Abstract

Background: Medical journals increasingly promote published content through social media platforms such as Twitter. However, gastroenterology journals still rank below average in social media engagement.

Objective: We aimed to determine the engagement patterns of publications in gastroenterology journals on Twitter and evaluate the impact of tweets on citations.

Methods: This was a retrospective cohort study comparing the 3-year citations of all full-length articles published in five major gastroenterology journals from January 1, 2012, to December 31, 2012, tweeted by official journal accounts with those that were not. Multivariate analysis using linear regression was performed to control for journal impact factor, time since publication, article type, frequency of reposting by other users ("retweets"), and media addition to tweets. Secondary analyses were performed to assess the associations between article type or subtopic and the likelihood of social media promotion/engagement.

Results: A total of 1666 articles were reviewed, with 477 tweeted by the official journal account. Tweeting an article independently predicted increased citations after controlling for potential confounders (β coefficient=13.09; *P*=.007). There was significant association between article type and number of retweets on analysis of variance (ANOVA) (*P*<.001), with guidelines/technical reviews (mean difference 1.04, 95% CI 0.22-1.87; *P*<.001) and meta-analyses/systemic reviews (mean difference 1.03, 95% CI 0.35-1.70; *P*<.001) being retweeted more than basic science articles. The manuscript subtopics most frequently promoted included motility/functional bowel disease (odds ratio [OR] 3.84, 95% CI 1.93-7.64; *P*<.001) and education (OR 4.69, 95% CI 1.62-13.58; *P*=.004), while basic science papers were less likely tweeted (OR 0.154, 95% CI 0.07-0.34; *P*<.001).

Conclusions: Tweeting of gastroenterology journal articles independently predicted higher 3-year citations. Wider adoption of social media to increase reach and measure uptake of published research should be considered.

(J Med Internet Res 2021;23(5):e25252) doi:10.2196/25252

KEYWORDS

social media; gastroenterology journals; gastroenterology research; journal citations

Introduction

Social media is playing an increasingly important role in health care as an inexpensive way to improve accessibility of medical information. In recent years, medical journals have created accounts on social media to share published content and improve visibility among both mainstream audiences and health professionals. Unlike traditional media, social media differs in its ability to curate content (using tools like hashtags) and to facilitate engagement by readers and viewers. It is often challenging to stay abreast of all newly published data from the multitude of scientific journals within a given medical specialty.

XSL•FO
RenderX

Social media promotion may help narrow the range of what is considered most relevant to target audiences and/or newsworthy.

Twitter is the prime social media platform for online discussion with 335 million active monthly users worldwide and more than 500 million "tweets" per day [1]. The content of each tweet is restricted to 280 characters and may contain links to external websites. Each tweet is visible to followers of the account, and individuals can engage by reposting (ie, "retweeting") content in their own Twitter feeds or "liking" posts.

Twitter activity may predict publication and overall journal performance. A prior study found a significant association between Twitter followers of an official journal account and both the journal impact factor and total citations [2], with an estimated 1% increase in journal citations for every 0.62% increase in Twitter followers. Among adult and pediatric urology journals, having an official Twitter account was found to be associated with a greater impact factor [3,4]. Following a targeted effort to promote published articles to their 700 followers, the *Journal of Neurointerventional Surgery* saw a "substantial increase" of 1500 visits to its scientific content [5].

The effects of social media exposure of published research in gastroenterology remain unclear. More specifically, the impacts on citations and patterns of social media promotion of these publications are also unknown. While the process that journals employ to select and promote articles on social media is largely opaque and likely not random, we may be able to glean the patterns of social media amplification and control for confounders like manuscript type and subject matter. Characterizing these patterns may serve to highlight areas that are lacking exposure or reflect what journals perceive as most relevant to the general public.

The primary aim of this study was to determine if social media promotion by gastroenterology journal Twitter accounts is associated with greater number of citations. We also aimed to determine if there is preferential promotion of certain types of publications and subtopics by gastroenterology journals on Twitter.

Methods

This was a retrospective cohort study assessing the citations of all full-length articles published in five major peer-reviewed gastroenterology journals (*American Journal of Gastroenterology*, *Clinical Gastroenterology and Hepatology*, *Gastroenterology*, *Gastrointestinal Endoscopy*, and *Pancreas*) from January 1, 2012, to December 31, 2012. These journals and this date range were selected for the following reasons: to allow sufficient time for citations to accrue, to account for the diminishing impact of a tweet over time, and to select a year where all five journals appeared on social media.

The number of citations in academic literature as of November 15, 2015, according to Google Scholar was compared between articles tweeted by the official journal accounts and those that were not. Google Scholar has been previously used in similar research to quantify citations [6]. Publications were further categorized by manuscript type and subtopic. Manuscript types included prospective research, retrospective research, basic science, meta-analyses and systematic reviews, guidelines and technical reviews, case reports, video publications, and editorials. Manuscript subtopics included esophagus, gastric, small bowel, colon, liver, pancreas, biliary, motility and functional bowel disease, cancer, basic science, quality improvement, cost-effectiveness, inflammatory bowel disease, endoscopy, education, and microbiome. Multiple assignments for subtopics were permitted.

The mean number of citations between tweeted articles and those that were not tweeted by the official journal accounts were compared using Student *t* test. To detect an independent association between social media promotion on Twitter and Google Scholar citations, multivariate analysis using linear regression was performed to control for the 2012 journal impact factor (as published by Thomson Reuters), time since publication, and article type. Among articles that were tweeted, the overall associations between manuscript types and number of citations were assessed using analysis of variance (ANOVA). Pairwise comparisons of manuscript types with regard to number of citations were performed using the Bonferroni method.

To evaluate the likelihood of specific subtopics being promoted on social media by gastroenterology journals, the rates of tweeted manuscripts for each subtopic were compared to those not containing the corresponding subtopic using the chi-squared test. Multivariate analysis was performed using logistic regression, controlling for potential confounders including the specific journal, manuscript type, and number of citations. Results of regression analyses are expressed as raw coefficients to demonstrate the effect of each variable on citations and to better generalize these results to other settings or populations.

All statistical analyses were performed using SAS Version 9.4 (SAS Institute).

Results

In total, 1666 gastroenterology articles were reviewed, with 477 having been tweeted by official journal accounts. In 2012, *Gastrointestinal Endoscopy* published 451 articles, *Pancreas* published 242 articles, *American Journal of Gastroenterology* published 226 articles, *Gastroenterology* published 473 articles, and *Clinical Gastroenterology and Hepatology* published 274 articles (Table 1). On univariate analysis, articles that were tweeted had a significantly higher number of citations compared with nontweeted articles (36.9 vs 27.4, *P*=.04) (Figure 1). On multivariate analysis, tweeting of an article (β coefficient=13.09, *P*=.007) was independently associated with increased citations after controlling for potential confounders (Table 2). Not surprisingly, the duration since publication (in days) was found to be a predictor for increased citations in the linear regression model. Among tweeted articles, those that were retweeted (a possible proxy for strong public interest or colleague endorsement) also had higher citations compared with those that were not retweeted (72.3 vs 17.6, *P*=.004) (Figure 1), although this did not reach statistical significance in the multivariate model (β coefficient=23.2, *P*=.28), likely due to a small sample size.

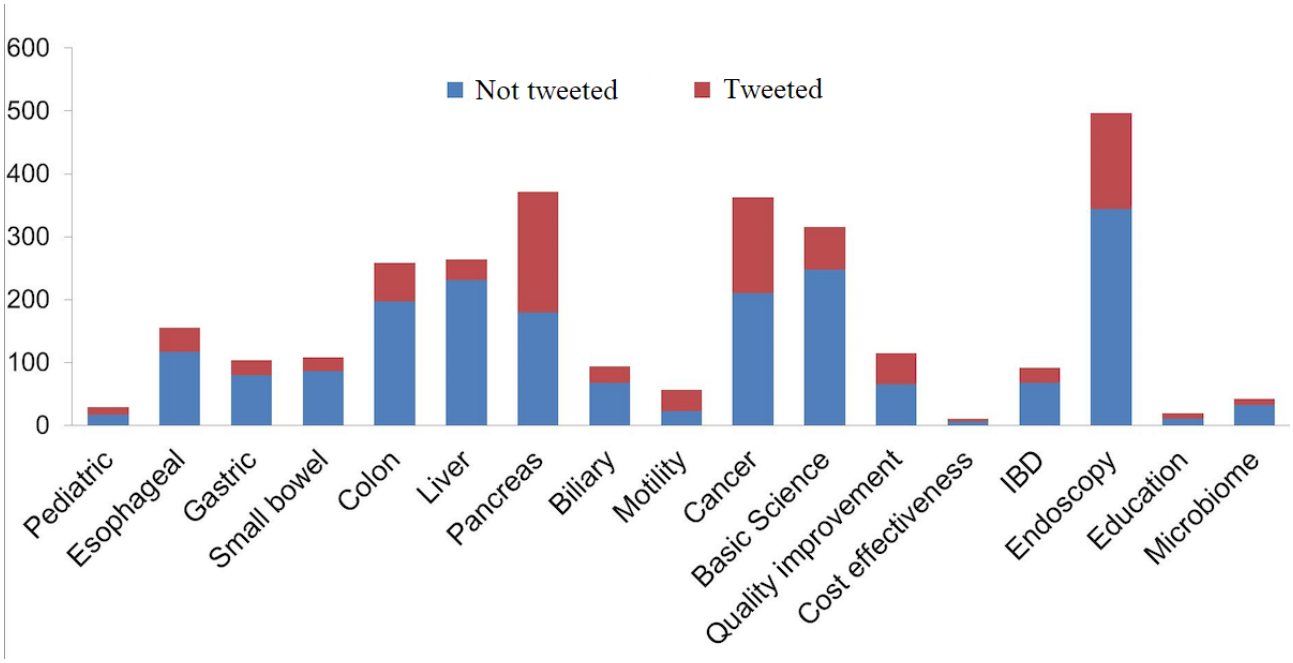
[a]GIE: Gastrointestinal Endoscopy.

[b]Gastro: Gastroenterology.

[c]AJG: American Journal of Gastroenterology.

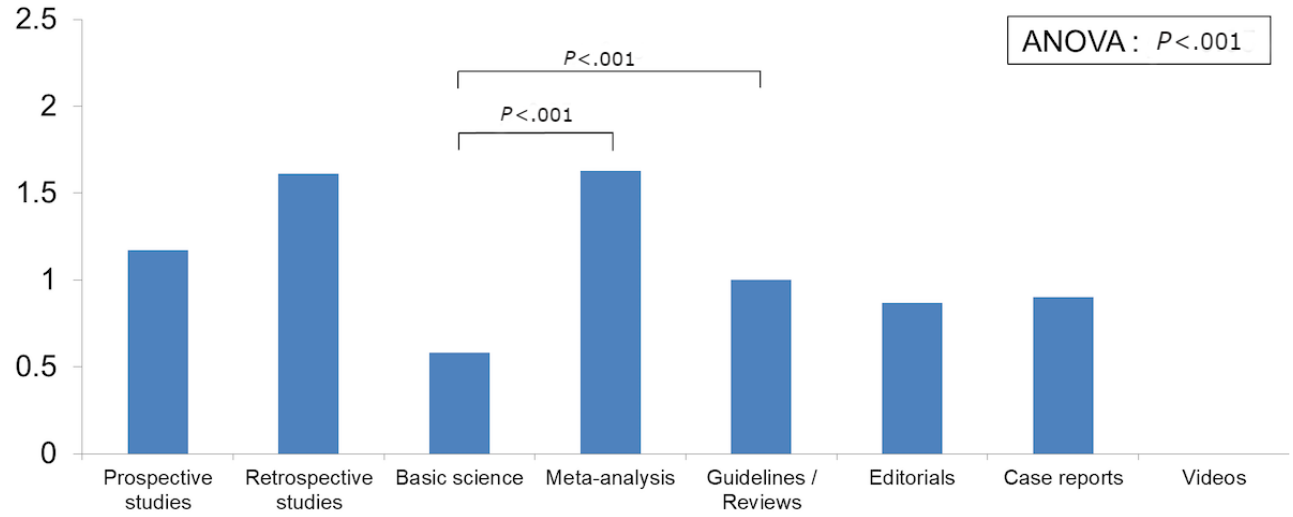
[d]CGH: Clinical Gastroenterology and Hepatology.



On univariate analysis, articles identified in the categories of pancreas (odds ratio [OR] 3.80, *P*<.001), cancer (OR 2.20, *P*<.001), and quality improvement (OR 2.05, *P*=.003) were associated with increased Twitter promotion, while small bowel (OR 0.62, *P*=.05) and basic science (OR 0.63, *P*=.002) articles were associated with less social media exposure.

After controlling for other covariates, including other manuscript subtypes, on multivariate analysis, the subtopics of motility and functional bowel disease (OR 3.84, 95% CI 1.93-7.64, *P*<.001), cancer (OR 1.392, 95% CI 1.016-1.909, *P*=.04), education (OR 4.69, 95% CI 1.62-13.58, *P*=.004), and quality improvement (OR 2.41, 95% CI 1.52-3.84, *P*<.001) were independently

XSL•FO
RenderX



associated with increased promotion on Twitter, while basic science articles were significantly less likely to be tweeted (OR 0.154, 95% CI 0.07-0.34, *P*<.001) (Figure 2).

Figure 2. Number of publications (both tweeted and nontweeted) in 2012 by subtopic among the five journals included. IBD: inflammatory bowel disease.

A significant overall association between article type and citations was noted on ANOVA (*P*<.001), with guidelines/technical reviews (mean 90.23, SD 355.57), meta-analyses/systemic reviews (mean 75.22, SD 124.85), and prospective studies (mean 42.96, SD 54.26) having the most citations. On multivariate analysis using prospective studies as a reference, guidelines/technical reviews (β coefficient=52.8, *P*<.001) and meta-analyses/systemic reviews (β coefficient=26, *P*=.001) were significantly more likely to be cited, while basic science articles (β coefficient=−23.5, *P*<.001), case reports (β coefficient=−43.2, *P*<.001), and editorials (β coefficient=−41.9, *P*<.001) had significantly fewer citations (Table 2). Among tweeted articles, there was a significant association between article type and number of retweets on ANOVA (*P*<.001). On pairwise comparison, guidelines/technical reviews (mean difference 1.04, 95% CI 0.22-1.87, *P*<.001) and meta-analyses/systemic reviews (mean difference 1.04, 95% CI 0.22-1.86, *P*<.001) were being retweeted significantly more than basic science articles (Figure 3). Media additions to tweets were not associated with the number of citations or retweets.

Figure 3. Mean number of retweets by article type.

Discussion

Principal Findings

Our study showed that social media promotion of gastroenterology journal publications on Twitter independently predicted a greater number of Google Scholar citations in 3 years after controlling for journal impact factor, type of article, and time since publication.

We also found that tweeted articles that were retweeted had significantly increased citations, perhaps a reflection that public engagement with these tweets might predict further academic interest. Our study also demonstrated that guidelines/technical reviews and meta-analyses/systematic reviews are among the most heavily promoted article types by official journal accounts on Twitter. Articles involving motility/neurogastroenterology, cancer, education, and quality improvement were independently associated with increased social media exposure, while basic science manuscripts were less promoted. This may reflect the perceived areas of public interest in gastroenterology and influence perception of gastroenterology research, resulting in potential secondary impacts on factors, such as funding. Further studies are needed to evaluate why these promotional differences exist and how this might affect research funding availability, public interest, and clinical and epidemiological outcomes.

As done in studies from other disciplines, Twitter was chosen given that it is the predominant mainstream social media platform where journal publications are regularly promoted, where academic discussion exists, and where analytics are most readily available. The evidence regarding the association between Twitter promotion and publication citations has varied across different disciplines. One study of 20 ecological journals showed a similar positive correlation between social media exposure and citations, independent of time since publication and impact factor [7]. In the *American Journal of Psychiatry*, a study of 438 published articles suggested that a greater frequency of Twitter mentions was associated with more citations [8]. One study of 286 articles from the *Journal of Medical Internet Research* showed that highly tweeted articles were 11 times more likely to be highly cited and that Twitter mentions in the first 3 days could predict highly cited articles [6].

However, this observation was not consistent across all disciplines. In a randomized trial of social media impact on 243 publications from *Circulation*, there was no significant association between social media exposure and 30-day article website views according to Google analytic data [9]. There were also no differences noted by article subtype (referring to the general categories of clinical, population, or basic science articles). One study of all 1.4 million biomedical publications between 2010 and 2012 found a weak correlation between Twitter mentions of journal articles and traditional bibliometric indicators, although the authors concluded that Twitter mentions did not reflect traditional research impact [10].

The number of annual citations by a journal is used to calculate a journal's impact factor [11]. Historically, journal impact factor has been directly correlated with citations, as impact factor is the ratio of the number of citations to the number of publications by a journal in a given year. Google Scholar was chosen as the source of citations given its inclusivity of citations among all sources, unlike Web of Science and Scopus, which only consider citations from within journals listed in their libraries. However, some researchers have raised concerns that certain tactics can be used to boost the journal impact factor, such as publishing more review articles, strategic publication timing, and internal citations. Citations also take time to accumulate. Social media may therefore play another role in measuring the societal impact of an individual article. As a result, other metrics collectively known as "altmetrics," which include not only number of citations, but also social media views and engagement, references by databases, and news media, are emerging [12].

In our study, guidelines and reviews published in major gastroenterology journals were the most heavily promoted types of manuscripts on social media. This promotional pattern may be a result of known interest in these articles, given existing knowledge that guidelines and reviews accrue more citations than other publication types, and they may be more relevant to a broader audience that includes general clinicians and practitioners [13]. For gastrointestinal subtopics, our finding of functional bowel disease and cancer articles as the most tweeted is also not surprising. Communities for these conditions are very active on social media, and journals may be preferentially promoting these articles knowing the discussion and engagement they tend to generate. Moreover, the high general prevalence of functional bowel conditions and the increased interest cancer-related topics tend to generate in the lay media may also play roles in the higher social media activities of these articles.

Social media engagement by the gastroenterology community is lagging behind other medical subspecialties. Adoption of Twitter by journals still varies widely by specialty, with 70% of the 20 leading radiology journals on Twitter, but only 28.1% of general medical journals and 39% of urological journals on Twitter [2,14]. Latest data suggest that the proportion of overall tweeted gastroenterology publications (7.8%) falls below the average rate of Twitter promotion (9.4%) of all medical journal articles [10]. A survey of 265 gastroenterologists in 2015 found that 82.1% of respondents did not access social media for journals or other educational purposes, and 47.7% reported never having used any form of social media. This is in contrast to patient acceptance of social media, where 84.4% (n=112) of inflammatory bowel disease patients and 72.9% (n=68) of chronic viral hepatitis patients favored interaction with health care professionals on social media [15]. This dynamic may be improving in recent years, as there has been a growing presence of gastroenterologists and young physicians on social media.

One limitation of this study is the inability to establish causality and elucidate the potential mechanisms of social media impact on citations. Articles addressing subjects of higher interest or "more popular" topics (therefore, more highly cited) may be selectively tweeted at a higher frequency. For instance, social media promotion has been associated with greater downloads of journal articles in clinical pain sciences, which could suggest greater readership as a catalyst for future citations [16]. The radiology community has observed a greater distribution of web links to published articles on Twitter [14]. In fact, the effect of

XSL•FO
RenderX

social media on journal article readership has been previously demonstrated in a study of the *Journal of the American College of Radiology*, which showed that a planned Twitter-based discussion increased monthly website journal article views by 31.4%, unique visitors by 20.0%, and website visits by 25.5% [17]. In a randomized controlled study of the same journal, Twitter promotion of publications was independently associated with significantly greater weekly webpage visits (18.2 vs 7.6 page visits) [17]. Another study showed that 7 out of 11 radiology journals new to Twitter experienced increases in impact factor after 1 year [14].

Moreover, it is unknown if social media alone can be credited for greater citations or if social media is simply one arm of a larger promotional effort that includes other avenues, such as press releases for traditional media coverage. It is worth noting, however, that because the initial promotional tweet precedes article downloads and subsequent citations, it is not possible for the number of citations to cause a reactionary increase in social media presence for that particular article. Additionally, various journals may adopt different methods to selectively promote certain subtopics or manuscript types (such as guidelines) on social media. To best account for these biases, we controlled for subtopics and manuscript types in the multivariate analysis. Another potential limitation was the potential overestimation of baseline academic impact using Google Scholar citations. Though Google Scholar may include duplicate citations or citations of a paper in a nonpeer-reviewed publication without scholarly relevance, the Google algorithm is standard and therefore objectively compares citation volume.

Conclusion

In conclusion, social media promotion on Twitter of gastroenterology publications independently predicted a greater number of citations in 3 years in this exploratory study. Publications and researchers should consider wider adoption of social media to increase reach and measure uptake of published research. Social media promotion of publications can not only potentially boost journal citations, but also help define the societal impact of an individual article and thus influence academic promotion. However, beyond citations and academic uptake, journals and physicians should be aware of other benefits of social media for professionals, patients, and family members. In addition to academic productivity, it is important to recognize how social media could have other important roles in public health. For instance, social media may help propel academic medicine by informing other professionals. Moreover, it is our public health responsibility as a medical community to serve as primary sources of accurate up-to-date medical information online in order to preserve the integrity of what readers consume. Internally, social media can provide an open forum for discussion, boost professional and institutional recognition, attract referrals for trial enrollment and research purposes, and perhaps encourage funding to sustain academic research.

Abstract

Background: The development of an author-level complementary metric could play a role in the process of academic promotion through objective evaluation of scholars' influence and impact.

Objective: The objective of this study was to evaluate the correlation between the Healthcare Social Graph (HSG) score, a novel social media influence and impact metric, and the h-index, a traditional author-level metric.

Methods: This was a cross-sectional study of health care stakeholders with a social media presence randomly sampled from the Symplur database in May 2020. We performed stratified random sampling to obtain a representative sample with all strata of HSG scores. We manually queried the h-index in two reference-based databases (Scopus and Google Scholar). Continuous features (HSG score and h-index) from the included profiles were summarized as the median and IQR. We calculated the Spearman correlation coefficients (ρ) to evaluate the correlation between the HSG scores and h-indexes obtained from Google Scholar and Scopus.

Results: A total of 286 (31.2%) of the 917 stakeholders had a Google Scholar h-index available. The median HSG score for these profiles was 61.1 (IQR 48.2), and the median h-index was 14.5 (IQR 26.0). For the 286 subjects with the HSG score and Google Scholar h-index available, the Spearman correlation coefficient ρ was 0.1979 (P<.001), indicating a weak positive correlation between these two metrics. A total of 715 (78%) of 917 stakeholders had a Scopus h-index available. The median HSG score for these profiles was 57.6 (IQR 46.4), and the median h-index was 7 (IQR 16). For the 715 subjects with the HSG score and Scopus h-index available, ρ was 0.2173 (P<.001), also indicating a weak positive correlation.

Conclusions: We found a weak positive correlation between a novel author-level complementary metric and the h-index. More than a chiasm between traditional citation metrics and novel social media–based metrics, our findings point toward a bridge between the two domains.

Introduction

Since the development of social media platforms and new communication channels, the use of traditional bibliographic metrics (ie, citation counts, h-indexes) as the predominant factors for academic performance has been questioned [1]. Traditional benchmarks such as citation counts fail to capture the authors' impact outside academic circles [2]. The ways in which research output is indexed, searched, located, read, and mentioned have significantly changed, and these ways do not describe the influence and impact that scholarly work may have outside core academic domains [3,4].

In the health care world, social media platforms (eg, Twitter, Facebook) are consistently used by patients, policy makers, clinicians, and researchers as efficient ways of sharing information, staying up to date with scientific knowledge, and collaborating with peers and patients [5]. The widespread use of social media by health care stakeholders has led to the development of alternative impact metrics, also known as "altmetrics" [6]. The altmetrics approach offers new ways to analyze and inform scholarship [7]. It complements rather than replaces traditional indicators of a scholar's performance [8]. Altmetrics have even been adopted aggressively by traditional publishing companies [9]. The study of these alternative metrics is an emerging field; unlike traditional parameters, such as the impact factor or h-index, it does not rely solely on citation counts but is a composite measure. It considers other features such as the number of knowledge databases that refer to the work, and the number of times the work has been viewed and downloaded; it also factors in the number of mentions in social media and traditional news outputs.

Academic merit and achievement should be appraised using frameworks such as the comprehensive researcher achievement model (CRAM) [8], encompassing a combination of four aspects: quantity of researcher outputs (productivity), value of outputs (quality), outcomes of research outputs (impact), and relations between publications or authors and the wider world (influence). Current traditional benchmarks focus mostly on productivity and quality, while alternative metrics focus on influence and impact. In 2011, Eysenbach proposed the Twimpact Factor, an article level social media impact metric consisting of the absolute cumulative number of tweetations 7 days after publication of the article, and the Twindex, which is the relative percentile of the Twimpact Factor of a given article compared with other articles in the same journal [10]. For articles published in the *Journal of Medical Internet Research*, Eysenbach found relatively strong article-level correlations between these metrics (number of tweets, adjusted by time and journal factors) and future citations and highlighted the importance of using social media–based impact measures to complement traditional citation metrics [10]. While social media metrics at the article or journal level already exist and have been correlated with traditional citation metrics [10], novel tools could also be used to evaluate features such as influence and impact at the author level. There is a clear need to improve the ways in which the different outputs of scholarly work are evaluated, as claimed by the Declaration on Research Assessment (DORA) movement [11]. The development of an author-level complementary metric could play a role in the academic promotion process through objective evaluations of scholars' influence and impact.

Recently, multiple organizations have created tools that attempt to measure influence and impact in the digital domain primarily by using network analysis of social media activity and digital publications [12]. Among these innovations, Symplur's Healthcare Social Graph (HSG) score has recently emerged [13]. In this context, we aimed to evaluate the correlation between the HSG, a social media influence and impact metric, and the h-index, a traditional author-level metric.

Methods

Study Design, Study Setting, and Participants

This report was written following the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines [14]. This study was deemed exempt by the Institutional Review Board.

This was a cross-sectional observational study of health care stakeholders with a social media presence randomly sampled from the HSG database in May 2020. Health care stakeholders included the following three taxonomic categories: "doctor" (ie, those identified as possibly licensed, MDs, DOs, PhDs), "health care professionals" (ie, those identified as other health care professionals such as nurses, dietitians, respiratory therapists, and pharmacists), and "researchers/academicians" (ie, people working in the field of health-related research or academia). Over 1 million Twitter profiles were labeled according to the health care stakeholder category as part of the database metadata. Only the profiles of those identifying themselves in their public Twitter profile received a label by Symplur partly through manual verification and partly through a machine learning process [15]. We did not exclude health care stakeholders based on their discipline. Considering the 6 million Twitter accounts that received an HSG score and individuals identified as health care stakeholders in May 2020, we performed stratified random sampling to obtain a representative sample with all strata of HSG scores. A random sample of 100 profiles from each HSG score decile (0-9, 10-19, etc) was obtained, yielding an initial list of 1000 subjects with their respective HSG scores. This stratification method was chosen owing to the skewness of the HSG scores in the Symplur database, where simple probability sampling would lead to a study population restricted to lower values of the HSG score.

Data Source, Variables, and Measurement

Symplur is a health care social media analytics company that created the HSG database holding public digital content (ie, conversations, interactions) originating from Twitter and obtained via the official Twitter application programming interface (API) while supplementing it with other public content from social media platforms including LinkedIn, YouTube, Instagram, Reddit, and Facebook. The HSG score was developed by Symplur to identify and rank influencers in any health care topic and is conceptually like an eigenvector [16]. This score ranks Twitter accounts by their global conversational impact in healthcare over the last 52 weeks. As long as Twitter accounts

XSL•FO
RenderX

have engaged (ie, tweeted at least once) in one of the 40,000 health care terms being tracked, they will be evaluated. The score is not determined by the absolute numbers of tweets or how many mentions they have received for the given time period, but by the impact of the posted messages. The score comprises three components, a social network analysis algorithm, health care stakeholder weighting, and conversation quality algorithm. The network analysis algorithm is inspired by the hyperlink-induced topic search (HITS) algorithm [17] and considers each Twitter account's conversation graph by recursively analyzing the health care influence of each individual conversation partner, the influence of the conversation partner's own conversation partners, and so on [18]. In this respect, it is similar to modern impact factor algorithms for academic journals and Google's PageRank [19]. The score is designed specifically for health care and considers the health care stakeholder groups to which the account holders belong. In other words, it matters what role a person has in health care. If, for example, an account is interacting with or being mentioned by another account that is not related to health care, then those conversations and mentions will have less weight as determined by the algorithm. If, on the other hand, the conversations and mentions are made by a health care stakeholder, then that has more weight according to the algorithm. Based on the analysis of these conversations, a quality score is factored with a conversation volume to provide a weighted measure for the impact scores. After that, the 52 weekly rankings and quality scores are combined into a single number for each social media profile and then normalized on a scale of 0 (very low influence) to 100 (very high influence).

For each of the 1000 Twitter profiles initially included in our stratified random sample, we manually queried their h-indexes in two reference-based databases (Scopus and Google Scholar) by searching their names in each profile service's search engine. Before extracting the data, we used a standardized verification process to confirm if the identified profiles corresponded to the Twitter user. Any profile found in Google Scholar or Scopus was verified using at least three of the following identifiers: name (first, middle, last), title, location (country/city), field/specialty, affiliation, and qualitative analysis of Twitter conversations or a free-form Google search using the associated name and any other identifier available. Once a profile was found in either of the platforms and the verification process confirmed with at least three identifiers, the h-index was extracted. This verification process was created to decrease the probability of extracting data from an incorrect profile (eg, similar name but not the author of interest). In Google Scholar and Scopus, the h-index is calculated as "number *n* of a researcher's papers that have all received at least *n* citations" [20]. Although there have been multiple studies [20-24] that have highlighted the advantages, disadvantages, and variations, no other traditional author-level metric has had the same level of acceptance or resilience over the past 15 years. Individuals can calculate the h-index of any researcher as long as they have access to a resource providing the citation count of that researcher's publications or research objects. The three most prominent resources or platforms that provide citation counts for researchers are the Web of Science (Clarivate Analytics – previously of Thomson Reuters), Scopus (Elsevier), and Google Scholar (Alphabet). To provide a more comprehensive reporting for this study, Scopus and Google Scholar were chosen to provide the traditional/benchmark h-index data for each individual. This decision was based on the 2018 study by Martin-Martin et al [25], which found that the greatest inclusion of citations in Health & Medical Sciences was on Scopus and Google Scholar. Additional factors were considered when choosing between Web of Science and Scopus. Scopus was seen as providing all authors better access to their own author profiles, which would allow authors to clarify their publications and correct inaccuracies. Additionally, a 2016 study by Walker et al [26] showed a higher interrater reliability in Scopus than in Web of Science for the h-index calculation.

The h-index for the first 100 profiles was independently extracted by three independent investigators (LOJS, GM, and TB). In this initial set of 100 profiles, there was a 98% overall agreement for the h-index extracted from Google Scholar and a 96% overall agreement for the h-index extracted from Scopus. Disagreements were discussed and resolved through consensus with the senior author (DC). Once our standardized verification process and data extraction methods exhibited adequate reliability, the remaining profiles were extracted independently; 600 were reviewed by the first author (LOJS) and 150 by each of the two other investigators (GM, TB). Investigators extracting the h-index for these profiles were blinded to the HSG scores of all subjects.

Data Analysis

From the initial list of 1000 subjects, we excluded those with incomplete names or non-individual user profiles. The remaining profiles were included for the main data analysis if an h-index was available from either Google Scholar or Scopus. All analyses were conducted using the BlueSky Statistics (Version 7.0.746.34007) graphic user interface (GUI) for R. Continuous features (HSG score and h-index) from included profiles were summarized as the median and IQR. Correlation analyses were performed between the HSG scores and h-index obtained from Google Scholar (overall h-index and 2015 h-index) and Scopus (overall h-index). Given the highly skewed nature of metrics such as the h-index [27], we calculated the Spearman correlation coefficient (ρ). This is similar to the Pearson correlation, but it is based on ranks rather than original values. Like the Pearson correlation, values range from –1 to +1, with larger absolute values indicating a stronger relationship. A correlation *t* test was conducted to evaluate the statistical significance of the correlation coefficients. *P* values <.05 were considered statistically significant. For sensitivity analysis, we considered the h-index as 0 for those subjects in which a Scopus h-index was not found.

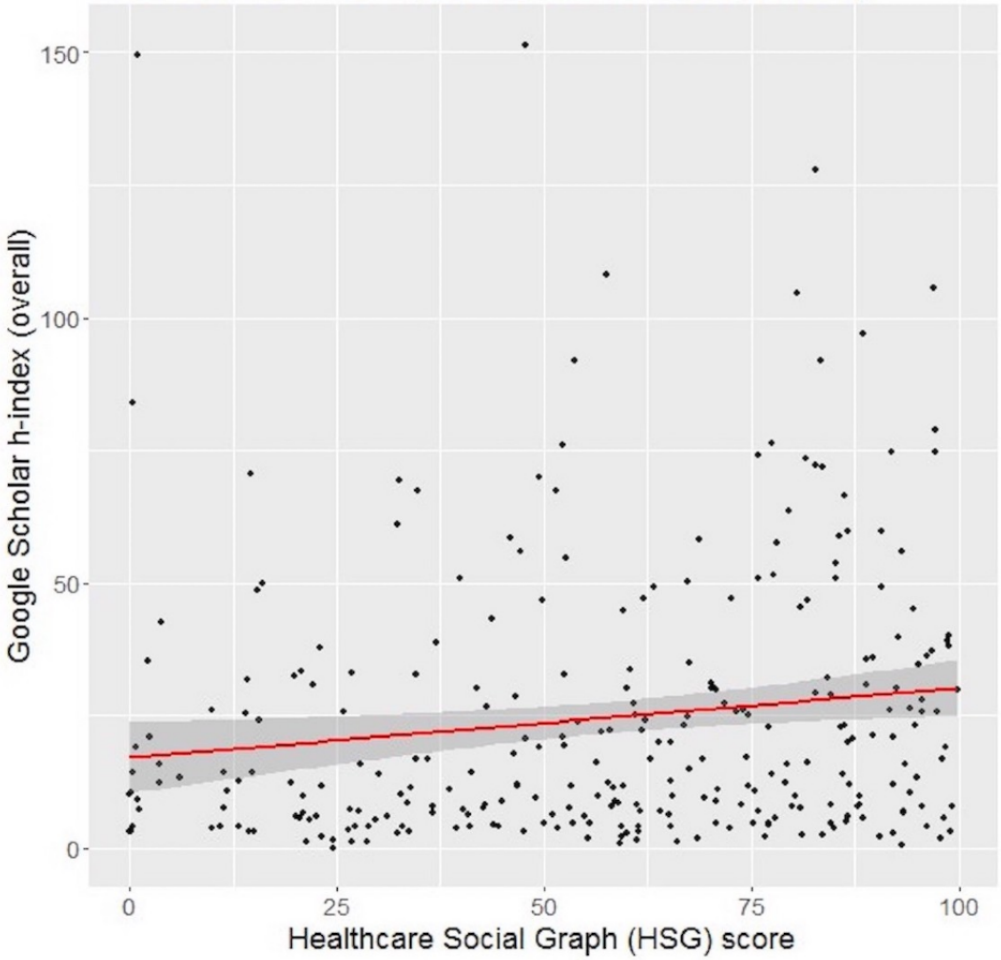
Simple linear regression was initially implemented to understand the linear relationship between the HSG score and h-index (Google Scholar and Scopus). To better understand the true relationship between the HSG score, and the overall h-index provided by Google Scholar and Scopus, negative binomial hurdle regression was performed. The h-index was used as the response variable, and the HSG score was the predictor of interest. A negative binomial model was chosen owing to the skewed nature of the h-index data and the overdispersion present

XSL•FO
RenderX

in the data distribution. To account for the high number of zeroes not covered by a negative binomial distribution, a hurdle model with a binomial logistic link function was also implemented. Model selection was performed using the Vuong test and the Akaike information criteria (AIC).

Results

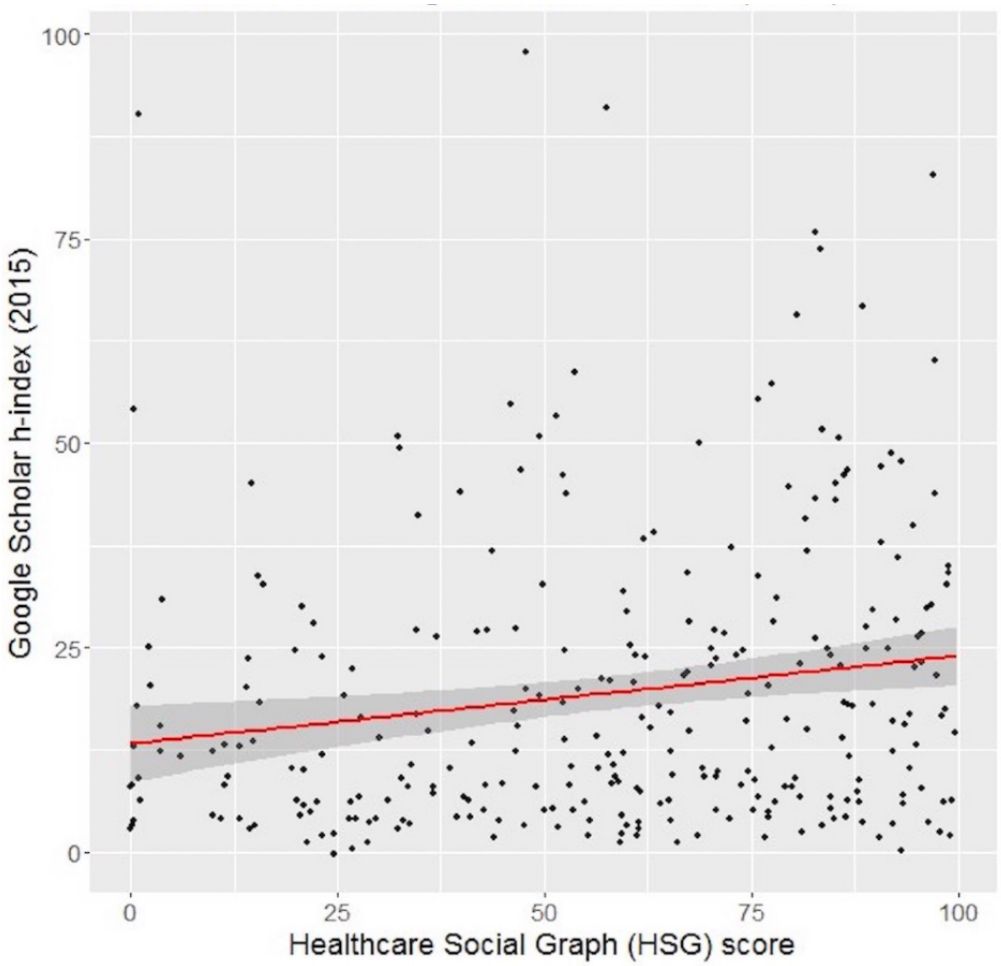
Twitter Profiles



Our stratified random sample generated an initial list of 1000 Twitter profiles from the Symplur database. Of these, 83 were excluded for the following reasons: 5 were repeated profiles, 62 had incomplete names on Twitter (ie, no first and last names, making it impossible to search for a corresponding Google Scholar or Scopus profile), and 16 were not individual user profiles. Among the 917 individual Twitter profiles with complete names for which h-indexes were searchable, 429 (46.8%) were from the United States, 173 (18.9%) from the United Kingdom, 54 (5.9%) from Canada, 49 (5.3%) from Spain, 41 (4.5%) from Australia, 17 (1.9%) from India, 13 (1.4%) from the Netherlands, 13 (1.4%) from France, 12 (1.3%) from Ireland, 9 (1.0%) from Brazil, and the remaining 11.6% from 36 other countries from all continents (only 5 profiles were from unknown countries).

A total of 286 (31.2%) of the 917 stakeholders had a Google Scholar h-index available. The median HSG score for these profiles was 61.1 (IQR 48.2), and the median h-index was 14.5 (IQR 26). A total of 715 (78%) of the 917 stakeholders had a Scopus h-index available. The median HSG score for these profiles was 57.6 (IQR 46.4), and the median h-index was 7 (IQR 16).

Google Scholar h-Index

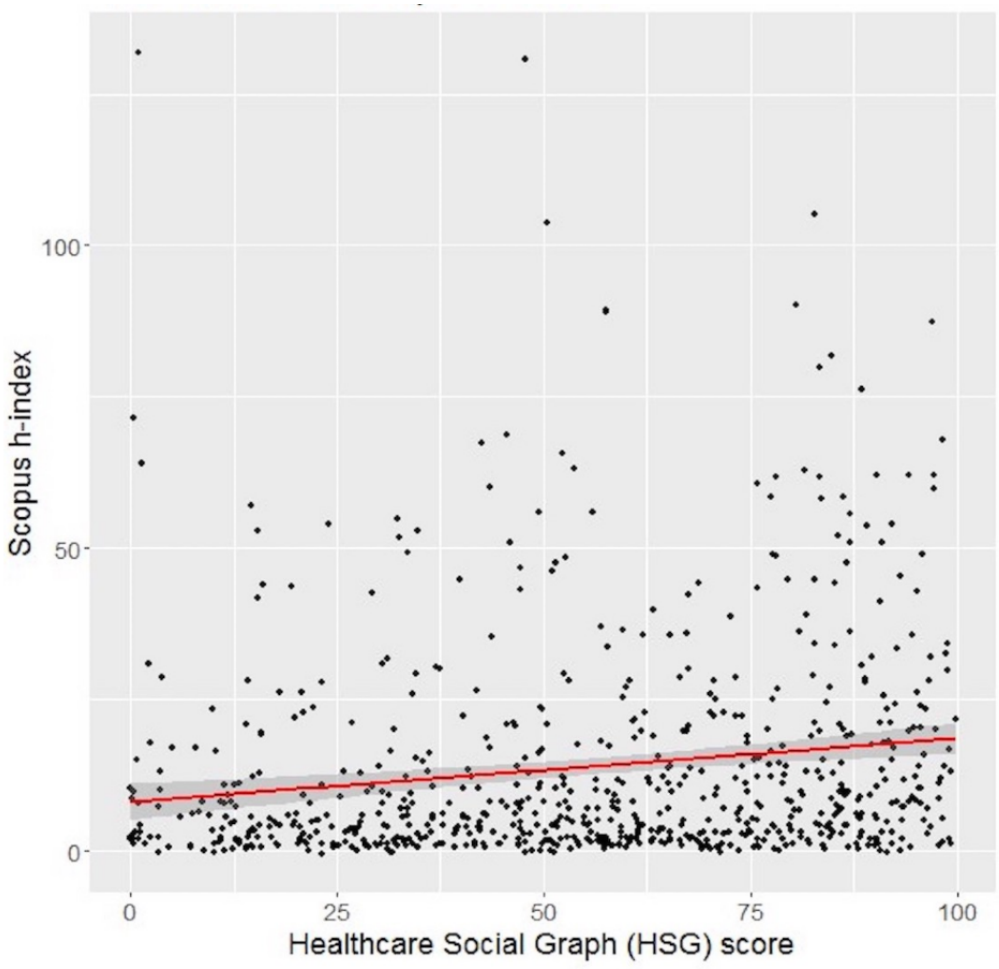


For the 286 subjects with the HSG score and overall h-index provided by Google Scholar available, the Spearman correlation coefficient ρ was 0.1979 (P<.001), indicating a weak positive correlation between these two metrics (Figure 1). When we analyzed the correlation for the 2015 h-index from Google Scholar, the results were similar (ρ=0.203) (Figure 2). Also, when we analyzed the Google Scholar i10 index, the results did not change significantly (see Multimedia Appendix 1 and Multimedia Appendix 2).

Figure 1. Correlation between HSG scores and Google Scholar overall h-indexes. Spearman correlation coefficient ρ=0.1979 (N=286). The red line is the regression line; the shaded area is the 95% CI.

XSL•FO
RenderX

Figure 2. Correlation between HSG scores and Google Scholar 2015 h-indexes. Spearman correlation coefficient ρ=0.203 (N=286). The red line is the regression line; the shaded area is the 95% CI.



Linear regression using the Google Scholar overall h-index as the response found a significant association between the HSG score and h-index. Assuming a linear relationship, for every 10-point increase in the HSG score, there was an associated increase of 1.134 in the h-index (95% CI 0.280-2.347; *P*=.01). The R^2 value was 0.0214 and the linear regression equation is expressed as (E[Google Scholar overall h-index] = 17.037 + 0.1314*[HSG score]). From the negative binominal hurdle model, there was no effect of the HSG score on whether an author's Google Scholar h-index is 0 or positive (log-odds=0.043; *P*=.31). However, for authors with a positive h-index, a 5-point increase in the HSG score was associated with a 2.7% increase in Google Scholar h-index (exp[coef]=1.027; 95% CI 1.006 -1.048; *P*=.01). Additionally, the Vuong test found that the hurdle model was a better fit than the negative binomial model (*z* statistic=3.092; *P*<.001).

Scopus h-Index

For the 715 subjects with the HSG score and Scopus h-index available, the Spearman correlation coefficient ρ was 0.2173 (*P*<.001), also indicating a weak positive correlation (Figure 3). In the sensitivity analysis, in which subjects without a Scopus h-index available were computed as having an h-index of 0, therefore including all 917 initially eligible profiles, the Spearman correlation coefficient ρ was 0.317 (*P*<.001) (see Multimedia Appendix 3).

XSL•FO
RenderX

Figure 3. Correlation between HSG scores and Scopus h-indexes. Spearman correlation coefficient ρ=0.2173 (N=715). The red line is the regression line; the shaded area is the 95% CI.

Univariate linear regression fitting of Scopus h-indexes found a significant association with the HSG score. Assuming a linear relationship, for every 10-point increase in the HSG, we expect a 1.049-point increase in the h-index (95% CI 0.567-1.530; P<.001). The R^2 value was 0.0249 and the linear regression equation is expressed as (E[Scopus h-index] = 8.0821 + 0.1048*[HSG score]). From the negative binomial hurdle model, we found no significant effect of the HSG score on whether an author's h-index is 0 or positive (log-odds=0.0072; P=.27). However, for authors with a positive h-index, a 5-point increase in the HSG score was associated with a 4% increase in h-index (exp[coef]=1.040; 95% CI 1.021-1.061; P<.001). The Vuong test found that the hurdle model was a better fit than the negative binomial model (z statistic=4.606; P<.001).

Discussion

Principal Results

The advent of digital scholarship is rapidly changing the way scholarship is created and appraised in academia. We are currently seeing a swift transition from a paradigm in which the impact of an academician was circumscribed to deliverables critiqued by a restrictive circle of peers to a novel model in which the importance of scholarly work is measured by the influence and impact it generates in academic circles and among the general public. This leads to the critical need to adopt new appraisal concepts and tools [1,10,28].

The HSG score represents a novel author-level tool within the domain of altmetrics. This metric aims to measure and illustrate the influence a particular stakeholder has in health care social media as a function of user-generated content and interactions. This method is common for analyzing the weight or importance of specific users that are part of larger networks [29]. In general, the more the connections and the more information users create or are involved with, the greater their importance in a network [30].

Citation-focused metrics such as the h-index assess the importance of academicians based on the number of times their work has been cited by other scholars, with a significant bias constructed to value certain outputs (eg, prestigious journals) more than others. This distorts the organic reach and impact of articles (eg, where bad articles in good journals are valued more than good articles in bad journals), conflagrating production and publishability with influence and impact [31].

