analyzing the performance of the proposed CAD model were calculated, where specificity was defined as the ability of the classifier to correctly identify individuals without COVID-19 (true-negative rate). Sensitivity was defined as the classifier’s ability to identify individuals with COVID-19 correctly (true-positive rate). These evaluations were performed using the following equations:

Figure 6 shows the confusion matrix for the evaluation in the test set for 2 classes. The evaluation criteria based on the confusion matrix are provided in Table 2.

Figure 6. (A) Confusion matrix and (B) normalized confusion matrix of the model performance for the test data.

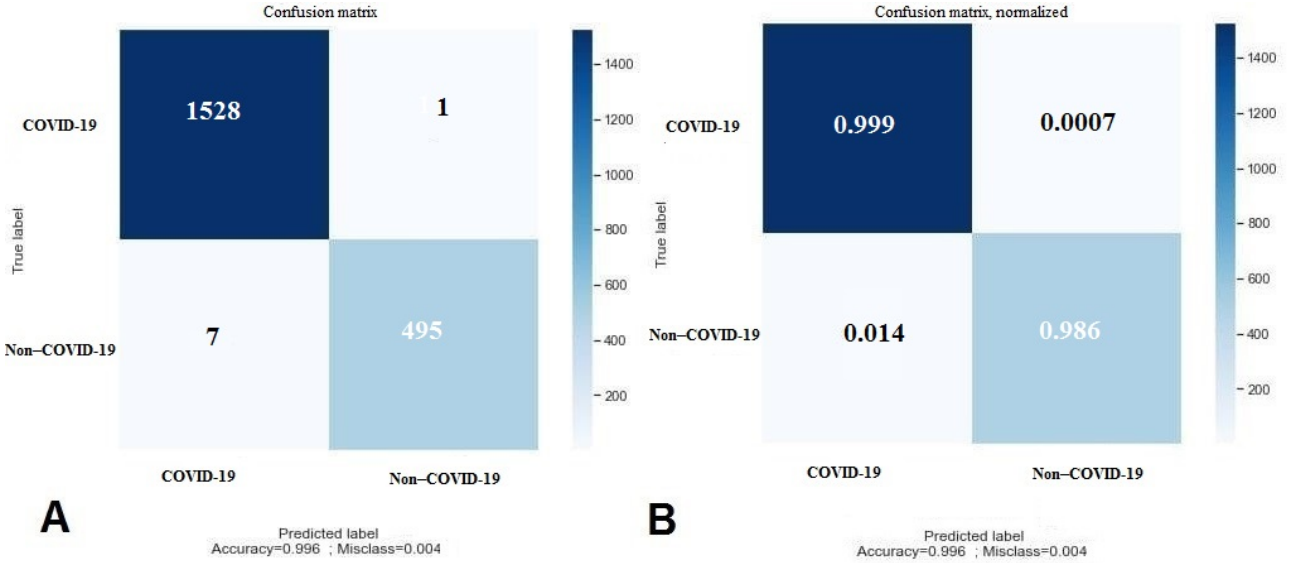

Table 2. Performance of the proposed method in the test data set.

Metric	Value
Sensitivity	99.9
Specificity	98.6
Accuracy	99.6

The learning curve of the proposed model for the training and validation sets is illustrated in Figure 7. On assessing the behavior of the proposed model in handling new validation data, we observed that with increased epochs, the model had a lower error rate, and thus enhanced accuracy for the unknown data, which suggests that the model has high potential for detecting new cases of COVID-19 from the CT scans. The mean square error in detecting all the COVID-19 and non–COVID-19 cases from among the test set images was 0.003938, which was significantly lower than that reported in previous studies.

The metrics of positive predictive value and negative predictive value, as well as the F_1 score, for the proposed model are shown in Table 3.

Figure 7. Training and validation loss and accuracy.

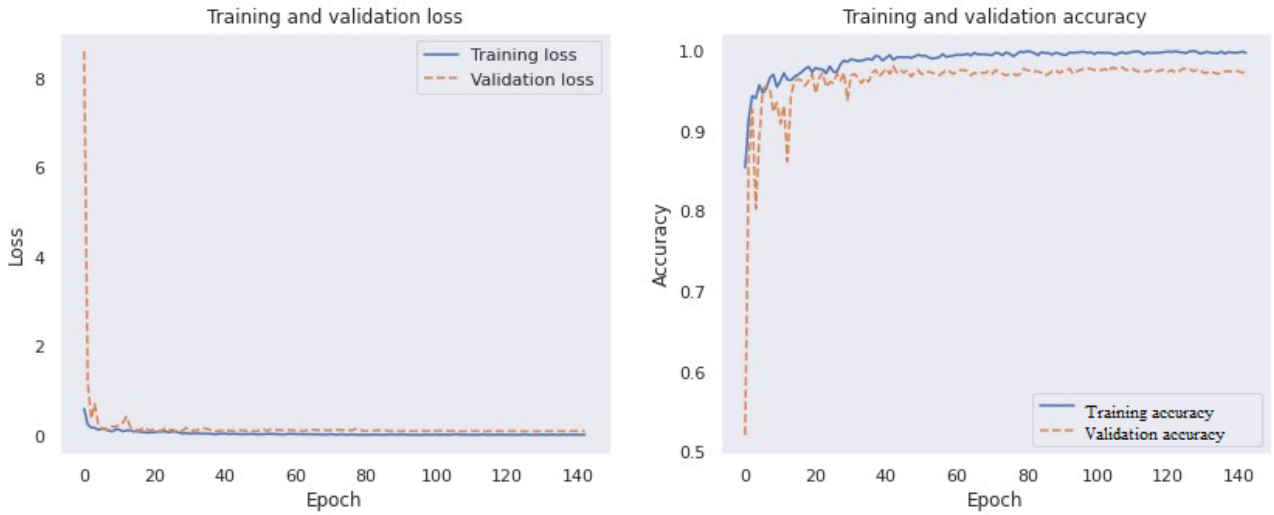

Table 3. Evaluation of the proposed model for the test set.

Metric	Value (%)
Positive predictive value = True positive / Positive calls	99.8%
Negative predictive value = True negative / Negative calls	99.7%
F_1 score = (True positive / True positive) + 0.5 (False positive + False negative)	99.8%

To evaluate the performance of the proposed model further in real-life applications and present a comparable evaluation, we tested our model on a publicly available and well-known data set [30] using the cross–data set evaluation approach. The results shown in Table 4 compare the proposed method with other state-of-the-art approaches, including traditional deep neural networks and pretrained networks [30-33,35].

Table 4. Comparison of the performance of different models for detecting COVID-19 using various evaluation metrics.

Model	Evaluation Metrics			
	Accuracy	Precision	Recall	F_1 score
SqueezeNet	95.1	94.2	96.2	95.2
ShuffleNet	97.5	96.1	99.0	97.5
GoogleNet	91.7	90.2	93.5	91.8
VGG-16	94.9	94.0	95.4	94.9
AlexNet	93.7	94.9	92.2	93.6
ResNet50	94.9	93.0	97.1	95.0
Xception	98.8	99.0	98.6	98.8
AdaBoost	95.1	93.6	96.7	95.1
Decision Tree	79.4	76.8	83.1	79.8
Explainable deep learning [30]	97.3	99.1	95.5	97.3
DenseNet201 [31]	96.2	96.2	96.2	96.2
Modied VGG19 [32]	95.0	95.3	94.0	94.3
COVID CT-Net [33]	90.7	88.5	85.0	90.0
Contrastive Learning [35]	90.8	95.7	85.8	90.8
Proposed	99.4	99.6	99.8	99.5