In this study, we aimed to find if there is a relationship between the HSG score, a marker for influence in a network, and the h-index, a metric for productivity. The assumption driving this comparison was that a high degree of productivity (greater h-index) would be associated with higher impact among

XSL•FO
RenderX

stakeholders in the field and subsequent influence on digital networks.

Approximately three quarters of health care stakeholders identified by HSG scores had a concomitant h-index profile; this simple observation illustrates that there is a significant overlap between academic endeavors and the participation of these users in social media. In other words, academicians are part of general public forums such as social media; they value such forums and participate in them.

When analyzing the relation between the HSG score and h-index, we found a correlation, albeit a weak one, between the two metrics. This positive relation seems to indicate that the higher the HSG score, the higher the h-index (and vice versa). We believe the association describes a relation between scholarly productivity and influence in a health care network; this is possibly explained by academicians using digital domains to disseminate their scholarly work and subsequently bring attention to it, by measuring interactions with other stakeholders and organically increasing their connections and weight in the network. Nevertheless, it is important to mention that the low R^2 value approximately at 2% implies that although we have a statistically significant correlation and are capturing similar trends, there is a sizable amount of variability that is not shared between these two metrics. This emphasizes the simple fact that these metrics measure *different* components of scholarly work and should be evaluated in an independent and complementary way.

The HSG score and h-index are metrics that are of interest for scholars and academic establishments. Per their definitions, these tools are aimed at different aspects of the CRAM framework [8], where the HSG score likely appraises impact and influence and h-index productivity and quality. Remarkably, from our analysis, we can describe an association bridging these four aspects; the influence and impact of a user in a health care–specific digital network are correlated with their academic productivity and quality. More than a chiasm between traditional citation metrics and novel social media–based metrics, our findings point toward a positive relation between the two domains.

Limitations

There are several limitations that need to be acknowledged. First, the accuracy of the metrics that were obtained (which were subsequently used to compute correlations) depends on the validity of the data provided by each reference-based database. Some of these platforms (eg, Google Scholar) can easily be manipulated [32]. Scopus automatically calculates the h-indexes of authors without a profile in their database, which explains why there were higher numbers of profiles and h-indexes available in Scopus when compared to Google Scholar, in which individuals need to create active profiles. In Scopus, authors may have more than one profile and, for this reason, we have used an available tool in their platform to combine profiles from the same author to obtain the most accurate h-index for that author. Second, Scopus and Google Scholar data are dynamic because new citations are constantly being added to their databases. As we were unable to automatically retrieve the h-indexes from these databases on the same day, manual data extraction occurred over a four-month period. Therefore, authors may have had their h-indexes extracted with a time difference as long as 100 days, and this, although unlikely, could have influenced the accuracy of our analysis. We assumed that the h-index would be time invariant (while in fact it is not) during the period of data extraction. Nevertheless, the h-indexes should theoretically be less dynamic than citations alone, and it is unlikely to change by a large magnitude even after a 100-day period [33]. Third, we have not considered the ages of the authors, which might have an impact on the correlation measures given that more experienced authors may exhibit distinctive behavior compared to emerging authors. Fourth, Google Scholar seems to overestimate author-level metrics when compared to Scopus owing to inclusion of gray literature citations, among other reasons. However, we extracted the h-indexes from both databases, and the results did not change when using one h-index over another. In fact, the h-indexes from Google Scholar and Scopus were strongly correlated with each other (see Multimedia Appendix 4).

Conclusions

It appears that novel author-level altmetrics based on network analysis in social media and digital publications have a positive association with traditional bibliometric benchmarks. This seems to indicate that not only can they coexist but can also supplement and augment each other's domains. Academicians interested in a comprehensive appraisal of their academic work and preparing for advancement need to be deliberate about investing time and attention into both spheres of appraisal (traditional and altmetrics), as they are relevant, significant, and most importantly appear to move in the same direction and amplify each other.

Acknowledgments

This research was supported in part through the Center for Clinical and Translational Science (CCaTS) Small Grant Program, part of Mayo Clinic CCaTS grant number UL1TR000135 from the National Center for Advancing Translational Sciences (NCATS), a component of the National Institutes of Health (NIH). Its contents are solely the responsibility of the authors and do not necessarily represent the official view of NIH.

Authors' Contributions

LOJS and DC conceived and designed the study. LOJS, GM, and TB conducted the acquisition of the h-index data. AU executed the stratified random sampling from the Symplur database and provided the HSG scores. AM analyzed the data and provided statistical expertise. LOJS, GM, TB, and DC interpreted the data. LOJS and DC drafted the manuscript and all authors contributed

XSL•FO
RenderX

substantially to its revision through critical reviewing of the manuscript for important intellectual content. DC (senior author) was responsible for overseeing the project.

Conflicts of Interest

AU is a Partner of Symplur. AU provided the initial sample of subjects included in the study with their corresponding HSG scores. Data extraction of h-index and data analysis were performed independently by the other investigators. AU did not influence the study design, did not participate in the data extraction of the h-index, and did not participate in the analysis of the results or writing of the conclusions. No other investigators have any conflicts of interest to disclose related to this study.

Abstract

Background: The COVID-19 pandemic has highlighted the urgency of addressing an epidemic of obesity and associated inflammatory illnesses. Previous studies have demonstrated that interactions between single-nucleotide polymorphisms (SNPs) and lifestyle interventions such as food and exercise may vary metabolic outcomes, contributing to obesity. However, there is a paucity of research relating outcomes from digital therapeutics to the inclusion of genetic data in care interventions.

Objective: This study aims to describe and model the weight loss of participants enrolled in a precision digital weight loss program informed by the machine learning analysis of their data, including genomic data. It was hypothesized that weight loss models would exhibit a better fit when incorporating genomic data versus demographic and engagement variables alone.

Methods: A cohort of 393 participants enrolled in Digbi Health's personalized digital care program for 120 days was analyzed retrospectively. The care protocol used participant data to inform precision coaching by mobile app and personal coach. Linear regression models were fit of weight loss (pounds lost and percentage lost) as a function of demographic and behavioral engagement variables. Genomic-enhanced models were built by adding 197 SNPs from participant genomic data as predictors and refitted using Lasso regression on SNPs for variable selection. Success or failure logistic regression models were also fit with and without genomic data.

Results: Overall, 72.0% (n=283) of the 393 participants in this cohort lost weight, whereas 17.3% (n=68) maintained stable weight. A total of 142 participants lost 5% bodyweight within 120 days. Models described the impact of demographic and clinical factors, behavioral engagement, and genomic risk on weight loss. Incorporating genomic predictors improved the mean squared error of weight loss models (pounds lost and percent) from 70 to 60 and 16 to 13, respectively. The logistic model improved the pseudo R^2 value from 0.193 to 0.285. Gender, engagement, and specific SNPs were significantly associated with weight loss. SNPs within genes involved in metabolic pathways processing food and regulating fat storage were associated with weight loss in this cohort: rs17300539_G (insulin resistance and monounsaturated fat metabolism), rs2016520_C (BMI, waist circumference, and cholesterol metabolism), and rs4074995_A (calcium-potassium transport and serum calcium levels). The models described greater average weight loss for participants with more risk alleles. Notably, coaching for dietary modification was personalized to these genetic risks.

Conclusions: Including genomic information when modeling outcomes of a digital precision weight loss program greatly enhanced the model accuracy. Interpretable weight loss models indicated the efficacy of coaching informed by participants' genomic risk, accompanied by active engagement of participants in their own success. Although large-scale validation is needed, our study preliminarily supports precision dietary interventions for weight loss using genetic risk, with digitally delivered recommendations alongside health coaching to improve intervention efficacy.

Introduction

Background

The global death toll of COVID-19 has eclipsed 1 million cases [1]. Obesity, following age, has emerged as the most critical risk factor for morbidity, hospitalizations, and complications [2]. The prevalence of obesity in the United States and in other Western countries has increased sharply in the last 2 decades. Since the early 1960s, when more than 10% of Americans were obese, that proportion has grown to 42.4% of adults [3]. Moreover, the prevalence of obesity is higher in minority communities: 49.6% of non-Hispanic Black individuals and 44.8% of Hispanic Americans are obese, compared with 42.2% of non-Hispanic White individuals. These same minority communities are experiencing disproportionate COVID-19–driven mortality, likely linked, at least in part, to the heightened prevalence of obesity [4]. Although the precise cause of obesity is yet to be discovered, several factors have been linked to its development [5]. In particular, biology interacts with behavior and demographics (such as socioeconomic status or ethnic and cultural cuisine) to influence obesity risk [6]. Obesity-associated biological factors include, but are far from limited to, genetics and epigenetics, microbiome composition, age, circadian rhythm disruption, pharmaceutical interactions, and comorbidities and their management [6,7].

The rapid increase in obesity prevalence has coincided with sociological factors, such as generally reduced physical activity alongside a rise in the consumption of highly processed, high-calorie, but nutrient-poor foodstuffs. However, these obesogenic conditions did not affect the population uniformly. Instead, a notable proportion of the population is still able to remain at a healthy weight, indicating that the heterogeneous response to obesogenic conditions may result, in part, from individual innate protection from these conditions, possibly conferred by the genetic makeup [8].

Most current clinical interventions for obesity management focus on lifestyle and dietary adaptation with varying levels of professional guidance and involvement, short- or long-term pharmaceutical therapies, and bariatric surgery [9]. Individual responses to these therapeutic interventions are confoundingly (for clinicians and participants alike) heterogeneous for multifactorial reasons [10], making the need for personalized, precision medicine courses of treatment imperative. Most Americans (63%) have made serious efforts toward weight loss over the course of their lives, and almost one-third are trying to lose weight [11]. In 2014, commercial weight loss services were a US $2.5 billion market consisting primarily of the following market shares—Weight Watchers (45%), NutriSystem (14%), and Jenny Craig (13%)—but the long-term effectiveness of various commercial *calorie restriction*–based weight loss programs is unclear [12-14] (Table 1).

Table 1. Commercial weight loss services

Program	Market share (%)	Intervention	Cost per month, US $
Jenny Craig	13	Low-calorie meal replacements with one-on-one counseling	>450
Nutrisystem	14	Low-calorie meal replacements with one-on-one counseling	300-350
Weight Watchers	45	Self-monitoring with web-based coaching and points tracking	43 (plus food)

Personalizing Weight Loss Interventions

Recent research has elucidated the mechanisms of food-derived biomarkers, allowing for stratification based on a participant's unique metabolism of given food products. This permits the targeting of personalized nutrition to groups that are better characterized [8,15,16]. For example, given that low-grade inflammation has been implicated in insulin resistance, mediating inflammation via targeted dietary approaches is a precision nutrition intervention [17,18].

Advances have already been made in the early intervention and risk assessment of participants who are obese by designing therapies based on unique genetic predisposition and risk. Environmental interventions such as diet and exercise can trigger epigenetic changes, altering gene expression in metabolic pathways. Recent research indicates that physical activity and high-fat diets may alter DNA methylation patterns in skeletal muscle and adipose tissue [19-21], influencing weight management [8]. Eventually, researchers hope to elucidate the genetic patterns that influence individual obesity and concomitant illness susceptibility, risk of progression, and response to therapy, to provide participants with optimal treatment [22].

Epigenetics and Their Role in Obesity

Even as science illuminates many genetic risk factors of complex metabolic diseases such as obesity and type 2 diabetes [23-27], these genetic variants account for only a fraction of BMI variation [25]. The *missing* heritability of obesity might be at least partially explained by interactions between genetics and environmental factors [28]. In particular, specific gene variants may influence sensitivity to certain environmental factors so that exposure to these factors in susceptible individuals can contribute to disease. As individuals who are obese are characterized by considerable heterogeneity within the spectrum of clinical obesity, supporting gene-diet interaction and precision nutrition in different subtypes of obesity is imperative [29-33].

Bariatric surgery is a weight loss option for participants with severe and complex obesity, for whom dietary interventions or digital therapeutics have been less than successful [34-36].

XSL•FO
RenderX

Genetics may be a significant predictor of weight loss following Roux-en-Y gastric bypass surgery [37], but few genetic variants have been characterized to date [38,39].

The Role of Diet in Obesity

Although obesity can, in some cases, be linked to excessive appetite and food consumption, these behaviors may have a genetic component, and even food preferences themselves may have a genetic basis [40,41]. For example, the alpha-ketoglutarate-dependent dioxygenase (FTO) locus rs9939609 has been associated with reduced satiety [42], increased caloric and fat intake [43,44], and a propensity to consume calorie-dense foods [43,45]. The TAS2R38 genotype differentiates potential super-, medium-, and nontasters of bitter-tasting thiourea compounds. These different bitter-tasting profiles appear to be predictive of differential dietary preferences, and in particular, nontasters were observed to have higher BMIs [46]. Considered together and alongside other evidence, this research implies that body weight and BMI may be affected by genetic variations in food preferences, tendencies, and eating behaviors. Elucidating how food intake and body metrics are mediated by genetics is challenging because of the difficulty of reproducing results across varying populations and the complexity of identifying causal interactions [47-49]. Research using randomized controlled trials (RCTs) and large sample–sized biobanks with electronic health records will better characterize how diet and genetics interact to mediate health outcomes [50,51].

The Role of Physical Activity in Obesity

Exercise that can prevent weight gain and promote weight maintenance has been well established through research [52-55]. Evidence suggests that body weight, waist-to-hip ratio, and BMI are significantly associated with adherence to an aerobic exercise intervention [56]. Interestingly, the propensity for exercise appears to be heritable, at least in part, with studies estimating heritability ranging from 9% to almost 80% [57]. MC4R genes appear to be associated with physical inactivity [58]; however, other genes may be associated with adherence and tolerance to physical activity regimens [56].

Gut Microbiome and Its Role in Obesity

The human gastrointestinal tract hosts millions of commensal micro-organisms comprising the gut microbiome, which acts as a virtual endocrine organ regulating nutrient production and metabolism, satiety, and even energy homeostasis [8,59]. These microbes are intrinsically linked to host health, as they are implicated in nutrient processing and metabolism, pathogen displacement, vitamin synthesis, and body weight regulation [60]. Researchers and clinicians have been studying alterations of the gut microbiome in individuals, as perturbations in the gut microbiome appear to underlie the pathophysiology of obesity and associated comorbidities, such as type 2 diabetes and metabolic syndrome [61,62]. Microbiome profiling for nutritional intervention is gaining prominence as a key feature of precision nutrition.

Research on the impact of specific dietary factors on microbiome diversity can guide interventions focused on optimizing gut microbial composition [63]. For example, variation in the lactase (LCT) gene region, associated with response to dairy intake, appears to be associated with the abundance of the gut microbiome Bifidobacterium [64]. In particular, variations in LCT were found to be predictive of the obesity-based modulation of dairy lactose and milk intake [65], indicating that shifts in gut microbiota across LCT genotypes could be tied to the caloric extraction of ingested food [65]. Similar to specific genes, specific bacterial species have also been directly implicated in the etiology of obesity. Methanobrevibacter smithii, for example, can itself metabolize dietary substrates or metabolic byproducts of other bacteria, thereby promoting weight gain [66].

Further evidence ties both an individual's genetics and diet to microbiome composition because lower microbial diversity appears to be associated with excess weight gain [67]. Even in early childhood, disruptions in the gut microbiome can have a long-lasting influence on adult body weight [68]. Moreover, nutritional interventions such as administering prebiotics and probiotics to manipulate gut microbiota that promote or are refractory to weight loss show potential as obesity interventions but require further study [69]. Weight loss, whether mediated by diet or via bariatric surgery, can alter the gut microbiome in ways that affect the efficacy of various weight loss strategies [70,71]. An interesting feature of bariatric surgery is that it appears to induce obesity-associated gut microbiota to shift toward lean microbiome phenotypes [72].

Behavioral and Digital Interventions in Obesity

As the obesity epidemic continues to proliferate, new digital programs available on websites or as smartphone apps are being leveraged to promote weight loss [73]. Digital programs are agile in that they can easily be modified to reflect the latest research and best practices in a rapidly changing field; they are more cost-effective than traditional in-person programs and are also more easily scalable, increasing their reach [74,75]. Resources can include activity trackers, videos, logs, device-to-device communication, and third-party app compatibility [76]. In addition, research indicates that remotely administered programs can result in significant weight loss [76-79].

Digital programs have the ability to provide personalization to address the plethora of needs presented by participants [76]. Individuals partaking in such programs are still able to leverage interpersonal relationships. Digital health coaching, for example, allows participants to discuss their weight loss journey via any number of communication platforms [75]. According to research, both in-person and telehealth coaching relationships are effective in motivating overweight individuals to work toward weight loss [80]. In a recent study of more than 600 participants in a smartphone-based weight loss program with a coaching component, participants lost, on average, more than 7% of their body weight, successfully passing the 5% weight loss marker that many in-person programs set [75].

The multifactorial nature of obesity is reflected in the myriad heritable, behavioral, and environmental factors that can lead to obesity risk [47]. The most successful interventions are likely to be those that leverage current findings across the full spectrum of obesity-related risk factors: dietary interventions accounting

XSL•FO
RenderX

for both genetic markers of food sensitivity, metabolic predispositions, and behavioral risk as well as those geared toward optimizing gut microbial diversity and composition; physical activity measures taken in consideration of genetic risk profiles; and behavioral modifications undertaken via digital care [59]. The precision nutrition therapy offered by Digbi Health aims to account for these various factors in delivering a personalized course of obesity intervention [59]. In this study, we describe the weight loss of a cohort of participants enrolled in the Digbi Health program, modeling and analyzing genomic, lifestyle and engagement factors that were found to be influential in this cohort. It was hypothesized that weight loss models would exhibit a better fit when incorporating genomic data than when using demographic and engagement variables alone.

Methods

Recruitment

For this study, we identified all Digbi Health participants who were enrolled between June 2019 and June 2020, had been in the program for at least 120 days, and had been genotyped by Digbi Health. Sample collection kits were shipped to 443 participants, of which 393 mailed back their samples for processing, thereby yielding a cohort size of 393. Among these participants, 315 individuals self-identified as female, 77 individuals self-identified as male, and one individual declined to state. All participants self-enrolled for the Digbi Health therapy via a large California-based insurance payor wellness program. The qualifying criteria to join the program were BMI >25 kg/m^2 with a comorbidity (eg, prediabetes, diabetes, cardiovascular disease, or hypertension) or BMI >30 kg/m^2, regardless of comorbidities. Participants were advised to remain under the care and supervision of their existing physicians and were further advised to notify physicians and other health care providers of their participation in the Digbi Health program. The data set included data from each participant's first 120 days in the program. This Digbi Health anonymized, retrospective research study was exempted from full review by the Ethical and Independent Review Services West Coast Board, Corte Madera, California, reference 20149-01. All participants agreed to the Digbi Health terms and conditions and privacy policy when enrolling in the therapy.

Intervention

Digbi Health is a next-generation, prescription-grade, digital therapeutic platform that uses artificial intelligence to analyze genetics, gut bacteria, lifestyle habits, and socioeconomic and behavioral risk patterns to create evidence-based personalized nutrition, fitness, sleep, and stress management programs to reduce weight and reverse weight-related inflammatory gut, musculoskeletal, cardiovascular, and insulin-related diseases. Digital precision care interventions are delivered via web-based or mobile apps to expand the accessibility, safety, and effectiveness of health care. Digbi Health's individualized program is geared primarily toward individuals who are overweight or obese, with or without a comorbidity, and functions as a weight loss management tool. The therapy is currently covered by a large California-based health insurance payor for their qualifying members through its obesity management wellness platform.

On enrolling in the Digbi Health program, participants were provided with web-based log-in credentials and were mailed a Bluetooth-compatible digital weighing scale and saliva and stool biosampling kits. App usage consisted of daily tracking of weight (via the Bluetooth scale), tracking of dietary intake (uploading photographs of all food items consumed), and tracking wellness-associated metrics (sleep quality and quantity, exercise type and duration, stress and meditation, energy levels, cravings, and recommended foods consumed or avoided).

Sample Collection

The individual's DNA was self-collected using a buccal swab (Mawi Technologies iSwab DNA collection kit, model no. ISWAB-DNA-1200). Saliva DNA extraction, purification, and genotyping using Affymetrix Direct to Consumer Array version 2.0 on the Affymetrix GeneTitan was all performed by the AKESOgen laboratory. The results presented in the genetics section of the report were determined by the number of markers and risk genotypes present in the genomic raw data, the Digbi Health reports were loaded into the app, and coaching was individualized based on participants' genomic risk factors. Individuals' gut microbiomes were self-collected via a fecal swab (Mawi Technologies iSWAB Microbiome collection kit, model no. ISWAB-MBF-1200). Sample processing and 16SrRNA-targeted next-generation sequencing were performed at the AKESOgen laboratory. Although the app and coaching are personalized based on participants' microbiome data, these data were not analyzed in this study and are the subject of a forthcoming research article. The personalized Digbi Health plan was systematically reviewed with the participants in individualized sessions with the health coach over a 4-month period at regular, predetermined, weekly, and biweekly intervals.

Genetic Report

The Digbi Health genetic report consisted of two sections: gene nutrition and gene fitness. The gene nutrition report analyzed participants' genotypes that have been shown to influence nutritional traits, such as diet and weight management, micronutrient requirements, food intolerance and sensitivity, and several other attributes relevant to nutritional well-being. For each of these traits, participants were assigned a *high*-, *medium*-, or *low*-risk score based on the number of risk alleles detected, and health coaches guided interventions based on these potential risks (eg, suggesting someone with high risk for gluten intolerance eliminates dietary gluten or someone with medium risk reduces consumption). The degree of risk associated with any specific single-nucleotide polymorphism (SNP) was determined by the presence of 0, 1, or 2 risk alleles. Several individual SNPs may have contributed to a single trait or function, and some of these SNPs might have increased the risk for a trait, whereas others may have decreased it. In Digbi Health gene reports, as many SNPs as possible were considered when determining the risk of a particular trait. Although Digbi Health coaching is individualized based on several different traits, a number of notable traits and associated SNPs and how risk factors for these traits inform individualized health coaching

XSL•FO
RenderX

have been highlighted in the *Results* and *Discussion* sections of this paper.

The gene fitness report analyzed SNPs studied in conjunction with fitness regimes, exercise motivation, and the ability to develop various types of muscle fibers. This section of the report also analyzed the potential inflammatory response to exercise, including endurance, strength, and flexibility training. As in the gene nutrition section, each trait was assigned a *high*-, *medium*-, or *low*-risk score based on SNP data, and health coaches guided participants through recommendations for healthy exercise.

Gut Microbiome Report

In addition to using genetic risk profiles to guide the course of participants' precision care, the Digbi Health program also analyzed gut microbiome profiles (collected from stool swab sampling) to guide the course of care. However, in this study, we aimed to analyze only the effect of demographics and lifestyle and genomic factors on weight loss; the incorporation of the related microbiome data and how they inform individualized health coaching is the subject of forthcoming analyses from our group, currently in preparation.

Lifestyle

The Digbi Health therapy is a 120-day program that uses body metrics, gut microbiome and genetic profiles, and personalized health coaching to manage weight loss. Participants use the Digbi Health app to track 10 key lifestyle and wellness markers (weight, sleep, hunger, cravings, stress, meditation, superfoods, morning energy, foods to avoid, and exercise) on a daily basis and take photos of the food they consume. Each participant is assigned a health coach who works personally with the participant through 12 guided sessions at various intervals to interpret the personalized wellness reports generated from sampling participants' DNA and gut microbiota. The reports also provide a breakdown of obesity risk based on individuals' genetic and gut microbiome profiles. The program is geared toward participants losing at least 5% of their baseline body weight by day 90 of the 120-day program. To achieve this goal, the program seeks to nudge participants toward making incremental lifestyle changes focused on reducing sugar consumption, timing meals to optimize insulin sensitivity, reducing systemic inflammation by identifying possible inflammatory and anti-inflammatory nutrients via genetic testing, and establishing a base level of physical activity. The personalized incremental behavioral modifications suggested by the program are designed to reduce inflammation, optimize gut health based on microbiome testing, and most importantly are supported by health coaching and the app to integrate into the participant's lifestyle so as to be sustainable long term. The genetic profile of Digbi Health users identifies several nutrient and food risk factors that have associations with obesity, comorbidity, or inflammatory risk (eg, gluten sensitivity, lactose tolerance, caffeine sensitivity, fatty acid metabolism, blood pressure response to salt or riboflavin intake, or reduced insulin resistance with exercise), and health coaching guidance is tailored specifically to incorporate participants' risk profiles.

Statistical Analysis

The data from our cohort of 393 participants over their first 120 days in the Digbi Health personalized digital weight loss program were analyzed retrospectively. Interpretable regression models (linear and logistic) were built, and visualizations generated using R software (R Core Team). Modeling of demographic and behavioral engagement was conducted by fitting 2 linear regression models of weight loss (pounds lost and percentage lost) in this cohort as a function of the variables listed in Table 2.

Table 2. Mean demographic and engagement variables overall and by gender.

Variables	Values, mean (SD)	Males, mean (SD)	Female, mean (SD)
Starting BMI	34.77 (6.66)	33.75 (5.36)	35.01 (6.92)
Age (years)	45.06 (12.02)	46.82 (11.58)	44.63 (12.1)
Number of weight entries	146.39 (133.01)	142.62 (110.18)	147.31 (138.16)
Number of food photos posted	115.2 (139.33)	108.64 (115.59)	116.81 (144.65)
Number of coaching sessions completed	4.95 (2.99)	5.17 (2.98)	4.9 (3)

Genomic-enhanced models were built by incorporating 197 SNPs from participant genomic data as predictors, using Lasso regression on SNPs for variable selection, and then fitting a model to the data set after adding the selected SNPs to the previous engagement variables. The 197 genomic variables were from Digbi-curated panels of SNPs associated with obesity, fitness, nutrient metabolism, and inflammatory markers (Table S1 in Multimedia Appendix 1 [81-88]). Each SNP value was encoded for each participant as their number of risk alleles (0, 1, or 2). One participant did not identify gender, therefore was excluded from all models, resulting in 392 observations included in each of the 4 linear regression models.

Success or failure logistic regression models were also fit, with and without genomic data. Genomic variables were similarly selected from the full panel of 197 SNPs using Lasso logistic regression. Success was defined as ≥5% weight loss, failure as weight gain or negligible change of <2 lb (0.9 kg). Removed from this model were observations of participants who were only partially successful, having lost weight but without reaching the milestone of 5% weight loss. This resulted in the inclusion of 251 cohort participants in the logistic models, both genomic-enhanced and demographic and engagement only.

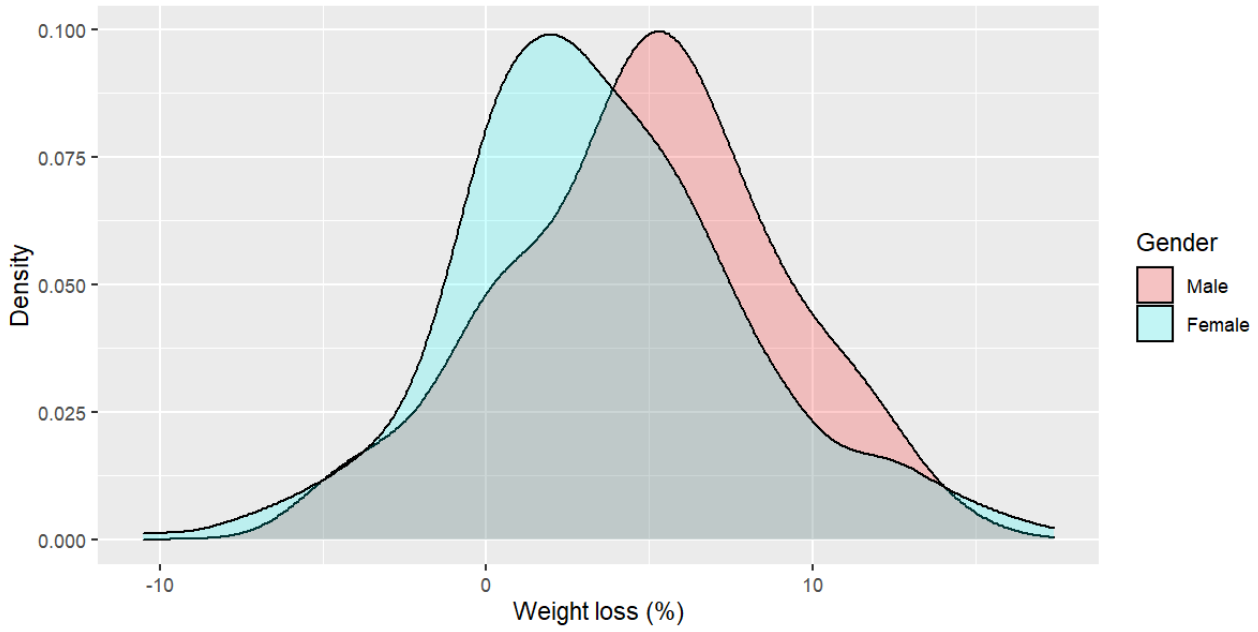
Insignificant variables were removed from each model, resulting in 6 final interpretable models, half containing demographic and behavioral engagement variables only, whereas the remaining 3 were genomic enhanced.

XSL•FO
RenderX

Demographic variables included gender, age, and baseline BMI. Behavioral engagement variables included the number of coaching sessions completed, number of weight entries, and number of food posts (Table 2). As the number of food posts and number of weight entries were highly correlated (Pearson correlation 0.98), each regression model could include one but not both. To incorporate both variables in modeling, the number of food posts was retained as a predictor for the linear models, whereas the number of weight entries was kept as a predictor for the logistic models.

For genomic-enhanced models, SNP variables were imputed to the most frequent value (mode). SNPs with >10% missing information, high (≥0.8) Pearson correlation with another variable, or zero variance were removed, resulting in 124 SNPs remaining for linear and 122 SNPs remaining for logistic model variable selection by Lasso regression. The SNPs with nonzero coefficients after Lasso regularization for that particular outcome variable (pounds lost, percentage weight loss, and successful weight loss) then served as predictors, along with the three demographic variables and two engagement variables (number of coaching sessions completed along with either number of weight entries or number of food posts).

Results



Weight Loss

A total of 393 participants were included in this study to describe and model the weight loss of participants enrolled in the Digbi Health program for 120 days. Of these, 80.4% (315/392) were female and 19,6% (77/392) were male, and one participant declined to state. Tables S1 and S2 in Multimedia Appendix 1 provide a full distribution of the baseline variables. A total of 72% (283/393) participants lost weight compared with 10.7% (42/393) who gained weight, whereas for 17.3% (68/393) participants, the weight remained within normal fluctuations (Table S3, Multimedia Appendix 1). A total of 142 participants lost ≥5% of their baseline body weight within the first 120 days. Improvement in both BMI measures and BMI class over 120 days of treatment is evident in Figure S1, with 25.0% of participants having lost enough weight to move to a lower BMI class (Table S4 in Multimedia Appendix 1). BMI class was defined as presented in Table S5 of Multimedia Appendix 1. The distribution of engagement variables, overall and by gender, is presented in Table 2. In our cohort, no significant difference was found in these variables between males and females (Welch two-sided two-sample *t* tests; results not shown). End points by the obesity class are presented in Table S4 of Multimedia Appendix 1.

As hypothesized, the addition of genomic predictors substantially improved the fit of weight loss models. For linear regression weight loss models (pounds lost and percent), the addition of genomic data improved the mean squared error from 70 to 60 and 16 to 13, respectively, whereas the logistic success or fail model improved pseudo R^2 from 0.193 to 0.285.

Figure 1 depicts the distribution by gender of percent weight loss. The difference in percent weight loss for males and females was found to be statistically significant (Welch two-sided two-sample *t* test, *P*=.02). At an average of 4.8 (SD 4.2) percent of body weight lost, the difference in weight loss between males and females was 1.3 (SD 0.5) percent of body weight. Gender was significant to all linear regression models (Tables S6-S9 in Multimedia Appendix 1) but not to the logistic success or fail models (Tables S10 and S11 in Multimedia Appendix 1), as both women and men succeeded in 5% weight loss within 120 days.

Figure 1. Weight loss (%) distribution by gender.

XSL•FO
RenderX

Significant Variables

Unsurprisingly, baseline BMI was significant to both pounds lost linear models (Tables S6 and S7 in Multimedia Appendix 1) but not for any other model. The participant's age was not significant in any of the models. Increased completion of coaching sessions was significantly associated with increased weight loss in all regression models (Tables S6 to S11 in Multimedia Appendix 1). The two highly correlated engagement variables, number of weight entries and number of food posts, were significant to all models in which they were considered (as described earlier, weight entries were in logistic models, whereas food posts were in linear models; Tables S6 to S11 in Multimedia Appendix 1).

Significant SNPs

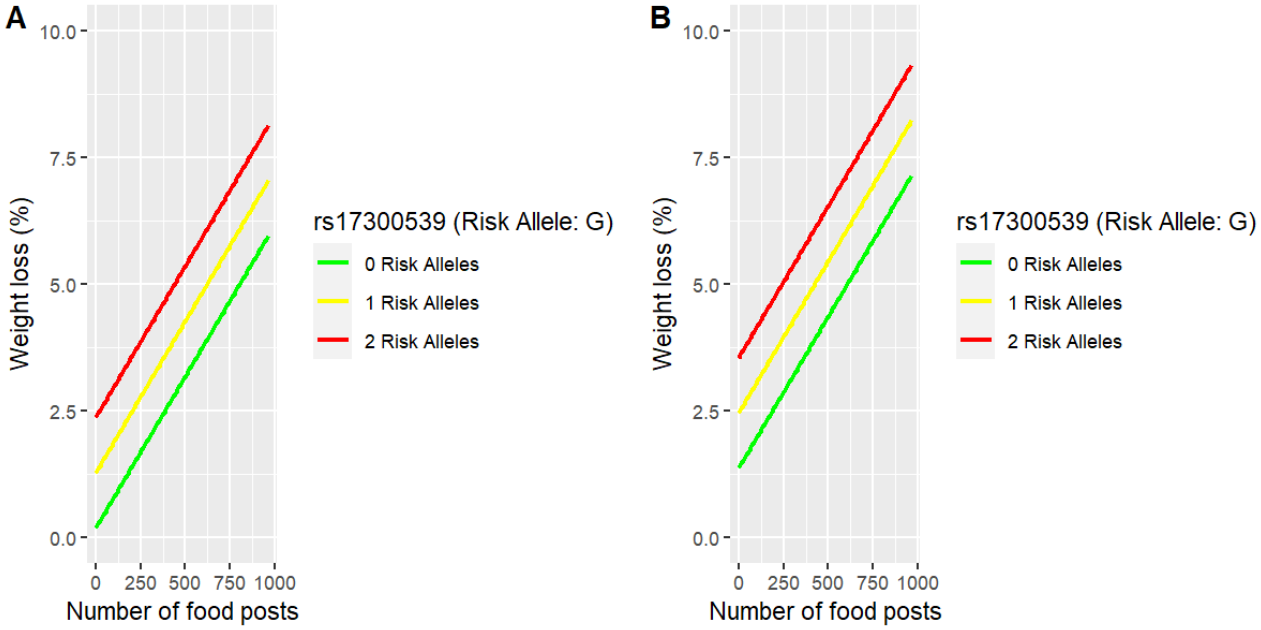
In addition to the demographic and engagement variables described earlier, the genomic-enhanced models identified 10 SNPs that were significant to the linear pounds lost model (Table S7 in Multimedia Appendix 1), 11 SNPs to the linear weight loss percentage model (Table S9 in Multimedia Appendix 1), and 6 SNPs to the logistic model (Table S11 in Multimedia Appendix 1). Of the SNPs found significant to the linear models, 8 SNPs were common in both genomic-enhanced linear models (Tables S7 and S9 in Multimedia Appendix 1). In total, 3 notable SNPs that were found to be strongly associated with changes in body weight for this cohort, rs17300539_G, rs2016520_C, and rs4074995_A, were further explored. The literature suggests explanatory metabolomic factors and findings from recent studies that provide context and explanation for these associations in our descriptive study.

Rs17300539 is located in the promoter region of the ADIPOZ gene, which encodes adiponectin [89]. The high-risk allele has been associated with insulin resistance, whereas the low-risk allele may be associated with protection from weight regain postweight loss intervention [90]. Moreover, the high-risk allele has been associated with higher weight, BMI, and waist and hip circumferences. However, genotype-related differences in BMI became undetectable in the interaction with a diet that is low, below the median (ie, <13% of energy intake) in monounsaturated fats (MUFAs) [91]. This led researchers to propose the possibility of moderating high risk with dietary interventions to reduce MUFAs for those with the risk alleles. Of the 392 participants, 334 were homozygous for the high-risk allele (G), 54 were heterozygous for the risk allele, and 4 were homozygous for the low-risk allele (Table 3).

Table 3. Risk allele distribution of highlighted single-nucleotide polymorphisms from weight loss models.[a]

SNP[b] id	Number of participants, n (%)				
	Risk allele	0 risk allele	1 risk allele	2 risk allele	Missing
rs17300539	G	4 (1.0)	54 (13.8)	334 (85.2)	0 (0.0)
rs2016520	C	244 (62.2)	127 (32.4)	20 (5.1)	1 (0.3)
rs4074995	A	159 (63.3)	67 (26.7)	25 (10.0)	0 (0.0)

[a]Distribution of risk alleles of single-nucleotide polymorphisms from weight loss models that were highlighted in plots and *Discussion* section of the paper.



[b]SNP: single-nucleotide polymorphism.

The regression models are interpretable models describing weight loss in this cohort and may be visualized to gain insight into variables found to be significant. Figure S3 in Multimedia Appendix 1 and Figure 2 depict the relationships of engagement variables and rs17300539 to weight loss in the genomic-enhanced weight loss percent model. These plots reveal the least squares fit of weight loss percent for females (panel A) and males (panel B), as the two visualized predictors are varied while holding all other model variables constant (SNPs were held constant at their most frequent [mode] values, whereas engagement variables were held constant at their gender-specific means, except for coaching sessions completed, which was fixed at its gender-specific median). The visualizations permit us to see the model relationships of particular predictors, as they impact the outcome variable. For example, the weight loss (%) model fit to this cohort describes the average male having 2 risk alleles who posts no food photos as losing 3.5% of body weight, whereas the average male with the same genomic risk who posts 975 food photos loses 8.75% of body weight (Figure 2). The coefficients of the fitted predictors reveal that in this model, for every 100 additional food posts, participants lose, on average, an additional 0.60% weight while holding all other model predictors constant (Table S9 in Multimedia Appendix 1).

In this model, for each additional risk allele (G) of rs17300539, participants lose, on average, an additional 1.09% weight while holding all other model predictors constant (Table S9 in Multimedia Appendix 1). Similarly, as the number of risk alleles of rs17300539 increases from 0 to 1 to 2, so does percentage weight loss as a function of greater behavioral engagement measured both in the number of completed coaching sessions (Figure S3 in Multimedia Appendix 1) and the number of food photos posted (Figure 2). In essence, participants in this cohort who were at higher risk lost a greater percentage of weight compared with their lower risk counterparts. Moreover, the percentage of weight loss increased in proportion to greater behavioral engagement.

XSL•FO
RenderX

Figure 2. Weight loss (%) versus food posts by rs17300539 (monounsaturated fat intake and weight gain tendency single-nucleotide polymorphism) in females (A) compared with males (B).

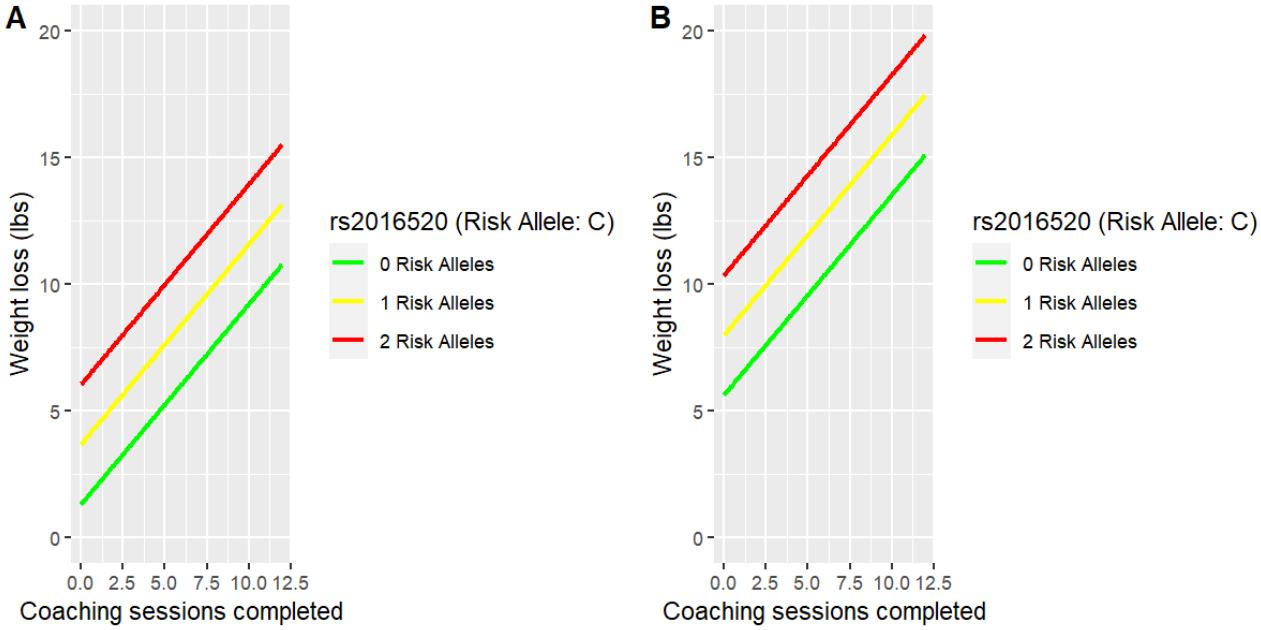
Rs2016520 is a variant of the PPARD gene, which encodes a protein implicated in fat metabolism and baseline cholesterol levels [92]. In women, this SNP has been shown to be associated with muscle development and blood cholesterol reduction after a 12-week exercise regime [93]. High-risk alleles predisposed women to less weight loss on exercise [93]. Of the 392 participants, 20 were homozygous for the high-risk allele (C) of SNP rs2016520, 127 were heterozygous for the risk allele, 244 were homozygous for the low-risk allele, and 1 had no available data (Table 3).

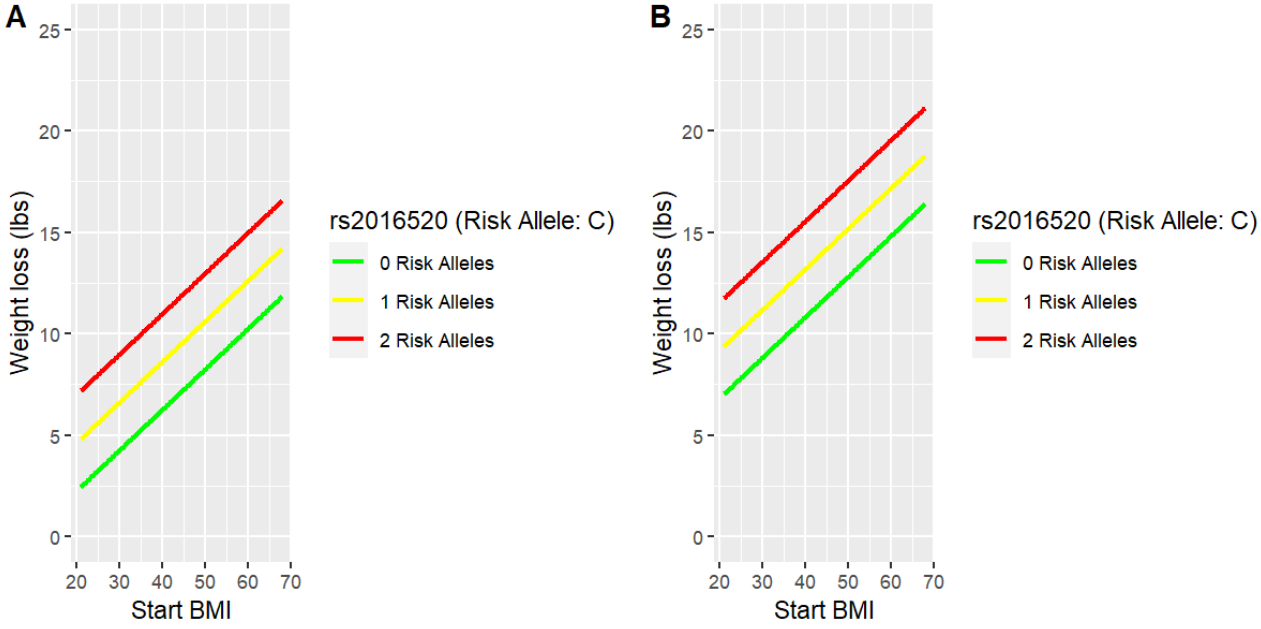
Similar to Figure 2 and Figure S3 in Multimedia Appendix 1, Figure 3 and Figure 4 and Figure S4 in Multimedia Appendix 1 reveal the least squares fit of weight loss in pounds for females (panel A) and males (panel B) as the two visualized predictors are varied while holding all other model variables constant. The weight loss pounds model fit to this cohort describes the average female having 2 risk alleles who posts 975 food photos as losing 21 lb (9.5 kg), but only 8 lb (3.6 kg) if no food photos are posted (Figure S4A in Multimedia Appendix 1). Similarly, this model describes the average male having 2 risk alleles as losing 25 lb (11.3 kg) with 975 food posts but only 13 lb (5.9 kg) with no food posts (Figure S4B in Multimedia Appendix 1). As visualized in Figures 3 and 4 and Figure S4 in Multimedia Appendix 1 the effect in this descriptive model of an increase in the number of risk alleles from 0 to 2 is that pounds of weight loss with respect to engagement increases when engagement is measured either as the number of coaching sessions or as the number of food photos posted in the Digbi Health app. Moreover, as seen in Figure 4, a higher baseline BMI was associated with more pounds lost. Males lost more weight than females in each risk group of this SNP.

The rs4074995 SNP has been implicated in calcium-potassium regulation [94]; it is located within the RGS14 gene and is associated with both serum phosphate [95] and serum calcium [96] levels. In particular, each copy of the A allele is correlated with an increase in serum calcium concentration [96]. For the rs4074995_A SNP, of the 251 participants, 25 were homozygous for the high-risk allele (A), 67 were heterozygous for the risk allele, and 159 were homozygous for the low-risk allele (Table 3). The sample size of 251 was smaller than for the abovementioned linear models because rs4074995 was chosen to be highlighted as a predictor of the genomic-enhanced logistic regression (success vs failure) model, which was fit to a subset of the cohort that experienced success, defined as ≥5% weight loss, or failure, defined as weight gain or negligible change of <2 lb (0.9 kg).

XSL•FO
RenderX

Figure 3. Weight loss (lb) versus completed coaching sessions by rs2016520 (cholesterol single-nucleotide polymorphism) in females (A) compared with males (B).





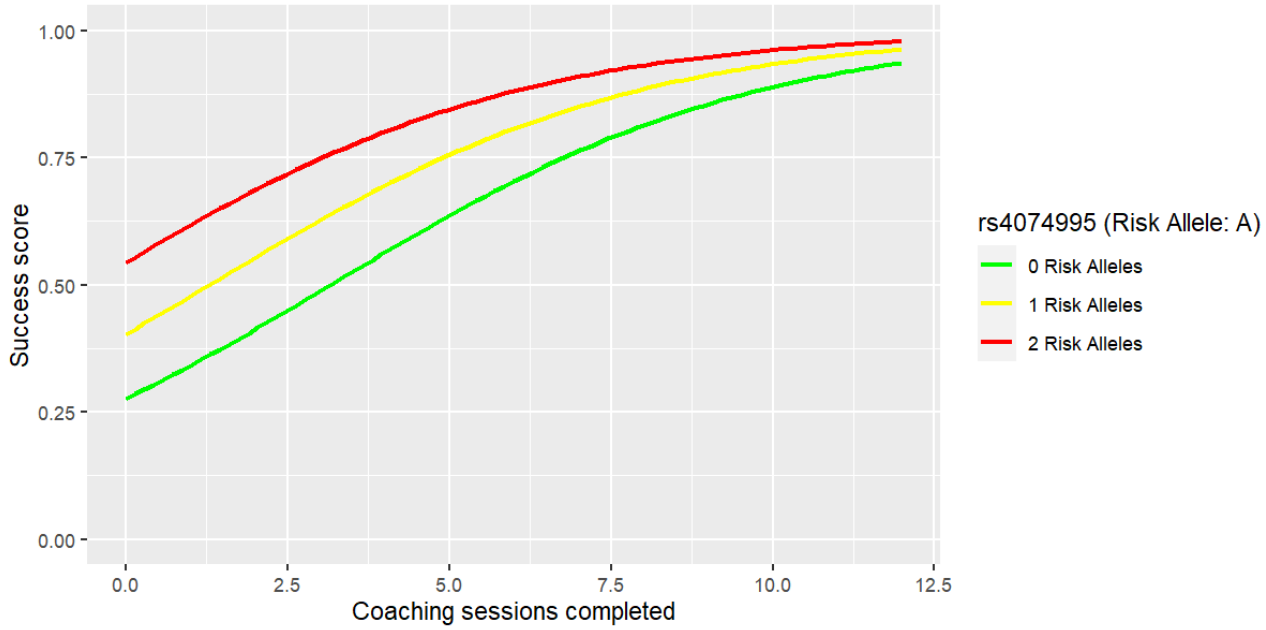


Figure 4. Weight loss (lb) versus baseline BMI by rs2016520 (cholesterol SNP) in females (A) compared with males (B).

As seen in Figure 5 and Figure S5 in Multimedia Appendix 1, as the risk alleles of SNP rs4074995 increase from 0 to 1 to 2, there is an increase in the success score, which is the likelihood of this model assigning a particular observation to the success class. Similar to the other models, we found that an increased number of coaching sessions completed is associated with a sharp increase in the success score. However, on highest engagement, the effect of risk status diminishes (those with 0, 1, or 2 risk alleles were approximately equally likely to achieve weight loss on highest engagement).

Discussion

Principal Findings

A group of 393 participants underwent lifestyle changes over 120 days through the Digbi Health program—a precision digital care program applying machine learning analytics to genetic and microbiome profiles, demographics, and self-reported lifestyle habits—delivering care through the app and weekly health coaching check-ins. Over the duration of the program, patients' genomic and gut microbiome data pertinent to weight loss (from Digbi Health–curated panels) were provided and translated into lifestyle recommendations and recipes. Of the participants, 72% (283/393) lost weight, whereas 10.7% (42/393) gained ≥2 lb. Of those who lost weight, 50.2% (142/283) were able to lose 5% or more over 120 days.

Interpretable linear regression models of weight loss in this cohort (pounds lost and percentage lost) as a function of demographic and behavioral engagement variables were fit to describe the weight loss of this cohort. Genomic-enhanced models were also built by adding participant genomic data as predictors. Interpretable success or failure logistic regression models were also fit, with and without genomic data. The addition of genomic predictors substantially improved the fit of all models.

The fitted models were examined to gain insights into the weight loss journey of this cohort. Gender, engagement, and specific SNP risk alleles were significantly associated with successful weight loss. The models described greater average weight loss in our cohort for participants having more of certain risk alleles. Here, we consider how successful weight loss may be obtained in the face of greater genetic risk factors. Notably, Digbi Health precision coaching for lifestyle modification is personalized to these genetic risks, and patients reported realizing success that was previously unattainable after being empowered by the knowledge of their genetic and microbiome risk factors, accompanied by advice on lifestyle modifications to address these risks.

We profiled three of these genetic markers (see Results section) to elucidate their relationships with explanatory metabolomic processes and weight gain and loss. Here, we connected these relationships with personalized recommendations delivered by the Digbi Health app and coaching staff. The profiled SNPs were associated with circulating adiponectin and response to dietary MUFA consumption, fat metabolism, and baseline cholesterol levels, and serum calcium levels and calcium-potassium metabolism were strongly associated with weight loss success.

As an example of personalized dietary advice delivered by both the app and coach for program participants who are at genetic risk of weight gain, we considered the advice delivered to participants with a different genetic outlook with regard to rs17300539, a risk allele for weight gain with high MUFA intake. This SNP is depicted in the visualizations of our linear model for weight loss percentage (Figure 2 and Figure S3 in Multimedia Appendix 1). As reported earlier, participants in this cohort who were at higher risk lost a greater percentage of weight compared with their lower risk counterparts, and percentages of weight loss correlated with greater behavioral engagement. This finding can be explained by the fact that those with high risk for this trait were advised by both the app and human coaching to avoid MUFA consumption as much as possible (contrary to the conventional wisdom that these—olive oils, almond oils, etc—are comparatively healthy fats). Instead, they were advised to shift to the consumption of polyunsaturated or saturated fats, depending on their genotypes [97]. Moreover, this SNP is associated with insulin resistance, and parts of the Digbi Health Nutrition Plan (eg, intermittent fasting and reducing processed carbohydrate consumption) would be expected to reduce insulin resistance, addressing the risk associated with this SNP, thereby helping with weight loss [93].

XSL•FO
RenderX

The linear regression pounds lost models found an association between higher baseline BMI and increased weight loss in this cohort (Figure 4). For each one-unit increase in baseline BMI, participants lost an additional 0.2 lb (0.09 kg) on average while holding the other variables in the model constant. This finding could be encouraging to new participants with higher BMI, who may have attempted weight loss with other programs but without much success. Adding genomic information (Figure 3), the model describes the average man of this cohort at the highest baseline BMI, having 2 risk alleles for rs2016520_C and completing five coaching sessions as losing 21 lb (9.5 kg), but women having the same risk outlook and behavioral engagement as losing, on average, 16.5 lb (7.5 kg). When compared with participants of the same gender, baseline BMI, number of coaching sessions, and genomic outlook for all SNPs except rs2016520_C, participants in this data set lost 2.4 lb (1.1 kg), on average, over their treatment for each additional risk allele they had of rs2016520_C (Table S7 in Multimedia Appendix 1).

This SNP is poorly characterized in the general population, but studies associate it with BMI and waist circumference among Han Chinese [98] as well as with cholesterol metabolism [99]. This latter association drives the recommendation by Digbi Health that participants presenting with the high-risk allele limit cholesterol consumption. The association between the number of risk alleles of rs2016520_C and increased weight loss in this data set may indicate the efficacy of data-driven coaching by Digbi Health. A visualization in Figure 3 of this descriptive model depicts a male of average baseline BMI and the most frequent genomic outlook for all except rs2016520_C as losing 20 lb (9.0 kg), on average, if he completed 12 coaching sessions, but only 11 lb (5.0 kg) on average with only one coaching session over the course of treatment.

Calcium is an essential mineral critical for vascular function, muscle function, neurotransmission, cell signaling, and hormone secretion [100]. Serum calcium levels tend not to respond directly to dietary calcium intake, and instead, the body relies on reservoirs in bone tissue to maintain consistent calcium concentrations [100]. Recent research has emerged tying higher serum calcium levels to the development of insulin resistance and cardiovascular hypertension [101]. High serum calcium levels have long been correlated with obesity [102]. Figure 5 depicts the success or fail logistic regression model of the associations between the number of coaching sessions completed and rs4074995_A with successful weight loss while holding all other variables in the model constant at their most frequent number of risk alleles. As with the linear model, in this Digbi Health treatment cohort, increasing total coaching sessions was associated with higher success in losing weight. Those at high risk for excess serum calcium levels were especially encouraged to embrace intermittent fasting and carbohydrate avoidance to combat insulin resistance. This may explain their higher success in achieving ≥5% weight loss (Figure S5 in Multimedia Appendix 1). We found that for participants with more risk alleles of the rs4074995 SNP, success in weight loss increased with more coaching, although it was not as pronounced in those with minimum (0) risk alleles. It may be that success for those with more risk alleles was not as heavily dependent on more coaching sessions, as the app itself conveys pertinent dietary advice.

In addition, our data strongly indicate that behavioral engagement, particularly coaching, contributed to weight loss success. Participants experienced, on average, 0.37% more weight loss with each additional coaching session while holding all other model variables constant (Table S9 in Multimedia Appendix 1). All models found weight loss to be significantly associated with behavioral engagement with the program and app (number of coaching sessions completed, weight entries logged, and food photos logged as predictors). Food photos and weight tracking showed more than 98% correlation with each other and both were significantly associated with weight loss success (Tables S6 to S11 in Multimedia Appendix 1). Prior research has shown that regular engagement with digital weight loss platforms and regular weight tracking is associated with greater weight loss success [103].

We hypothesized that successful weight loss was achieved by adhering to data-driven dietary recommendations that depart from conventional nutritional weight loss advice. Of those 10.7% (42/393) of the participant population who gained weight, there was a notable lack of engagement in the program. Those who gained weight, compared with their counterparts who lost weight, tended to neither engage in coaching nor regularly use the Digbi Health app to log body weight and post food photos of meals. Those who checked in with the coach regularly and logged into the app frequently to post weight and food photos were more likely to lose weight than those who did not.

Coaching sessions completed, along with other behavioral engagement variables, differed between participants who lost weight and those who gained weight, whereas baseline weight and BMI did not. The density plots in Figure 6 fairly compare distributions of the two groups: although many more people lost weight than gained, the area under the curve of each group is uniform at 1. Figure 6A illustrates the distributions of completed coaching sessions for those who lost weight (blue) versus those who gained weight (red). The difference is striking: only a fraction of those who failed to lose weight completed at least five (the mean and median) coaching sessions, whereas those who succeeded generally completed five or more. All three measures of engagement were significantly higher in participants who lost weight (blue) versus those who gained weight (red). These distributions are visualized in Figure 6. In contrast, however, Figure S6 in Multimedia Appendix 1 shows no statistical difference in means in (A) baseline weight and (B) baseline BMI, confirmed by the Welch two-sided two-sample *t* test (P=.64 and P=.42, respectively) between participants who lost (blue) versus gained (red) weight.

XSL•FO
RenderX

Figure 6. Distributions of engagement variables differ by weight loss group. Measures of engagement were higher in participants who lost weight (blue) versus those who gained weight (red). Statistical difference in means confirmed by the Welch two-sample t test (A) coaching sessions (P<.001), (B) number of weight entries (P<.001), and (C) number of food posts (P<.001). Less than 2-lb gain or loss was considered negligible and excluded from this figure. Engagement variables were summed over the study period of 120 days.

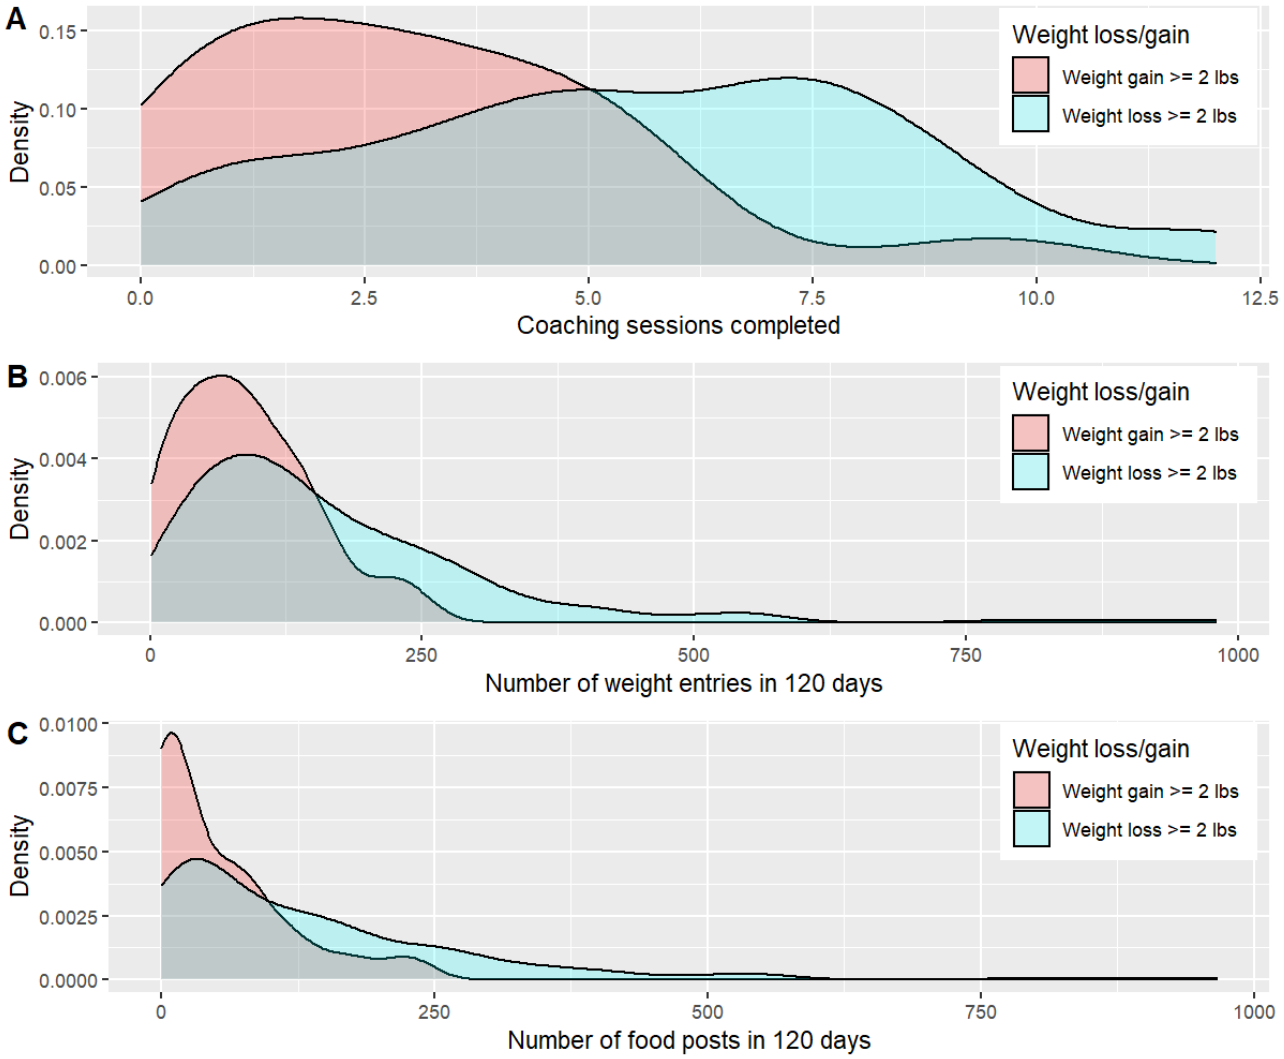

Table 2 and Table S1 in Multimedia Appendix 1 show the distributions of variables based on gender. A notable feature of this cohort is that women are grossly overrepresented—a feature that is not specific to the demographics of obesity. Although globally, more women are obese than men, the disparity is driven in large part by demographics, particularly in Africa and the Middle East. In Western countries, men are more likely to be obese [104], which is not reflected in our sample. Instead, our participant demographics may be more reflective of individual self-image. Women appear more likely to perceive themselves as overweight and are more likely to attempt weight loss [105]. Exploration of gender differences in weight loss maintenance reported that men comprised only 27% of participants in behavioral weight loss programs [106,107].

Additionally pertinent to the gender composition of this cohort is that patients self-select and continue with the weight management program of Digbi Health based on the approach they feel works for them. One study indicated that women were more than twice as likely to report having used an organized weight loss program, whereas men were more self-directed in their weight loss [108]. In a single-blinded, randomized clinical trial, the efficacies of three e-coaching approaches were compared: no coaching, nondirected coaching, and directed coaching. Women achieved most success (weight loss, reduction of waist circumference, and improvement of physical activity) in the first 12 weeks with directive e-coaching (similar to Digbi Health), whereas men lost more weight with nondirected e-coaching [80,109]. Men who chose the Digbi Health program succeeded in weight loss. In this cohort, men lost more weight than women over 120 days, consistent with previous findings that men lose weight faster than women [110]. However, the low participation in behavioral weight loss programs, such as that examined here, points to the importance of identifying the underlying factors that impact early engagement and success in weight loss. We are currently undertaking such a study, with the aim of innovating for a level of personalization that will empower and drive success with different subgroups of clients, including men.

Recent research has explored the incorporation of genotypic information into nutritional advice. Researchers have tested the hypothesis that dietary interventions using personalized genotype information have greater efficacy than the same

XSL•FO
RenderX

interventions without genomic data, achieving mixed findings [111-115]. However, these studies tested only a few SNPs. Some groups found no benefit from genomic information [22,111], whereas others found specific SNPs (eg, APOE and ACE genes) to be associated with improved dietary changes [21,23]. Some studies observed an increase in positive dietary behaviors on the part of participants who carried a risk allele pertinent to a dietary factor (eg, sodium and fat) with whose recommendations they had not been adhering [21,23]. This aligns with our anecdotal experience of Digbi Health clients, including those in this cohort who had risk alleles for rs17300539, rs2016520, and rs4074995, as described earlier.

Food4Me [111] conducted an RCT to investigate the effectiveness of internet-based personalized nutrition interventions on weight loss and dietary intake with 1269 participants randomized into four groups: one control without personalization and three personalized groups, each with an additional level of personalization: personalized by individual baseline diet, by baseline diet and phenotype (anthropometry and blood markers), and by baseline diet, phenotype, and genotype (5 SNPs). The group comprising participants combined from all three levels of personalized nutrition experienced significantly better improvements in body weight and BMI at month 3 and a more positive behavioral change than the control group. The authors found no evidence that the addition of either phenotype or phenotype plus genotype information to individual baseline diet data enhanced the efficacy of the personalized intervention. However, none of the three personalization interventions, including individual baseline diet, were reportedly tested in isolation for differences in outcomes from the control protocol, and furthermore only five variants were used in genomic personalization.

The five variants used in the Food4Me genomic personalization were from the MTHFR, FTO, TCF7L2, APOEε4, and FADS1 genes [116]. Of these five variants, three were present in the Digbi Health panel of 197 curated SNPs, and of these 3 SNPs, only rs7903146 from the TCF7L2 gene was found to be significant to any of our 3 genomic-enhanced models (linear percent weight loss, linear pounds lost, and logistic success or fail). Rs9939609 (FTO gene) and rs1801133 (MTHFR) were the 2 SNPs that were a part of our gene panel, and hence included as variables, but were found to not significantly contribute to any of the three weight loss models. Rs7903146 was found to be significant to the linear percent weight loss model, and although it was selected as a variable by Lasso for the pounds lost model, it was not statistically significant. Research associates rs7903146 with a higher risk of gestational [117,118] and type 2 [119-121] diabetes as well as reduced insulin levels [119,122]. These medical implications are especially relevant to postmenopausal women [123] as well as those in childbearing years. Unlike the pounds lost model, the percent weight loss model captures weight loss independently of start weight and more aptly models women's weight loss alongside that of men. Digbi Health has a robust protocol to address diabetes risk and insulin resistance, which differs substantially from the Food4Me personalization based on rs7903146 as reflected in the Food4Me article (including the decision tree for TCF7L2-based information delivered to level 3 "*Diet plus phenotype plus genotype*" in Figure S3 in Multimedia Appendix 1) [111]; thus, we would not expect the outcomes of our personalization regarding this SNP to be the same. We noted that Digbi Health personalization arises from the much broader set of traits in our curated panels and a greater number of SNPs associated with those traits, enabling personalization that is more fine-grained than that informed by a few SNPs. We are not aware of any RCT to test the added value of genomic data that uses the breadth of genotypic markers considered in the Digbi Health program.

Conclusions

Over the last two decades, the obesity epidemic has coincided with a dramatic change in unhealthy eating habits, a sedentary lifestyle, and physical inactivity. In the United States, more than 40% of the adult population is now overweight or obese. Hereditary predisposition to obesity may have interacted with the obesogenic environment and contributed even further toward the epidemic. The recent accumulation of genomic and lifestyle data has led to the demonstration of possible effects of gene-environmental interactions on obesity [124]. Data from dietary intervention trials indicate that genetic variants, particularly those linked to obesity, metabolism, and nutrient consumption, may significantly alter changes in adiposity and metabolic responses to nutritional interventions and promote effective weight loss [59].

In the foreseeable future, the incorporation of data on genes, eating patterns, metabolites, and gut microbiome into weight loss interventions will be one of the most promising fields of precision care and may allow for the generation of predictable weight loss models based on individual genomic, microbiomic, and metabolomic factors. The goal is precision nutrition, individually tailored to enable effective weight loss and prevent chronic diseases on the basis of genomic history; habitual consumption of food and drink; intake of nutrients (especially those that contribute to disease risks); and metabolomics, microbiome, and other omics profiles of a person [59].

Although using precision medicine to target heterogeneous conditions may seem counter-intuitive, it is the heterogeneous nature of conditions, such as obesity and metabolic illness, that make them such potent targets for intervention, impacting the greatest number of people [8]. Obese subpopulations identified as genetically predisposed to favorably or unfavorably respond to a given weight loss intervention could be targeted accordingly.

To date, few studies have investigated metabolomic functioning, lifestyle and behavioral mechanisms, and gut microbiome, which can affect obesity and health at the interface between genetic variation and the environment. The Digbi Health digital precision weight loss program operates at this interface. This study was limited by its retrospective and descriptive nature. The field of precision nutrition would benefit from additional prospective randomized controlled studies on a larger scale. Although such studies will be needed to validate these findings, the analysis and modeling presented here appear to support dietary precision interventions considering genetic predisposition to disease and genetic variants defining dietary preference and metabolic risk. In addition, our results point to the efficacy of

XSL•FO
RenderX

coaching that empowers and actively engages participants in their own success.

Future studies should explore the synergistic effects of genomic variables in interactions with other genome, microbiome, and lifestyle and behavior variables. A follow-up to the work presented here, exploring not only the effect of incorporating genomic data but also including the microbiome data used in Digbi Health precision care, is currently in preparation. Personalized protocols that incorporate data on genes, eating patterns, metabolites, and gut microbiome into weight loss interventions may well be a promising field of precision care, allowing for the generation of predictable weight loss models that account for the synergistic effect of these influential factors.

KEYWORDS

COVID-19; SARS-CoV-2; coronavirus; pandemic; topic modeling; research; literature; medical research; publishing; force majeure

We read with interest the recent article on medical publication of COVID-19-related research by Älgå et al [1]. We acknowledge their topic modeling approach to analyze publications about COVID-19. However, we would like to emphasize that although research on COVID-19 is receiving wide support, other areas in medicine are facing a lasting problem. Many studies are blocked or slowed down due to delayed or interrupted recruitment of patients and/or delayed analyses or processing. With entire wards and hospitals converted to COVID-19 units, the numbers of elective surgeries and hospitalizations are substantially reduced and many nonessential hospital visits are postponed, substantially reducing the possibilities for patient recruitment and follow-up. Many resources primarily used for research and clinical and translational studies have shifted to the diagnostics and management of COVID-19; although this shift testifies to the positive robustness and flexibility of the medical system, it inevitably slows down other, at this moment "nonessential," research activities. Many physicians are working on COVID-19–related topics and with patients with COVID-19, temporarily suspending their regular research activities. In the situation of lockdown set by governments, researchers continued working on the already available specimens and data from their home offices and communicating via web-based platforms [2]. Despite no apparent decline in manuscript submissions, a reduction in publishing by women has already been observed in some fields [3], suggesting that the real consequences for scientific publishing are yet to come. Processing already available data and manuscript preparation is possible from home, but patient recruitment and conduction of ongoing clinical trials are essential for further scientific breakthroughs. In this context, scientific progress will be one of many victims of COVID-19, and discoveries related to a spectrum of diseases other than COVID-19 will be delayed, especially if funding is reduced [4,5]. Although risk management strategies are a regular part of scientific work and are already obligatory at the step of writing grant proposals, this prolonged uncertainty and worldwide blockade go beyond what anyone could have imagined as a "force majeure." Therefore, we need to find new, creative solutions for continuing research in such situations, guaranteeing safety for patients, researchers, and research quality, to ensure that the society is not deprived of new discoveries in medicine. In this context, computer-based

XSL•FO
RenderX

simulations and analysis of open data will become increasingly important in the future.

As reported by Älgå et al [1], the types and topics of published articles on COVID-19 have evolved during the pandemic, updating the scientific audience in a timely fashion. In contrast, in some previous epidemics, such as H1N1 [1] or Middle East respiratory syndrome and severe acute respiratory syndrome, most results were published after the outbreak [6]. From the administrative side, we think that the COVID-19 pandemic should be accepted as a "force majeure" for non–COVID-19 research, where the funding agencies should provide flexibility and allow extensions or delays of currently running grants. Indeed, major funding agencies already announced supportive measures, such as "no-cost extensions" and reallocation of funds [7], but these are usually granted on a case-by-case basis [8]. However, if COVID-19 affects the realization of a grant at the most sensitive phases (eg, during patient recruitment), the delivery of the results is seriously endangered, even when the funding agencies allow time extensions. From the scientific side, we recommend the following solutions wherever applicable. First, as a *damage-minimizing strategy* for projects that had been already running when the pandemic started, the researchers may try to reevaluate their goals (with consent from the funder) and opt for realistic targets if the original endpoints are no longer achievable. In translational science, when a particular technique is unavailable due to reallocation for COVID-19 patient care, closed laboratories, or restricted international cooperation, alternative but available techniques should be considered. As the situation gets better, researchers could complement the research agenda with the originally planned materials and methods. However, for new grant proposals that are about to be submitted, it is mandatory to provide a clear plan of implementation that would take COVID-19 into account. Specifically, the implementation strategy may provide two scenarios (one more optimistic and one more pessimistic) with respect to the unpredictable times. In any case, a list of measures for ensuring the safety of patients and researchers along with as realistic an estimation as possible of the number of patients and tests required and prepared alternatives for various research methods may increase the confidence of both the researchers and the funders in realistic and good implementation. In this context, we believe that use of the internet and internet-based technologies should be encouraged. Indeed, medical research should not stop, but adaptations to new conditions are crucial. Although we hope that vaccination will soon bring the pandemic to an end, fear of new and mutated strains of the same or different viruses and a rebound pandemic or some new pandemics should keep us thinking about how to do research in such no-longer-so-unimaginable situations.

KEYWORDS

COVID-19; SARS-CoV-2; coronavirus; pandemic; topic modeling; research; literature; medical research; publishing; force majeure

We thank Petar Milovanovic and Igor Dumic [1] for raising the complex issue of challenges associated with non–COVID-19–related research. We share their view that many of the effects that the COVID-19 pandemic has had on such research are likely yet to be seen and that researchers and funders need to find pragmatic ways to deal with this new reality. However, some of the authors' suggested actions, such as to adjust endpoints and power calculations, risk compromising research quality and should be done with caution. In times and settings associated with poor preconditions for clinical studies, we encourage researchers to assess the utility of alternative data sources, such as readily available medical image and routine clinical data.

We concur with the authors that analysis of open data and computer-based simulations have the potential to play a vital role in the future of medical research, apart from experimental and clinical studies. Additionally, we believe that methods like the one used in our study [2] may also prove to be a way forward. The number of published scientific studies is rapidly increasing, and traditional ways of compiling study results to generate new knowledge are slow and not suitable for these numbers. Therefore, the application of existing machine learning text analysis methods and the development of new ones holds promise of scientific gains not only from *existing data* but also from *already completed studies*.

KEYWORDS

COVID-19; dentistry; oral health; dental health; online health; social media; tweet; Weibo; China; health information

I read the article regarding the nature and diffusion of COVID-19–related oral health information conducted by Tao et al [1] with great interest. Information, education, and communication are the best tools to prevent and control any disease. The paper described the temporal and geographic distribution of COVID-19–related oral health information circulated on the social media platform Weibo in China. The study’s focus was to assess COVID-19–related oral health information and explore public reaction.

The introduction was built on existing literature describing COVID-19, its impact on dental practice and specific concerns, and the necessity of information on social media. The authors presented the need for the study in this section; however, it could be elaborated to better understand the target audience.

The authors implemented their research with reproducible methods and described all necessary steps, including screening criteria, piloting and reliability assessment, and statistical methods. The authors included 4 search keywords (“pneumonia of unknown cause,” “coronavirus,” “COVID-19,” and “epidemic”) for COVID-19; however, only 2 keywords (“stomatology” and “dentistry”) were selected to search for oral health and disease-related information. The authors could have included at least 2 additional popular keywords (“oral examination” and “oral health”) to make the search more comprehensive [2,3]. The authors included 15,900 tweets, which strengthened the precision and power of the study.

The study results were well described and presented in a logical and comprehensible manner using tables and graphs. However, some inconsistencies were observed in the x-axis parameters in some figures, and one typo was observed in one of the tables’ data. The authors could also have highlighted the point related to the supply and demand for dental health services during the epidemic.

The authors mentioned some limitations, such as the Weibo platform being more popular among younger age groups than older ones, the nonavailability of information regarding individual users’ characteristics, and the nonavailability of information on online consultation quality services. However, users’ education, academic background, job profile, socioeconomic status, past dental treatment experience, and status of existing oral health problems are essential to categorize and associate oral health information within different parameters.

XSL•FO
RenderX

Other limitations include the use of a single social media source and data collection within a short period of time. These limitations can affect the generalizability of the study. Despite the discussed limitations, the authors are to be congratulated for their novel enrichment of evidence through this exploratory research, and with great excitement, I anticipate future research to highlight further circulation of COVID-19–related oral information carried out in a broader time frame and extended to various geographical locations.

Conflicts of Interest

KEYWORDS

COVID-19; dentistry; oral health; dental health; online health; social media; tweet; Weibo; China; health information

We sincerely thank Yadav [1] for the comments on our paper, "Nature and Diffusion of COVID-19–related Oral Health Information on Chinese Social Media: Analysis of Tweets on Weibo" [2]. We appreciate the insightful and constructive opinions on this topic. Indeed, oral health information on social media during the pandemic is important and worthy of in-depth study. Here, we would like to further discuss this topic.

The aim of our study was to investigate oral health information on Chinese social media during the COVID-19 outbreak. As a scientific publication with open access, this study is available to any member of the general public who is interested in this topic; thus, our paper is not oriented toward a specific audience. In this study, the nature and diffusion of COVID-19–related oral health information on Weibo was overviewed. The government can get useful ideas for public health surveillance or policymaking during the epidemic, while dental care providers and potential patients might be inspired knowing that social media is a good communication tool for exchanging oral health knowledge and dental care needs during an emerging crisis.

In terms of the keywords used in this study, we only selected "stomatology" and "dentistry" because these 2 keywords in Chinese provide broad coverage, including oral, mouth, tooth, etc. As such, when we conducted the search with "stomatology" and "dentistry," tweets containing "oral examination" or "oral health" were included in the results as well.

As pointed out by Yadav [1], there was inconsistency in the x-axis parameters (date) in Figure 5 in our published manuscript [2]. This was due to the difference in the starting point of the x-axis, which was the date when each piece of misinformation began to be disseminated on Weibo, while the ending point of the x-axis was March 16, 1 day before we carried out the search. Additionally, there was a typo in Table 2, in which "prosthetics" should be replaced by "prostheses."

We have discussed the imbalance in dental service supply-demand during the epidemic and proposed that social media might be a potential solution at this unprecedented time. The tweets on Weibo reflected the great needs and short supply of dental treatment, but the specific fluctuation of dental demand-supply relationships with time was not able to be evaluated through Weibo. Nevertheless, social media can still serve as an important market indicator for both government policymakers and commercial companies to meet oral health needs during the pandemic.

XSL•FO
RenderX

Obviously, oral health information tweeted on social media is significantly influenced by the users' socioeconomic status (educational background, job profile, income level) and oral health status (dental treatment experience, existing oral health problems). However, when performing social media–based studies, researchers have no access to this information due to the confidentiality and privacy of social media users, which means it is technically impossible to estimate the association between users' background and the information they tweet about. This can be considered as an innate limitation of social media studies.

In China, Weibo is representative of all social media, especially during emerging epidemics when active users and tweets increase sharply [3,4]. According to the financial report of Sina Weibo for the first quarter of 2020 [5], the number of active users reached as high as 550 million per month and increased by 85 million compared with the same period last year. Therefore, we chose Weibo as the only social media platform for our study to avoid potential overlapping of users registered on other platforms. The large amount of Weibo users provided sufficient data for conducting the study.

The outbreak of COVID-19 in Wuhan, China, started on December 31, 2019. Since mid-March 2020, COVID-19 has been well controlled in Wuhan, with less than 10 new cases per day. Since then, dental hospitals and clinics have started to provide services to the public, leading to a significant reduction in tweets about COVID-19–related dentistry information. Accordingly, the scenario in Wuhan provides a unique and important social model to study the pandemic and related oral health information within a short time frame. Our study, covering the time period from December 31, 2019, to March 16, 2020, completely documents the changes in oral health information on social media from the beginning to the end of the outbreak in the world's first COVID-19 epicenter.

The distribution of oral health information is closely related to the health care system of individual countries. We agree that future studies should be carried out to highlight further circulation of COVID-19–related oral information using a broader time frame and extended geographical locations. Comparisons of information between different geographical locations and different social media platforms in various languages will be of great value. It will not only provide insight into the global influence of the pandemic but will also shed light on the policy-making of health care systems around the world. This highlights a truly interesting and impactful research direction for the future.

COVID-19; symptom checkers; benchmark; digital health; symptom; chatbot; accuracy

We congratulate Munsch et al [1] on their recent publication, “Diagnostic Accuracy of Web-Based COVID-19 Symptom Checkers: Comparison Study.” The study investigated the relative performance of web-based COVID-19 screening tools between April 3 and 9, 2020. It is important to have literature comparing the relative performance of tools; however, it is also important that the approaches used in reports of this type compare “like with like” and are reported rigorously.

There are a number of important limitations in Munsch et al’s [1] paper, the first being that the principal results reported are not fully addressed in the publication, and the second being it is an inappropriate evaluation of COVID-19 screeners designed for use by laypersons at home. COVID-19 screeners were brought into the market at a time of need to lower the burden on health authorities and health care institutions [2]. Overall, they were meant for use at home by people who were either worried about their symptoms or who were anxious about the pandemic in general and in need of reassurance. These people could either be put at ease that their symptoms were likely not caused by COVID-19, or be provided with appropriate localized advice through screeners tailored to their region.

The paper [1] does not investigate the COVID-19 screeners according to their intended purpose and compares tools with fundamentally different intended purposes. The Symptoma tool, developed by the paper’s authors, was designed to use the professional interpretation of both patients’ symptoms and the results of diagnostic tests, such as interpreted CT (computed tomography) images (eg, ground-glass opacities); both provide a predictive likelihood of COVID-19 status. All the other screeners examined in the study were designed for use at home by layperson users, providing a first line of advice to those experiencing possible COVID-19 symptoms. Importantly, none of these tools provide a diagnosis, neither their design concept nor regulatory approval includes this, and testing their diagnostic accuracy is therefore testing something they are specifically labeled as not providing. A meaningful evaluation would be to evaluate the appropriateness of the advice given according to the use context of these screeners (ie, do the screeners provide appropriate information and advice to users based on their symptoms, risk factors, exposure, and their location [including local COVID-19 status and national guidelines]?).

The ability of Symptoma to make use of the professional interpretation of clinical findings might be useful in some hospital settings as a clinical decision support tool, but COVID-19 tests are available in this setting, and at this stage in the patient journey, the tool cannot lessen the burden on the

XSL•FO
RenderX

health care system. Based on the arguments above, it is critical to interpret the results in Multimedia Appendices 8-12 [1], which show that Symptoma is not superior in specificity and sensitivity as claimed in the main manuscript, and to remember that the appropriateness of specific advice in a given situation is more important to the user than either specificity or sensitivity.

KEYWORDS

COVID-19; symptom checkers; benchmark; digital health; symptom; chatbot; accuracy

We thank Millen et al [1] (Ada Health) for having taken the time to read our recently published COVID-19 symptom checker comparison study [2] and for their letter to the editor. Millen et al [1] identified three opportunities for improvement to our manuscript. We wish to provide an itemized response to their letter as outlined below.

First, Millen et al [1] state that the Symptoma symptom checker is a fundamentally different tool, which "might be useful in some hospital settings as a clinical decision support tool" but should not be compared to other layperson COVID-19 symptom checkers. We disagree with this assessment. Indeed, the opposite is true: the same Symptoma engine is widely used by laypersons and therefore the comparison as executed in our publication is appropriate.

Second, Millen et al [1] state that Symptoma's superior accuracy is due to its unique ability "to make use of professional interpretation of clinical findings" and that such data should not be used by any of the symptom checkers. At Symptoma, we have found that the greater the wealth of data flowing into the symptom checker AI (artificial intelligence), the better the output and results generated for our users. Further, Millen et al [1] state that "Symptoma does not indeed perform superiorly" if no clinical findings are taken into account while referring to the appendix of our study [2]. We respectfully disagree with this on several fronts: (1) the appendix shows a different analysis than that referred to by Millen et al [1] and (2) that if the analysis is modified to fit Millen et al's [1] suggestion, which we consider less appropriate, the ranking still remains unchanged. The F1 scores will be slightly modified (from 0.92 to 0.90 for "high risk" only while it remains at 0.91 for "high risk" and "medium risk") while still ranking Symptoma first.

Lastly, Millen et al [1] suggest that the evaluation of their symptom checker should not be based on "accuracy." The most prevalent outcome parameter of comparative symptom checker studies is diagnostic accuracy [3-5]. Even though the symptom checker results do not represent a diagnosis, the importance of accurate results as generated by a symptom checker is paramount to its functionality. Other outcome parameters such as the ones suggested by Millen et al [1] are poorly measurable, harbor the potential for bias, and lack comparability.

artificial intelligence; big data; COVID-19; electronic health records; tachypnea; SARS-CoV-2; predictive model; prognosis; classification bias; critical care

The paper by Izquierdo et al [1], published in the recent issue of the *Journal of Medical Internet Research*, employed a combination of conventional and machine learning tools to describe the clinical characteristics of patients with COVID-19 and the factors that predict intensive care unit (ICU) admission. We would like to make some comments about its design.

The authors should have provided the proportion of patients with a positive microbiological diagnosis. If the artificial intelligence software's capacity for retrieving this information is limited in some way, this should be explained. The classification bias introduced by the lack of microbiological confirmation may have been significant since the study includes patients from January 1, 2020. Although some undiagnosed cases have likely been present prior to the first declared case (March 1, 2020) [2] in Castilla-La Mancha, it is improbable that there were many of them.

ICU admissions are related to many factors not addressed in the study. The decision not to admit a patient to the ICU because of short life expectancy, low quality of life, or high burden of comorbidities may have had a great impact during the first wave of the COVID-19 pandemic, when a scarcity of ICU beds manifested in some regions of Spain. The 6.1% ICU admission rate reported by the authors was 36% lower than the 8.3% reported in a national survey of 15,111 patients from 150 hospitals in Spain [3]. We could hypothesize that the patients included in the study had a milder form of the disease. However, given the absence of a microbiological diagnosis in an unknown percentage of patients, the inclusion of a significant proportion of patients without a real COVID-19 diagnosis cannot be ruled out. These doubts could have been resolved if a microbiological diagnosis had been a requisite for inclusion. The mortality rate, the most robust and relevant endpoint, should also have been reported and the factors related to it analyzed.

XSL•FO
RenderX

Artificial intelligence is having an increasing impact on the rate of health care information processing. However, minimization of selection and classification biases should be guaranteed in the design of investigations. In this case, this could have been achieved by including only microbiologically confirmed cases and prolonging the period of inclusion, since most COVID-19 cases emerged after the end date of the study inclusion period. These changes in the design would have allowed for a better evaluation of the performance of artificial intelligence techniques, making the results obtained in the sample closer to those of the real population.

KEYWORDS

artificial intelligence; big data; COVID-19; electronic health records; tachypnea; SARS-CoV-2; predictive model; prognosis; classification bias; critical care

We acknowledge the letter by Martos Pérez et al [1] and take this opportunity to clarify related issues from our publication [2]. Of our 10,504 patients with COVID-19, 2737 (26.5%) were tested with PCR (polymerase chain reaction). Within the 5 provinces of Castilla-La Mancha, the province that tested the most was Toledo (28.9%), while the least was Guadalajara (21.2%). Those patients in whom PCR was performed were 6.5 years older (63.0 vs 56.5 years). All these differences were highly statistically significant.

You must take into account that our study period was from March 1 to 29, 2020, and including only microbiologically confirmed cases or prolonging the period of inclusion would have resulted in a biased assessment. From March 30, 2020, onwards, most intensive care units (ICUs) at our hospitals collapsed and ICU admissions were highly distorted due to a lack of beds. As we commented in the *Discussion* section, the ICU capacity in Castilla-La Mancha during the study period had not yet been compromised, which protects against possible bias in our training data (all patients requiring critical care were indeed admitted to the ICU). Therefore, it is unlikely that the absence of a confirmed diagnosis with PCR during the first weeks of the pandemic influenced our results. This was a generalized situation throughout Spain and in most European countries early in 2020. At that time, when a patient was hospitalized, a wide battery of viruses was considered for which there were reagents before performing PCR for coronaviruses. Patients seen during the month of March, in the midst of an avalanche of COVID-19 cases in our region, with negative tests for other viruses and clinical, radiologic, and blood tests highly compatible, did not raise doubts about their diagnosis of COVID-19, and the probability of error was considered negligible [3-5]. For all these reasons, bias in our AI (artificial intelligence) algorithms is highly unlikely. We, however, agree that admission to the ICU can be related to many factors. One strength of our study is that it analyzes the usual clinical practice in the whole population cared for in an entire health care region of Spain during a period when the lack of beds was not a limiting factor. It was not a sample—it was the entire population. Finally, our study objective was not mortality. In other studies, when

XSL•FO
RenderX

we addressed mortality, the study period was extended to reliably collect this variable [6,7].

We read with great interest the study by Poncette et al [1] on the development of a curricular module for digital health and undergraduate medical competencies.

The paper [1] illuminates the importance of implementing digital health training for future physicians in the curricula of medical universities. While the paper discusses the benefits of building a critical and experience-based mindset among future physicians, we believe that measuring the performance of and skills acquired by students before and after participation may augment the development and implementation of digital health competencies in the medical curricula.

A survey found high levels of satisfaction among students participating in the elective module. Confidence levels, as well as the acquisition of knowledge and skills in digital health, were reported to be high. However, this analysis is subjective as it is based on the student's own opinion of their knowledge. In order to obtain more objective results, we recommend the assessment of individual skills by a standardized exam before and after participating in the module. Supplementing the opinion-based survey with exam performance may shed light on the actual perceived level of student competence while reducing selection bias. This would highlight the effectiveness of the course and give medical departments and universities more confidence to adopt digital health competencies in their curricula.

We commend Poncette et al [1] not only for their findings but for how they encourage a more interactive and nonclassical way of teaching. We hope that the high satisfaction among students may encourage medical universities to adopt this new model of teaching. The passive transfer of knowledge has been the dominating system used in medical universities [2] whereas active learning methods such as a "peer-to-peer" [1] teaching approach with an open discussion is rarely found, thus, resulting in high levels of satisfaction [3]. Therefore, we hope that this paper may persuade medical universities to adopt this new teaching approach.

The introduction of digital health competencies into the medical curricula remains key to the success of future physicians as shown by Poncette et al [1]. Therefore, we advocate for more objective student evaluation methods—before and after participating in learning modules—so that traditional medical institutions may be compelled to adopt this new teaching approach.

KEYWORDS

coronavirus; COVID-19; pandemic; scientific publishing; PubMed; literature searching; research; literature; search; performance; search strategy

Recently, a very interesting study on the performance of different search strategies for COVID-19 records in PubMed was published in the *Journal of Medical Internet Research* [1]. In this article, Lazarus et al compared the performance of PubMed's one-click search option with both simpler and more complex search strings. Novice and expert searchers do well to keep these in mind when searching. For instance, a search strategy for a review is a time-consuming endeavor, and energy spent on locating relevant controlled vocabulary and keywords can be undermined by errors in formatting, compilation, and translation of these terms. Unfortunately, the presence of these errors is extremely common even among published studies. Sampson and McGowan [2] reviewed studies published in Cochrane and discovered that 90.5% of their sample had a search strategy that contained one or more errors. Some related to errors regarding term, or term variant, identifications, but others pertained to errors in the formatting and basic compilation of the terms. The latter category included Boolean errors (19%), incorrect line numbers (1.6%), the use of Medical Subject Headings (MeSH) and free text terms combined on the same line (20.6%), and the search strategy not being appropriately translated for other databases (20.6%).

In 2018, a study with a random sample of 70 Cochrane Reviews found problems in the design of the search strategies in 73% of reviews, and 53% of these contained problems that could limit both the sensitivity and precision of the search [3]. Recently, Salvador-Oliván et al (2019) [4] evaluated the search strategies of 137 systematic reviews in PubMed to identify errors, analyze their impact on information retrieval, and propose solutions. The results of this study reveal that the percentage of search strategies that contain various types of errors is quite high (92.7%) and that 78.1% of these errors affect recall. Although a substantial proportion of the errors came from inadequate identification of terms, errors were also introduced at the formatting level, with an absence of field tags (21.2%) and lack or incorrect use of quotation marks (5.8%), Boolean operators (1.5%), and parentheses (5.1%) [4].

As to be expected, some errors have graver effects on results than others. Errors that have no effect at all on the number of results include redundant terms and morphological repetition; these "search errors" do not affect recall or negatively affect information retrieval with respect to either recall or precision.

An example of redundancy is as follows: "2019 novel coronavirus disease"[tw] OR "2019 novel coronavirus infection"[tw] OR "2019-nCoV disease"[tw] OR "2019-nCoV infection"[tw] OR "COVID-19 pandemic"[tw] OR "COVID-19 virus disease"[tw] OR "COVID-19 virus infection"[tw] OR

XSL•FO
RenderX

"COVID19"[tw] OR "SARS-CoV-2 infection"[tw] OR "coronavirus disease 2019"[tw] OR "coronavirus disease-19"[tw] OR "COVID-19 pandemic"[tw] OR "COVID-19"[tw]. Authors justify redundancy because the decision to include or exclude terms depends on the references retrieved, as the effect of the terms on the results is impossible to predict. However, it is known beforehand that the first 11 terms in a PubMed search can be easily discarded because using the 12th variation will cover all 11, so other terms are unnecessary.

In terms of the search process, tools pertaining to data mining have been developed to help librarians identify relevant terms. Some text-mining approaches have been documented by Stansfield et al [5], including TFIDF, Termine, and BibExcel. Also recommended are librarian tools that often have a particular focus on the MeSH thesaurus, such as PubMed PubReMiner [6] and Yale MeSH Analyzer [7] for keywords and controlled vocabulary.

Created and updated by the United States National Library of Medicine, MeSH vocabulary is used by the ClinicalTrials.gov registry to classify which diseases are studied by the trials registered in its database. This hierarchically organized terminology for indexing and cataloging of biomedical information is divided into four types of terms. The main terms are the "headings" (also known as MeSH headings or descriptors), which describe the subject of each article. Most of these are accompanied by a list of synonyms or very similar terms (known as entry terms). When performing a MEDLINE search via PubMed, entry terms are automatically translated into (ie, mapped to) the corresponding descriptors with a good degree of reliability. In this sense, we highlighted the importance of using the controlled vocabulary "COVID-19" (unique id: C000657245) and "SARS-CoV-2" (unique id: D000086402) in PubMed searches focused on COVID-19–related studies, and not the set of terms (search 1, 2, 3, 6, 7, and 8) analyzed by Lazarus and collaborators [1].

Redundant terms in a search strategy do not affect the retrieval of information; however, the principle of parsimony instructs us to eliminate that which is unnecessary. Applied to information retrieval, this principle prompts us to eliminate any terms or phrases from a search strategy that do not retrieve or provide new records, as they are thus unnecessary.

Acknowledgments

KEYWORDS

coronavirus; COVID-19; pandemic; scientific publishing; PubMed; literature searching; research; literature; search; performance; search strategy

We appreciate the interest in our analyses and dedication to informing clinicians, reviewers, information specialists, and others about searching for articles in PubMed.

The letter authors [1] highlight the importance of avoiding search errors and the principle of parsimony in formulating search strings, encouraging searchers "to eliminate any terms or phrases from a search strategy that do not retrieve or provide new records, as they are thus unnecessary." We support the ambition and principle of parsimony, agreeing that redundant terms should be avoided. In our view, search 1 contains no redundant terms [2]. It is unclear to us what search the letter authors refer to, and we encourage them to specify their critique regarding this. To avoid misunderstandings, the example search string in the letter does not originate from any that we tested.

Our analysis showed how term choice and combinations impacted the sensitivity, precision, and F-score of selected search strings in PubMed in the 10 weeks from when the World Health Organization declared COVID-19 a public health emergency of international concern. Our results demonstrated that the more elaborate searches 1 and 2 had higher sensitivity than the ones singled out in the letter (searches 4 and 5). Please note that searches 3 and 4 were in practice identical, which some readers may overlook. In both the abstract and article, we highlighted the value of applying the single-term search "COVID-19" (searches 3 and 4) for everyday searches. However, as reflected by the F-score, searches 1 and 2 performed best.

We acknowledge that the differences between some of the analyzed search strings are minor to some PubMed users and for some search purposes. For Cochrane-style systematic reviews, we recommend the more comprehensive search strings with the higher sensitivity and specificity unless resources are scarce. For everyday informational needs, less comprehensive searches may suffice.

Our study had limitations, importantly the timeframe represented. As COVID-19 has evolved (eg, variants have been detected and have spread), new terms may be pertinent to add to search strings, including relevant Medical Subject Headings (MeSH) terms, which were not available during our search. Instead, we used all available Supplementary Concepts identified

XSL•FO
RenderX

as relevant to COVID-19 in June 2020. Since the beginning of 2021, COVID-19–relevant MeSH terms have been available [3], which we would include if we were developing a comprehensive search string now.

We note that the suggestion from the letter authors to include the controlled vocabulary term "COVID-19" (unique ID: C000657245) would not activate the MeSH term "COVID-19" (unique ID: D000086382). Instead, it activates the obsolete Supplementary Concept "COVID-19", which we included in our search string.

The change in availability of relevant controlled vocabulary terms highlights the need to quickly add additional features, enabling PubMed users to perform effective searches during a pandemic. In line with our suggestion that the National Library of Medicine add a new subject filter, such as covid-19[sb], to address this issue, they have recently added several COVID-19 filters, such as LitCGeneral[filter], that may become useful [4]. For future pandemics, we hope that such features would be made available sooner and that diseases and their variants would be named earlier.

Conflicts of Interest

LNR, ON, and THA are employed at Steno Diabetes Center Copenhagen, a public hospital and research institution under the Capital Region of Denmark, which is partly funded by a grant from the Novo Nordisk Foundation. The funders had no role in this work. There are no other conflicts to declare.

Correction of: https://www.jmir.org/2021/4/e26558/

(J Med Internet Res 2021;23(5):e30101) doi:10.2196/30101

In "Impact of the COVID-19 Pandemic on Health Care Utilization in a Large Integrated Health Care System: Retrospective Cohort Study" (J Med Internet Res 2021;23(4):e26558) the authors noted two errors.

In the originally published manuscript, the following sentence appeared under the "Data Source and Identification of Visits" section:

> *They were not considered telehealth consultations in this study.*

This sentence has been corrected to:

> *They were not considered telehealth visits in this study.*

In the originally published manuscript, the following sentence was included under the "Principal Findings" section:

> *We observed that KPSC membership generally remained stable during the pandemic, largely owing to the KPSC's decision to not cancel health coverage for groups or individuals who could not pay for most of the study period [16].*

In the corrected version, the citation to Reference 16 has been removed from this sentence.

The correction will appear in the online version of the paper on the JMIR Publications website on May 5, 2021, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Submitted 30.04.21; this is a non–peer-reviewed article;accepted 30.04.21; published 05.05.21.

(J Med Internet Res 2021;23(5):e30215) doi:10.2196/30215

In “Benchmarking Triage Capability of Symptom Checkers Against That of Medical Laypersons: Survey Study” (J Med Internet Res 2021;23(3):e24475) the authors noted two errors.

In the originally published manuscript, Reference 24 in the reference list was cited incorrectly. This citation has now been corrected to the reference listed below [1].

In the originally published paper, there was an error in the phone number of the Corresponding Author. The number has been corrected from "49 30 450 5704" to "49 30 450 570425".

The correction will appear in the online version of the paper on the JMIR Publications website on May 6, 2021, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Abstract

Background: We developed a questionnaire on a web application for analyzing COVID-19 contamination circumstances in France during the second wave of the pandemic.

Objective: This study aims to analyze the impact on contamination characteristics before and after the second partial lockdown in France to adapt public health restrictions to further prevent pandemic surges.

Methods: Between December 15 and 24, 2020, after a national media campaign, users of the sourcecovid.fr web application were asked questions about their own or a close relative's COVID-19 contamination after August 15, 2020, in France. The data of the contamination's circumstances were assessed and compared before and after the second partial lockdown, which occurred on October 25, 2020, during the second wave of the pandemic and was ongoing on December 24, 2020.

Results: As of December 24, 2020, 441,000 connections on the web application were observed. A total of 2218 questionnaires were assessable for analysis. About 61.8% (n=1309) of the participants were sure of their contamination origin, and 38.2% (n=809) thought they knew it. The median age of users was 43.0 (IQR 32-56) years, and 50.7% (n=1073) were male. The median incubation time of the assessed cohort was 4.0 (IQR 3-5) days. Private areas (family's or friend's house) were the main source of contamination (1048/2090, 50.2%), followed by work colleagues (579/2090, 27.7%). The main time of day for the contamination was the evening (339/961, 35.3%) before the lockdown and was reduced to 18.2% (86/473) after the lockdown (P<.001). The person who transmitted the virus to the user before and after the lockdown was significantly different (P<.001): a friend (382/1317, 29% vs 109/773, 14.1%), a close relative (304/1317, 23.1% vs 253/773, 32.7%), or a work colleague (315/1317, 23.9% vs 264/773, 34.2%). The main location where the virus was transmitted to the users before and after the lockdown was significantly different too (P<.001): home (278/1305, 21.3% vs 194/760, 25.5%), work (293/1305, 22.5% vs 225/760, 29.6%), collective places (430/1305, 33% vs 114/760, 15%), and care centers (58/1305, 4.4% vs 74/760, 9.7%).

Conclusions: Modalities of transmissions significantly changed before and after the second lockdown in France. The main sources of contamination remained the private areas and with work colleagues. Work became the main location of contamination after the lockdown, whereas contaminations in collective places were strongly reduced.

KEYWORDS

COVID-19; web application; digital health; analysis; transmission; France; self-assessment; lockdown; observational; survey; impact; public health

Introduction

Patient-reported outcome applications have been shown to improve the health outcomes of patients including decreasing mortality [1-3].

We developed and launched a self-assessment and participatory surveillance web application called maladiecoronavirus.fr during the growing phase of the COVID-19 pandemic in March 2020 in France. This self-triage tool aimed to help patients who were symptomatic to be directed toward the emergency call or the general practitioner after analysis of symptoms and comorbidities. We showed that data from this web application could be a relevant tool to reduce the burden on emergency call centers [4]. It also proved to be useful in monitoring COVID-19 spread during the whole pandemic, with time and spatial correlations between number of hospitalizations and daily reported anosmia by users being higher than large-scale reverse transcription polymerase chain reaction (RT-PCR) positive tests [5,6]. A national partial lockdown was initiated in France on October 25, 2020, against the second wave of the COVID-19 pandemic. Contrary to the first complete lockdown from March to May 2020, this one maintained scholar, professional, and shopping activities. However, the circumstances of virus transmissions before and after this lockdown are not well known in France. We thus developed a specific questionnaire on a web application (sourcecovid.fr) for COVID-19 source of contamination analysis in France in December 2020 just after the second wave of the pandemic [7]. The objective of this national survey was to analyze the impact on contamination circumstances before and after the second partial lockdown in France initiated on October 25, 2020, associated with the second wave of the pandemic to optimize health public policy to further pandemic surges.

Methods

Users of sourcecovid.fr were recruited via a national media campaign in France from December 15 to 25, 2020, including through social media, radio, and magazine campaigns, between December 15-18, 2020. Participants were recruited through the website. Respondents provided information on sociodemographic data, zip code, coexisting disorders anonymously, and the severity of their disease. Only symptomatic users were recruited. They were asked to enter data about their own contamination or the contamination of a close relative, about their sureness about the contamination's circumstances ("I am sure," "I think I know," or "I don't know"), and they also had to answer when, by who, and where they thought they (or the close relative) were contaminated. Users who answered "I don't know" were excluded from analysis.

Questionnaires were excluded from the analysis if completion duration was considered inconsistent (below 100 or above 800 seconds); if users were asymptomatic; if they did not know about the contamination's circumstances; and if contamination occurred before August 15, 2020, to reduce memory bias.

We excluded incubation times greater than 14 days from the analysis. Incubation time was calculated by comparing the date of presumed contamination and the date of first symptoms. The study was approved by the French National Health-Data Institute, which reviews ethical conduct of human participant research, data confidentiality, and safety. The website was not considered a medical device by regulatory authorities since no tracking was performed and data were anonymous. The web application did not have access to testing results. Access to the web application did not require a log-in or creating an account. The web application did not identify participants who responded several times.

Data of the contamination circumstances were assessed and compared before and after the second partial lockdown, which occurred on October 25, 2020, during the second wave of the pandemic and was ongoing on December 24, 2020. Fisher exact test was performed to assess changes in circumstances of contaminations.

Results

As of December 24, 2020, 441,000 connections on the web application were observed. There were 2118 questionnaires assessable for analysis; 61.8% (n=1309) of the users were sure of their contamination circumstance, and 38.2% (n=809) thought they knew it. Sureness was not different according to age (P=.43). The median age of users was 43.0 (IQR 32-56) years, and 48.3% (1073/2218) were female. The total population older than 65 years made up 12.5% (n=265) of users, and 4.4% (n=93) of the questionnaires concerned people younger than 18 years. The median incubation time was assessable in 1676 questionnaires and was 4.0 (IQR 3-5) days. Whatever the sureness, time incubation was not different (P=.36). Among the incubation sample, 41.7% (699/1676) declared a positive RT-PCR or antigenic test.

Mild or moderate infection was reported by 85.1% (n=1802) of the 2118 questionnaires, severe infection in 10.8% (n=229), and hospitalization in 4.6% (n=98).

The partial lockdown occurred on August 25, 2020, and was associated with an 80% reduction of daily contaminations (Figure 1).

During the period between August 15 and December 24, 2020, the private area (family and friends) was the main source of contamination in the 2090 questionnaires (n=1048, 50.2%) followed by work colleagues (n=579, 27.7%), or an unknown person (n=299, 14.3%), and 3.9% (n=83) did not know who contaminated them.

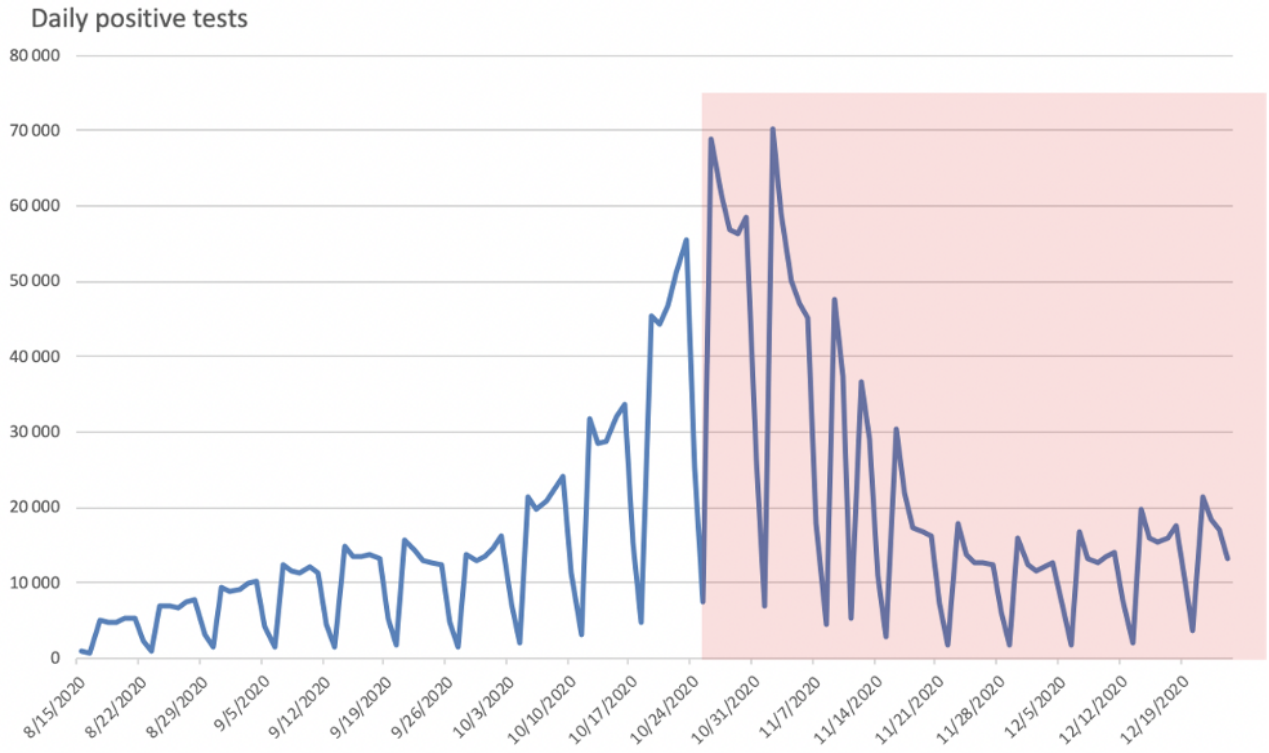
The lockdown occurred on October 25, 2020; 1334 questionnaires described the contamination's circumstances

XSL•FO
RenderX

between August 15 and October 24, 2020, and 784 described it between October 25 and December 24, 2020.

The person who transmitted the virus to the user before and after the lockdown was significantly different (P<.001): a friend (382/1317, 29% vs 109/773, 14.1%), a close relative (304/1317, 23.1% vs 253/773, 32.7%), and a work colleague (315/1317, 23.9% vs 264/773, 34.2%; P<.001; Figure 2).

Figure 1. Impact of the partial lockdown on daily reverse transcription polymerase chain reaction positive tests. Red area: national partial lockdown period initiated on October 25, 2020.



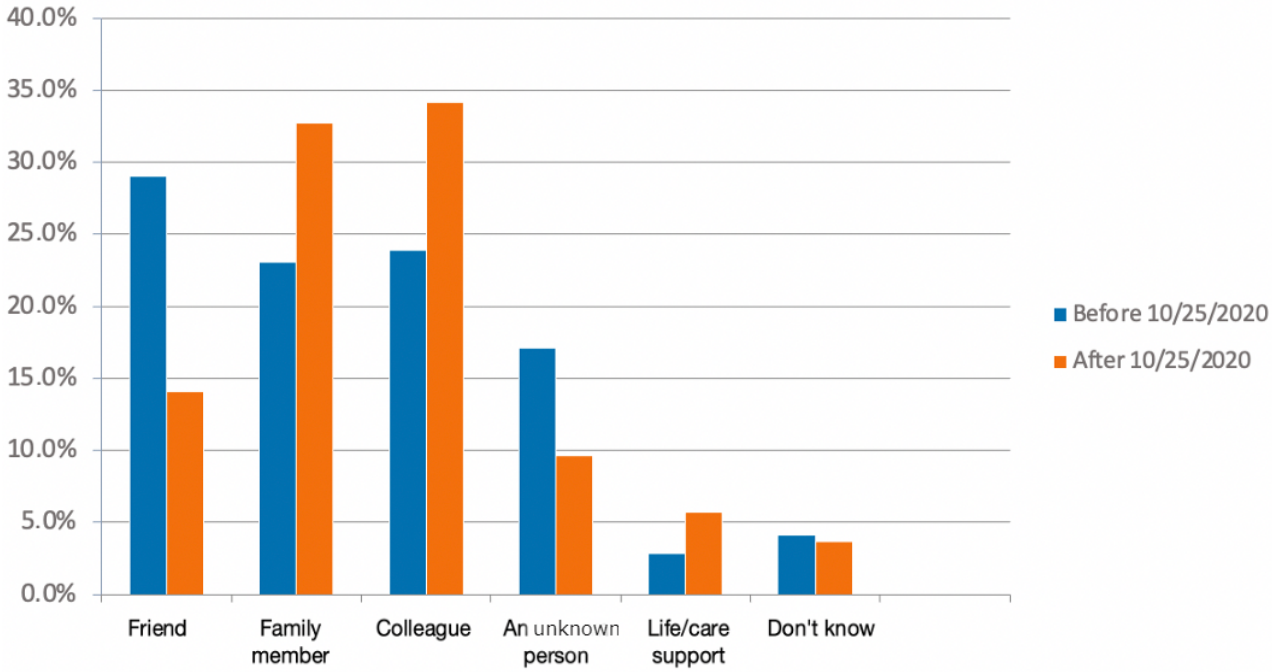


Figure 2. Contamination circumstances before versus after the partial lockdown, which was triggered in France on October 25, 2020. Answer to the question "Who contaminated you or your close relative?" (P<.001).

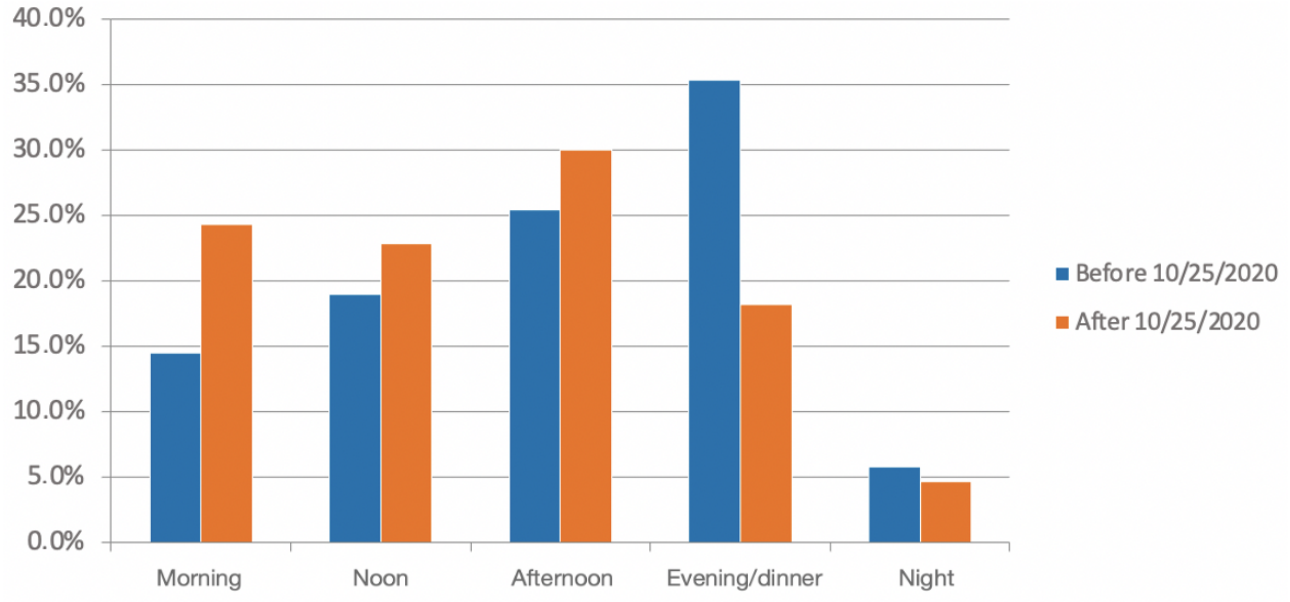


The distribution of responses regarding the people who had contaminated the user was different between users who were sure and users who thought they knew the origin of their contamination (P<.001). If professional relation was privileged for both group, users were more, in proportion, likely to think

XSL•FO
RenderX

it was an unknown person who infected them (151/790, 19.1% vs 148/1300, 11.4%).

The main time of contamination also changed after the lockdown. Among people who knew the time of contamination (n=1434; n=961 before the lockdown; n=473 after the lockdown), the main time was the evening (339/961, 35.3%) before the lockdown, which was reduced to 18.2% (86/473) after the lockdown (P<.001). The main time of contamination became the morning after the lockdown initiation. Morning and noon together became 47.2% (223/473) of the contamination times (Figure 3).

Figure 3. Contamination circumstances before and after the partial lockdown, which was triggered in France on October 25, 2020. Answer to the question "When do you think the contamination occurred?" (P<.001).

The distribution of responses regarding the moment of contamination was different according to the level of certainty expressed by the user (P=.005). Even if the preferred time of day was the evening, it was observed that users who were less sure estimated more than users who were sure to have contracted the virus in the morning: 21.5% (114/529) vs 15.5% (140/905), respectively.

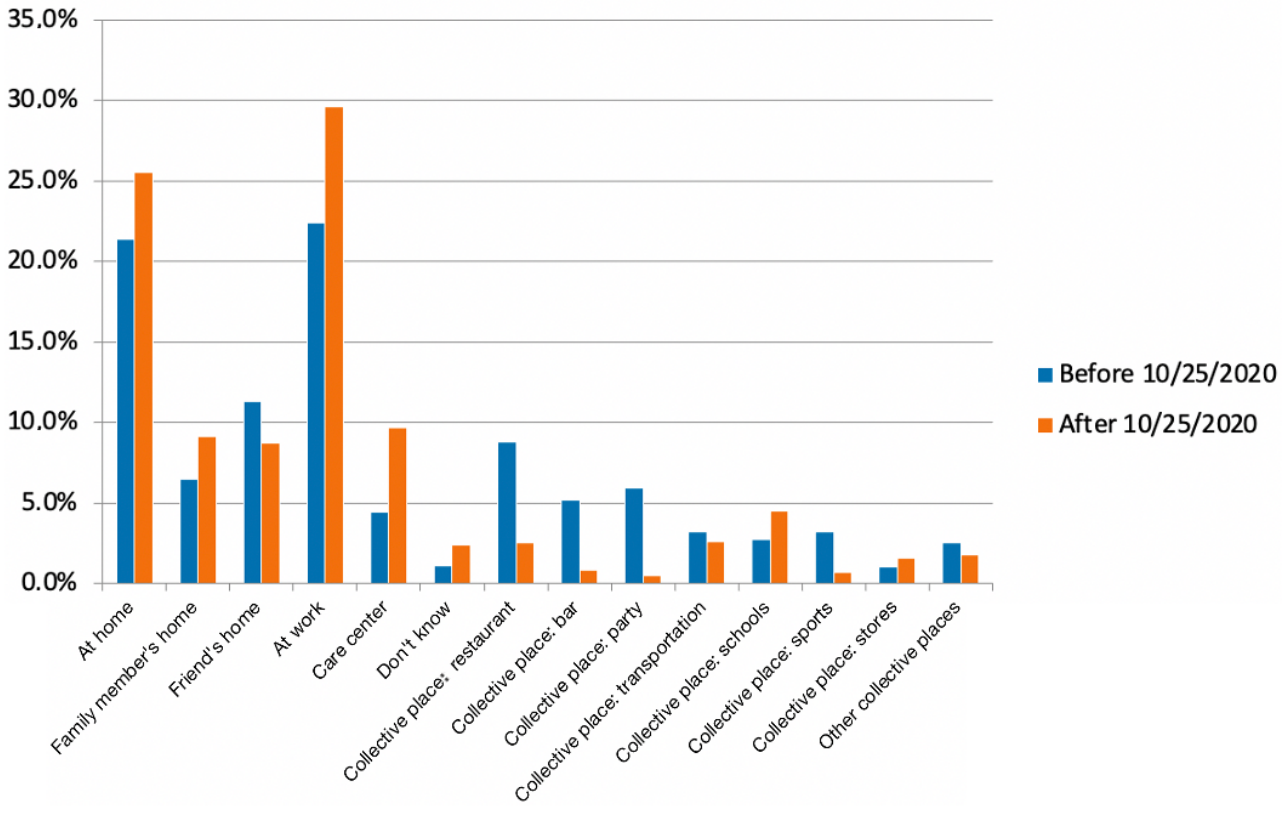
The distribution of responses regarding the location of suspected contamination was different according to the sureness of contamination (P=.003). For users who though they knew where or when they were contaminated, they privileged the collective place compared to users who were sure: 29.8% (231/775) vs 24.3% (313/1290), respectively.

The location of suspected contamination by users of the web application questionnaire was home (own home, family's home, or friend's home) in 39.1% (510/1305) of the declarations before the lockdown and remained high after the lockdown: 43.3% (329/760). The other locations where the virus was transmitted to the users changed before versus after the lockdown (P<.001). It was increased in the work area (293/1305, 22.5% before the lockdown vs 225/760, 29.6% after it), reduced in collective places (430/1305, 33.0% vs 114/760, 15.0%), and increased in care centers (58/1305, 4.4% vs 74/760, 9.7%). Work became the main location of contamination after the lockdown (Figure 4).

Collective places where transmission occurred were significantly different before and after the lockdown (P<.001). The main collective places in terms of virus transmission before the lockdown were restaurants with a reduction from 27.0% (114/422) to 16.7% (19/114), bars (from 68/422, 16.1% to 6/114, 5.2%), parties (from 76/422, 18.0% to 4/114, 3.5%), and sports (from 42/422, 10.0% to 5/114, 4.4%). Among collective places, transportation and schools became the main collective places of transmissions after the partial lockdown: 17.5% (20/114) and 29.8% (34/114), respectively (Figure 5).

XSL•FO
RenderX

Figure 4. Contamination circumstances before and after the partial lockdown, which was triggered in France on October 25, 2020. Answer to the question "Where do you think the contamination occurred?" (*P*<.001).



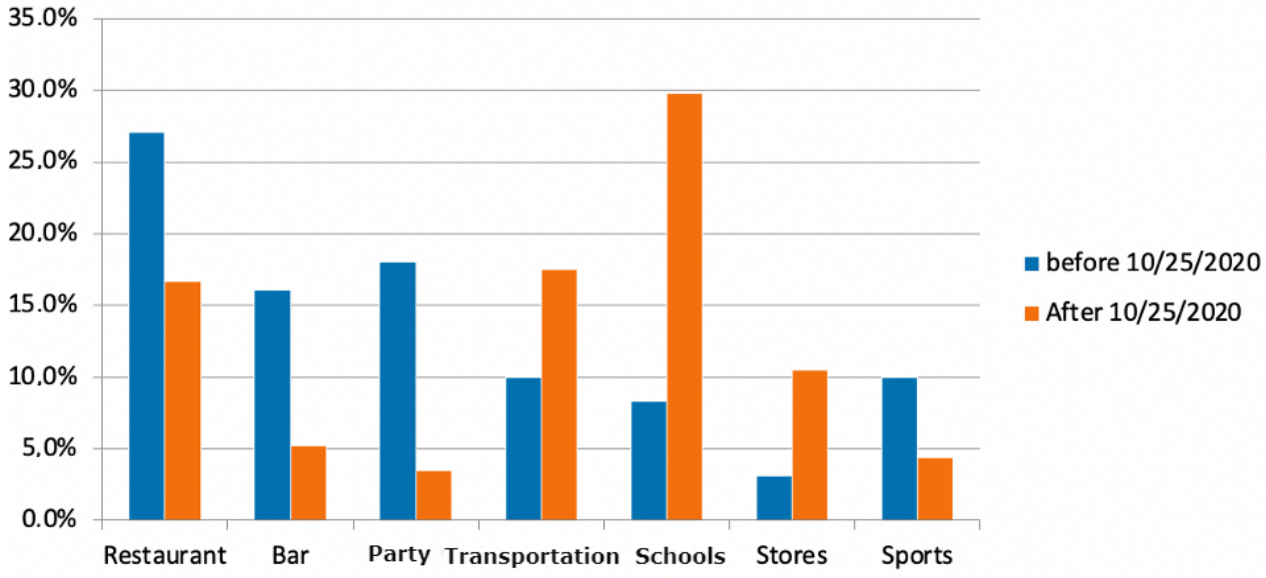


Figure 5. Main collective places concerned by contaminations before and after lockdown (*P*<.001); only principal location of collective area).

Among collective places, other collective places than those previously cited were reported by 4.5% (19/422) and 11.4% (13/114) of the users before and after the lockdown initiations, respectively (19/1334, 1.5% and 13/784, 1.7% of all contaminations, respectively).

For the total contaminations, restaurants were the source of only 2.5% (19/760) of infections after the lockdown versus 8.8% (114/1297) before the lockdown; bars were the source for 0.8% (6/760) of infections versus 5.2% (68/1297) before the lockdown; schools and stores were the source of 4.5% (34/760 vs 35/1297, 2.7%) and 1.6% (12/760 vs 13/1297, 1.0%, respectively) before the lockdown.

Discussion

Our results suggest that virus transmission occurred mainly in private areas (1048/2090, 50.2%) between August 15 and December 24, 2020, in France or by a colleague at work (579/2090, 27.7%). The partial lockdown, which occurred on

XSL•FO
RenderX

October 25, 2020, during the second wave of COVID-19, changed the circumstances of contamination.

Contamination by a friend was significantly reduced (382/773, 29.0%) before and (109/773, 14.1%) after the lockdown but increased from a family member or a colleague. Among people who knew the time of contamination, the main time of the day was the evening before the lockdown (339/961, 35.3%), and the morning and noon became the main time of contamination after the lockdown (86/473, 18.2%). The main location of suspected contamination by users of the web application questionnaire was private home (own home, family's home, or friend's home) in 39.1% (510/1305) of declarations before the lockdown and remained high after the lockdown (329/760, 43.3%).

Contaminations increased in the work area (293/1305, 22.5% vs 225/790, 29.6%; *P*<.001), reduced in collective places (430/1305, 33% vs 114/760, 15.0%; *P*<.001), and increased in care centers (58/1305, 4.4% vs 74/760, 9.7%; *P*<.001). Work became the main location of contamination after the lockdown. The main collective places impacted by the shutdown were restaurants, bars, and parties in which reduction of contaminations was significant.

Our results showed that contaminations occurred in collective places 33.0% (430/1305) of the time, and that the lockdown reduced it to 15.0% (114/760) of contaminations (ie, a 54.5% reduction), whereas daily anosmia reported on the national website maladiecoronavirus.fr showed an 80% reduction after the partial lockdown initiation. This can be explained by the voluntary decisions of people to reduce social meetings at a higher rate than government-imposed restrictions on activity during the lockdown and especially among friends, from which contaminations decreased from 29.0% to 14.1% [8]. As work and school were maintained during the shutdown, higher rates of contaminations were observed in those places. The partial lockdown concerned all cultural locations such as theaters or cinemas. We did not ask users of the web application sourcecovid.fr specifically if they thought they were contaminated in those sites but only "other locations." However, "other locations" was answered by nearly 1.5% of users before and after the lockdown, suggesting that cultural sites were not a significant source of contamination.

Although this study is based on unverifiable data, the quality of the data is consolidated by the incubation period calculated at 4.0 days, which is the median time reported in the literature; the equity between males and females; 10.8% (229/2118) of users with severe disease (15% in Guan et al [9]); the median age of users (43 years in our study, 47 years in Guan et al [9]); and 61.8% (1309/2118) of users reporting sureness of contamination circumstances. Moreover, results were consistent with published reports on excess of contamination risk in restaurants (times 2.4) or bars (times 3.9) and households (times 10), with a higher number of questionnaires in our study (n=2218) than in Fisher et al [10-12].

Our study has limitations. A user of the web application could use it several times and could have filled out more than one questionnaire. Memory bias could occur to users contaminated at the beginning of the study period, which explains the relative high number of users during the recent lockdown period.

The population older than 65 years made up 12.5% (265/2118) of users, whereas contamination circumstances were not the same as in the active population. Moreover, only 4.4% (93/2118) of questionnaires concerned people younger than 18 years. This has probably underestimated contaminations at school. We do not have enough data to assess geographic variations of the lockdown effect, especially to differentiate urban and rural area impact.

However, our study is the first to assess a partial lockdown effect on contamination circumstances and may help health authorities to adapt a policy of preventing COVID-19 spread.

Acknowledgments

We thank users for their participation in this study and Magali Balavoine, MSc (Weprom, Angers, France).

We also thank the Caisse Primaire d'Assurance Maladie de Sarthe, Le Mans Metropole (Stéphane Le Foll), Docaposte, Adobis group, and Le Figaro.fr.

Weprom designed and conducted the study; collected, managed, analyzed, and interpreted the data; prepared, reviewed, or approved the manuscript; and decided to submit the manuscript for publication.

Authors' Contributions

FD had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis. DP also contributed toward the concept and design of the study. All authors were involved with acquisition, analysis, or interpretation of the data; drafting of the manuscript; and critical revision of the manuscript for important intellectual content. FD and ALS contributed toward the statistical analysis. FD, Weprom, Docaposte, and Kelindi were involved with administrative, technical, or material support. FD supervised the study.

Conflicts of Interest

All authors have completed and submitted the International Committee of Medical Journal Editors Form for Disclosure of Potential Conflicts of Interest. FD reports receiving personal fees from Astrazeneca, Ipsen, Kelindi, Pfizer, Chugai, and Roche. He is a cofounder of Kelindi. FLG is a cofounder of Kelindi. SJ is the founder of Adobis Group.

Abstract

Background: The scale and quality of the global scientific response to the COVID-19 pandemic have unquestionably saved lives. However, the COVID-19 pandemic has also triggered an unprecedented “infodemic”; the velocity and volume of data production have overwhelmed many key stakeholders such as clinicians and policy makers, as they have been unable to process structured and unstructured data for evidence-based decision making. Solutions that aim to alleviate this data synthesis–related challenge are unable to capture heterogeneous web data in real time for the production of concomitant answers and are not based on the high-quality information in responses to a free-text query.

Objective: The main objective of this project is to build a generic, real-time, continuously updating curation platform that can support the data synthesis and analysis of a scientific literature framework. Our secondary objective is to validate this platform and the curation methodology for COVID-19–related medical literature by expanding the COVID-19 Open Research Dataset via the addition of new, unstructured data.

Methods: To create an infrastructure that addresses our objectives, the PanSurg Collaborative at Imperial College London has developed a unique data pipeline based on a web crawler extraction methodology. This data pipeline uses a novel curation methodology that adopts a human-in-the-loop approach for the characterization of quality, relevance, and key evidence across a range of scientific literature sources.

Results: REDASA (Realtime Data Synthesis and Analysis) is now one of the world’s largest and most up-to-date sources of COVID-19–related evidence; it consists of 104,000 documents. By capturing curators’ critical appraisal methodologies through the discrete labeling and rating of information, REDASA rapidly developed a foundational, pooled, data science data set of over 1400 articles in under 2 weeks. These articles provide COVID-19–related information and represent around 10% of all papers about COVID-19.

Conclusions: This data set can act as ground truth for the future implementation of a live, automated systematic review. The three benefits of REDASA’s design are as follows: (1) it adopts a user-friendly, human-in-the-loop methodology by embedding

XSL•FO
RenderX

an efficient, user-friendly curation platform into a natural language processing search engine; (2) it provides a curated data set in the JavaScript Object Notation format for experienced academic reviewers' critical appraisal choices and decision-making methodologies; and (3) due to the wide scope and depth of its web crawling method, REDASA has already captured one of the world's largest COVID-19–related data corpora for searches and curation.

KEYWORDS

structured data synthesis; data science; critical analysis; web crawl data; pipeline; database; literature; research; COVID-19; infodemic; decision making; data; data synthesis; misinformation; infrastructure; methodology

Introduction

Between December 31, 2019, and August 3, 2020, 37,362 papers related to COVID-19 were published on PubMed [1], with Dimensions reporting over 100,743 publications, 1503 policy documents, and 1097 data sets [2]. The speed and scale of the production of published data on COVID-19 across both peer- and nonpeer-reviewed literature presents considerable challenges for stakeholders (eg, policy makers, clinicians, and patients) who must make subjective quality judgements on new data and rapidly synthesize information in order to make optimal, evidence-based decisions. Traditional approaches to data synthesis are unable to keep pace with the rapidly changing information landscape. For example, in the United Kingdom, the National Institute for Health and Care Excellence was unable to publish their initial therapeutic guidance on managing COVID-19 until March 20, 2019 [3]. Ultimately, they modified their methodology for publishing rapid guidance materials on COVID-19 [4]. Moreover, there have been concerns regarding data credibility and the political misuse of information, resulting in the World Health Organization announcing its campaign for discouraging the spread of misinformation [5]. The COVID-19 pandemic highlights the urgent need to prospectively capture, structure, and interpret expansive and complex data sets in real time to support the rapid development of clinical guidance and, most critically, ensure that various key stakeholders can make the best possible evidence-based decisions during an "infodemic."

Previous strategies have attempted to address these challenges by using the concepts of live systematic reviews, which involve the continuous, structured analysis of data that target specific clinical questions [6,7] as well as the clear presentation of such data [8]. However, despite the progress in this field, major obstacles remain in establishing automated data mining frequency, depth, and robustness. Moreover, major barriers exist in the development and validation of machine learning methodologies for the autonomous analysis of heterogeneous clinical data sets.

This paper outlines the methodology of REDASA (Realtime Data Synthesis and Analysis)—a novel, prospective clinical information platform that was developed during the COVID-19 pandemic. It was designed for use across a wide range of data-rich subject areas while keeping application and impact in mind. Our objective was to continuously capture and synthesize both academic and relevant grey literature (eg, news websites, policy documentation, and social media posts) on COVID-19 and to develop a validated data curation approach that could supplement machine learning methodologies and be used as the basis for conducting live systematic reviews.

Methods

Components of REDASA

REDASA was built and deployed on the Amazon Web Service (AWS) cloud. Cloud computing is the on-demand delivery of compute power, database storage, applications, and other information technology resources through a cloud service platform on the internet. A cloud services platform, such as AWS, owns and maintains the network-connected hardware required for these application services. By using the AWS cloud, REDASA components were rapidly designed. REDASA components were integrated and deployed by using AWS tools and the solutions developed by AWS Partners, MirrorWeb, and Cloudwick. These components were comprised of a real-time data extraction pipeline that was implemented by using MirrorWeb's digital archiving technology, a data lake storage repository and workflow orchestration platform (Amorphic) that was developed by Cloudwick, a natural language search engine that was implemented by using Amazon Kendra, and a document curation pathway that was implemented by using Amazon SageMaker Ground Truth.

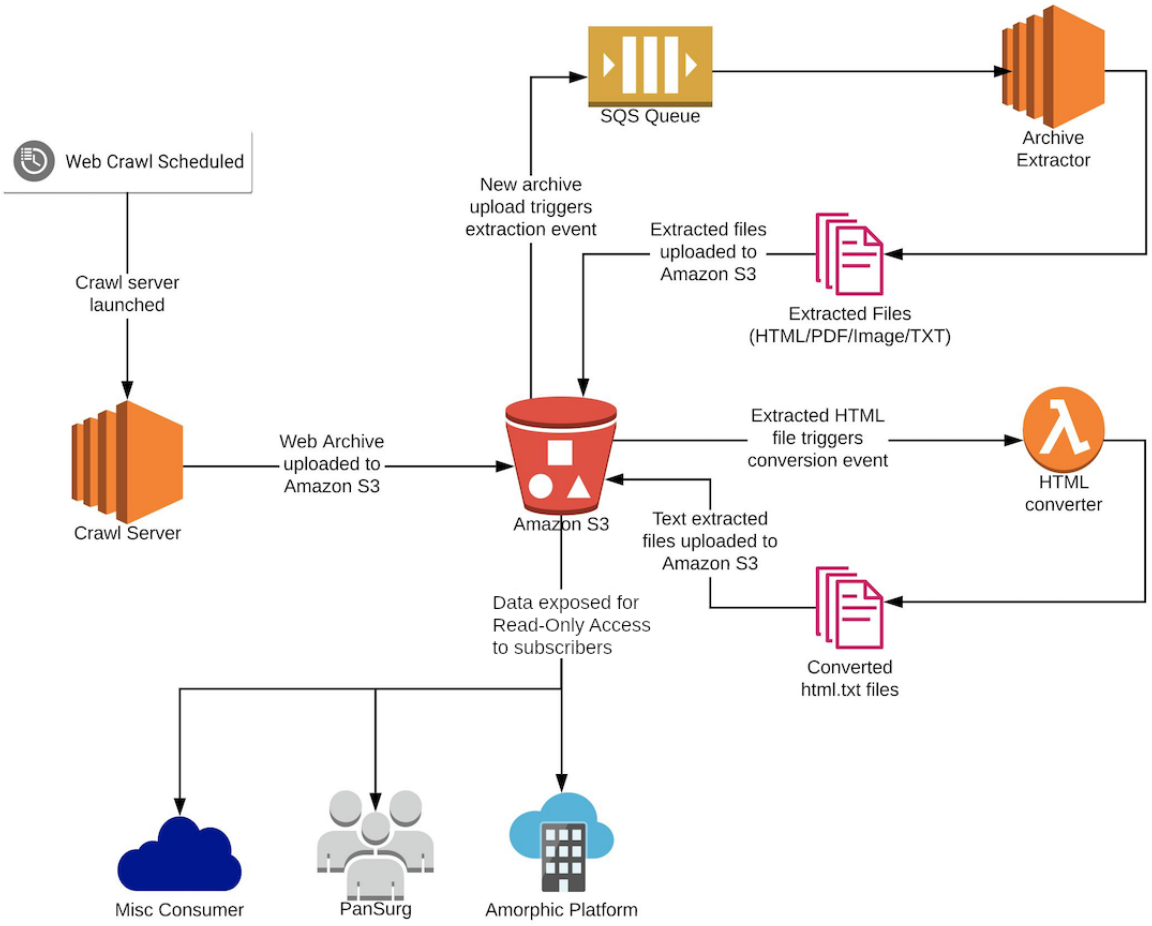
Real-Time Data Extraction Pipeline

MirrorWeb was used to conduct an exploratory review of the target websites via manual and automatic content detection for informing crawl scoping decisions. Exploratory reviews involve the domain composition analysis of initial web estate archives, which can be produced via multiple methods, including basic link harvesting, Domain Name System lookups, the gathering of URL lists at crawl time (to identify content delivery networks and perform manual verifications), and the inspection of websites. This ensures that (1) the relevant areas of websites are identified and followed by the archive tools and (2) content that can be confidently omitted is avoided. With the adoption of machine learning algorithms, this process can be further assisted by technology.

Scoping decisions can encompass a range of factors. For instance, scoping decisions can ensure that the website crawl stays within the target domain. Further, they can refine the website crawl to only include relevant URL patterns within the domain. For example, if there is a domain.com/coronavirus/ subfolder that contains relevant content, the web crawler will use a series of URL pattern matches and regular expressions to allow or disallow URL strings via exact matching or wildcard pattern matching, thereby containing the crawl to specific areas

XSL•FO
RenderX

of the website. Additionally, scoping decisions can expand the crawl scope to include any outlying content that would be excluded by the refinement rules. Some websites have nonstandard locations for storing assets such as images, stylesheets, and scripts, which are needed to create a high-fidelity representation of the source material. Some websites also contain relevant documents that are located in prescribed location structures outside of the primary target folder.



Successful, high-fidelity targeted web crawling has been well documented. However, considerable challenges remain in the development of a qualitative and quantitative method for real-time relevant URL detection [9]. This is because the web ecosystem is a constantly evolving landscape with continuous advancements in available technology; construction techniques; and the consideration of desktop, mobile, and accessible display devices. Furthermore, the sheer number of content management systems that adopt their own proprietary content structures, the advent of single page applications, the prevalence of JavaScript, and people's dependence on asynchronous loading and POST method requests (which returns the same URL for multiple requests) render traditional URL similarity detection a particular challenge. Programmatic links with no human-readable semantic structures and features, such as "Latest News" sections within a web page, can often skew the results of link-based page relevance analyses.

These challenges are exacerbated in the REDASA system, which is required to target data in both academic and nonacademic sources without a guaranteed schema, dialect, or topic. Previously developed methodologies for addressing this issue have been used to apply anchor text similarity scores, content similarity scores, and URL prediction scores (which are based on a set of starting keywords) to seed data [10,11]. These scoring models promote and remove keywords based on the detection of commonalities in discovered crawl data. However, this approach presents several challenges because it relies on good starting URLs that present a reliable and consistent pattern of data. To counter this, REDASA performs downstream content filtering after the crawl is complete in order to eliminate extraneous data, which eliminates the risk of losing vital information that comes with the analysis of a potentially biased set of keywords. Due to REDASA's ability to perform a retrospective analysis of retained data, it will serve as a future platform that can be further enhanced by discovery automation.

In practice, REDASA performs an initial crawl that is launched by using crawl scope definitions that are governed by the aforementioned decision rules. The process for completing a crawl is outlined in Figure 1, which provides an interactive replica of the website content that is accessible to curators. MirrorWeb's Crawl Quality team reviewed the quality of the archive by using a replay engine to create a navigable replica of the target website archive. In addition to clicking the links and manually reviewing the content, an automated link checker was used to recursively spider the archive, identify page and document links in the HTML content, and attempt to open the target URLs in the archive instance in an effort to detect any missing referenced content. If any changes to the scoping rules are needed to make the web crawl more permissive or more restrictive, the scoping rules will be amended as required by using the same, aforementioned scoping principles. This iterative cycle repeats until the crawl is of sufficient quality to be used for human curation and accurate natural language processing (NLP) searches.

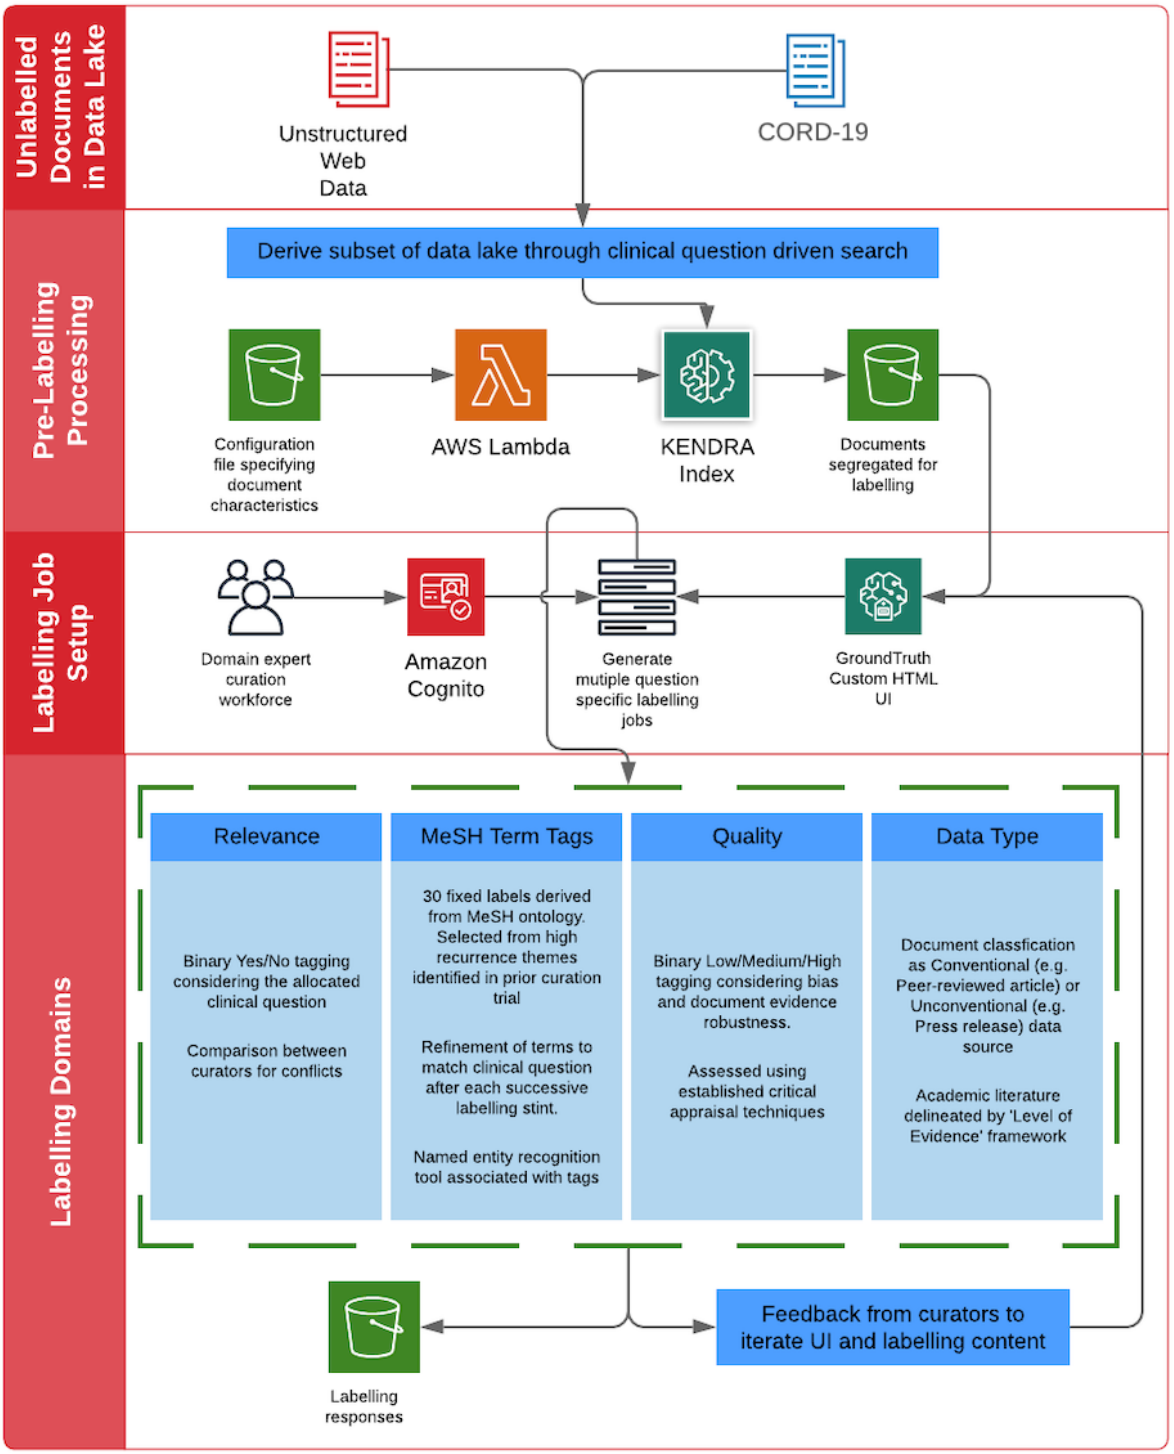
Data Lake

Cloudwick's Amorphic platform provides a core REDASA data lake repository and data workflow orchestration service. MirrorWeb data initially lands in the storage layer of Amorphic, which consists of a landing zone. After validation checks are performed, data are moved and stored in a data lake zone and made available for document curation and search index workflows, as described in the following section.

Search Index for Question-Specific Curation Documents



REDASA uses an AWS enterprise search service—Amazon Kendra—to provide search functionality across the entire data lake. Amazon Kendra is an NLP machine learning service that uses deep learning models to understand natural language queries and document content and structures. Amazon Kendra provides support for the following three broad types of questions: (1) factoid questions (who, what, when, and where), which are questions that require fact-based answers that may be returned in the form of a single word or phrase (the precise answer however must be explicitly stated in the ingested text content); (2) descriptive questions, which involves answers that could be a sentence, passage, or an entire document; and (3) keyword searches, wherein the intent and scope of the question may not be clear. In REDASA's question-specific curation model, Amazon Kendra exclusively received factoid questions and used a series of deep learning models to return relevant documents (Figure 2).

The key component of Amazon Kendra is an index. Conceptually, an index is an abstraction that encompasses a set of documents and the underlying hardware and software infrastructure that makes it possible to query documents that use natural language. Aside from its actual content, each document may include some associated metadata (eg, the source of the document, the document's logical unit group, etc). Users can specify custom metadata fields to suit their needs. These metadata tags are accessible through the Amazon Kendra query application programming interface.

A Kendra index may consist of one or more data sources, and a data source is a logical unit of documents. For REDASA, data source file types were limited to plain text, HTML, and PDF. Compared to other file types, these better integrate with our curation platform and allow for consistent labeling outputs when performing named entity recognition (NER).

AWS: Amazon Web Service; CORD-19: COVID-19 Open Research Dataset; MeSH: Medical Subject Headings; UI: user interface.

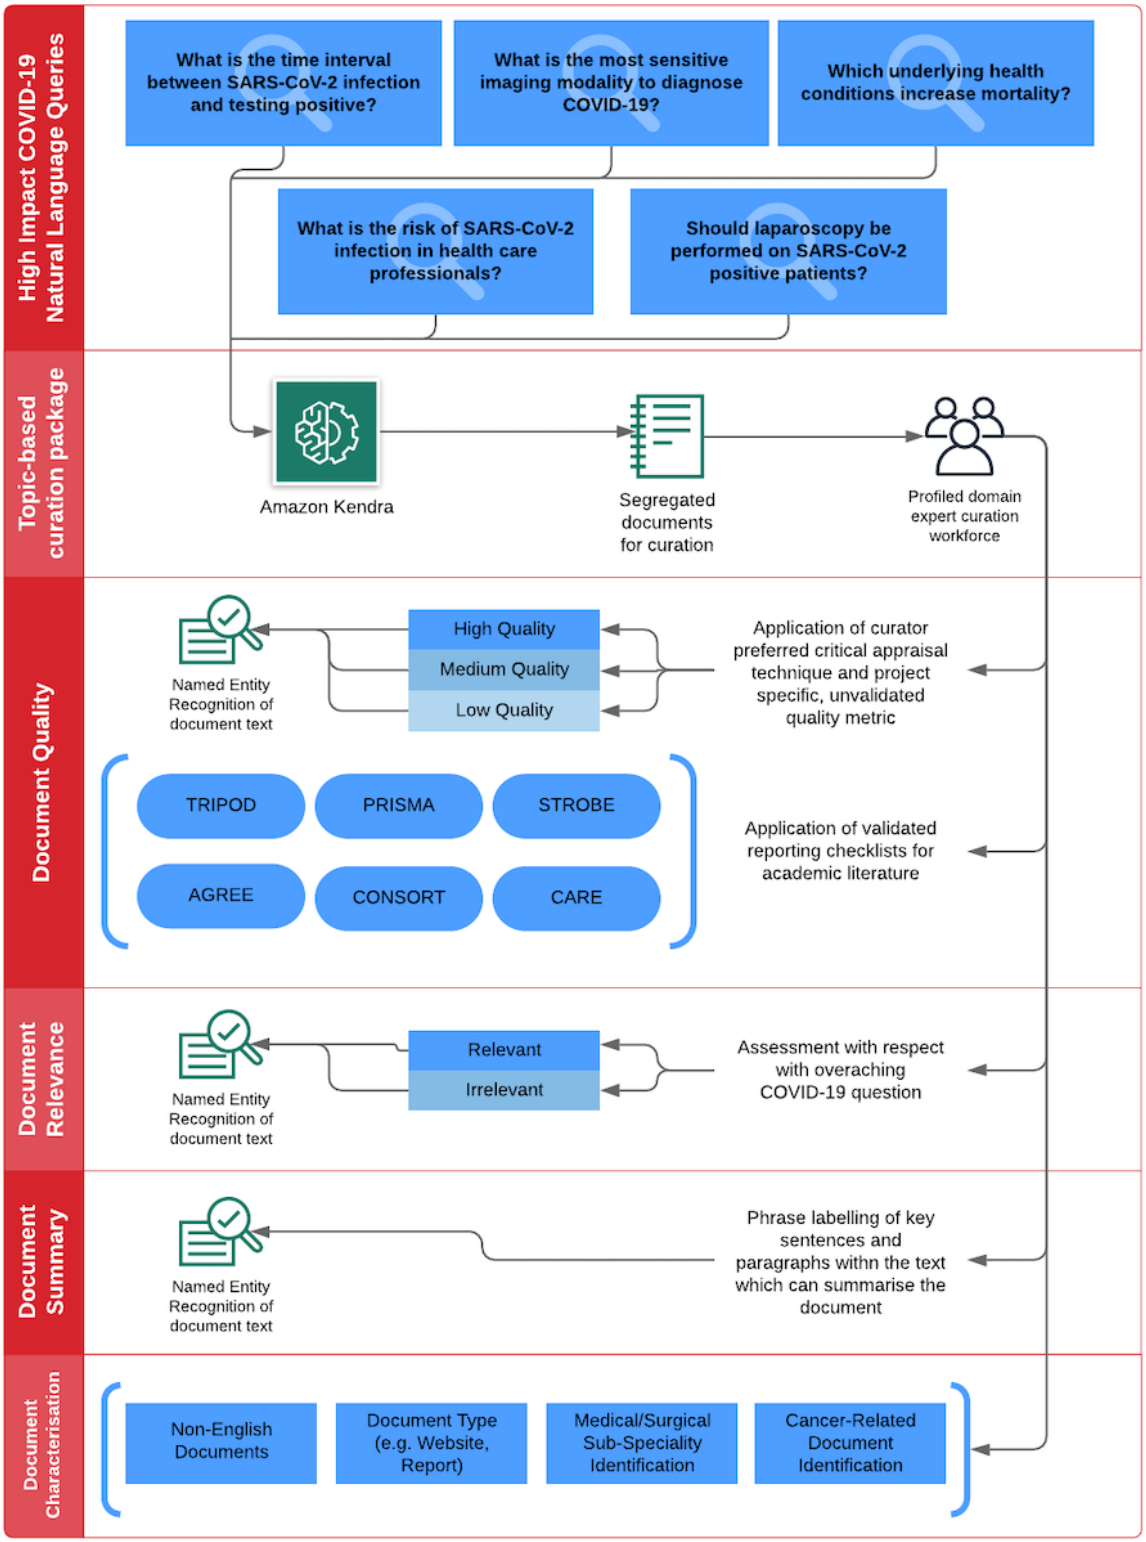
Document Curation

Document curation was implemented by using the custom workflows in Amazon SageMaker Ground Truth, which is a data labeling service that is used to build training data sets for machine learning workflows. REDASA uses a question-based curation approach. PanSurg investigators posed a series of COVID-19–related key questions to the search index (Textbox 1). These questions were chosen to obtain answers, and we were able to validate the quality of the data lake and the adequacy of REDASA's data mining depth with our curation relevance metric.

XSL•FO
RenderX

Textbox 1. COVID-19–related natural language processing queries that were posed to the REDASA (Realtime Data Synthesis and Analysis) search index to develop a question-specific curation methodology.

Queries in natural language



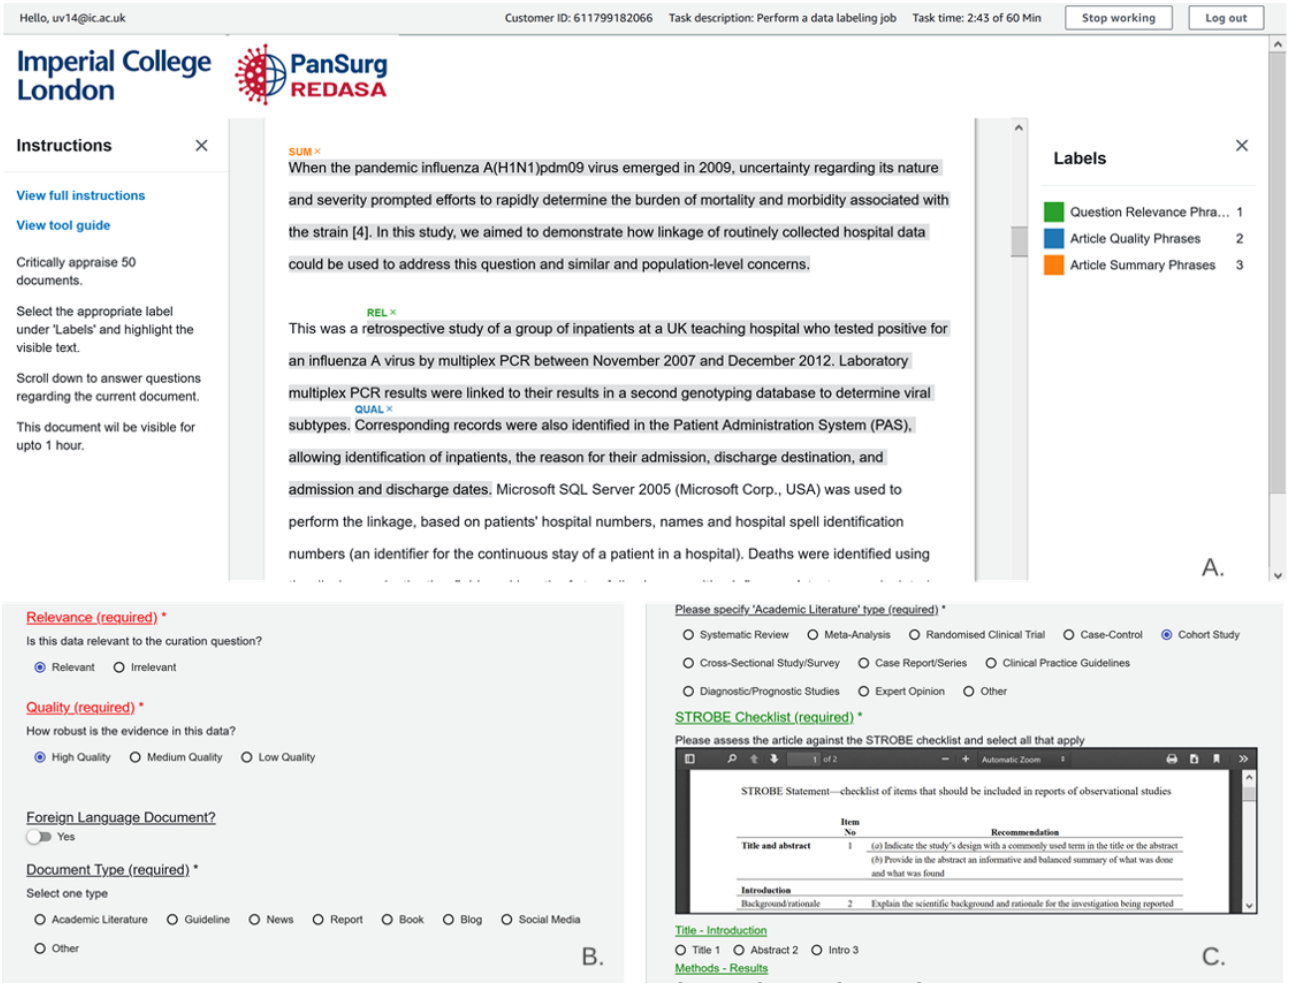
1. What is the time interval between SARS-CoV-2 infection and testing positive?
2. What is the most sensitive imaging modality to diagnose COVID-19?
3. Which underlying health conditions increase mortality?
4. What is the risk of SARS-CoV-2 infection in health care professionals?
5. Should laparoscopy be performed on SARS-CoV-2 positive patients?
6. What is the estimated global economic impact of COVID-19?
7. How effective are masks at minimizing the transmission of COVID-19 in public?
8. What is the evidence for COVID-19 mutations and how many subtypes are responsible for the pandemic?
9. Does a positive SARS-CoV-2 antibody test mean an individual is immune to further COVID-19 infections?
10. Is COVID-19 airborne transmitted?
11. Can asymptomatically infected individuals transmit COVID-19?
12. What is the evidence for 1-meter and 2-meter separations for social distancing?
13. What has the evidence-base been for lockdown compared to no lockdown during this COVID-19 pandemic?
14. Is universal preoperative testing for SARS-CoV-2 beneficial compared to selective testing?
15. Can individuals be reinfected with SARS-CoV-2?

The REDASA search index provides a list of selected documents, which are randomly provisioned to curators for labeling via Amazon SageMaker Ground Truth. This allows them to assess documents' relevance and quality in relation to the original query and further categorize the data based on the labels described in Figure 3. Reflecting the living nature of the REDASA platform, queries were adapted in accordance with the knowledge priorities of different phases of the pandemic. For example, in stint 1 of curation (February 6 to September 6, 2020), which was scheduled during the peak of the UK COVID-19 outbreak and when uncertainties regarding best practices for screening and management planning were rife, questions 1-5 were posed to REDASA. In contrast, stint 2 of curation was performed during the nationwide lockdown relaxation period and the public health transition for minimizing the risk of a second wave of COVID-19. Consequently, questions 6-15 focused upon themes such as reinfection, transmission mitigation, and the global impact of the pandemic.

The relevance of articles in relation to the query that was posed to the search index was a subjective binary measure (ie, irrelevant or relevant). This assessment was paired with NER labels, which enabled curators to highlight phrases and paragraphs that indicated the relevance of articles.

XSL•FO
RenderX

Figure 3. Curation labels for generating document metadata. AGREE: Appraisal of Guidelines for Research and Evaluation; CARE: Case Reports; CONSORT: Consolidated Standards of Reporting Trials; PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses; STROBE: Strengthening the Reporting of Observational Studies in Epidemiology; TRIPOD: Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis.



The quality of the academic literature was assessed via a 3-stage process. First, we ascertained the study type, and this allowed us to assign an evidence rating level (the levels proposed by the Oxford Centre for Evidence-Based Medicine [12]). Second, we invited curators to provide an independent, subjective rating of an article's quality by using their own critical appraisal methodology and assign 1 of the 3 following binary ratings: low, medium, or high. Third, akin to the relevance metric, NER annotation was made available to curators and correlated with their low, medium, or high ratings. Depending on the type of academic literature that curators were assessing, curators were automatically given (through their user interface) the relevant EQUATOR (Enhancing the Quality and Transparency of Health Research) checklist for quantitative quality assessment [13].

XSL•FO
RenderX

For example, if the document that curators were assessing was a systematic review, they were automatically able to assess the article against the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist (Figure 4).

Figure 4. (A) A document with curation user interface labels (the NER of quality, relevance, and summary phrases). (B) Binary labels for classifying documents and correlating them to NER responses. (C) Embedded reporting checklists for document assessment, which were provided based on the selected academic study type. NER: named entity recognition; REDASA: Realtime Data Synthesis and Analysis; STROBE: Strengthening the Reporting of Observational Studies in Epidemiology.

Collectively, the relevance and quality metrics' utility was threefold. First, they enabled us to capture data on curators' decision-making and critical appraisal processes. Second, they minimized the number of undesirable irrelevant documents, which allowed us to implement a human-in-the-loop optimization methodology for the search index. Third, they allowed us to perform multiple curator passes on a single document, assess for labeling response conflicts, and ascertain the article factors responsible for any disparities. To obtain further data, we allowed our curators to assess the risk of bias in the articles by using the bias metrics designed by Cochrane [14]. The results from this novel curation process were intended to (1) act as ground truth for data science models that aimed to facilitate the future semiautomation or full automation of article screening, and (2) be used for a structured assessment of evidence quality.

This question-specific approach was selected over the more traditional approach of randomly sectioning data to help us preserve the relevance metric for specific questions. This factor would have otherwise been more challenging to implement and capture. Further, this metric is key to future work streams that determine the relevance of specific articles for inclusion in an automated systematic review.

Curation Methodology

Structured and Unstructured Data Lake

Our proof-of-concept analysis for data mining during predefined time periods was feasible. In this iteration of REDASA, a 1-week time period was chosen to enable the capturing of the highest possible number of new data points at the lowest mining frequency, thus minimizing the computing costs of both COVID-19–structured and unstructured data sources. In this paper, we only present a text-based analysis of the data set. In the future, we intend to assess structured, quantitative data from target data sources.

Unstructured Web Crawl Data

Textual information was extracted from a precurated set of internet sites. A range of frequently accessed but disparate data types that are typically used by frontline clinicians and policy makers were extracted. These included high-quality journal websites and portals containing COVID-19–related literature;

XSL•FO
RenderX

medical and surgical society guidance web pages; and guideline repositories from local, governmental, and international public health bodies. By being able to dynamically capture data and automatically obtain updates from sources, this type of data mining demonstrates the power of REDASA in terms of amalgamating qualitative and quantitative insights for generating future reports. Each website was independently assessed and evaluated for inclusion into the REDASA data lake by clinical (n=4) and data science (n=2) reviewers. Disagreements were resolved through consensus. These sources were selected in accordance with criteria for including usable content and determining the reliability and breadth of target topics and categories pertaining to COVID-19. To systematize the data lake prior to data ingestion, sources were categorized into the following broad groups, which were independently defined a priori by the three members of the research team based on the source of the original data: all (miscellaneous), critical care, medical care, surgical care, drug development and pharmacological therapy, mental health, risk, translational research, biological sciences, engineering, and policy. The content of the data from each of the sources was screened by these three independent members of the research team. If disagreements regarding categorization occurred, a meeting was conducted. Unanimous agreement was sought prior to final categorization.

Structured Data From the COVID-19 Open Research Dataset

The White House and a coalition of leading research groups developed the COVID-19 Open Research Dataset (CORD-19) [15]. The CORD-19 is a data set that contains over 157,000 scholarly articles, including over 75,000 full-text articles regarding COVID-19, SARS-CoV-2, and related coronaviruses. This freely available data set was provided to the global research community of Kaggle and was used as a test data source when initially developing the REDASA infrastructure.

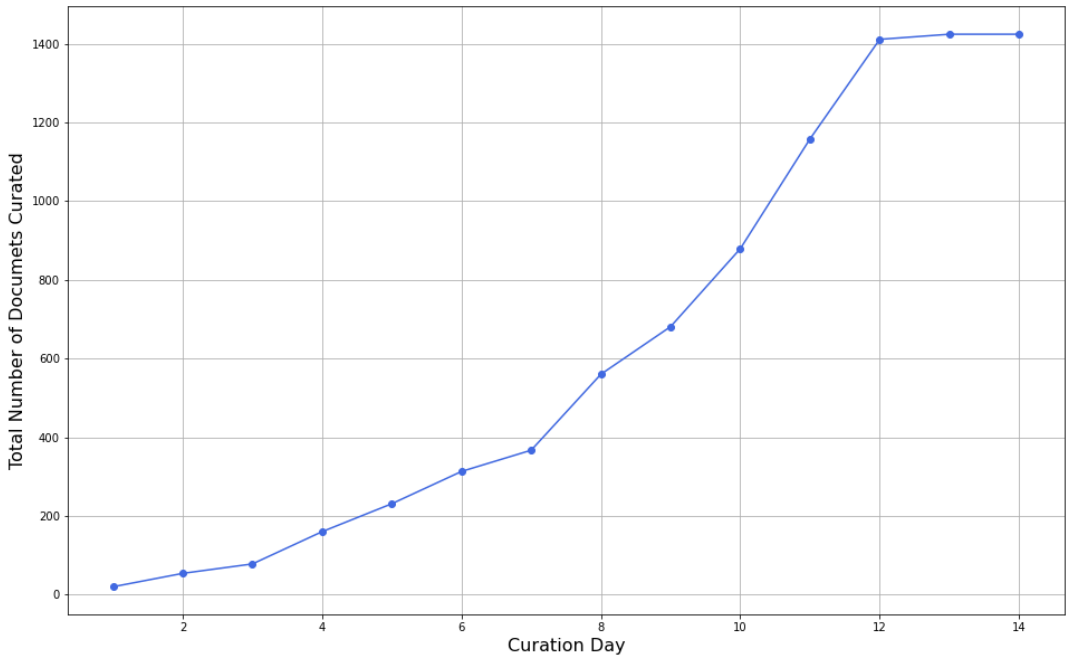
Collectively, these assimilated data sources make REDASA one of the world's largest and most contemporaneous COVID-19–related evidence sources, consisting of 104,000 documents.

Data Availability

The curation labels can be found on GitHub [16].

Results

Curation Results



The first-pass document curation responses from 42 curators underwent the preliminary analysis of the domains of relevance to free-text queries and information quality. These data were collected over 2 time-limited curation stints. Both stints were 1 week in duration. We obtained a total of 1424 documents pertaining to 15 different COVID-19–related queries (around 99 text documents derived per query from the search index for the structured and unstructured data lake), and an average of 42 documents per query were assessed by 1 curator. Our aim was for each document to be assessed by at least 2 different reviewers so that we could assess intercurator variability and identify the reasons for discrepancies in evidence quality verdicts.

Each curator was profiled to ascertain their academic or clinical backgrounds. This was initially performed for the vetting and quality control of curation responses. These data will also be used to further discriminate between labeling responses that are based on critical appraisal expertise and to assign weights to curation responses. To date, the REDASA project's international curator community includes people from 9 different countries, and the project is supported by medical and surgical health care professionals who range from senior consultant vascular surgeons in Italy to general practice physicians who are involved in community and public health decision making in the Philippines. Data curators were recruited by invitation through the PanSurg email subscriber list and by open invitation via the @pansurg Twitter account. Curators were included if they had a medical degree or a higher degree in science-related fields. Data curators were asked to state their interest and were verified by direct contact. The number of data curation responses for REDASA, which exponentially rose between our two stints as more curators were onboarded (stint 1: n=12; stint 2: n=42; Figure 5), was indicative of an efficient, novel methodology for the digital, community-based peer review of literature by domain experts. This was exemplified by the ability of some of our experienced curators, who were able review over 100 scientific documents of varying length in as little as 3 days. Furthermore, with curators' 100% follow-through rate between stint 1 and stint 2, our curation model suggests that, when combined with our simplified critical appraisal interface, the peer review of literature at scale is viable and sustainable.

In total, 70.9% (1009/1424) of the pool of curated articles was composed of peer-reviewed, traditional, academic literature; the remainder consisted of web crawl–derived data, including governmental policies and reports from professional bodies. Based on the subset of the 900 academic literature documents that were curated, the most common study type encountered was systematic reviews (98/1009, 9.7%). The least common study type in the data lake was randomized controlled trials (RCTs; 3/1009, 0.3%). Nonsystematic reviews (eg, rapid reviews and comprehensive reviews) were not given the systematic review label to avoid inappropriate assessments against the PRISMA checklist. Such outlier academic literature types were aggregated into the miscellaneous category, which included 427 documents that were assessed solely against the curator-reported binary quality ratings.

XSL•FO
RenderX

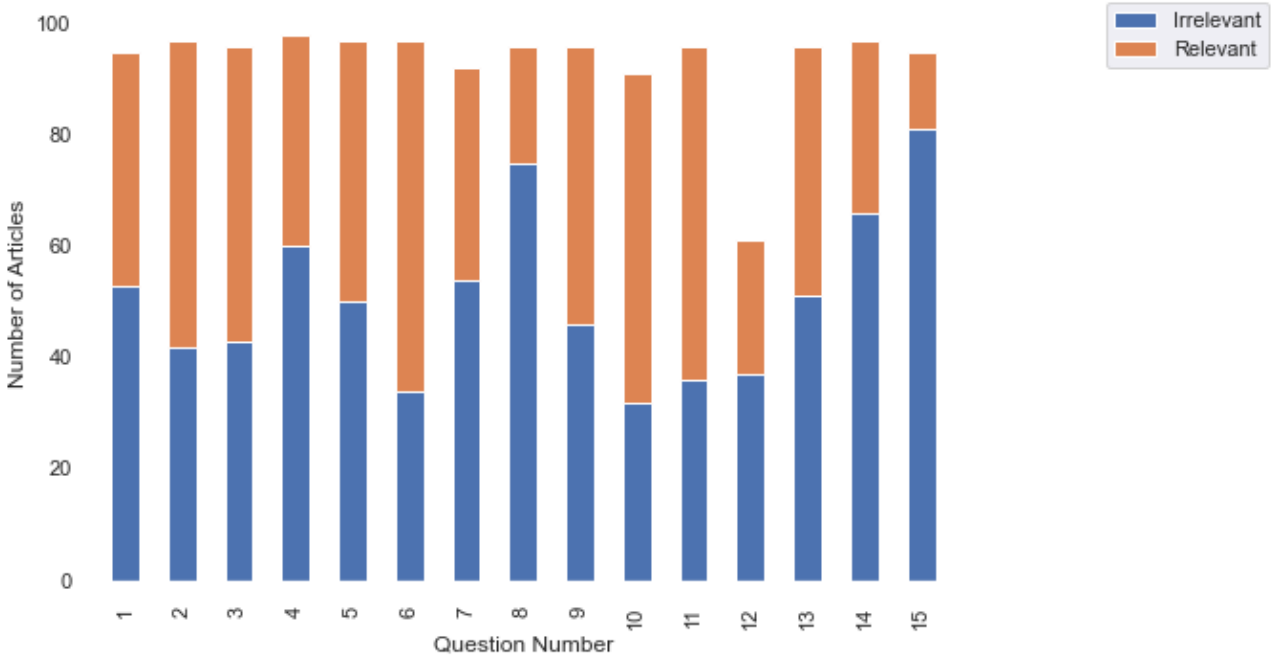


Figure 5. Rate of COVID-19–related scientific literature curation over 2 weeks. This was associated with the growth of the number of curators, which plateaued on day 13. This was when all of the documents available for curation were assessed before the end of stint 2.

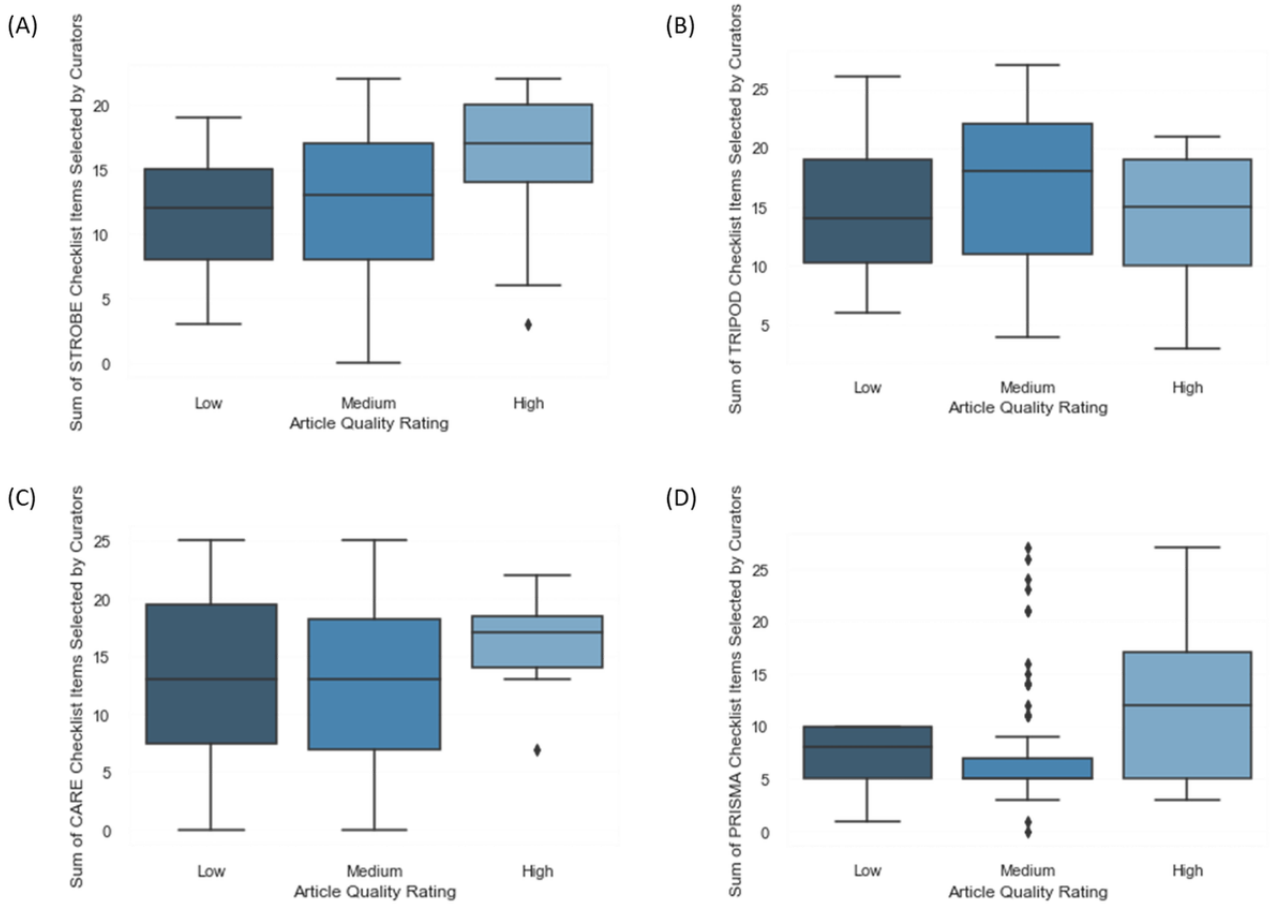
Articles' Relevance to Queries

The relevance metric that curators used provided insight into the performance of the search index in terms of providing cogent and useful document results associated with the 15 COVID-19–related queries (Textbox 1). Overall, 50.49% (719/1424) of articles were considered relevant to their respective queries. When observing the question bank, this variance in article relevance (which was based on the search index) was reflected by the lack of consistency in the ratio of the number of relevant articles to the number of irrelevant articles (Figure 6). These data can be used to provide feedback for the search index with regard to the optimization of provided results.

Figure 6. Curators' responses determined the relevance of documents to search index queries. Responses were matched to the query number.

XSL•FO
RenderX

Critical Appraisal of Article Quality



The uneven distribution of academic study types that have been curated thus far precludes the interpretation of results for quantitative reporting checklist responses based on the qualitative rating system (low, medium, and high) for RCTs (CONSORT [Consolidated Standards of Reporting Trials] checklist) and clinical guidelines (AGREE [Appraisal of Guidelines for Research and Evaluation] checklist). These studies were poorly represented in this run of analysis.

Quality was quantified by ascertaining the sum of the number of EQUATOR Network–derived checklist items that were fulfilled by each document. Hence, documents with methods and results that aligned more closely to their respective reporting checklist were scored higher and deemed to be of greater quality. This outcome was compared to the curators' subjective ratings for diagnostic and prognostic studies (TRIPOD [Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis] checklist), case reports and series (CARE [Case Reports] checklist), case-control studies (STROBE [Strengthening the Reporting of Observational Studies in Epidemiology] checklist) and meta-analyses and systematic reviews (PRISMA checklist) (Figure 7). Notably, the subjective quality rating was assigned prior to assessment by using the checklist under our curation protocol to mitigate observer bias.

Based on our independently assessed and subjective quality metric, our preliminary results suggested that more than 50% (726/1424, 50.98%) of the documents derived from the REDASA data pipeline were of medium quality, and 13.55% (193/1424) were deemed high quality. Thus, during data aggregation, 64.53% (919/1424) of the documents derived from our data lake for curation were of a sufficient quality to inform their professional decision-making processes or could be used as reliable sources of information.

With regard to the TRIPOD-relevant (score: mean 15.6, SD 6.9) and STROBE-relevant (score: mean 13.2, SD 5.8) study types, there was some correlation between curators' subjective assessments of the articles that had low-to-high ratings and underwent the validated checklist–based quality assessment. However, with regard to the CARE-relevant (score: mean 13.8, SD 6.8) and PRISMA-relevant (score: mean 8.4, SD 6.1) study types, there was substantial variance in the number of checklist items that were selected for each quality rating, thus indicating an apparent dissociation between these two metrics. Further data collection and the comparison of intercurator responses for the removal of outliers will provide clarity on the role of subjective quality ratings versus the role of validated reporting checklists as a surrogate marker of evidence quality.

Figure 7. Relationship between the low, medium and, high curator-determined quality ratings of (A) case-control studies, (B) diagnostic and prognostic studies, (C) case reports and series, and (D) meta-analyses and systematic reviews and their respective reporting checklist scores. CARE: Case Reports; PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses; STROBE: Strengthening the Reporting of Observational Studies in Epidemiology; TRIPOD: Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis.

Discussion

Globally, there are several efforts underway for systematically accruing COVID-19–related data and specifically querying these data and output-relevant literature [17]. These efforts, such as Google's COVID-19 Research Explorer [18], COVIDask [19], and COVIDScholar [20], are fundamentally based on NLP searches. Additionally, Google's solution incorporates the use of follow-up queries associated with a primary question to obtain more focused results. These efforts universally incorporate the CORD-19 and intuitively present output data. Nevertheless, these approaches do not account for the quality of the data source, which is left to the interpretation of the user. Other efforts, such as SciSight [21] and COVID-19 Primer [22], structure data from the CORD-19 into themes (author and engagement), thereby allowing users to make links and review specific topics, albeit without a natural language interface for answering specific questions.

The crucial difference between REDASA and the aforementioned platforms is threefold. First, REDASA adopts a human-in-the-loop methodology by embedding an efficient, user-friendly curation platform into an NLP search engine. REDASA can iteratively refine its search outputs at scale, particularly in the domains of the relevance and quality of data sources. This can ultimately contribute to a fact-checking function for conducting a reliable assessment of the utility of an article [23]. Second, it provides a curated data set in the JavaScript Object Notation format for experienced academic reviewers' critical appraisal choices and decision-making methodologies. These data on the peer-review process provide a unique framework for modelling, quantifying, and ultimately automating the evidence quality assurance process and are unavailable elsewhere. Finally, due to the wide scope and depth of REDASA's web crawling methodology, REDASA has already captured one of the world's largest COVID-19–related data corpora for searches and curation. Our aim is to make these crucial data freely available and ensure that they are continuously updated to allow for rapid review and dissemination during and beyond the evolving pandemic.

For the long-term goal of conducting a semisupervised, live systematic review of data, several limitations and challenges need to be overcome. Our curation methodology resulted in a high turnover rate for the assessment of data. However, there was still variability in curator output, which was secondary to the variability in curators' subjective critical appraisals. In this project, we relied on the prescreening of curators, which was conducted via academic portfolio screening and assessments for relevant literature review experience. This crucial quality control approach needs to be further developed to fully validate and enhance the accuracy of our curation methodology. A limitation of our preliminary data analysis was the qualitative, summative comparison of the EQUATOR checklist ratings to our quality ratings. This was due to the subcomponents of the used EQUATOR checklists, which did not use equal metrics for article quality, and the nonexhaustive quality criteria captured by these tools. Hence, future studies are needed to validate our quality ratings and identify a reliable metric for quality that is applicable across the academic and nonacademic literature captured by REDASA. In addition to ensuring the consistency of quality ratings, sustained curation work is required to ensure that the corpus includes greater numbers of studies across all designs and methodologies—specifically, RCTs (if available)—to ensure that the corpus is truly representative of data under examination.

Our framework has demonstrated proof-of-concept that by combining the discovery and ingestion pipeline, data lake repository, human curation platform, and NLP semantic search index of REDASA, it can provide curated responses to questions that are posed in natural language in the short term. In the long term however, based on the data insights that progressively validated the critical appraisal of our curation methodology, the ambition of REDASA is to conduct live systematic reviews by using semisupervised machine learning techniques to rapidly return high-quality, relevant evidence in response to queries for any discipline experiencing an "infodemic," such as cancer or cardiovascular disease.

Acknowledgments

We would like to thank the team at AWS Healthcare for their support and help throughout the development of this project and Simon Russell and Steve Neufville for their technical and project management support, respectively. We would also like to thank the PanSurg Collaborative for their support during the project. We thank David Hilman for his technical support with the final stages of this paper. We also thank Elizabeth Burgnon for carefully proofreading the final paper. This work was supported by Defence and Security Accelerator (grant ACC2015551), the Digital Surgery Intelligent Operating Room Grant, the National Institute for Health Research Long-limb Gastric Bypass RCT Study, the Jon Moulton Charitable Trust Diabetes Bariatric Surgery Grant, the National Institute for Health Research (grant II-OL-1116-10027), the National Institutes of Health (grant R01-CA204403-01A1), Horizon H2020 (ITN GROWTH), and the Imperial Biomedical Research Centre.

The members of the PanSurg REDASA Curators are Ademola Adeyeye (Afe Babalola University), Ahmed Ezzat (Imperial NHS Trust), Alberto Porcu (Università degli Studi di Sassari, Italia), Alexander Walmsley (University of Liverpool), Ali Farsi (King Abdulaziz University, Jeddah, Saudi Arabia), Alison Faye O Chan (Institute of Biology, College of Science, University of the Philippines Diliman), Aminah Abdul Razzack (Dr NTR University of Health Sciences), Andee Dzulkarnaen Zakaria (School of Medical Sciences, Universiti Sains Malaysia), Andrew Yiu (Guy's and St Thomas' NHS Foundation Trust), Antonios Soliman (Assiut University Hospitals), Ariana Axiaq (Queen's University Belfast), Avinash Aujayeb (Northumbria HealthCare NHS Foundation Trust), Catherine Dominic (Barts and the London School of Medicine, Queen Mary University of London), Eduarda

Authors' Contributions

JK, GM, and MH were responsible for project conception and overall management. The development of the data pipeline and data lake structure was steered by KS, EF, HS and DB. The implementation of the MirrorWeb web crawling technology was led by KS, who received guidance from UV, SR, PB, and OS. The initial development of the curation platform was performed by EF, and subsequent optimization and tailoring for REDASA use was conducted by CL, UV, SR, and OS. The coordination and development of the data curation methodology was performed by UV, SR, PB, and OS. Data analysis and manuscript composition was performed by UV and SR, who received input from JK, GM, OS, SP, JC, KS, EF, and MH. All authors reviewed and contributed to the manuscript. We would like to thank the PanSurg REDASA Curators for their support on the project.

Conflicts of Interest

GM received equity from Medical iSight (Augmented Reality). SP provides consultations for Medtronic, T.M.L.E. Ltd., and Roche. SP is also the cofounder and director of Mangetoo, 1 World Medical, and the London General Surgery Clinic. SP is also a partner of One Welbeck Hospital. JK provides consultations for Verb robotics, Safeheal, YSOPIA bioscience, and Universal Diagnostics (UDX). JK also received equity from Mangetoo (teledietetics), 1 Welbeck Day Surgery (Hospital), 1 World medical (Personal Protective Equipment), and Medical iSight (Augmented Reality). The other authors have no conflicts of interest to declare for this paper.

Abstract

Background: During the COVID-19 pandemic, the internet has significantly spread information, providing people with knowledge and advice about health protection regarding COVID-19. While a previous study demonstrated that health and eHealth literacy are related to COVID-19 prevention behaviors, few studies have focused on the relationship between health literacy, eHealth literacy, and COVID-19–related health behaviors. The latter includes not only preventative behaviors but also conventional health behaviors.

Objective: The objective of this study was to develop and verify a COVID-19–related health behavior questionnaire, explore its status and structure, and examine the associations between these behaviors and participants' health literacy and eHealth literacy.

Methods: A snowball sampling method was adopted to recruit participants to complete anonymous cross-sectional questionnaire surveys online that assessed sociodemographic information, self-reported coronavirus knowledge, health literacy, eHealth literacy, and COVID-19–related health behaviors.

Results: Of 1873 college students who were recruited, 781 (41.7%) had adequate health literacy; the mean eHealth literacy score was 30.16 (SD 6.31). The COVID-19–related health behavior questionnaire presented a two-factor structure—COVID-19–specific precautionary behaviors and conventional health behaviors—with satisfactory fit indices and internal consistency (Cronbach α=.79). The mean score of COVID-19–related health behaviors was 53.77 (SD 8.03), and scores differed significantly (P<.05) with respect to residence, college year, academic major, family economic level, self-reported health status, having a family member or friend infected with coronavirus, and health literacy level. Linear regression analysis showed that health literacy and eHealth literacy were positively associated with COVID-19–specific precautionary behaviors ($\beta_{\text{health literacy}}$=.149, $\beta_{\text{eHealth literacy}}$=.368; P<.001) and conventional health behaviors ($\beta_{\text{health literacy}}$=.219, $\beta_{\text{eHealth literacy}}$=.277; P<.001).

Conclusions: The COVID-19–related health behavior questionnaire was a valid and reliable measure for assessing health behaviors during the pandemic. College students with higher health literacy and eHealth literacy can more actively adopt COVID-19–related health behaviors. Additionally, compared to health literacy, eHealth literacy is more closely related to COVID-19–related health behaviors. Public intervention measures based on health and eHealth literacy are required to promote COVID-19–related health behaviors during the pandemic, which may be helpful to reduce the risk of COVID-19 infection among college students.

Introduction

COVID-19–Related Health Behaviors

The COVID-19 pandemic, a major public health emergency, has become a serious burden not only for China but also worldwide in terms of threatening people's lives as well as their mental health. At present, governments and institutions worldwide have introduced a series of policies to curb the spread of the epidemic, which have prevented and delayed the spread of COVID-19 to a certain extent [1]. However, vigilance continues to be required as global spread of COVID-19 is still very grim. World Health Organization data showed that as of March 22, 2021, the number of confirmed cases worldwide was 123,968,187, and 2,729,330 people have died worldwide [2]. Fortunately, new coronavirus vaccines have been developed. However, as current supply is insufficient, with potentially inconsistent quality among the different vaccines and manufacturers, many people have expressed suspicion and fear regarding vaccines [3] . Therefore, public preventive measures remain key to slowing the spread of COVID-19.

As a major public health event, the COVID-19 pandemic has required action from both governments and individuals. Since the COVID-19 outbreak, the Chinese government has implemented family-based isolation measures and other COVID-19 response measures, such as disease prevention strategies and advice for psychological adjustment [4]. In January 2020, the Guidelines for Public Protection Against Pneumonia Caused by the Novel Coronavirus Infection, which were compiled by the Chinese Center for Disease Control and Prevention (China CDC) [5], were provided to the public for free. These guidelines, which contain COVID-19 knowledge and prevention advice, such as personal protection, home medical observation, and psychological counseling, have been widely disseminated on online platforms such as social media. In addition to government measures, personal health behaviors also play a vital role in curbing the spread of COVID-19. Many previous studies have shown that public compliance with preventive behaviors can help reduce the spread of COVID-19 [6-8]. In addition to preventive behaviors, people's conventional health behaviors, such as physical exercise and diet, also play an important role in maintaining physical and mental health during the COVID-19 epidemic. Therefore, it is important to understand the characteristics of COVID-19–related health behaviors. In this study, we define COVID-19–related health behaviors as those that are in response to the perceived threat of COVID-19, including government-recommended preventive behaviors and self-adaptive conventional health behaviors. It is noted that few studies have developed specific tools by which to assess the degree of public COVID-19–related health behavior participation. A previous study in the United States developed a 9-item scale based on health behavior recommendations proposed by the US Centers for Disease Control and Prevention to assess individual health behaviors [9]. However, due to the different national conditions of the United States and China, this tool may not be suitable for the Chinese population. Through a literature review, we found that most research on COVID-19 health behavior in China was conducted using a single item or a count of checklist items; the reliability and validity of such approaches remain unclear. Therefore, objectively measuring people's COVID-19–related health behaviors and conducting research into the factors related to such behaviors may help formulate effective interventions for COVID-19 prevention and control.

Health Literacy

Due to the implementation of family isolation, people have had to rely on internet searches to obtain relevant COVID-19 health information (eg, prevention information and control guidelines), which may be associated with their COVID-19–related health behaviors. However, early studies have shown that although the internet can provide resources for individuals seeking health information, people do not always correctly utilize these resources to solve health problems [10]. Additionally, previous studies have demonstrated that individuals with greater health literacy may more precisely distinguish the authenticity and accuracy of COVID-19–related information on media platforms and have superior understanding of health information in general [11,12].

Health literacy is defined as an individual's ability to acquire, process, and understand basic health information and services in order to make appropriate health decisions [13]. Such literacy has long been associated with indicators of health [14]. A previous study showed that health literacy is associated with depression and health-related quality of life during the COVID-19 pandemic [15]. Specifically, medical students with higher health literacy have been shown to exhibit less fear of COVID-19 [16]. Additionally, adolescents' health literacy was shown to be significantly related to handwashing-related knowledge and behavior during the pandemic's early stages in Norway [17]. These examples indirectly illustrate that individuals with adequate health literacy are more likely to adopt COVID-19–related health behaviors, and the health literacy skill framework suggests that individuals' health behaviors were affected by their health literacy skills [18]. Therefore, we hypothesized that health literacy would be positively correlated with COVID-19–related health behaviors.

eHealth Literacy

In contrast, eHealth literacy specifically should be emphasized because while not everyone has a high level of health literacy during the COVID-19 crisis, they can still search, acquire, and utilize health information through the internet, allowing them to adopt relevant health behaviors based on this information. Health and eHealth literacy have distinct but related definitions, as both emphasize the individual's ability to collect, evaluate, and utilize health information; however, unlike health literacy, eHealth literacy focuses on the ability to obtain and apply online health information via electronic media [10]. Therefore, the hypothesis concerning the relationship between health literacy and COVID-19–related health behaviors may be extended to

XSL•FO
RenderX

include eHealth literacy, even though specific associations may be different for the two types of literacy.

Although previous studies emphasized the importance of eHealth literacy during COVID-19 [19,20]—and in the research of netizens [21], health care workers [22], and nursing students [23] it was found that eHealth literacy was related to COVID-19 prevention behavior—few studies have focused on the relationship between eHealth literacy and other COVID-19–related health behaviors other than preventive behaviors, especially among college students. Conventional health behaviors, such as physical exercise and nutritious eating, are also COVID-19–related health behaviors. In addition, a literature review indicated that eHealth literacy, healthy behaviors, and health outcomes are related [24]. Finally, although a previous study found that college students with a low level of eHealth literacy engaged in poor health-promoting behaviors [25], this relationship has not been adequately explored in a pandemic environment. Therefore, it is necessary to further analyze the relationship between eHealth literacy and COVID-19–related health behaviors. Overall, this online cross-sectional survey in China had two purposes: (1) develop and verify a COVID-19–related health behavior questionnaire and explore its status and structure and (2) study the relationship between health literacy, eHealth literacy, and COVID-19–related health behaviors.

Methods

Study Participants

A snowball sampling method was used to recruit the subjects. First, we published a recruitment announcement on QQ, which is a social media platform commonly used by Chinese college students. After screening, we identified 20 college students as the first group of participants from 20 universities across five regions of eastern, western, southern, northern, and central China. Each region included four universities to ensure that the sample broadly represented college students from all of China's regions.

Then, these participants anonymously completed an internet-based, cross-sectional questionnaire and were asked to send the link to the blank questionnaire to their classmates. Participation was voluntary and no financial incentive was given for participating in the study. The purpose of both the survey and informed consent form was displayed on the first page of the online questionnaire. If they agreed to participate, subjects could click the *Next* button to complete the questionnaire; if they chose not to participate, they could click the *X* button. The questionnaire could be completed in 15 minutes, and there was only one chance for a given internet protocol address from which to complete the questionnaire.

This study was approved by the Ethics Committee of Xiangya School of Public Health of Central South University. The survey started on May 10, 2020, and ended on May 20, 2020, recruiting a total of 2152 participants. Of these, 279 were excluded for their illogical completion of the questionnaire (eg, they took less than 5 minutes to complete it or their age was under 10 years). Finally, 1873 valid questionnaires were considered for our data analysis.

Measurements

Health Literacy

Health literacy was measured using the National Health Literacy Survey Questionnaire, as compiled by the China Health Education Center [26]. The overall Cronbach α of the scale was .95, and the Spearman-Brown coefficient was .94, indicating strong psychometric properties with minor measurement invariance [27]. The questionnaire was divided into three aspects: (1) basic health knowledge and literacy, (2) healthy lifestyle and behavior literacy, and (3) basic health skills literacy. These aspects covered the following six types of health problem literacy: scientific health, infectious disease prevention, chronic disease prevention, safety and emergency, basic medical information, and health-related information. The questionnaire consisted of 50 questions, including 34 multiple-choice questions and 16 multiple-answer questions (Multimedia Appendix 1). The total score ranged from 0 to 66 points, with 1 point per multiple-choice question and 2 points per multiple-answer question. A higher total score indicated a higher health literacy level; specifically, a total score of 53 or more indicated that the individual had adequate health literacy [28]. The Cronbach α coefficient for the questionnaire in this study was .83.

eHealth Literacy

eHealth literacy was measured using the Chinese version [29] of the eHealth Literacy Scale for College Students, originally developed by Norman and Skinner [30] to assess an individual's abilities in terms of accessing, understanding, and evaluating health information from electronic media and utilizing this information to solve health problems. The scale has eight items in total; each item was rated on a scale of 1 (disagree) to 5 (agree) (Multimedia Appendix 1). The total score ranged from 8 to 40; the higher the score, the higher the eHealth literacy. The Cronbach α coefficient for the scale in this study was .92.

COVID-19–Related Health Behaviors

We designed a questionnaire for measuring COVID-19–related health behaviors. First, we conducted an extensive literature review and identified 2 categories—government-recommended preventive behaviors and self-adaptive conventional health behaviors—to serve as the questionnaire's dimensions and overall framework. Based on the literature and the Guidelines for Public Protection Against Pneumonia Caused by the Novel Coronavirus Infection [5], we designed 24 items, 12 in each of the two categories. Second, an expert team composed of emergency management experts, public health experts, psychologists, respiratory doctors, and nurses evaluated the 24 items. According to their recommendations, seven items were deleted from the self-adaptive conventional health behaviors category, while three items were added to the preventive behaviors dimension because the experts believed that behaviors to prevent infection were the most important to adopt during the COVID-19 pandemic. Third, the 20 remaining items were sent to a different expert group, consistent with the previous group's composition, for review. According to the group's

XSL•FO
RenderX

opinions, five items were deleted from the preventive behaviors category.

Finally, a 15-item questionnaire was formed (Multimedia Appendix 1). We recruited 85 college students (41 males [48%] and 44 females [52%] with mean age of 20.1 years, SD 1.4) to conduct an online preliminary assessment. A 5-point Likert scale was used to test whether individuals understood each item's description, and they were asked whether they thought the item needed to be modified. The results showed that all respondents understood the descriptions (mean 4.48, SD 0.30), as all respondents indicated that no changes were required.

The questionnaire's 15 items focused on problem solving, such as wearing masks and handwashing; seeking social support, such as contacting relatives and friends online; distraction, denial, or avoidance, such as smoking and drinking; and positive appraisals, such as physical exercise and maintaining a reasonable diet. Participants were asked to indicate their practice of each behavior over the past 2 weeks. Each item used a 5-level scoring method: 1 (none of the time), 2 (a small amount of the time), 3 (sometimes), 4 (most of the time), and 5 (almost all of the time). It should be noted that the scores for smoking and drinking were reversed. Therefore, for this questionnaire, the higher the score, the healthier and more positive a COVID-19–related health behavior was considered.

Covariates

Covariates included sociodemographic characteristics (ie, age, gender, residence, college year, academic major, and self-rated family economic level) and information related to COVID-19 (ie, self-reported health status, family members or friends infected with the coronavirus, and self-reported coronavirus knowledge level) (Multimedia Appendix 1). The self-reported COVID-19 knowledge level was evaluated via five questions, regarding the source of COVID-19 infection, incubation period, main transmission route, susceptible population, and primary clinical manifestations (Multimedia Appendix 1). The questions and answers were based on the COVID-19 Diagnosis and Treatment Protocol (Tentative Version Seven) that was issued by the National Health Commission of China [31]. For these questions, 1 point was assigned to correct answers and no points were assigned to answers that were either incorrect or unknown. The total score ranged from 0 to 5; the higher the score, the higher the coronavirus knowledge level.

Statistical Analysis

Descriptive analysis was used to summarize participants' sociodemographic information and other variables. Categorical variables were described using a frequency and percentage, whereas continuous variables were described by mean and SD. Then, to evaluate the factor structure and structural validity of the COVID-19–related health behavior questionnaire, a principal component exploratory factor analysis (EFA) with a varimax rotation and a confirmatory factor analysis (CFA) were used. It should be noted that we randomly divided the total samples into Sample A (511 men and 426 women), which was used for EFA, and Sample B (458 men and 478 women), which was used for CFA.

The Kaiser-Meyer-Olkin (KMO>0.50) measure of sampling adequacy and the Bartlett test of sphericity (*P* value of the Bartlett test <.05) were used to assess the questionnaire's suitability for factor analysis [32]. Eigenvalues of greater than 1 were used to determine the number of factors, and a factor loading of greater than 0.50 was regarded as the criterion for keeping items.

Then, CFA, using SPSS Amos, version 23.0 (IBM Corp), was conducted to examine the factor structure of the COVID-19–related health behavior questionnaire. The CFA's goodness of fit was evaluated using the following indicators: goodness-of-fit index (GFI >0.90), adjusted GFI (AGFI >0.90), root mean square error of approximation (RMSEA <0.80), comparative fit index (CFI >0.90), Tucker-Lewis index (TLI >0.90), and standardized root mean square residual (SRMR <0.80) [33]. The Cronbach α coefficient was used to evaluate the questionnaire's internal consistency reliability.

The Student *t* test, or one-way analysis of variance (ANOVA), was used to evaluate the statistical differences in the distribution of COVID-19–related health behaviors across different sociodemographic characteristics and health literacy levels. Cohen *d* was used to evaluate effect size. Pearson correlations were used to quantify the bivariate associations between self-reported coronavirus knowledge level, health literacy, eHealth literacy, and COVID-19–related health behaviors. Hierarchical linear regression was used to analyze the relationship between health literacy, eHealth literacy, and COVID-19–related health behaviors. Correlation magnitudes were reported as standardized regression coefficients (β). SPSS, version 23.0 (IBM Corp), was used to perform statistical analyses. All statistical significance levels were set at α=.05, and the statistical tests were two-tailed.

Results

Participant Characteristics

The mean age of the participants was 19.6 years (SD 1.8), ranging from 18 to 25 years. Of the 1873 participants, 1505 (80.4%) had good self-reported health status, while 66 (3.5%) had family members or friends infected with coronavirus. The mean self-reported coronavirus knowledge level score was 4.11 (SD 1.18), and nearly half of the participants (903/1873, 48.2%) correctly answered five COVID-19 knowledge questions. The mean health literacy score was 50.05 (SD 9.55), and 781 out of 1873 participants (41.7%) had adequate health literacy. The mean eHealth literacy score was 30.16 (SD 6.31). For further details, see Table 1.

Internal Consistency and Structural Validity of the COVID-19–Related Health Behavior Questionnaire

First, we used the total sample for a presupposed two-factor structure analysis: 10 items for government-recommended preventive behaviors and five items for self-adaptive conventional health behaviors. However, the two-factor model for a 15-item questionnaire did not satisfactorily fit the data in the total sample (GFI=0.804; AGFI=0.735; RMSEA=0.131; CFI=0.658; TLI=0.597; SRMR=0.127). Therefore, we performed an EFA and a CFA. Table 2 shows the EFA results for each item of the COVID-19–related health behavior questionnaire. The value of the KMO test was 0.85, and the *P* value of Bartlett test was <.001. For each item, the factor loading ranged from 0.50 to 0.75 (all ≥0.50), such that the conditions for conducting EFA were satisfied. The results revealed two

XSL•FO
RenderX

factors with eigenvalues greater than 1, accounting for 45.96% of the total variance. Factor 1 was comprised of eight items; its eigenvalue was 4.40 and it explained 29.34% of the variance. Factor 2 was comprised of seven items; its eigenvalue was 2.49 and it explained 16.62% of the variance.

Next, we performed CFA with Sample B. The results showed that a two-factor model had adequate goodness of fit (GFI=0.948; AGFI=0.919; RMSEA=0.068; CFI=0.924; TLI=0.909; SRMR=0.057). Based on the items that loaded on each factor, we preliminarily named the two factors COVID-19–specific precautionary behaviors, which contained eight items related to prevention, and conventional health behaviors, which contained seven items related to conventional health behaviors. Among the items, the highest score was for *cover your mouth and nose when you cough or sneeze* and the lowest score was for *insist on physical exercise*. For the 15 items in the total sample, the Cronbach α internal reliability coefficient was .79.

Table 2. Exploratory factor analysis and descriptive statistics of the COVID-19–related health behavior questionnaire for college students.

Item	Sample A factor loading (n=937)		Total sample score[a] (N=1873), mean (SD)
	Factor 1	Factor 2	
Maintain hand hygiene	0.75	0.20	3.84 (0.96)
Open windows for ventilation to maintain air circulation	0.70	0.16	3.87 (0.96)
Wear a mask when going out	0.69	0.06	4.10 (0.97)
Reduce instances of going to public places	0.63	0.30	3.70 (0.95)
Cover your mouth and nose when you cough or sneeze	0.61	0.19	4.28 (0.96)
Disinfect daily necessities	0.60	0.36	3.52 (1.03)
Contact relatives and friends online	0.52	0.30	3.50 (0.98)
Communicate or confide with others when you are in trouble	0.51	0.22	3.54 (1.07)
Maintain adequate nutrition and balanced diet	0.23	0.66	2.86 (1.06)
Drink alcohol because of COVID-19	0.26	0.65	4.11 (1.16)
Insist on physical exercise	0.08	0.64	2.72 (1.21)
Smoke because of COVID-19	0.35	0.63	4.18 (1.28)
Follow the latest developments on COVID-19	0.30	0.63	3.07 (1.07)
Take body temperature frequently	0.25	0.53	3.24 (1.11)
Guarantee good sleep	0.34	0.50	3.25 (1.09)

[a]Responses were based on a 5-level scoring method: 1 (none of the time), 2 (a small amount of the time), 3 (sometimes), 4 (most of the time), and 5 (almost all of the time).

The Distribution of COVID-19–Related Health Behaviors Across Different Characteristics

The mean scores of COVID-19–related health behaviors, COVID-19–specific precautionary behaviors, and conventional health behaviors were 53.77 (SD 8.03), 30.36 (SD 5.17), and 23.41 (SD 3.87), respectively. The results of *t* tests and ANOVAs showed that the differences in COVID-19–related health behavior scores and COVID-19–specific precautionary behavior scores among college students with different genders, residences, college years, academic majors, family economic levels, self-reported health statuses, family members or friends infected with coronavirus, and health literacy levels were statistically significant ($P<.05$). In addition, there were also significant differences in conventional health behavior scores among the college students with different residences, college years, family economic levels, self-reported health statuses, family members or friends infected with coronavirus, and health literacy levels ($P<.05$). Further details are displayed in Multimedia Appendix 2.

Associations Between Self-Reported Coronavirus Knowledge Level, Health Literacy, eHealth Literacy, and COVID-19–Related Health Behaviors

Table 3 shows that self-reported coronavirus knowledge levels were positively associated with health literacy ($r=0.162$; $P<.001$), eHealth literacy ($r=0.220$; $P<.001$), and COVID-19–related health behaviors ($r=0.244$; $P<.001$). Additionally, health literacy was positively associated with eHealth literacy ($r=0.270$; $P<.001$) and COVID-19–related health behaviors ($r=0.338$; $P<.001$), while eHealth literacy was positively associated with COVID-19–related health behaviors ($r=0.476$; $P<.001$).

Factors Associated With COVID-19–Related Health Behaviors: Multivariable Analyses

Hierarchical linear regression analysis was conducted with the score of the COVID-19–related health behaviors (COVID-19–specific precautionary behaviors and conventional health behaviors) as the dependent variable, while the independent variables consisted of sociodemographic characteristics, health literacy, and eHealth literacy. In Block 1, the following sociodemographic characteristics were entered first, accounting for 17.4% of the variance in COVID-19–specific precautionary behaviors (R^2=0.174; $F_{13, 1859}$=33.890; P<.001) and 7.4% of the variance in conventional health behaviors (R^2=0.074; $F_{13, 1859}$=13.393; P<.001): gender, residence, college year, academic major, family economic level, self-reported health status, having a family member or friend infected with coronavirus, and self-reported coronavirus knowledge level. The score for health literacy was entered into Block 2 and contributed to explaining an additional 4.2% of the variance in COVID-19–specific precautionary behaviors (R^2=0.216; $F_{14, 1858}$=40.692; P<.001) and an additional 6.4% of the variance in conventional health behaviors (R^2=0.138; $F_{14, 1858}$=24.045; P<.001). Finally, the score for eHealth literacy was entered into Block 3 and contributed to explaining an additional 11.5% of the variance in COVID-19–specific precautionary behaviors (R^2=0.332; $F_{15, 1857}$=67.449; P<.001) and an additional 6.5% of the variance in conventional health behaviors (R^2=0.203; $F_{14, 1858}$=35.083; P<.001). The linear regression results are presented in Multimedia Appendix 3.

Multimedia Appendix 3 illustrates that the listed sociodemographic characteristics, other than residence and academic major, were related to COVID-19–related health behaviors. Overall, participants were more likely to have superior COVID-19–specific precautionary behavior scores if they were female versus male (β=.153; P<.001), freshmen versus seniors (β=.094; P<.001), juniors versus seniors (β=–.061; P=.02), from a family with a medium versus low economic level (β=.122; P<.001), had a self-reported health status that was good versus bad (β=.205; P=.001), had a family member or friend infected with coronavirus versus not infected (β=.095; P<.001), and had a higher self-reported coronavirus knowledge level (β=.156; P<.001). Conventional health behaviors were more likely to be performed by individuals who were sophomores versus seniors (β=.074; P<.001), from a family with a high or medium economic level (high vs low: β=.082, P=.03; medium vs low: β=.077, P=.03), had good or medium self-reported health status (good vs bad: β=.273, P<.001; medium vs bad: β=.171, P=.008).

After adjusting for covariates, both health literacy and eHealth literacy were positively associated with COVID-19–specific

XSL•FO
RenderX

precautionary behaviors ($\beta_{\text{health literacy}}$=.149, $\beta_{\text{eHealth literacy}}$=.368; *P*<.001) and conventional health behaviors ($\beta_{\text{health literacy}}$=.219, $\beta_{\text{eHealth literacy}}$=.277; *P*<.001). Among the related factors, eHealth literacy was most strongly associated with COVID-19–related health behaviors.

Discussion

Principal Findings

Based on the China CDC's guidelines and expert advice, we developed and verified a COVID-19–related health behavior questionnaire among college students. The questionnaire was found to be valid and reliable for assessing health behaviors during the pandemic. This study also examined whether health literacy and eHealth literacy were associated with the COVID-19–related health behaviors of college students. To the best of our knowledge, this is one of few studies to consider the relationship between these factors for this population group. The study results showed that health and eHealth literacy were positively related to COVID-19–related health behaviors among college students.

The factor analysis showed that the COVID-19–related health behavior questionnaire had a two-factor structure, which is consistent with the two-factor structure we had previously assumed. That is, the eight items for Factor 1 primarily reflected individual protective measures, such as wearing a mask, maintaining hand hygiene, and reducing the amount of time that one leaves the house. Therefore, Factor 1 was named *COVID-19–specific precautionary behaviors*. Furthermore, the seven items for Factor 2 reflected individuals' conventional health behaviors, such as physical exercise and diet during the COVID-19 pandemic; therefore, it was named *conventional health behaviors*. In addition, the results showed that the internal consistency reliability of the questionnaire was adequate. Based on these two relatively simple psychometric indicators, the COVID-19–related health behavior questionnaire appears to have satisfactory internal consistency reliability and construct validity in this context, so that it could be used among Chinese college students. This questionnaire may be useful for government officials and school health educators to assess the COVID-19–related health behaviors of college students in order to carry out targeted interventions.

The results of the descriptive analysis showed that college students' COVID-19–specific precautionary behaviors were high, and the scores of eight items were all higher than 3.5, among which the score of *cover your mouth and nose when you cough or sneeze* was the highest. A European study of adolescents obtained similar results, namely that adolescents seemed to be generally aware of the recommendations regarding protective behaviors during the COVID-19 crisis [17]. In contrast, this study found that college students' conventional health behaviors were poor, especially in terms of their scores for physical exercise and maintaining both adequate nutrition and a balanced diet, which were lower than the median (3 points). Zhao et al also found that after the COVID-19 outbreak, only a small number of Chinese people participated in physical exercise, and most consumed vegetables and fruits even less frequently than usual each week [34]. This may be related to affective disorders, such as anxiety and depression during the COVID-19 pandemic. A cross-sectional study suggested that less physical exercise was found to negatively impact anxiety and depressive symptoms in college students during the COVID-19 pandemic [35]. However, in turn, anxiety and depression can cause a lack of motivation to exercise and eat healthily. Thus, this study indirectly reflects the changes that the COVID-19 pandemic caused in people's lifestyles and behaviors. Additionally, previous studies showed that unhealthy behaviors were related to COVID-19 mortality rates and hospital admissions, and although they provided some specific lifestyle recommendations [36,37], few studies have analyzed intervenable factors related to COVID-19–related health behaviors during the pandemic.

In this study, after adjusting for sociodemographic characteristics, health and eHealth literacy were shown to be significantly related to COVID-19–related health behaviors, which supports the findings of previous research on the relationship between health literacy and COVID-19–related attitudes and behaviors [38]. For example, a study in Hong Kong demonstrated that health literacy significantly and positively correlated with hand hygiene habits in older persons [39], consistent with a study of adolescents [17], indicating that health literacy is closely related to COVID-19 health protection behaviors. In addition, health literacy's positive relationship with physical exercise, diet, and sleep has been confirmed by numerous studies [40-42]; likewise, this study confirmed this relationship. This indicates that, even during the COVID-19 pandemic, health literacy remains related to healthy behaviors. Nevertheless, these results cannot explain the causal relationship between health literacy and COVID-19–related health behaviors. However, based on previous research experience [43], individuals with a high level of health literacy are more likely to adopt positive behaviors in their response to the COVID-19 pandemic. Additionally, although it was obviously difficult to improve the health literacy of individuals on such a short-term basis, significantly curbing the disease's spread will involve finding new intervention strategies and incorporating the abundance of information related to COVID-19 on the internet.

This study showed that eHealth literacy was also positively correlated with college students' COVID-19–related health behaviors. Similarly, a previous study illustrated that people who had obtained more health information online related to COVID-19 were more frequently involved in various types of preventive behaviors [44]. Researchers have attributed this association to risk perception; COVID-19 pandemic information on the internet exacerbates concerns and may prompt users to adopt protective behaviors [45]. Further, a related study of college students reported that their eHealth literacy is associated with regular exercise, healthy eating, and routine sleep [46]. Moreover, a study found that eHealth literacy is related to disease prevention behaviors, such as finding vaccination information [47]. These results indirectly support the association between eHealth literacy and COVID-19–related health behaviors. Furthermore, a recent study showed that eHealth literacy is related to preventive behaviors in relation to the COVID-19 pandemic [21], consistent with findings in this study.

XSL•FO
RenderX

However, the previous study had notably few people under the age of 20 years, so that this study, which included a substantial number of subjects under this age, further expanded upon their findings.

This study also found that a higher level of eHealth literacy was associated with superior conventional health behaviors, indicating that college students with a higher level of eHealth literacy in China could maintain healthy lifestyles during the COVID-19 pandemic. While previous studies have paid more attention to health protection behaviors, few have examined other behaviors during the COVID-19 pandemic, such as exercise, diet, sleep, smoking, and consuming alcohol. For example, while the significance of COVID-19–specific precautionary behaviors focuses on reducing the possibility of an individual becoming infected with the coronavirus, conventional health behaviors provide for greater reflection in an individual's daily life during this period of isolation from family due to COVID-19 prevention and control measures. Conventional health behaviors emphasize the ability to adapt to life events, which is particularly important when promoting physical and mental health, such as maintaining resilience, reducing and avoiding the occurrence of other diseases, and relieving both mental pressures and stress. Therefore, this study suggests that improving health and eHealth literacy may help college students adopt healthy lifestyles and adapt to the isolation that has been caused by the COVID-19 pandemic.

Compared to health literacy, eHealth literacy was a stronger predictor of COVID-19–related health behaviors, which may be due to COVID-19 being a sudden infectious disease. That is, the nature of this disease causes people to lack sufficient understanding about it, which leads to a lack of knowledge about how to take preventive measures. Since the Chinese government implemented family isolation measures during the COVID-19 crisis, they published knowledge and guidelines on the internet about various COVID-19 prevention and control measures. A previous study showed that individuals with higher levels of eHealth literacy more often search for health information on the internet [48], which means that college students with a high level of eHealth literacy may acquire more COVID-19 information online, enabling them to adopt health behaviors. Considering that health literacy is the result of personal, long-term learning and behavioral practice [49], it is difficult to change this feature in a short-term period. Therefore, this study suggests that it is particularly important to pay more attention to improving individual eHealth literacy.

This study's results have important value in terms of public health, especially concerning the prevention and control of COVID-19 in universities. Many universities around the world have resumed studies on campus, causing numerous students to gather on small campuses, which places greater pressure on the need for COVID-19 prevention and control. For instance, once an asymptomatic patient who is infected with the coronavirus appears at school, they could transmit the infection to other students, especially persons not practicing health protection measures. Since college students are the primary users of electronic media and the internet in general, the feasibility and practical effects of related prevention and control interventions through eHealth literacy are potentially significant.

Regarding limitations, snowball sampling is nonprobability sampling that is generally used when it is difficult to identify the members of the population. Since the Chinese government adopted the family segregation policy when we conducted the survey and schools did not open, it was difficult for us to use probability sampling when conducting the survey. Snowball sampling has the possibility of sampling and selection bias, which limits the extrapolation of our research. Second, a cross-sectional survey cannot explain the causal relationships among health literacy, eHealth literacy, and COVID-19–related health behaviors. Third, in the survey, we did not use a standardized questionnaire to assess participants' knowledge of COVID-19, which may not adequately reflect knowledge of COVID-19. Recent research developed a health literacy scale related to the coronavirus [50]; future research could utilize this scale to obtain more in-depth understanding. Finally, the COVID-19–related health behavior questionnaire was compiled according to China's cultural background as well as the state's COVID-19 prevention and control guidelines. Thus, it may not be applicable to other countries, which limits the inferences one may make from these results.

Conclusions

The COVID-19–related health behavior questionnaire was a valid and reliable measure for assessing health behaviors during the pandemic. The results of this study suggest that college students with higher health literacy and eHealth literacy can more actively adopt COVID-19–related health behaviors. Additionally, compared to health literacy, eHealth literacy is more closely related to COVID-19–related health behaviors. These findings are significant for COVID-19 prevention and control in the college environment, including for relevant health education activities or other intervention measures based on health and eHealth literacy that can be carried out in a timely manner to enhance COVID-19–related health behaviors and reduce the risk of infection among college students.

Acknowledgments

We would like to thank all participants who participated in this study.

Authors' Contributions

SL and GC designed the study, conducted surveys and data analysis, and wrote the first draft of the manuscript. ACK and SC revised all versions of the manuscript. HX made a number of constructive suggestions and revised the final draft of the manuscript. All authors have read and agreed to the final draft of the manuscript.

Abstract

Background: Acceptance rates of COVID-19 vaccines have still not reached the required threshold to achieve herd immunity. Understanding why some people are willing to be vaccinated and others are not is a critical step to develop efficient implementation strategies to promote COVID-19 vaccines.

Objective: We conducted a theory-based content analysis based on the capability, opportunity, motivation–behavior (COM-B) model to characterize the factors influencing behavioral intentions toward COVID-19 vaccines mentioned on the Twitter platform.

Methods: We collected tweets posted in English from November 1-22, 2020, using a combination of relevant keywords and hashtags. After excluding retweets, we randomly selected 5000 tweets for manual coding and content analysis. We performed a content analysis informed by the adapted COM-B model.

Results: Of the 5000 COVID-19 vaccine–related tweets that were coded, 4796 (95.9%) were posted by unique users. A total of 97 tweets carried positive behavioral intent, while 182 tweets contained negative behavioral intent. Of these, 28 tweets were mapped to capability factors, 155 tweets were related to motivation, 23 tweets were related to opportunities, and 74 tweets did not contain any useful information about the reasons for their behavioral intentions (κ=0.73). Some tweets mentioned two or more constructs at the same time. Tweets that were mapped to capability (P<.001), motivation (P<.001), and opportunity (P=.03) factors were more likely to indicate negative behavioral intentions.

Conclusions: Most behavioral intentions regarding COVID-19 vaccines were related to the motivation construct. The themes identified in this study could be used to inform theory-based and evidence-based interventions to improve acceptance of COVID-19 vaccines.

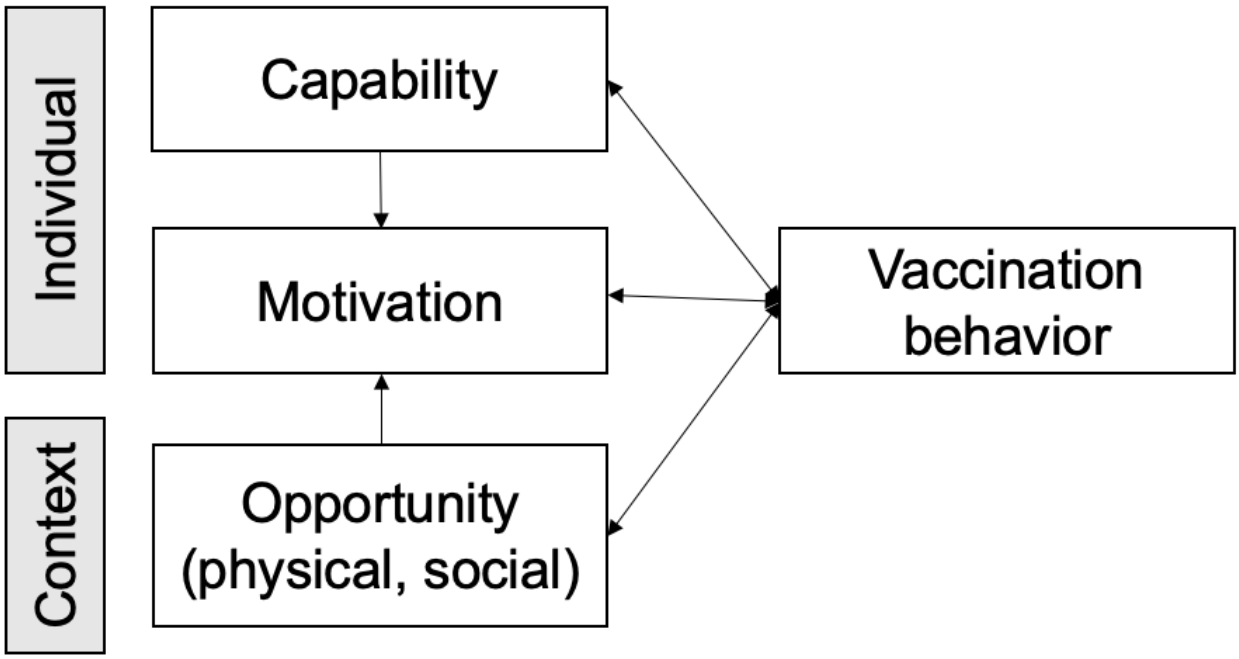
Introduction

The global COVID-19 pandemic is affecting 219 countries worldwide [1]. An important component of managing COVID-19 is preventing the infection [2,3]. Fortunately, development of vaccines against the disease is progressing well. In December 2020, the US Food and Drug Administration authorized COVID-19 vaccines for emergency use. Another currently pressing issue is how to increase vaccine acceptance rates [4]. In previously published survey studies, the acceptance rate of COVID-19 vaccines was a concern. Of 672 participants in the United States, approximately 67% said they would be willing to receive a vaccine [5]. It is necessary to vaccinate an estimated 55%-82% of the population to create herd immunity

XSL•FO
RenderX

and slow the spread of a pandemic [6]. Therefore, it is critical to understand why some people are willing to be vaccinated and others are not.



Previous studies have described potential impediments to COVID-19 vaccines, including questioning the need for vaccines and preferring to benefit from the immunity conferred by surviving COVID-19 [7]; safety issues regarding the rapid development and testing process of vaccines [7]; issues related to mandatory vaccination [7]; and conspiracy beliefs [8]. Some researchers conducted surveys based on theoretical models to explore facilitators and barriers to COVID-19 vaccination. Williams et al [9] conducted a survey to examine factors that influenced respondents' decisions to be vaccinated against COVID-19 and identified three facilitators (personal health, severity of COVID-19 disease, health consequences to others) and one barrier (concerns regarding vaccine safety). Lin et al [10] used the health belief model (HBM) to identify two facilitators (reduced likelihood of contracting COVID-10; others getting vaccinated) and one barrier (concerns about efficacy and side effects). Wong et al [11] also used the HBM to identify one facilitator of perceived benefits (the belief that the vaccination can reduce infection probability and alleviate concerns about COVID-19).

Compared with surveys, Twitter can gather timely information regarding behavioral intentions toward COVID-19 vaccines, especially to understand "anti-vaxxers" and those influenced by misinformation who are inclined not to get the vaccine. These types of users could be the most vulnerable population for COVID-19 vaccine outreach interventions. On the Twitter platform, there are more than 330 million users, and the median number of posts per person each month is 2 [12,13]. A recent survey of US Twitter users showed that they are younger and have a higher education level than the general population; however, their gender, race, and ethnicity distributions are similar to those of the general population [13]. The Twitter platform has been validated as a way to develop a public perception–tracking tool based on real-time content [14]. In addition, Twitter has been flooded with information about COVID-19, influenced by social isolation policies enacted during the epidemic [15]. The Twitter platform could be used to explore determinants of health-related behavior intentions [16]. Because the maximum length of each tweet is 280 characters, in addition to mentioning potential behavioral intentions, users can also briefly describe the reasons that led to their decision. In addition, using geotagged Twitter data, it is easier and faster to identify people's perceptions in different geographic locations. Therefore, we chose to use the Twitter platform to analyze behavioral intentions toward COVID-19 vaccines.

To better characterize the factors that influence behavioral intentions on the COVID-19 vaccines mentioned in the tweets, we conducted a theory-based content analysis based on the capability, opportunity, motivation–behavior (COM-B) model. The COM-B model was proposed by Michie et al [17] in 2011, and it contains three basic constructs: capability (physical and psychological), motivation (automatic and reflective), and opportunity (social and physical). The COM-B model is a comprehensive theoretical model based on causal mechanisms to identify individual and context factors that influence behavioral change. It was developed by merging 19 behavior change frameworks through a systematic literature review and discussions with behavior change experts. It has been successfully applied to many health-related behaviors, such as smoking cessation [18-20] and obesity reduction [21,22]. In contrast to other health behavior theories (eg, HBM, theory of planned behavior), the COM-B model was developed based on the behavior change wheel, which not only provides a theoretical analysis of behavior but, more importantly, provides results that can be used to assist with intervention design [17,23]. In addition, the World Health Organization (WHO) Regional Office for Europe has adapted it to vaccination behaviors to design its Tailoring Immunization Programmes (TIP) approach [24,25]. They merged subconstructs in capability and motivation, respectively. Because of vaccination behavior, the physical capability is interlinked with the psychological capability. Likewise, automatic motivation (ie, emotions, impulses) interacts with reflective motivation (ie, intentions, beliefs). Another advantage of the adapted COM-B model is that it focuses on vaccination behavior and provides refined details for each construct in the vaccine context. Therefore, we used an adapted COM-B model (see Figure 1) as the theoretical model of this study. The objectives of this study are to (1) determine if the adapted COM-B model can explain behavioral intentions toward COVID-19 vaccines using tweets; (2) examine theory-informed factors that may affect behavioral intentions toward COVID-19 vaccines; and (3) extract themes to provide information for public health researchers to develop theory-based and evidence-based promotion interventions.

Figure 1. The theoretical model based on the capability, opportunity, motivation—behavior (COM-B) model adapted to vaccination behavior, developed by the World Health Organization Regional Office for Europe [24,25].

Methods

Adapted COM-B Model

The adapted COM-B model has three theoretical constructs: (1) capability, (2) motivation, and (3) opportunity. The WHO Regional Office for Europe also provided examples for each construct (see Table 1). Capability refers to the individual's physical and psychological ability to perform the behavior, along with the knowledge and skills required to complete the activity [17]. In particular, psychological ability is the ability of an individual to have the necessary thought processes, such as being able to understand, reason, etc [17]. Motivation has a broad definition that includes goals and conscious decision-making as well as all other individual processes that motivate and lead to behavior, such as automatic processes (habitual processes, emotional responses) and reflective processes (analytical decision-making) [17]. Opportunity refers to the contextual factors that prompt the behavior to occur, including the physical opportunity and the environment and social opportunity [17]. The adapted COM-B model also provides a dynamic relationship between constructs. For example, both capability and opportunity can affect motivation. All three constructs of competence, motivation, and opportunity can generate behavior; on the other hand, behavior can influence these three constructs.

Table 1. The theoretical constructs in the adapted capability, opportunity, motivation–behavior (COM-B) model and associated examples by the World Health Organization Regional Office for Europe.

Theoretical construct	Examples
Capability	• Knowledge • Skills, trust in own skills • Resilience, stamina, will power, surplus energy • Physical fitness, ability
Motivation	• Attitudes, perceptions, risk assessment • Values, beliefs • Emotions, impulses, feelings • Confidence, trust
Opportunity (physical)	• Access, affordability, availability of vaccination • Convenience, appeal, appropriateness of vaccination • Structural efficiency • Availability of information
Opportunity (social)	• Social, cultural demands, support • Social, cultural cues, norms, values

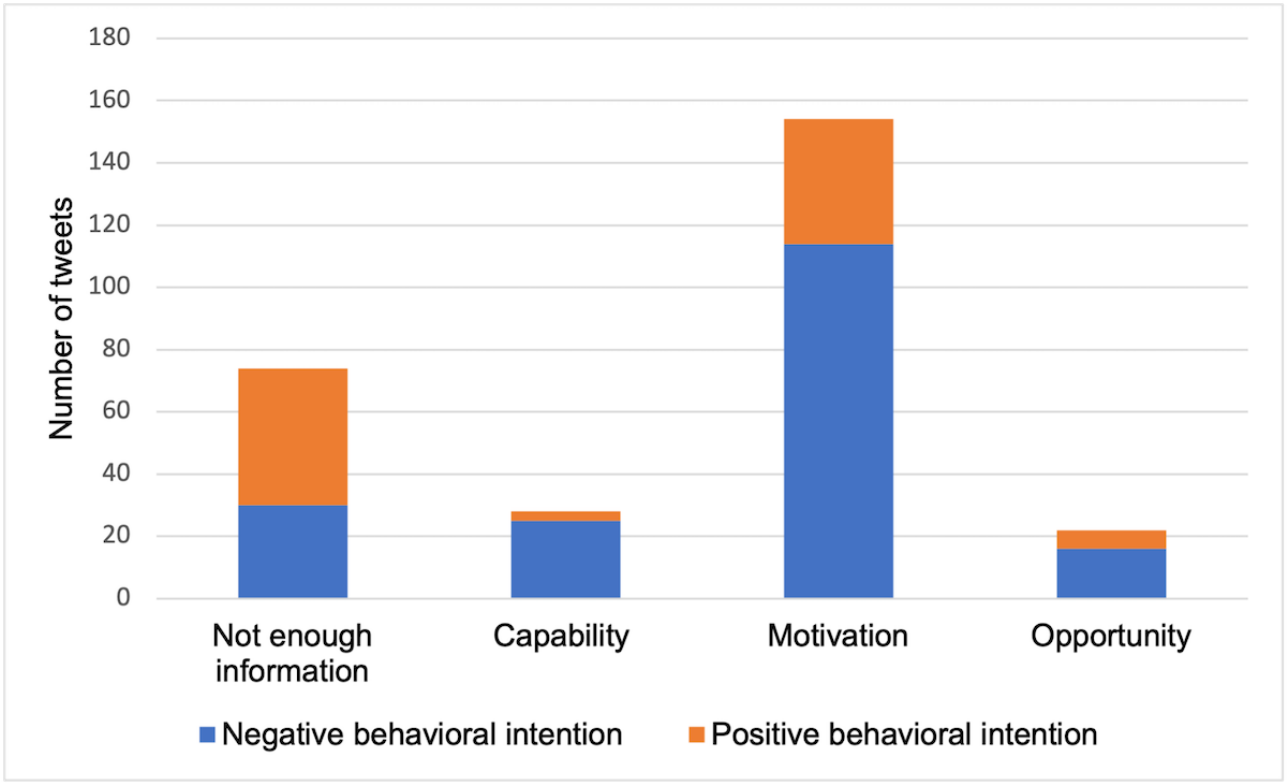
Data Collection

We collected English tweets posted from November 1-22, 2020, using a combination of relevant keywords and hashtags: (#covid OR covid OR #covid19 OR covid19) AND (#vaccine OR vaccine OR #vacine OR vacine OR vaccinate OR immunization OR immune OR vax). After excluding retweets, we randomly selected 5000 tweets for manual coding and content analysis. The random numbers were generated through the NumPy package in Python. Then, we mapped the random numbers with the index of collected tweets.

Content Analysis



We performed a content analysis informed by the adapted COM-B model. The coding schema was developed iteratively. First, we developed the coding schema based on the definitions of constructs in the adapted COM-B model. Two reviewers (SL and JL) independently coded 1000 tweets in each round. After completing one round of coding, the two reviewers met with a third reviewer to discuss disagreements and update the coding schema until consensus was reached. We calculated the interrater reliability for the last round. If a tweet mentioned ≥2 constructs simultaneously, we coded it with multiple labels. We conducted chi-square tests to explore the relationship between theoretical constructs with the positive/negative behavioral intention. The statistical significance threshold was .05.

Results

Data Collection

We coded 5000 COVID-19 vaccine–related tweets, which were posted by 4796 unique users. We found 279 tweets that stated their behavioral intentions. The remaining tweets did not state any behavioral intentions toward COVID-19 vaccines. A total of 97 tweets were labeled with positive behavioral intentions, while 182 tweets contained negative behavioral intentions. Among them, 28 tweets were mapped with capability factors; 155 tweets were related to motivation; 23 tweets were related to opportunities; and 74 tweets did not contain any useful information about reasons for their behavioral intentions (see Figure 2). The κ value was 0.73. Of the tweets, 2 mentioned ≥2 constructs at the same time. Tweets that mentioned capability (χ^2_1=17.286, P<.001), motivation (χ^2_1=35.558, P<.001), and opportunity (χ^2_1=4.545, P=.03) were more likely to have negative behavioral intentions (Table 2).

Figure 2. Numbers of tweets containing different theoretical constructs.

Table 2. Themes and example tweets (n=204).

Theme	Value, n (%)	Example tweets
Capability (n=28)		
Knowledge	24 (11.8)	• "I am not getting a covid vaccine because there will be a microchip in there so the government can track my weekly shop in Lidls" • "No way I'm taking it. In one study out of women became steril [sic] from taking the vaccine. Is this the one that alters your DNA and can cause cancer? Thanks but I would rather get COVID." • "As I said it's not a 'from scratch' situation...covid is one version of a virus that a lot of work has already been done on. It's just a case of isolating the correct strain to vaccinate against. Look if you don't want to get it fine...all the more for me and my family."
Physical condition	4 (2)	• "I got my flu shot a few days ago. For now there is no way I will get a COVID vaccine." • "I have severe adverse reactions to vaccines and I meet of the exclusion criteria for the COVID vaccine trials."
Opportunity (n=22)		
Rights, regulation and legislation (eg, charging for vaccination, mandatory vaccination, inadequate regulation of vaccines, poor availability of information)	11 (5.4)	• "Tbh[a] I'm not against every vaccine in history. Just this specific COVID-19 vaccine. There are many reasons why, for example the nonsensical social regulations, that people like you probably want to be over so bad. But you seem to hot headed to absorb any legit information." • "If they charge us for this vaccine. I don't give. Not a single person should have to pay for a Covid Vaccine." • "Please stop volunteering me for this COVID-19 vaccine. I need more information. I've been close enough to death this year, no thank you. -a healthcare worker."
Social and cultural demands and support	9 (4.4)	• "Someone that works for the CDC[b] told me, do NOT get the covid vaccine.. Not sure but I'm not OK with her saying that at all." • "I'm not getting a covid vaccine. Do what yall want with that info to write me off. But its against my culture and everything I've been practicing."
Social consequences and reactions to vaccination	2 (1)	• "when anti vaccs realize everything is gonna start requiring the covid vaccine i can't wait to see. and for natural selection to do what it does best (unless you're immunocompromised and can't take certain vaccines, then they'll accept testing of course)"
Motivation (n=154)		
Attitudes and perceptions about the COVID-19 vaccine or the disease itself (eg, disease severity, vaccine effectiveness)	68 (33.3)	• "Yeah, with an average age of over you forgot to mention, a minute percentage of those that have had it and almost elderly and/or with underlying health conditions. For many of us, taking the rushed vaccine may more likely to cause us harm than covid itself" • "OK. so we each make our own risk/benefit decision. As the virus is what, % fatality, why would someone choose an unproven mRNA vaccine, with phase trials only since July? a biotech never before used programming RNA transcriptase to produce Covid in your cells? No thx."
Strong emotions about COVID-19 vaccine (eg, fear of side effects, unfairness to COVID-19 survivors)	5 (2.4)	• "We shouldn't have a COVID vaccine because it'll make those who lost loved ones to COVID angry."
Values and beliefs (eg, natural immune system, alternative medicine, value of vaccination)	37 (18)	• "My immune system is better than any vaccine. And a vaccine works in tandem with the way how your immune system beats virus No COVID Vax for me!" • "I had covid19 because I'm a long haul trucker and travel all over to different states..what I did to cure myself was take % alcohol and pour it on a rag and breathing in the fumes before I went to bed..I did that minutes a night..I got well in no time.. don't need no vaccine"

Theme	Value, n (%)	Example tweets
Confidence and trust (vaccine, health authorities, science, and government)	13 (6.3)	• "I do not trust the FDA[c], especially concerning the brand new Covid vaccine being rushed to market. Covid poses almost zero risk to my demographic. The pharmaceutical companies face zero risk if the vaccine damages their customers. For me the vaccine is riskier than the virus." • "I won't accept COVID vaccine offered by Biden administration..."

[a]Tbh: to be honest.

[b]CDC: US Centers for Disease Control and Prevention.

[c]FDA: US Food and Drug Administration.

Capability

The first theme regarding capability was that some users lacked knowledge about the COVID-19 vaccines and were influenced by misinformation. mRNA vaccines are a new technology, and some believe that these vaccines can alter DNA. As for the vaccine itself, some users believe that it contains a microchip that can be tracked by the government. Some people expressed that they did not know the side effects of COVID-19 vaccines or even their long-term effects. Based on this concern, misinformation was generated that the vaccine could cause sterility, cancer, etc. Other reasons for not getting the vaccine included the belief that the vaccine could make people sick, the belief that there is no need for people who have been infected with COVID-19 to get the vaccine, and that the vaccine does not prevent infection but only alleviates symptoms. All these beliefs reflect a lack of understanding of the COVID-19 vaccines among users. Having more knowledge about vaccines could help people develop positive behavioral intentions; for example, some people mentioned that they could understand why the development process was fast because researchers only needed to isolate the correct strain rather than create one. Others mentioned understanding that vaccines do not contain live viruses, so they would be willing to get the vaccine.

Some users emphasized that their physical condition was not suitable for COVID-19 vaccination and that they were unsure how their body would react after vaccination (eg, recently had an influenza vaccine shot, had a suppressed immune system, had a severe adverse reaction to vaccination in the past, had a stroke).

Opportunity

In the physical opportunities category, some users said they would not accept the vaccine if they had to pay for it. Many users said vaccination should be a free choice and that they would refuse to receive the vaccine if it became mandatory. Some users wanted more regulation of the COVID-19 vaccine, and some were concerned about the availability of information.

Among the social opportunities, we found some factors influencing the COVID-19 vaccination related to social and cultural demands and support, such as going against religion, defying culture, health workers not recommending vaccination, and family members actively discouraging vaccination. Others intended to be vaccinated because of the fear of the social consequences and reactions to vaccination, such as fear of affecting their work and requiring proof of vaccination for many activities in the future.

Motivation

Most of the reasons for behavioral intentions were categorized into the motivation construct. Many users expressed attitudes and opinions about the COVID-19 vaccine or the disease itself, such as not considering the disease to be severe or life-threatening and not considering the vaccine to be effective (because of low efficiency and mutation of the virus). Others assessed the risks and considered the rushed vaccine to be more harmful than COVID-19. Some of those with positive behavioral intentions stated that they chose vaccination because they did not want to be infected with COVID-19.

Some users expressed strong emotions and feelings about COVID-19 vaccines, such as fear of the vaccine and concern about its side effects because it is new. Notably, others felt that vaccination was selfish or unfair, as they would not be exposing themselves to the same risk as others who survived COVID-19; thus, they were reluctant to be vaccinated.

Other themes were values and beliefs. Some users expressed a belief that the body's natural immune system is better than any vaccine, or they believed more in alternative medicine. On the other hand, others who wanted to be vaccinated emphasized the positive values of vaccination, such as saving more lives, reopening the economy, and returning to normal life.

Confidence and trust were dominant themes. Users expressed distrust in many areas: the quality of the vaccines (hastily manufactured, untested), health authorities, science, companies, and government. For Twitter users in the United States, we found that unlike with other vaccines, part of the reason people do not trust the government is because of their past handling of the COVID-19 pandemic. In addition, the COVID-19 vaccine rollout came during a time when a new president was being elected in the United States, and some people lacked confidence in the newly elected president's party.

Discussion

Principal Findings

In this study, we conducted a theory-based content analysis using a dataset of 5000 tweets posted from November 1-22, 2020. We identified 279 tweets that contained behavioral intentions regarding COVID-19 vaccines and mapped them to constructs in the adapted COM-B model. We generated nine themes that influence Twitter users' intentions to receive COVID-19 vaccines. The constructs in the COM-B model could be applied systematically to characterize factors that influence behavioral intentions toward COVID-19 vaccines. In addition,

XSL•FO
RenderX

we found that among tweets that simply stated behavioral intentions without including any reason, the number of positive intention tweets was higher than that of negative intention tweets. The results also implied that more than half of the tweets expressing the decision-making process were negative intention tweets. This finding aligns with our expectation of understanding the factors that contribute to vaccine hesitancy to better develop tailored vaccine promotion programs.

The novelty of COVID-19 vaccines and the current social context have created further difficulties in vaccine rollout. Identified barriers of influenza vaccination intention and behavior include lack of confidence (eg, negative attitudes, mistrust), inconvenience (eg, cost, access), calculation (eg, risk assessment), and complacency (eg, underestimating disease severity) [26]. Our results revealed the presence of several other factors that influence behavior toward COVID-19 vaccination. First, misinformation or conspiracy theories about COVID-19 and COVID-19 vaccines are much more prevalent on social media than those about other diseases or their related vaccines [27-29]. Some users were influenced by this misinformation, and this led to refusal of the vaccine. Second, Twitter users expressed concerns about mandatory vaccination. At the Emergency Use Authorization stage, mandatory vaccination is legally and ethically questionable [30]. However, with full Biologics License Application approval, policy makers may mandate vaccination for all populations. Given the existence of users who have strongly indicated that they would not accept mandatory vaccination against COVID-19, policy makers must be cautious in determining vaccination policies for the public. Some studies have suggested that vaccine mandates do not improve vaccine acceptance rates, and a proposed alternative approach is to apply informed risk communication and give people the freedom to choose without compromising personal autonomy [30]. Third, users with positive behavioral intentions emphasized that the positive value of vaccination to society, such as restoring economic and normal life from before the epidemic, motivated them to be vaccinated. This facilitator is uncommon in other vaccination behaviors. This facilitator could be matched with a strategy of converting personal decisions into public acts [31]. Fourth, we observed that some users were reluctant to be vaccinated because they felt that the COVID-19 vaccine was unfair to those who survived. Based on this concern, it may be helpful to select COVID-19 survivors as opinion leaders to promote COVID-19 vaccines, increasing public awareness of the severity and risk of the disease. Fifth, in addition to the mistrust of vaccines and science that also exists for other vaccines, for the COVID-19 vaccine, users in the United States expressed more mistrust of the government for two specific reasons: (1) the previous administration's inappropriate behavior in handling COVID-19 and (2) the lack of confidence in the newly inaugurated president's political party. These findings were also aligned with previous studies that proposed a role of politics in COVID-19 vaccine hesitancy [8]. Sixth, it is worth noting that even though previous studies have identified that past vaccination behavior can be used to predict future vaccination behavior [32], we found that past experiences with other vaccines may not affect COVID-19 vaccination. For example, one user mentioned:

> *I'm not against every vaccine in history. Just this specific COVID-19 vaccine. There are many reasons why, for example the nonsensical social regulations.*

The above differences contribute to the fact that the rollout of COVID-19 vaccines could be more complicated than that of other vaccines. Researchers need to develop interventions specific to the COVID-19 vaccine to improve acceptance rates. This also provides an opportunity for future studies to comprehensively analyze why behavioral intentions toward COVID-19 vaccines are different from those toward other vaccines.

In several studies, Twitter content analyses have been conducted of health care behaviors other than COVID-19 vaccination. For example, Chew and Eysenbach [14] collected 2009 H1N1-related tweets and identified the resource content posted most often, followed by personal experience, personal opinion, jokes, marketing, and spam. Li et al [33] extracted COVID-19 stigma–related tweets and found that group labeling, responsibility, and peril tweets disseminated the stigma. Furthermore, several studies have validated the usability of tweets through theory-based content analysis to promote breast cancer promotion programs [16,34]. Our study is the first study to analyze the behavior intention of COVID-19 vaccines through a theory-based content analysis using social media content.

Limitations

This study has several limitations. First, we only analyzed the behavioral intentions of users on Twitter. Previous studies have shown that health care providers are the primary advocates for vaccination and largely influence vaccination acceptance rates [35-38]. In this platform, we could not distinguish users' occupations. However, the themes reported in this study could help researchers to develop evidence-based interventions for the general public. To examine the vaccine behavior of health care providers, we will conduct a questionnaire-based survey, and the results from that study could aid the development of clinical guidelines for health workers. This approach of considering the general public separately from health care providers is also recommended by the TIP approach developed by the WHO Regional Office for Europe [24]. Second, there are differences between behavioral intentions and actual vaccine behaviors. However, behavioral intentions have been shown to directly influence actual behaviors [39-41]. Third, Twitter users are considered to be younger and have a higher level of education than the general public [13]. Based on this concern, further qualitative research could be conducted on the older population, those with lower education levels, or those with limited access to the internet.

In future research, a literature review could be conducted to summarize current implementation strategies for COVID-19 vaccine promotion and map them to the themes identified in this study to determine gaps in recent research. The inner mechanism of the adapted COM-B model—the behavior change wheel—could inform evidence-based and theoretical implementation strategies to improve the effectiveness of COVID-19 vaccine promotion programs.

XSL•FO
RenderX

Conclusion

The study demonstrates the capability of applying the COM-B model to characterize behavioral intentions toward COVID-19 vaccines on the Twitter platform. We successfully generated nine themes of factors that affect behavioral intentions. Positive behavioral intentions were affected by the positive values of vaccination (eg, reduced risk of infection, socioeconomic recovery, return to normal life). In contrast, negative behavioral intentions were associated with attitudes and perceptions about COVID-19 vaccines or the disease itself (eg, underestimation of disease severity, low vaccine effectiveness), values and beliefs (eg, greater belief in the natural immune system), confidence and trust (eg, distrust of government or vaccines), and lack of knowledge. The generated themes could be used to create theory-based and evidence-based implementation strategies to promote COVID-19 vaccines.

Authors' Contributions

JL and SL conceived the study. SL and JL performed the analysis, interpreted the results and drafted the manuscript. All authors revised the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Millions of individuals with visual impairment use vision assistance apps to help with their daily activities. The most widely used vision assistance apps are magnifier apps. It is still largely unknown what the apps are used for. Lack of insight into the visual needs of individuals with visual impairment is a hurdle for the development of more effective assistive technologies.

Objective: This study aimed to investigate how needs for visual aids may vary with social activities, by observing the changes in the usage of a smartphone magnifier app when many users take breaks from work.

Methods: The number of launches of the SuperVision Magnifier app was determined retrospectively from 2018 to 2020 from among active users worldwide. The fluctuation in app usage was examined by comparing weekday vs weekend periods, Christmas and new year vs nonholiday seasons, and COVID-19 lockdowns vs the easing of restriction during the pandemic.

Results: On average, the app was used 262,466 times by 38,237 users each month in 2020 worldwide. There were two major trough points on the timeline of weekly app usage, one aligned with the COVID-19 lockdowns in April 2020 and another aligned with the Christmas and new year week in 2018 and 2019. The app launches declined by 6947 (11% decline; $P<.001$) during the lockdown and by 5212 (9% decline; $P=.001$) during the holiday weeks. There was no significant decline during March to May 2019. App usage compensated for seasonal changes was 8.6% less during weekends than during weekdays ($P<.001$).

Conclusions: The need for vision assistance technology was slightly lower during breaks and lockdowns, probably because the activities at home were different and less visually demanding. Nevertheless, for the entire user population, the needs for visual aids are still substantial.

Introduction

People with impaired visual acuity typically use magnifying devices for a wide range of daily reading tasks. As smartphones and tablets have become popular in recent years, there has been an increase in the use of vision assistance mobile apps, which utilize embedded cameras and turn mobile devices into handheld electronic magnifiers. As the mobile devices are already at hand, their convenience, together with the benefits of electronic magnification, such as an adjustable zoom level, have provided significant advantages over traditional optical magnifiers. The mobile apps are increasingly used by young [1] and older individuals with visual impairment [2]. A recent survey reported that >50% of people with visual impairment use smartphone magnification apps [3]. Our recent study with more than 16,000 magnifier app users reported that they mostly use the app for

XSL•FO
RenderX

short spot-reading tasks [4]. This finding is consistent with a view accepted among those with low vision: magnifier use is not limited to reading only long-passage text. Some studies have focused on spot reading in activities of daily living, such as finding phone numbers and reading instructions on medicine bottles [5-8].

However, what constitutes the spectrum of activities for which people are using mobile magnifier apps is still an open question. Understanding the purposes of app use can be significant for low vision research, because technology development and evaluation ideally should respond to the actual, real-life needs of users. Otherwise, a visual aid, although reportedly useful, might not be as useful in everyday life.

The important knowledge about the needs of individuals with visual impairment for vision assistance include, albeit not exclusively, the purpose of visual tasks (eg, mobility and leisure reading), visual targets (eg, text, object, and pet), environment (eg, location and lighting conditions), effectiveness (or gap), and the availability of vision assistance means (eg, magnifiers and sighted companions). It should be noted that their needs may evolve dynamically. Starke et al [9] recently classified the visual needs of 32 people with low vision on the basis of images captured by body-mounted cameras over a 1-week period. They reported that individuals with visual impairment frequently need help with using mobile devices, which were not widely available 10 years ago.

This study reports an important finding that can contribute to our understanding of the visual needs of smartphone magnifier app users. Specifically, this study aimed to investigate whether vision assistance app users are those who are mostly confined at home owing to vision impairment. Our goal is to find evidence indicating that some of app usages are involved in social activities outside of home.

Instead of a direct approach to interview users, this study harnessed a global event, the COVID 19 pandemic, as an unexpected intervention to deduce the underlying purpose of magnifier app uses. The approaches to directly observe users' behaviors can result in less ambiguous data, but it is usually very challenging to enroll a large sample of participants owing to the potential introduction of a sampling bias. Our chosen method studies the entire app user population as a black box. While the study has a limitation with regard to the lack of an experimental control, obtaining big data from tens of thousands of users has the potential to reveal larger population-level trends and may yield valuable findings.

Specifically, if a significantly large number of magnifier app users are not confined at home under normal circumstances and go to work or school, app usage is expected to decrease during the COVID-19 lockdown. On the contrary, if the magnifier apps are mostly used for household activities at home, app usage is not expected to decrease but rather increase during the lockdown, as people spend more time at home. As this study is related to social activity, we also investigated app usage during weekends and holidays, with the same expectation of observing the same effect as that during the lockdown.

Methods

SuperVision Magnifier App and Users

Data presented here were collected for 38 weeks, from November 2019 to July 2020, using the freely available SuperVision Magnifier app, which was developed by our group. The iOS version of the SuperVision Magnifier (version 1.7.16 used in this study) was released worldwide in October 2016. The app provides vision assistance features, which are commonly available in other smartphone magnification apps and dedicated handheld video magnifiers: up to 16× digital zoom, the ability to capture a snapshot, color inversion (and binarizing images), and a toggling flashlight. The app can be considered a representative of many other similar magnifier apps available in the App store.

Data were collected from active users worldwide, which included 92% of returning users, who repeatedly used the app at different frequencies, and 8% of new users, who installed the app for the first time. Because the log data of 1 app launch are always uploaded to the server when the app is opened the next time, those new users must have used the app at least twice. A new user becomes a returning user if he/she launches the app at least 1 day after the first time. People who installed the app but did not use it during the period of data collection were not included in this study.

Data Collection Methods

A data collection module is embedded in the app to collect runtime usage data. Each time the app became the foreground app, a launch event was recorded. The data logging module was developed using the analytics software development kit of Umeng (Beijing, China). Data were received in a consolidated form from the whole user group, and the users' privacy was not compromised as no participant-identifiable information was collected. The study was approved by the institutional review board of the Massachusetts Eye and Ear Infirmary and was exempt from the regulations of studies on human subjects because the aggregated data prevented the identification of participants.

To further obtain direct evidence regarding the geolocations where the app is used, we released a new version (1.8.1) in September 2020, in which the distance between 2 consecutive app launches is calculated and uploaded to the Umeng server. The specific geolocation data are not saved because of the requirement of privacy protection. These types of data would indicate whether the app is used only at the same location.

For user activity analysis, consolidated weekly app usage reports were downloaded from the website of the analytics service provider, Umeng. For the timeline of major events related to the COVID-19 pandemic, information was extracted from several reliable websites [10-15].

Statistical Analysis

Statistical analysis was performed using the time series data for global weekly app launches from November 2019 to July 2020. Since the time series observations are not independent, autoregressive integrated moving average (ARIMA) modeling

XSL•FO
RenderX

was used for analysis. The effect of COVID-19 lockdowns on magnifier app usage was analyzed using an ARIMA model, which included a predictor that indicated the presence of an intervention; that is, the occurrence of COVID-19 lockdowns. A similar but separate analysis was conducted to determine the effect of holidays on app usage.

The following segments of the weekly app launch data time series were identified: (1) “Holidays”: a 2-week duration related to Christmas and new year’s day; (2) “Prelockdown”: the weeks before March 15, 2020, excluding holidays, which were assumed to represent normal app usage in the absence of interventions; (3) “Lockdown”: 8 weeks starting from the week of March 15 to May 10, 2020; and (4) “Postlockdown”: the weeks after May 10, 2020. Given that the pandemic affected different countries and regions worldwide at slightly different times, the rationale for choosing the period between March 15 and May 10, 2020, as the lockdown period was that these 8 weeks coincided with the spread of the pandemic across a large part of the world, including North America, Europe, and Asia.

The effects of lockdown and holiday interventions on app usage were analyzed separately. When analyzing the effect of holidays, only the prelockdown and holidays segments of the time series were considered. When analyzing the effect of lockdowns, only the prelockdown and lockdown segments were considered.

Statistical analysis was performed using the ARIMA function from the standard library in R (The R Foundation), along with associated functions for evaluating and diagnosing the fitted model. Coefficient (β) values, SE, and *P* values are reported when describing the effect of the interventions. An effect with a *P* value of <.05 was considered significant.

Because the active users of the app grew over time, when investigating app usage during weekends, the number of daily app launches was normalized by the weekly average to exclude the effect of the growing trend. This measure could also compensate for the seasonal changes because of holidays and COVID-19 lockdowns in this study.

Results

Between November 2019 and July 2020, the app was used 262,466 (SD 10,277) times by 38,237 (SD 983) users each month and 60,505 (SD 2,877) times by 14,585 (SD 474) users each week on average, worldwide. On average, each user launched the app 4.1 (SD 0.1) times per week. The solid curve in Figure 1 shows the fluctuation in weekly app launches from November 2019 to July 2020. There are 2 major troughs in the curve, which appear to be aligned with the new year holiday and COVID-19 lockdowns. The number of app uses decreased from the preholiday weekly peak of 63,807 to 56,510 during the holiday weeks, and it decreased from the prelockdown peak of 66,182 to the lowest point at 54,702 during the lockdowns. As some countries started to ease lockdown restrictions, the weekly app launches rose to 58,730 in mid-May 2020, and the recovery appears to have continued through July 2020. To exclude the possibility that the decline during the lockdown period was due to a seasonal change and not lockdowns, the weekly app launches from November 2018 to July 2019 are also plotted as a dotted curve in Figure 1. As shown in Figure 1, there was a decline in app launches around the new year holiday of 2019, but there was no major decline in April 2019. This observation suggests that the decline during April 2020 was not seasonal but rather possibly due to the COVID-19 lockdowns.

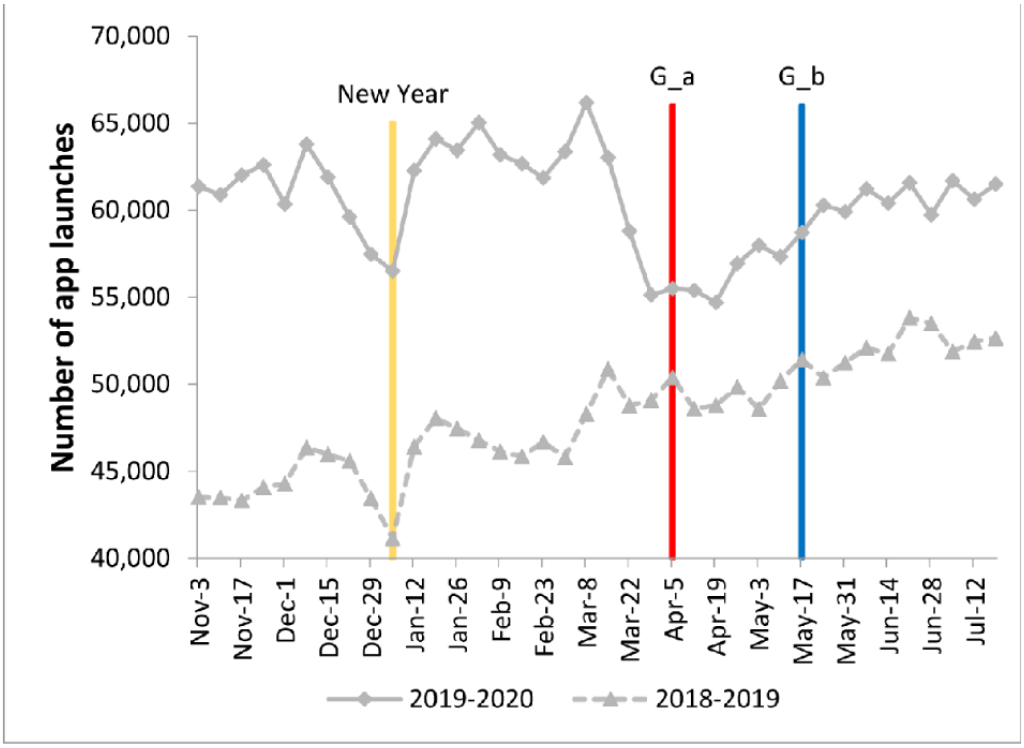
An ARIMA (0,1,1) model with interventions was fitted to the weekly app launch data. The effect of lockdowns on app use was found to be significant (β=–6947, SE=1039; *P*<.001). The negative value of the coefficient for the lockdown variable indicates that the number of app launches decreased by an average of 6947 per week (approximately 11%) during the lockdown compared to the prelockdown phase. Similarly, the intervention resulting from holidays had a significant effect (β=–5212, SE=1307; *P*=.001). Again, the negative value of the coefficient indicates that the weekly average app launches decreased by 5212 during the holiday weeks.

From November 2018 to July 2019, there was a significant reduction in app launches around the holiday weeks of Christmas and new year’s day (β=–2168, SE=720; *P*=.003). However, there was no significant change in the number of app launches per week during mid-March to early May 2019 (β=–643, SE=603; *P*=.29).

Since the pandemic’s course was not the same across all countries, the fluctuation in app usage was also visualized by country or region to confirm that the patterns observed in the global data could still be observed in each country or region. App users were located in more than 120 countries, but most of the countries had only a small number of users. We selected four countries or regions with most users for further analysis: Russia, the United States, Japan, and Europe (Figure 2). There were more than 1500 active users weekly in each of these selected regions. No other country had an average of more than 588 weekly users.

XSL•FO
RenderX

Figure 1. Weekly app launches (number of times of app usage) from November 2019 to July 2020, compared to the previous year's data for the same duration (dotted line). For the curve representing November 2019 to July 2020, there are 2 troughs around new year's day and COVID-19 lockdowns in April 2020. A corresponding trough near new year's day 2019 is observed in the previous year's curve, but there is no corresponding decline in April 2019. G_a: approximately one-third of the world's population is living with COVID-19 restrictions, G_b: some countries, including Spain, Iran, Italy, Denmark, Israel, Germany, New Zealand, and Thailand began to ease lockdown restrictions.



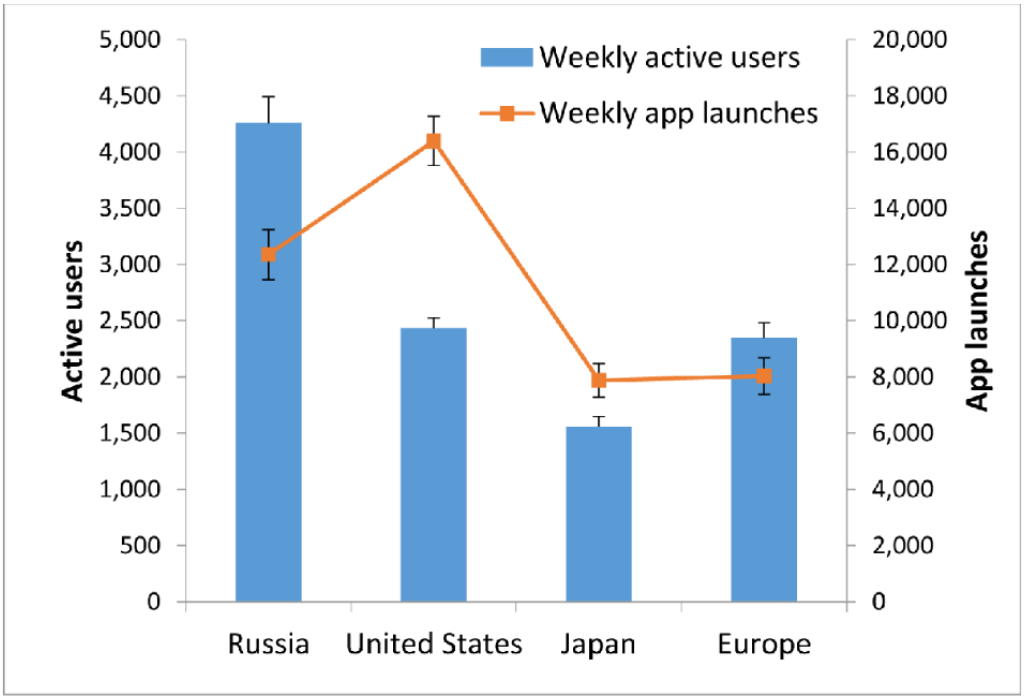


Figure 2. Four regions were included for separate analysis: Russia, the United States, Japan, and Europe. Their average numbers of weekly active users were 4259, 2436, 1558, and 2346, respectively. The corresponding average numbers of weekly app launches (number of times the app was used) were 12,353, 16,393, 7880 and 8031, respectively. Error bars indicate SD values.

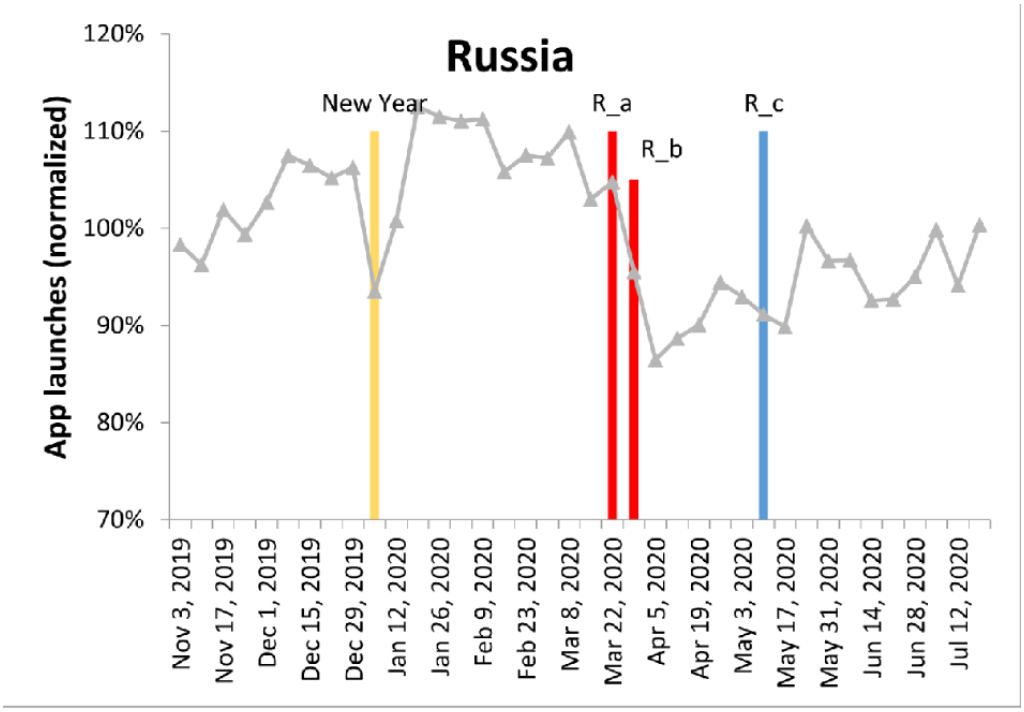
Figures 3-6 show the fluctuation in weekly app launches during a period of 38 weeks from November 2019 to July 2020 in the aforementioned 4 regions. The timeline of some major events are superimposed on the fluctuation curves. Three types of events are color-coded: yellow=holiday, red=lockdown, and blue=easing of lockdown restrictions. It can be seen that Christmas or new year are aligned with one of the major troughs in the 4 regions. For the United States, there seemed to be an additional holiday trough around Thanksgiving.

XSL•FO
RenderX

Figure 3. App launch fluctuations in Russia, normalized by the average number of weekly app uses. Yellow: holiday, red: lockdown, and blue: postlockdown. In Russia, Eastern Orthodox Christmas was on January 7. R_a: Ministry of Culture announced the closure of all cultural institutions under its jurisdiction; Minister of Education Sergey Kravtsov announced the closure of all Russian schools from March 23, 2020. R_b: Moscow issued a stay-at-home order for all residents. R_c: President Vladimir Putin announced an end to Russia's 6-week nationwide lockdown despite a record increase in COVID-19 cases.



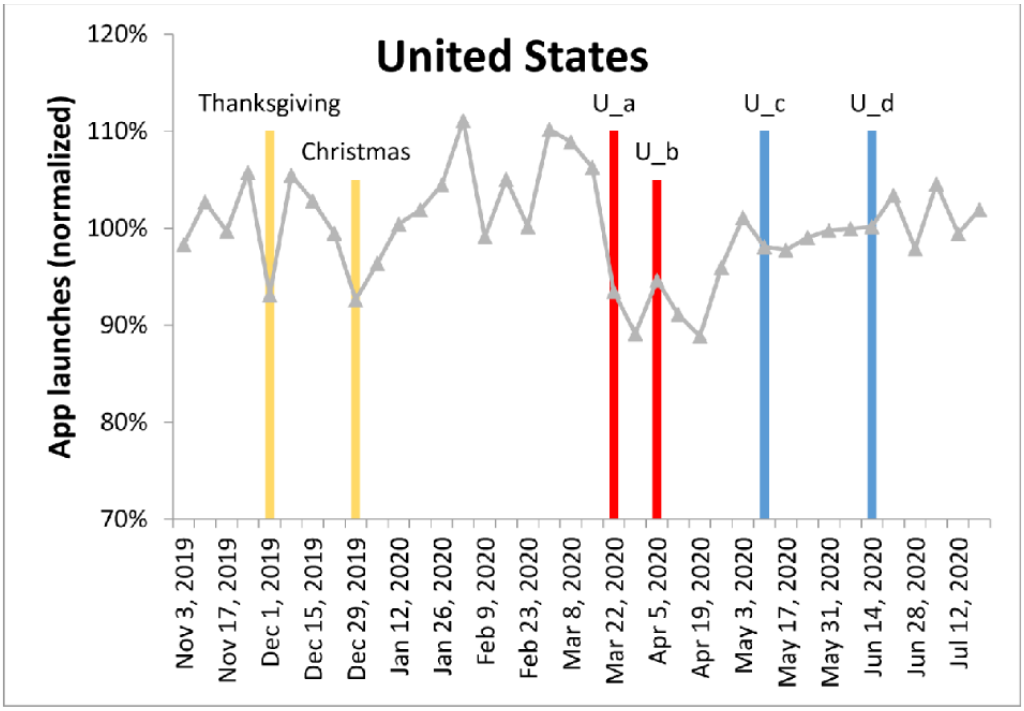


Figure 4. App launches in the United States, color-coded as in Figure 3. U_a: New York City public schools closed, and California issued a stay-at-home order for all 40 million residents. U_b: approximately 91% of people in the United States were instructed to stay at home. U_c: Florida and California reopened. U_d: New York City began phase I of reopening.

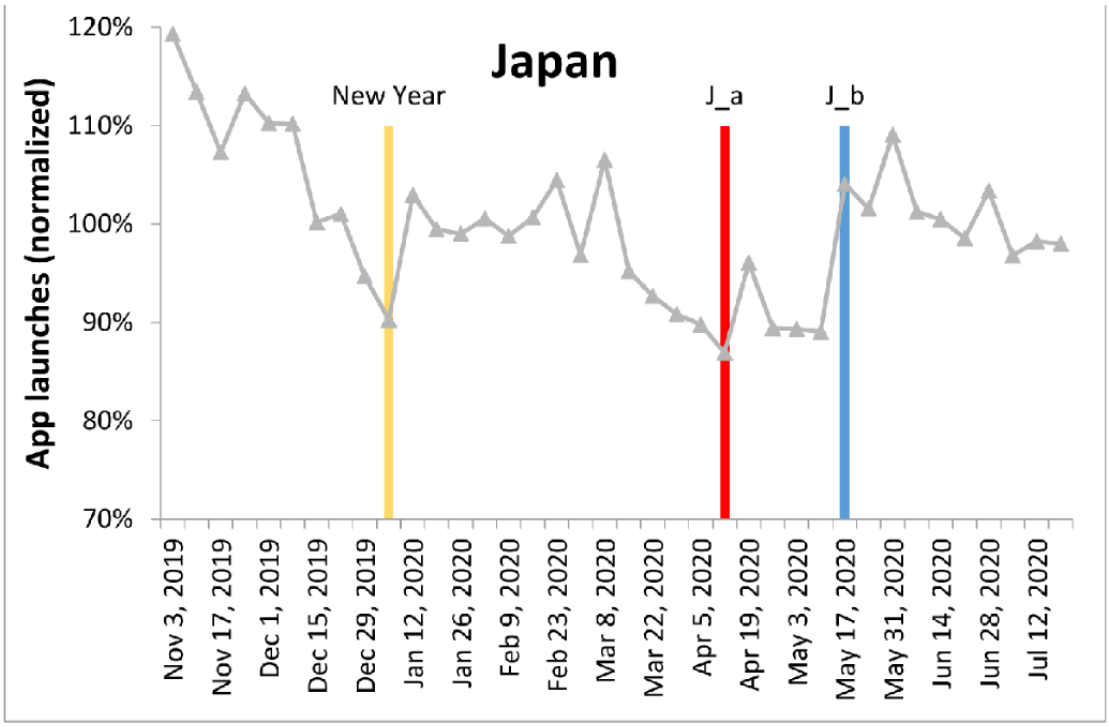
XSL•FO
RenderX

Figure 5. App launches in Japan, color-coded as in Figure 3. J_a: Japan's prime minister proclaimed a 1-month state of emergency from April 8 to May 6, 2020, for Tokyo and the prefectures of Kanagawa, Saitama, Chiba, Osaka, Hyogo, and Fukuoka. J_b: Japan's prime minister lifted the state of emergency imposed in 39 of 47 prefectures, announcing that the nation's rate of infection has decreased to one-seventh of its peak.



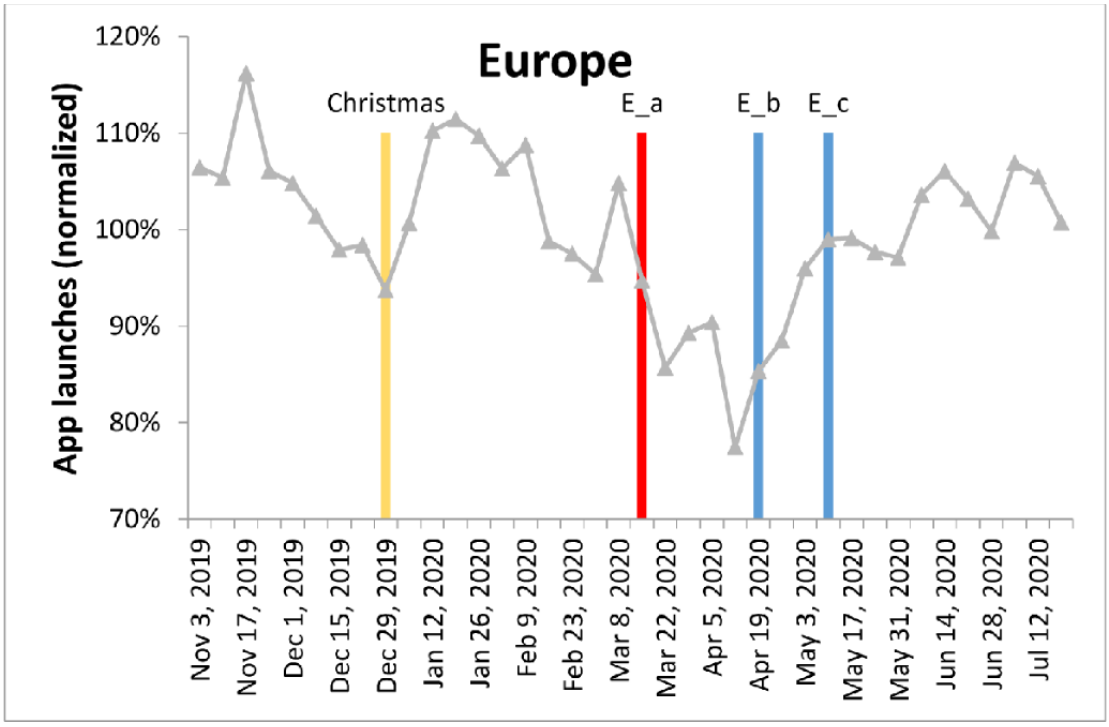


Figure 6. App launches in Europe, color-coded as in Figure 3. E_a: All shops and venues closed nationwide in Italy. E_b: Economy reopened in Germany. E_c: Lockdown restrictions started to be eased in several countries such as Spain, Italy, Denmark, and Germany.

Consistently, the lockdown events in these 4 regions were either during the major trough in the global data or during the decreasing phase shortly before that trough. Similarly, the regional lockdown easing events occurred during the increasing phase of global app use.

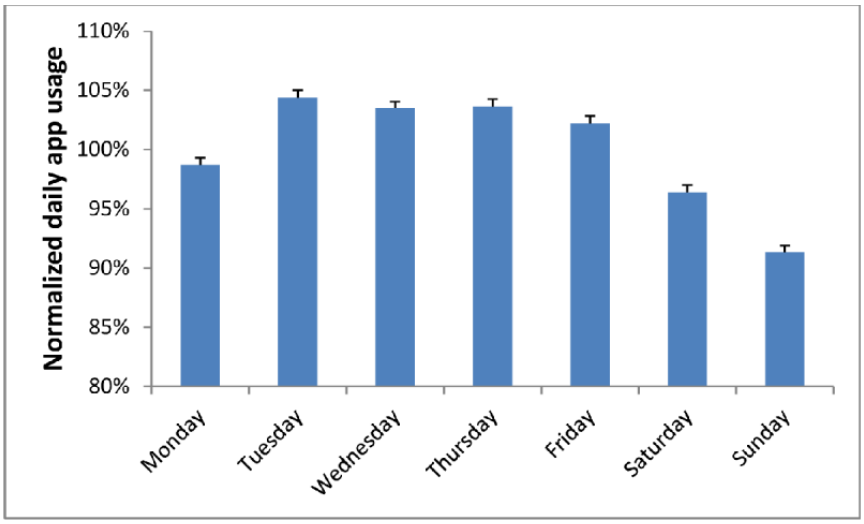
Figure 7 shows the normalized daily app usage by days of the week between November 2019 and July 2020. Overall, app usage on weekends was 8.6% lesser than that on weekdays (93.9% vs 102.5%, respectively; $P<.001$). As shown in Figure 7, app usage was the lowest on Sunday. App usage on Saturday and Monday, which are similar to that on Sunday, were also lower than the that during other weekdays. Because app users were at different time zones worldwide, the local time for most users differed from the time of the Umeng analytic server (GMT+8 hours). Therefore, the effect of the weekend spills

XSL•FO
RenderX

over 1 day before and 1 day after. If Saturday and Monday are excluded, usage on Sunday was 12% lesser than the average usage from Tuesday to Friday.

Figure 8 shows the distribution of the distance between 2 consecutive app launches. The data were collected across a period from September 15, 2020, to February 16, 2021, including total of 414,618 samples. Far from being restricted to 1 place, a small number of users travelled more than 500 km. Most consecutive app uses were recorded at the same locations, but this does not necessarily indicate that 1 pair of (consecutive) app launches occurred at the same location as that of another pair of (consecutive) app launches. A sizeable peak was observed between 5 km and 50 km (7.2%). For reference, the average commute distance in the United States is 24 km each way [16].

Figure 7. Daily app launches normalized by the weekly average for the period between November 2019 and July 2020. Bars indicate mean app usage by the days of the week. Error bars indicate SD values.



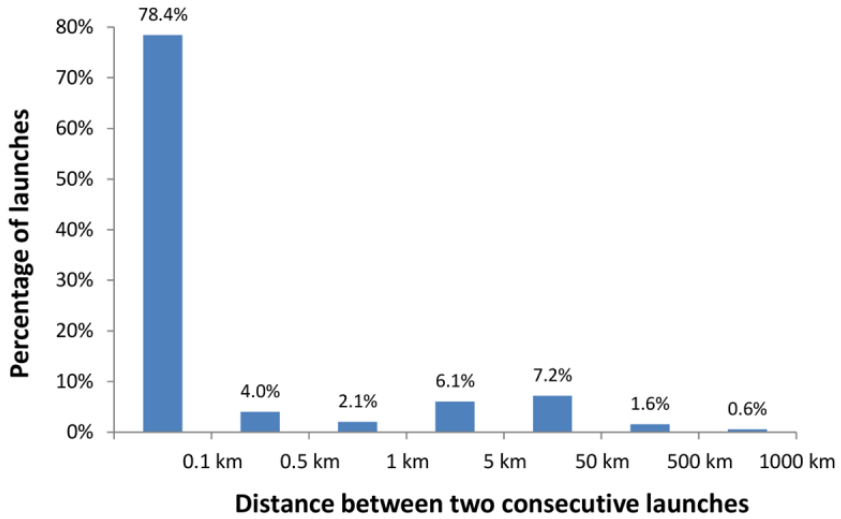


Figure 8. Percentage of app launches vs the distance to the location of the previous launch. Most consecutive app launches occurred at the same place. Excluding the bin for the same location, there is a sizeable peak between 5 km and 50 km, which indicates that 7.2% of the consecutive app launches were separated by a distance of 5-50 km.

Discussion

Principal Findings

This study investigated the impact of changes in social activities on the app launch pattern of tens of thousands of SuperVision Magnifier app users and observed a declining trend in app usage corresponding to weekends, major holidays, and the initiation of lockdowns in different regions compared to the prelockdown usage frequency. Given the black box of the mixed user population, the global COVID-19 lockdown effectively provided a window through which insights can be gained by investigating the effect of a behavioral intervention, which is not planned or designed. In this study, this opportunity was utilized to help deduce the situations where the vision assistance app was used.

Our previous study reported that the mobile magnifier app is mostly used for short spot-reading, while a small number of users may use the app for long passage–reading for ≥30 minutes each time [4]. In terms of app launch, a small portion of users used the app many times on a daily and weekly basis, and many users used it only occasionally. It should be noted that the number and duration of app uses are not necessarily a measure

XSL•FO
RenderX

of helpfulness. Those metrics are typically used to gauge the customer adherence to video game and social media apps. For vision assistance apps, those metrics reflect the needs of users (especially returning users). For instance, Google Maps is very useful for traveling to unfamiliar places, but many people do not use it every day. In addition to launch and duration measures, our latest study on visual targets viewed by users through the app reported that more than half of the targets are nontextual targets including indoor and outdoor contexts, food, animals, and plants [17]. Furthermore, our study shows that the locations, where vision assistance is needed, are not restricted to home. Together, the wide range of frequency, the variety of target categories, and the effects of social activity–related locations suggest that the magnifier app can probably meet many different visual needs in the daily lives of people with visual impairment. Our ongoing studies are attempting to generate an overview of the visual needs of these individuals from different perspectives.

It remains unknown what factors influence the needs or in what context those visual tasks are performed with help from the app. Without fully understanding the actual visual needs in the real world, limited studies on low vision and technologic developments have been relying on subjective opinions and limited surveys. Thus far, previous studies have evaluated the spot reading performance of vision assistance interventions based on visual tasks that are typically carried out at home [5,7], including reading information on medicine bottles, product labels, and utility bills, all of which are textual targets. However, visual tasks outside of home (eg, at work, school, or during traveling) have been rarely considered. If we assume that the magnifier app is mostly used at home, app use would have increased during lockdowns; however, we observed the opposite trend from the app usage data.

The data on distance between 2 consecutive app launches directly indicate that the magnifier app is also frequently used outside home. Interestingly, the travel distance seemed to be in line with the average commute distance in the United States. While our study population was large, detailed information on geolocations could not be collected. However, considering a consistent reduction in app usage globally during weekends, holidays, and COVID-19 lockdowns, it is a reasonable speculation that the reduction could be due to reduced work- or school-related activities. If this association is accurate, it would suggest that normally the magnifier app is used not only at home for activities of daily living but also at workplaces, schools, or while traveling. Regarding the proportion of app usage away from home, this study could not collect direct data. The 11% decline during lockdowns and 8.6% of decline on weekends might be a rough indicator of the frequency of such usage. According to anecdotal reports we received, the app was used by some people to read road signs or to watch presentations in conferences. However, these are only a few examples of app use outside of home. More precise estimation will be conducted in future studies.

A counter argument might be made that the reduction in app usage during COVID-19 lockdowns may not necessarily be due to a reduction in work- or school-related activities but instead, it could be simply because the users had less chances to use the app when staying at home during lockdowns. This study did not identify the environment in which the app was used, but the hypothesis cannot explain the reductions during holidays and weekends. The time people spend outside their home for traveling, socializing, outing, and shopping during these breaks should be more than that during COVID-19 lockdowns. More activities outside home during weekends in 2019 and Christmas and new year holiday weeks in 2018 and 2019 did not appear to increase app usage. On the other hand, if the decline during holidays and weekends were to be explained by less time spent at home, assuming that the magnifier app is primarily used for activities of daily living at home, then the explanation based on the time staying at home would not be able to account for the decline during lockdowns. Taken together, a more plausible explanation could be that decreased app usage during weekends, holidays, and lockdowns are due to reduced work- or school-related activities carried out away from home. As many people worked from home and many students practice remote learning during the lockdowns, it is possible some users still use the vision assistance app at home to help with their work. This study could not distinguish this portion from that of nonwork- or nonschool-related app usages. If this were true, it would imply that the app is normally used even outside home when there is no lockdown.

Another possible reason for the reduction in app usage may be that when users with visual impairment were at home, their family members and friends could help with some of the activities of daily living, or the visual tasks at home was less demanding overall than those at workplaces; hence, they did not need to use the app in some cases. Nevertheless, for the whole user population, the need for vision assistance devices on a daily basis is still substantial, as the reduction in app usage during breaks was only approximately 10%.

To confirm the aforementioned speculations, future studies are required to collect direct evidence indicating the detailed nature of activities for which the app was used, and to conduct some necessary surveys (eg, on demographics and vision status) to help interpret the behavioral data. Further big data analysis studies will help reveal the wide spectrum of visual demands for vision assistance among people with visual impairment. This knowledge will be important for developing personalized, more effective solutions in future low vision rehabilitation research. The development of vision assistance technologies can target a particular group of users (eg, elderly individuals) or the entire cohort. Whatever the targeted group is, ideally, the composition of visual tasks should roughly match the spectrum of visual needs in the targeted cohort's actual visual needs. Otherwise, studies may miss important needs while over-representing others. Without accurate feedback from appropriate evaluation studies, the utility of technologies may be compromised.

Conclusions

Considering our large user sample, this longitudinal study observed a slight reduction in the usage of the SuperVision Magnifier app during weekends, holidays, and COVID-19 lockdowns. We surmise that the possible reasons could be that the magnifier app is normally used in some work- and school-related activities in addition to daily tasks performed at

XSL•FO
RenderX

home, and the visual tasks at home may be relatively less demanding than those performed outside of home.

Acknowledgments

This study is supported in part by a National Institutes of Health award (award# P30EY003790). We thank Anurag Shubaham for upgrading the app.

Conflicts of Interest

GL is involved in the development of the vision app, which is completely free to the public. He has no financial competing interest related to the app.

Abstract

Background: The prevalence of depressive and anxiety symptoms in patients with COVID-19 is higher than usual. Previous studies have shown that there are drug-to-drug interactions between antiretroviral drugs and antidepressants. Therefore, an effective and safe treatment method was needed. Cognitive behavioral therapy (CBT) is the first-line psychological therapy in clinical treatment. Computerized CBT (cCBT) was proven to be an effective alternative to CBT and does not require face-to-face therapy between a therapist and the patient, which suited the COVID-19 pandemic response.

Objective: This study aims to evaluate the efficacy of the cCBT program we developed in improving depressive and anxiety symptoms among patients with COVID-19.

Methods: We customized a cCBT program focused on improving depressive and anxiety symptoms among patients with COVID-19, and then, we assessed its effectiveness. Screening was based on symptoms of depression or anxiety for patients who scored ≥7 on the Hamilton Depression Rating Scale ($HAMD_{17}$) or the Hamilton Anxiety Scale (HAMA). A total of 252 patients with COVID-19 at five sites were randomized into two groups: cCBT + treatment as usual (TAU; n=126) and TAU without cCBT (n=126). The cCBT + TAU group received the cCBT intervention program for 1 week. The primary efficacy measures were the $HAMD_{17}$ and HAMA scores. The secondary outcome measures were the Self-Rating Depression Scale (SDS), Self-Rating Anxiety Scale (SAS), and Athens Insomnia Scale (AIS). Assessments were carried out pre- and postintervention. The patients' symptoms of anxiety and depression in one of the centers were assessed again within 1 month after the postintervention assessment.

Results: The cCBT + TAU group displayed a significantly decreased score on the $HAMD_{17}$, HAMA, SDS, SAS, and AIS after the intervention compared to the TAU group (all P<.001). A mixed-effects repeated measures model revealed significant improvement in symptoms of depression ($HAMD_{17}$ and SDS scores, both P<.001), anxiety (HAMA and SAS scores, both P<.001), and insomnia (AIS score, P=.002) during the postintervention and follow-up periods in the cCBT + TAU group. Additionally, the improvement of insomnia among females (P=.14) and those with middle school education (P=.48) in the cCBT + TAU group showed no significant differences when compared to the TAU group.

XSL•FO
RenderX

Conclusions: The findings of this study suggest that the cCBT program we developed was an effective nonpharmacological treatment for symptoms of anxiety, depression, and insomnia among patients with COVID-19. Further research is warranted to investigate the long-term effects of cCBT for symptoms of anxiety, depression, and insomnia in patients with COVID-19.

KEYWORDS

mental health; depression; anxiety; COVID-19; treatment; cCBT; computerized cognitive behavioral therapy

Introduction

In the past decades, the effects of physical and psychological distress have increased with each successive public health emergency, such as with the severe acute respiratory syndrome (SARS) in 2003 [1], the Middle East Respiratory Syndrome (MERS) [2] in 2012, the Ebola virus disease in 2014 [3], and COVID-19 in 2020 [4]. COVID-19, caused by a novel coronavirus (SARS-CoV-2) [5], continues to spread worldwide. On January 30, 2020, the World Health Organization Emergency Committee declared a global health emergency based on growing case notification rates at Chinese and international locations [6]. At present, there have been nearly 30 million confirmed cases and nearly 1 million deaths worldwide [7].

The COVID-19 epidemic is similar to SARS and MERS [8] but has spread more quickly and efficiently [9]. In the acute stage of SARS and MERS, the prevalence of psychological distress among confirmed patients was 63.0%; common symptoms included insomnia (41.9%), anxiety (35.7%), and depression (32.6%) [10]. A cross-sectional study on psychological distress in patients with COVID-19 showed that the prevalence of symptoms of depression and anxiety was 35.9% and 38.5%, respectively [11].

The common clinical symptoms of patients with COVID-19 include cough, fever, fatigue, hypoxia, and occasionally gastrointestinal infection [12]. Moreover, the patients experienced various stressors during isolation, including but not limited to drug side effects, a fear of severe disease consequences, a fear of infecting others, and an inability to get correct information in a timely manner [13]—all of which may lead to several psychological distresses including anxiety, depression, and insomnia [8,14]. A lack of timely intervention in psychological distresses may affect the quality of life for patients in the future. As a survey of SARS survivors showed, 42.5% were diagnosed with at least one psychiatric disorder 4 years following the outbreak, with the most common diagnoses being posttraumatic stress disorder (PTSD; 54.5%) and major depressive disorder (39.0%). Further, 40.3% of survivors experienced chronic fatigue [15].

Early, brief, and trauma-focused mental health services may have the potential to reduce or delay the development of adverse outcomes [16]. An effective method may be cognitive behavioral therapy (CBT), which is widely used to treat mild to moderate depression and anxiety [17]. However, traditional CBT requires a face-to-face implementation, which is inconvenient for patients with COVID-19 who are quarantined in hospitals. Computerized CBT (cCBT), as an alternative mode of delivery, can make up for this deficiency. There is substantial evidence that cCBT is an effective alternative to CBT for the treatment of mild to moderate depression and anxiety [18-20]. Compared to CBT, cCBT offers a range of benefits. cCBT can be accessed with a computer, smartphone, or tablet without the need for face-to-face therapy, and this is especially key during a pandemic to reduce the risk of spreading infection [21]. cCBT does not require appointments, allowing instead for time flexibility and cost-effectiveness [22]. The privacy of patients is better protected, and the stigma of face-to-face therapy is mitigated [23].

Thus, to solve the psychological problems that may occur during the epidemic, we independently developed a cCBT program for patients with COVID-19. The program is a brief self-guided, online psychological intervention that consists of cognitive training, cognitive consolidation, and behavioral therapy via video and animation content, all of which is easy to understand and operate. It may comprehensively regulate mental distress that includes anxiety, depression, panic, and fear among patients with COVID-19; it may also help patients build confidence as they confront the disease.

Moreover, evidence from epidemiological studies revealed the relationship between gender, age, education level, and severity of mental problems [24]. Females and relatively high educational level were found to be predictors of mental distress of adults 1 month in the COVID-19 epidemic [25]. Additionally, several studies also suggest differences between men and women in response mechanisms to psychological distress. Men tend to *externalize* their distress by directing action outward, while women tend to *internalize* their distress by directing action inward [26,27]. Such gender difference may influence the treatment response [28]. Other studies have shown that the patients' age and educational level at the beginning of treatment may affect the final outcomes [29].

Based on all these factors, we conducted a multicenter, randomized, placebo-controlled clinical trial to evaluate the efficacy of the cCBT program. The program was developed with the aims of improving the symptoms of depression and anxiety among patients with COVID-19. We hypothesized greater symptom improvement with respect to mitigating anxiety and depression in the intervention group compared to the treatment as usual (TAU) group at both the postintervention and follow-up periods. We also hypothesized that online self-help may not be suitable for all patients, and the overall responses in mental problems may vary by gender, age, and educational level.

XSL•FO
RenderX

Methods

Trial Design

This was a prospective, multicenter, two-arm (allocation ratio was 1:1), parallel group; further, it was a nonblinded randomized controlled trial that was registered at the Chinese Clinical Trial Registry with the study number ChiCTR2000030084. Participants were recruited from five hospitals in China from March 2020 to June 2020. Eligible participants were screened for symptoms of anxiety or depression. Patients with symptoms of anxiety, depression, or both were included because these two symptoms often occur simultaneously. Patients were then randomly allocated to a 1-week course of the cCBT program we developed in addition to TAU (cCBT + TAU group), or they were randomly allocated to the control condition, the TAU group, when they completed the baseline assessment. The outcomes of both groups were measured twice—at the baseline and post intervention. To investigate the relative continuous effects of cCBT on symptoms of depression and anxiety, the outcomes of both groups in one of the sites were measured again 1 month after the postintervention.

Participants and Recruitment

The participants were recruited from the following five hospitals: Affiliated Tongji Hospital of Huazhong University of Science and Technology, Wuhan Institute for Tuberculosis Control, Central Hospital of Chongqing Three Gorges, Chongqing Public Health Medical Center, and the Fourth People's Hospital of Taiyuan. The inclusion criteria those who were aged between 18-75 years (including threshold), regardless of gender; were under isolation observation while diagnosed with a mild or common type of COVID-19 and could cooperate to complete a corresponding psychological intervention; had mild to moderate depressive or anxiety symptoms as defined by the 17-item Hamilton Depression Rating Scale ($HAMD_{17}$) score≥7 or the Hamilton Anxiety Scale (HAMA) score≥7; had sufficient compliance to complete the experiment according to the protocol; and informed consent was provided by patients and (if necessary) guardians. The exclusion criteria were patients who were clearly diagnosed with a psychiatric disorder, including depression, bipolar disorder, etc, in the 6 months prior to their diagnosis of COVID-19; patients with psychotic symptoms; patients with $HAMD_{17}$ score≥24 or HAMA score≥21; patients with a high risk of suicide, defined as having a history of attempts by suicide in the 6 months prior to the study or who scored more than 3 on item three (suicide item) of the $HAMD_{17}$ scale; patients with organic mental disorders; patients with substance abuse or dependence; patients undergoing treatment currently (pharmacological or psychological) for mental health problems; or patients presenting other conditions that the researchers believed were not suitable for this clinical trial.

The researcher explained to the eligible patients they had been introduced to the study because they were experiencing mental symptoms related to the burden of COVID-19 and that the intelligent therapy via the cCBT program we developed may help to reduce these distresses. Patients were also told that the aim of the study was to find out whether receiving this intelligent therapy might help them to relieve these mental symptoms linked to COVID-19. Participants were informed that they had a 50% chance of receiving the cCBT intervention and that the study would be offered as an additional source of support for free, not as a replacement or restriction to their current physical care. Besides, they would be provided with free medical consultation for a period of 3 years after discharge.

Randomization

Resman, a public management platform for clinical trial management of China's clinical trial registration agency, was used to carry out random grouping; the allocated sequence was kept by the administrator. Patients with mild to moderate anxiety or depression were randomized to the cCBT + TAU group or to the TAU group at a 1:1 ratio. Randomization was balanced using a block size of four and was stratified by institution.

Intervention

The cCBT Program

The program is a remote intervention model based on cCBT that we developed. The system can systematically intervene in patients' cognition, emotions, and behavior through an offline mobile terminal. It is easy to understand and operate, so patients can complete the work with the help of nonpsychological professionals or with self-guidance. Participants in the cCBT + TAU group were informed of how to access the program and use it during the study after registration.

Compared to other forms of digital CBT for anxiety and depression, the most unique feature of the cCBT program we developed is its targeting of patients with COVID-19. Components of the intervention were presented to patients with COVID-19 with anxiety and depressive symptoms through computer-based, visually attractive, and interactive examples, exercises, and videos. Given that the focus of CBT is on patients' irrational cognition. The first module of cCBT, called the cognitive therapy module, aims to minimize or even eliminate patients' negative thoughts about COVID-19. This part is presented in videos to participants. It mainly includes rational cognition of COVID-19, stress status during isolation, and psychosomatic mechanisms under stress in addition to sleeping management and education about status post isolation.

To further deepen the correct cognition of patients, we set up a cognitive consolidation module. Unlike the first module, this part is presented in the form of a miniature game, which undoubtedly increases the flexibility and interest of the intervention. The participants are required to answer questions based on videos related to the cognitive therapy module.

For the last part, the behavioral therapy module is targeted at teaching methods of regulating negative emotions. This module is also presented in the video to guide participants in relaxation training. Information about the following three relaxation training methods was provided:

1. Relaxation mental imagery training: The patients are taught to subjectively follow their own ideas and imagine some pleasant situations such as prairies, streams, trees, and greenery of native mountains. During the whole training process, patients are completely in a relaxed state with

XSL•FO
RenderX

gentle and even breathes. With the vivid image gradually becoming clear in their mind, the patients will feel a warm current running through the whole body. It is during these moments that patients can now enter a deep state of relaxation benefiting both body and mind.

2. Mindfulness meditation: The goal of this training is to improve the ability of self-regulation. Using the training of concentration and relaxation, it requires the patients to consciously maintain attention on the current internal or external experience without making any judgments about it.
3. Counting meditation: Patients with COVID-19 are generally unable to relax due to the fear of the highly contagious disease. Based on this, the training guides the patients to focus on the breath while meditating. The patient's physical and mental state will gradually calm down, and the ability to focus will continue to improve during this period of training.

This experimental treatment was delivered through more than 10 minutes of self-directed individual therapy per day for 1 week at each trial center. The program is installed on an iPad and is only available to research therapists. After the therapist shows the patients how to use the system, the patients can begin their journey of *self-help intervention*.

Treatment as Usual

TAU consisted of periodic psychological assessments, general psychological support, and consultations discussing overall well-being and disease activity. Patients whose assessment results suggested a certain risk to themselves or others at the time of each assessment were to be treated by a professional psychiatrist and were withdrawn from this study.

Measures

Data Collection Procedure

Demographic and clinical characteristics including age, gender, and education levels (years) were collected at baseline. $HAMD_{17}$ and HAMA scores were determined by trained researchers at the baseline, postintervention, and 1-month follow-up (hosted by only one of the centers). Secondary outcome measures were also recorded at the same point. These measures included the Self-Rating Depression Scale (SDS), the Self-Rating Anxiety Scale (SAS), and the Athens Insomnia Scale (AIS).

Outcome

Before the study, a questionnaire was completed by the participants including demographic and clinical characteristics. The primary efficacy outcomes were $HAMD_{17}$ and HAMA, both well-established interviewer-rated measures of depression and anxiety severity, respectively, from baseline to the end of treatment, and to the 1-month follow-up. For $HAMD_{17}$ [30], items are scored on a 5-point Likert scale (0-4) for a total score range from 0 to 68, with higher scores indicating more depressive symptoms. In the study sample, the total Cronbach alpha coefficient of HAMD17 was .89 (95% CI 0.86-0.92). Similarly, HAMA [31] consists of 14 items on a 5-point Likert scale (0-4) for a total score range from 0 to 56, with higher scores indicating more anxiety symptoms. Additionally, the internal consistency of this questionnaire was also good (α=.87, 95% CI 0.82-0.90). Given the severity of the COVID-19 epidemic, all assessors for $HAMD_{17}$ and HAMA scales from different centers were trained by one professional psychological assessment specialist through online conferences. The interviewer reliability is both high for $HAMD_{17}$ (intraclass correlation coefficient [ICC]=0.91, 95% CI 0.78-0.98) and HAMA (ICC=0.90, 95% CI 0.75-0.98).

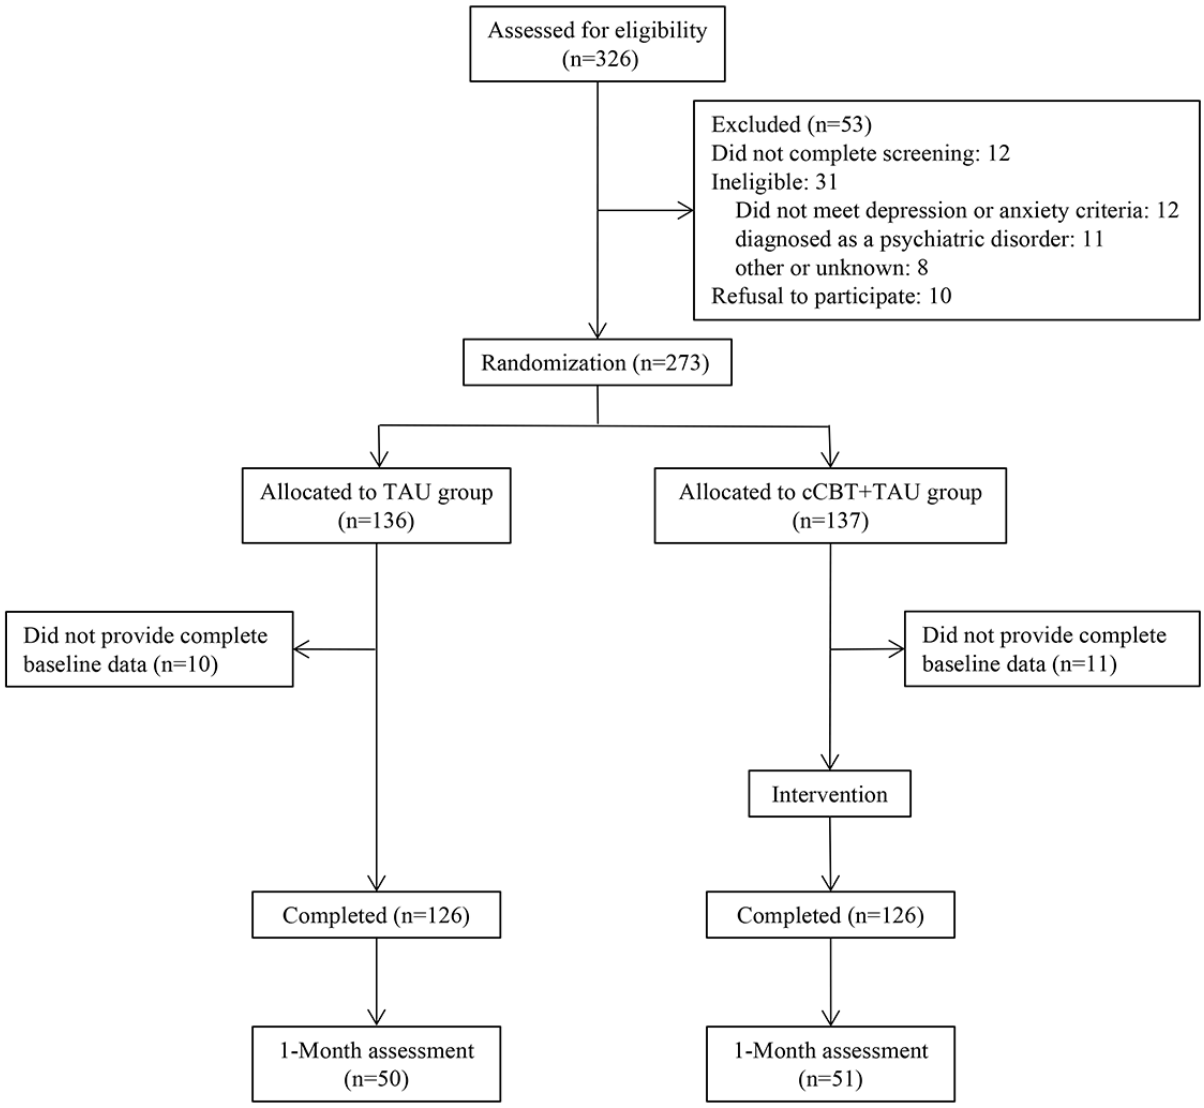
Secondary end points for evaluating the efficacy of cCBT were SDS to assess self-rated depressive symptoms, SAS to assess anxiety symptoms, and AIS to assess insomnia symptoms. SDS [32] contains 20 items that reflect subjective feelings of depression. It is rated on a 4-point Likert scale (from 1, "no or a little of the time," to 4, "most of the time or all the time"), containing 10 symptom positive items and 10 symptom negative items. SAS [33] is also composed of 20 items and is rated on a 4-point Likert scale (from 1, "no or a little of the time," to 4, "most of the time or all the time"). Higher scores reflect more severe anxiety symptoms. The last secondary outcome measure is AIS [34], a validated brief questionnaire for a total score range from 0 to 24. Each item is measured on a 4-point Likert scale, with total scores between 4 and 6 representing suspicious symptoms of insomnia, scores higher than 6 representing insomnia, and scores less than 4 representing no insomnia. All three scales have been shown to have high internal consistency in this study sample (SDS: α=.93, 95% CI 0.90-0.96; SAS: α=.92, 95% CI 0.88-0.95; AIS: α=.87, 95% CI 0.81-0.92).

Sample Size

To estimate the sample size, a pilot study was conducted for measuring the $HAMD_{17}$ and HAMA score in 30 patients who received TAU. The standard deviation (σ) of the $HAMD_{17}$ and HAMA score in this group were both 10.50. Additionally, based on the previous studies on such interventions for depressive or anxiety symptoms [35-38], we expected to achieve a value δ≥5 in the level of depressive and anxiety symptoms with the cCBT intervention. Assuming a 5% significance level, two-tailed, and a power of 90%, a sample size of 188 patients (ie, 94 per group) was estimated. To include an estimated dropout rate of 25%, the entire sample size was increased from 188 to 250 participants (ie, 125 per group).

Statistical Analysis

SPSS software version 22.0 (IBM Corp) was used for all statistical analyses. Descriptive statistics were conducted for demographic and clinical characteristics in each treatment group. The measurement data were described by means and SDs. Two-sample *t* tests and chi-square or Fisher exact tests were used where appropriate, and these assessed demographic variable differences between the cCBT + TAU group and the TAU group. To confirm the improvements in each symptom at postintervention, the baseline and postintervention results of the dependent variables were analyzed using the paired *t* test, whereas the two-sample *t* test was used to detect differences between the treatment and control groups. Moreover, to explore the influence of gender, age, and education level on treatment response, we conducted a subgroup analysis to examine the changes in the scores of patients with different gender, age, and



XSL•FO
RenderX

education level. For patients who finished the follow-up assessment, a mixed-effects model for repeated measures (MMRM) was used to compare data obtained at the baseline, postintervention, and follow-up periods between the cCBT + TAU group and the TAU group. Post hoc analysis was performed using the Bonferroni multiple comparison test. All tests were two-sided, and a *P* value less than .05 was considered statistically significant.

Results

A total of 326 patients with COVID-19 from five centers agreed to participate to the program. There were 273 participants that completed screening (see Figure 1 for details on reasons for exclusion); of these, 21 did not provide the complete baseline data and were therefore excluded. Thus, the analyzable sample consisted of the remaining 252 participants, who were randomly assigned to either the cCBT + TAU group (n=126) or the TAU group (n=126). All participants completed the assigned intervention (Figure 1). As shown in Table 1, no significant differences were found in the demographic characteristics between the cCBT + TAU group and the TAU group. None of the participants were taking any psychiatric medication at baseline and during the intervention. For physical symptoms of COVID-19, all patients were given corresponding treatments according to the Diagnosis and Treatment Protocol for COVID-19 issued by the National Health Commission, mainly including antiviral therapy, antibacterial therapy, and traditional Chinese medicine treatment. The results for the efficacy variables are presented in Table 2. Compared to the TAU group, the cCBT + TAU group showed significant improvement in both the primary outcomes of $HAMD_{17}$ and HAMA scores and the secondary outcomes of SDS, SAS, and AIS scores (all $P<.001$). Additionally, there were significant differences between the two groups in $HAMD_{17}$, HAMA, SDS, and SAS scores post intervention (all $P<.001$).

Exploratory subgroup analyses examined the influence of gender, age, and education level on treatment response. For both male and female patients, the cCBT + TAU group showed some evidence for a greater reduction in $HAMD_{17}$, HAMA, SDS, and SAS scores compared with the TAU group. For female patients, we found no evidence of significant between-group differences for the change of AIS scores (Table S1 in Multimedia Appendix 1). Additionally, the cCBT + TAU group showed some evidence of greater improvement in symptoms of anxiety and depression compared with the TAU group, regardless of education level. However, changes in sleeping, as measured using AIS, did not differ between the cCBT + TAU group and TAU group for patients with middle school education (Table S2 in Multimedia Appendix 2). Additionally, the cCBT + TAU group also showed significantly decreased scores on all 5 scales compared with the TAU group, regardless of age (Table S3 in Multimedia Appendix 3).

Details about sociodemographic characteristics of participants who completed the 1-month follow-up assessment for each group are presented in Table 1. The results indicated that there were no significant differences between the cCBT + TAU group and TAU group for any of these variables. Besides, compared to the full sample in each condition, the follow-up sample showed no significant differences in demographic and psychological characteristics (Table 3). The patients who finished the follow-up assessment were analyzed using the MMRM and Bonferroni post hoc multiple comparison, with $HAMD_{17}$, HAMA, SDS, SAS, and AIS scores as the dependent variables, to reveal the relationship between the two groups and three periods.

As demonstrated in Table 4, a significant difference in the interaction between groups and periods (all $P<.001$) was observed in all scale scores. Post hoc analysis revealed significant reduction in all five scores during the postintervention and follow-up period in the cCBT + TAU group from baseline (all $P<.05$, adjusted by the Bonferroni method).

Discussion

Principal Results

This study tested the effectiveness of the cCBT program we developed in patients with COVID-19 who have mild to moderate depressive or anxiety symptoms, compared with the TAU condition. The results implicated that the cCBT intervention was beneficial, given significant between-group differences in depression ($HAMD_{17}$, SDS), anxiety (HAMA, SAS), and insomnia (AIS). Other notable between-group observations were no significant differences in the improvement of insomnia among females and those with middle school education.

Facing public health emergencies, people experiencing stress responses are likely to encounter mental health problems [39]. The pandemic has increased the risk of psychological disorders, especially in confirmed cases of COVID-19 [40]. A meta-analysis about the prevalence of mental health problems in patients with COVID-19 showed prevalence rates of depression at 15.97%, anxiety at 15.5%, PTSD at 21.94%, and insomnia at 23.87% [41]—all far higher than usual [42]. Another survey of early rehabilitation on patients with COVID-19 showed that 43.1% of them had flashback symptoms, 27.8% had voiding symptoms, 40.5% had increased alertness, 22.2% had anxiety, and 38.1% had depression [43]. It can be implied that the main mental health problems of patients with COVID-19 were depression, anxiety, and PTSD. Selective serotonin reuptake inhibitor antidepressants are the first-line drug treatment for depression, anxiety, and PTSD [44,45]. Nevertheless, in the conditions of the pandemic, medication for COVID-19–prompted trauma responses is not the best option because it takes effect slowly. Moreover, only an approximate 33% of the patients were clinically cured [46], and these demonstrated residual symptoms following acute treatment [47]. Further, a review indicated there is a great potential for drug-to-drug interactions between antiretroviral drugs and psychotropics, especially antidepressants and anxiolytics, which could hinder treatment efficacy or even produce life-threatening adverse drug reactions [48].

As such, nonpharmacological treatment is considered an effective and safe option without adverse effects. CBT is the first-line psychological treatment recommended by the guidelines of depression, anxiety, and PTSD (ie, Canadian Network for Mood and Anxiety Treatments and National Institute of Health and Care Excellence guideline [49,50]. Li et al [51] designed a randomized controlled trial to prove traditional CBT significantly decreased depression, anxiety, and stress symptoms in patients with COVID-19 [51]. However, administering CBT effectively using face-to-face techniques is very time-consuming and costly, and is unavailable to most patients in isolation [52].

In this study, the independently developed cCBT program for patients with COVID-19 was used as a systematic cognitive, mood, and behavior intervention. Through this program, selected patients were subjected to 7 interventions for a period of 1 week, and each intervention was divided into three steps. Step 1 was designed to help patients acquire knowledge of novel coronavirus pneumonia, recognize their own stress statuses, learn the methods of adjusting negative emotions, educate themselves about postisolation, and practice behavioral relaxation training. Step 2 was designed using several games to reinforce the knowledge acquired from Step 1. Step 3 was designed to guide the patients in relaxation techniques.

The cCBT program we developed was used in five hospitals in China that isolated patients with COVID-19 during the outbreak. A total of 252 patients with COVID-19 were collected in this study and randomly divided into a cCBT + TAU group (n=126) and a TAU group (n=126); 51 patients in the cCBT + TAU group and 50 patients in the TAU group finished the follow-up assessment in one of the centers. We observed that the symptoms of depression, anxiety, and insomnia were relieved significantly in the patients who underwent the cCBT program. The results were consistent with other short-term studies about online or digital CBT treatment of mental health problems among patients with COVID-19 in the pandemic [53,54]. In the 1-month follow-up, the results of our study still showed a significant improvement of the efficacy in the cCBT + TAU group, which was in accordance with previous research on cCBT relieving depression, anxiety, and insomnia symptoms in the short-term follow-up [55,56]. However, some studies revealed that the efficacy of cCBT was no different from the control group after a long-term follow-up [57,58]. Mental status was influenced by various factors such as environment, social and family support, and psychological adjustment. Therefore, long-term follow-up needs to be further explored.

We subsequently explored subgroup analyses examining the influence of gender, age, and education level on treatment response. Compared to the TAU group, insomnia symptoms were not improved significantly in female patients and those with middle school education treated by cCBT. Previous studies indicated that females were a high-risk population for insomnia [59]. A meta-analysis revealed the prevalence of insomnia in females was higher than that in males [60]; also, females were the predicted risk factor of insomnia during the COVID-19 pandemic [61,62]. Our results supported previous studies. Zhang et al [63] investigated the relationship between insomnia and education levels in Chinese females, and they found there was a negative correlation between them. Another research study obtained the opposite result, which reported that higher education levels were associated with sleep disorders [62]. Notably, an investigation that focused on patients with COVID-19 who were treated in the Fangcang shelter hospital in Wuhan, China found that lower education levels were more likely to prompt depression, anxiety, and stress but had no impact on insomnia [64]. There are great differences in the results of previous research studies; the correlation between education levels and insomnia remains unclear, and our study provided a little evidence of that.

Advantages and Limitations

This study has several strengths. First, the cCBT program we independently developed is focused on patients with COVID-19 and is more suitable for the psychological adjustment of the patients than an ordinary cCBT program. Second, the use of a strict inclusion and exclusion standard ensured the homogeneity

XSL•FO
RenderX

of participants. We controlled patient inclusivity through scores on $HAMD_{17}$≥7 and <24 or HAMA≥7 and <21 to ensure that all patients had mild to moderate depressive and anxiety symptoms. The study involved five different hospitals from China to make the results representative. Finally, the patients were randomized to the cCBT + TAU group or the TAU group with a 1:1 ratio to balance confounding factors.

Inevitably, our trial has some limitations. First, participants in our trials were nonblinded, while the study looks at a multiplicity of outcomes, thereby increasing the risk for a type I error. We designed the trial initially to have patients and the evaluators blinded; however, to reduce the risk of infection, only a few doctors were permitted to enter the isolated ward. Such a situation impeded the use of blind methods in this study. Second, the sample sizes were relatively small, and the time before the follow-up was relatively short. In the future, we will continue to develop the cCBT program for a broader range of scenarios such as alleviating preoperative anxiety and depression in patients. Bigger sample sizes and a longer follow-up will be adopted to identify the long-term influence of cCBT, and the influencing factors of cCBT's efficacy will be analyzed in more detail. Additionally, we did not account for more confounding factors such as drug side effects and related adversity, which may be also highly relevant to the symptoms of depression and anxiety.

Conclusions

In sum, this was a prospective, multicenter, two-arm, parallel-group, and randomized controlled trial to identify the efficacy of a short-term cCBT program for treating symptoms of depression, anxiety, and insomnia among patients with COVID-19. The results suggested that the cCBT was significantly effective in relieving symptoms of depression, anxiety, and insomnia in patients with COVID-19 post intervention or after a 1-month follow-up. However, the insomnia symptoms in females and those with middle school education were more difficult to improve. Further research is needed to expand the sample size and to investigate the long-term effects of cCBT for symptoms of depression, anxiety, and insomnia.

Acknowledgments

We wish to express our thanks to all the patients for their participation. This study was supported by the National Natural Science Foundation of China (81601193), the Key Research and Development Project (International Cooperation) of Shanxi Province (201903D421059), the Transformation and Cultivation Project of Scientific and Technological Achievements of Universities in Shanxi Province ([2020]3), the Shanxi Province Science Foundation for Youths (2015021204), the Research Project Supported by Shanxi Scholarship Council of China (2015-100), and the First Hospital of Shanxi Medical University Foundation for Youths' Innovation (YC1409).

Authors' Contributions

ZL and Yong Xu contributed to the conception and design of the study. XL and DW administered the surveys. YY designed the program. XN, ST, YD, YJ, YW, and JZ collected the data. DQ and WZ analyzed the study data. DQ and Yifan Xu wrote the initial version of the manuscript. All authors contributed to the manuscript revision and both read and approved the submitted version.

Abstract

Background: The rapid outbreak of COVID-19 around the world has adversely affected the mental health of the public. The prevalence of anxiety among the public has increased dramatically during the COVID-19 pandemic. However, there are few studies evaluating the effects of positive psychological responses and information-seeking behaviors on anxiety experienced among social media users during the COVID-19 pandemic.

Objective: This study evaluated the prevalence of anxiety and its associated factors among WeChat users in mainland China during the early stages of the COVID-19 pandemic.

Methods: From February 10 to February 24, 2020, a nationwide, web-based cross-sectional survey study was carried out using convenience sampling. Participants' levels of anxiety, positive psychological responses, and information-seeking behaviors were assessed. The survey was distributed among WeChat users via the WeChat smartphone platform. Chi-square tests and multivariable logistic regression analyses were performed to examine the factors associated with anxiety.

Results: This study found that the prevalence of anxiety (Generalized Anxiety Disorder 7-item [GAD-7] scale score ≥7) among WeChat users in China was 17.96% (446/2483) during the early stages of the COVID-19 pandemic. Results of multivariable logistic regression analysis showed that information-seeking behaviors such as cannot stop searching for information on COVID-19, being concerned about the COVID-19 pandemic, and spending more than 1 hour per day consuming information about the pandemic were found to be associated with increased levels of anxiety. Additionally, participants who chose social media and commercial media as the primary sources to obtain information about the COVID-19 pandemic were found more likely to report anxiety. Conversely, participants who were confident or rational about the COVID-19 pandemic were less likely to report anxiety.

Conclusions: This study found that positive psychological responses and information-seeking behaviors were closely associated with anxiety among WeChat users during the COVID-19 pandemic in China. It might be paramount to enhance mental well-being by helping people respond to the COVID-19 pandemic more rationally and positively in order to decrease symptoms of anxiety.

Introduction

In January 2020, the World Health Organization classified COVID-19 as a public health emergency of international concern [1,2]. COVID-19 spread rapidly to 208 countries and regions and became a global pandemic, resulting in more than 30 million cases of infection and over 950,000 deaths worldwide, as of September 18, 2020 [3,4]. The sudden outbreak of COVID-19 adversely impacted the daily life and mental health of the public, which demanded urgent solutions [5-12].

The COVID-19 pandemic generated a psychological crisis among the public as the prevalence of mental disorders, including anxiety and depression, increased [13-18]. Various sources of information, including official media channels, social media, and the local government or community, could significantly affect the public's psychological responses to emergency events and their mental well-being. Recent research has found that excessive information-seeking behaviors have been closely related with mental disorders, including anxiety and depression, during the COVID-19 pandemic [19,20]. Individuals with anxiety tend to focus on negative information and correspondingly experience negative psychological responses [21]. The frequency and daily duration of social media use was higher in areas with a higher number of COVID-19 cases. High levels of social media consumption were associated with increased mental distress, especially among individuals with high levels of fear [22]. The metacognitive model illustrates that certain behaviors such as controlling behaviors, reassurance seeking, and checking behaviors are positively associated with anxiety [23-25]. Thus, excessive media consumption could lead to harmful psychological responses, which could increase anxiety among these individuals during the COVID-19 pandemic.

Positive psychological responses to the COVID-19 pandemic among the public play a crucial part in reducing anxiety. Positive thoughts and attitudes could help individuals cope with stressors [26]. A recent study found that hope can contribute to anxiety prevention [27]. The theory of rational emotive behavior therapy indicates that rational beliefs can alleviate symptoms of anxiety and other mental distress [28,29]. Additionally, cognitive behavioral models of health anxiety indicate that negative emotions and misinterpretations of health-related stimuli could increase the chances of developing anxiety [30-33]. Therefore, promoting positive psychological responses and initiating emotion regulation and positive perceptions of health-related information, such as keeping a positive attitude and being rational, are necessary for the public to be able to better cope with stress [34].

Researchers have studied the pathogenic and epidemiological characteristics, epidemiological trends, as well as the prevention and treatment of COVID-19 [35-43]. However, studies focused on the relationship between information-seeking behaviors and anxiety during the COVID-19 pandemic are sparse. Therefore, this study focused on the evaluation of the prevalence of anxiety and its association with positive psychological responses and information-seeking behaviors among users of WeChat—the most popular social media platform in Mainland China—during the COVID-19 pandemic.

Methods

Study Participants and Procedure

In order to examine the prevalence of anxiety among WeChat users during the COVID-19 pandemic, a cross-sectional study design using convenience sampling was employed via a web-based WeChat platform developed by the Department of Environmental Health of China Medical University in China. Due to the urgency of the COVID-19 pandemic and the necessity of timely acquisition, the questionnaire was first uploaded to this web-based WeChat platform. Next, the survey was distributed via all the open WeChat groups of the research assistants, to render the survey easily available to their close contacts. The survey was distributed between February 10 and February 24, 2020, during which we achieved a sample size that was adequate in accordance with previous related studies [44-47]. The questionnaire comprised the validated Chinese version of the Generalized Anxiety Disorder 7-item (GAD-7) scale, questions on positive psychological responses, and questions on information-seeking behaviors practiced during the early stage of the COVID-19 pandemic. The questionnaire took about 20 minutes to complete.

The inclusion criteria for participation in this study were as follows: at least 18 years of age, ability to read and write Chinese, ability to complete the web-based questionnaire by themselves using a smartphone, ability to offer electronic signed informed consent, and voluntary participation. The exclusion criteria were as follows: undergoing any therapy for psychological illness, history of any drug dependence, and diagnoses of any diseases or impairments that would prevent them from completing the questionnaire independently. The questionnaire had been preset for submission only after all the questions were answered within the range of the selected choices. Only data from complete questionnaires were analyzed.

Ethics Statement

This study was carried out in conformance with the Declaration of Helsinki (1989). The study protocols were approved by the Ethics Committee of China Medical University.

Demographic Characteristics of WeChat Users

The survey collected participants' demographic characteristics, including gender (male or female), age, marital status (married or other), occupation, education, and monthly income. Occupation was further classified into government worker, health care worker, professional staff (teacher, lawyer, journalist, etc), employee of enterprises, commercial personnel, soldier, student, and other. Education was further classified into junior college or below, bachelor's degree, and master's degree or above. Monthly income was categorized as follows: ≤¥5000 (≤US $725.19), ¥5001-10,000 (US $725.34-1450.39), and >¥10,000 (>US $1450.39).

Measurement of Anxiety

The validated Chinese version of the GAD-7, one of the most reliable tools to measure generalized anxiety disorder, was used

XSL•FO
RenderX

to assess anxiety among the study participants during the early stages of the COVID-19 pandemic [48]. Psychological problems related to anxiety were evaluated with a 4-point Likert-type scale, with options including "not at all sure=0", "several days=1", "over the half of the days=2" and "nearly every day=3," resulting in a total score ranging from 0 to 21. The cutoff score for anxiety was set at ≥7, based on the total GAD-7 score [49-51], with Cronbach α=.939 for GAD-7. The results of the factor analysis indicated that the seven items of the positive psychological responses tested were extracted as one component, which contributed to 73.518% of the variance (Kaiser-Meyer-Olkin [KMO]=0.935, *P*<.001]. The indicators of reliability and validity were good.

Measurement of Positive Psychological Responses

Positive psychological responses included "being confident," "being hopeful," and "being rational" in the past 2 weeks. They were measured by "yes" or "no" questions (Cronbach α=.788). The results of the factor analysis indicated that the three items of the positive psychological responses tested were extracted as one component, which contributed to 70.932% of the variance (KMO=.638, *P*<.001). The indicators of reliability and validity were good.

Measurement of Information-Seeking Behaviors

Information-seeking behaviors were assessed using three self-developed questions; these behaviors were assessed in the following four categories: (1) cannot stop searching for information about the COVID-19 pandemic, (2) being concerned about the COVID-19 pandemic, (3) time spent consuming information about the COVID-19 pandemic (ie, <1 h, 1-2 h, or ≥3 h), and (4) sources of information about the COVID-19 pandemic (social media and commercial media, central and local official media, basic-level government media, and community media). Responses to the item "cannot stop searching for information about the COVID-19 pandemic" included "agree," "not sure," and "disagree." Whether participants were concerned about the COVID-19 pandemic and their sources of information about the pandemic were assessed by "yes" or "no" questions.

Statistical Analyses

SPSS software (version 23.0; IBM Corp) was used to perform all statistical analyses. Chi-square tests were applied to assess bivariate associations with anxiety and the variables of interest. Anxiety was assessed using the binary variable (*anxiety* or *no anxiety*, as measured by the GAD-7 scale). Multivariable logistic regression analysis showed that the factors associated with anxiety were assessed while controlling for confounding variables. The variables included in the multivariable logistic regression analysis included age as a continuous variable and other variables as categorized variables. The responses were not included in the analysis when more than 95% of individuals had the same response to the categorical independent variables. Findings were considered statistically significant when a two-tailed *P* value was <.05.

Results

Demographic Characteristics and Prevalence of Anxiety Among WeChat Users

In this study, we observed that 446 of 2483 (17.96%) Chinese WeChat users who participated in our survey experienced anxiety. A total of 2501 adults participated in this survey and 2483 of them provided complete and logical answers, resulting in a valid response rate of 99.28%. The demographic characteristics of the participants and results from the bivariate analysis of anxiety are presented in Table 1. The mean age of participants was 34 (SD 12.82) years. Of the 2483 participants, 1550 (62.42%) were female, and 278 (17.94%) of them reported having experienced anxiety. About half of the participants (1239/2483, 49.90%) were married. Their occupations were classified into three groups according to their distribution and frequency: (1) government worker, health care worker, teacher, lawyer, or journalist (515/2483, 20.74%); (2) student (954/2483, 38.42%); and (3) other, including employee of enterprises, commercial personnel, or soldier (1014/2483, 40.84%). More than half of the participants had a bachelor's degree (1394/2483, 56.14%), and many had a master's degree or above (800/2483, 32.22%). The remaining 11.64% (289/2483) participants whose educational level was "some college or below" showed significantly higher prevalence of anxiety (61/289, 21.11%) than the other two groups. With regard to the distribution of monthly income, 40.03% (994/2483) of the participants earned ≤¥5000 (≤US $725.19), 35.60% (884/2483) earned ¥5001-10,000 (US $725.34-1450.39), and 24.37% (605/2483) earned >¥10,000 (>US $1450.39).

Positive Psychological Responses

The prevalence of anxiety according to the participants' positive psychological responses are presented in Table 1. We observed that the prevalence rate of anxiety was lower for the participants who felt confident (2339/2483, 94.20%), hopeful (2358/2483, 95.01%), or rational (2281/2483, 91.87%) about the COVID-19 pandemic (*P*<.001).

Information-Seeking Behaviors

The distribution and prevalence of anxiety with different information-seeking behaviors during the COVID-19 pandemic is shown in Table 1. In this study, participants who could not stop searching for information about the COVID-19 pandemic (1474/2483, 59.34%) or those who were concerned about the pandemic (1223/2483, 49.24%) were found to have a significantly higher prevalence of anxiety (*P*<.001) than other participants. The prevalence of anxiety was also observed to be higher for participants who spent more than 1 hour a day on searching for information about the COVID-19 pandemic (*P*<.001).

Our study findings also showed that participants who sought information about COVID-19 via social media and commercial media (2159/2483, 86.95%) had a higher prevalence of anxiety (408/2159, 18.90%) than those who did not seek information through social and commercial media (*P*=.001).

Factors Associated With Anxiety

Table 2 shows the final results of the multivariable logistic regression analysis. Participants who were confident (odds ratio [OR] 0.434, 95% CI 0.243-0.775) or rational (OR 0.286, 95% CI 0.202-0.405) about the COVID-19 pandemic were found to be less likely to experience anxiety. In contrast, the information-seeking behaviors among the study participants, including cannot stop searching for information on COVID-19 (OR 1.593, 95% CI 1.236-2.052) and being concerned about the COVID-19 pandemic (OR 1.389, 95% CI 1.080-1.788) were found to be associated with anxiety. Moreover, participants spending more than 1 hour a day consuming information about the COVID-19 pandemic were also found to be more likely to report anxiety (1-2 h: OR 1.622, 95% CI 1.209-2.176; ≥3 h: OR 3.915, 95% CI 2.823-5.430). Additionally, participants who chose social media and commercial media as the primary source of information about the COVID-19 pandemic were observed to be more likely to report anxiety (OR 1.531, 95% CI 1.043-2.246).

Thus, the final model of multivariable logistic regression and forest plot (Figure 1) indicated that the following factors were associated with anxiety: cannot stop searching for information about the COVID-19 pandemic, being concerned about the COVID-19 pandemic, spending more than 1 hour a day consuming information about the COVID-19 pandemic, and use of social media and commercial media as the primary source of information about the COVID-19 pandemic. Conversely, being confident and being rational were independently found to be inversely associated with anxiety.

Discussion

Principal Findings

We observed that 17.96% of WeChat users in China who participated in this study reported having experienced anxiety during the early stages of the COVID-19 pandemic. This exceeds the prevalence of anxiety reported among the people in China before the pandemic (3.2%-8.1%) [52,53]. However, comparing the prevalence of anxiety during the severe acute respiratory syndrome (SARS) outbreak in 2002 (24.4%-35.0%), the prevalence of anxiety during the COVID-19 pandemic was slightly lower [54,55]. There remains a dearth of research on the relationship between information-seeking behaviors and anxiety during public health emergencies [56-58]. It is of vital importance to provide advice on how to cope with anxiety, including how to enhance positive psychological resources and prevent excessive information-seeking behaviors in order to prevent or reduce anxiety during public health emergencies. Our findings provide evidence-based recommendations on the promotion of positive psychological responses, psychological interventions, and information management to reduce anxiety for WeChat users in China.

Our study findings showed that anxiety was closely associated with positive psychological responses. Among the positive psychological responses, being confident and being rational were observed to be associated with lower prevalence of anxiety, which suggests that being confident and rational might prompt individuals to cope better with adverse events and difficult challenges during public health emergencies. Being rational also has been found to influence anxiety in previous studies, wherein people who were more positive coped better with life stressors and had low levels of anxiety [59,60]. WeChat users in this study had been exposed to a variety of stressors such as the perception of severe health risks of COVID-19, negative emotions associated with home quarantine, financial hardships caused by delays in work, and uncertainty during the pandemic, which might have resulted in reduced positive psychological responses and higher prevalence of anxiety. The framework of intolerance of uncertainty states that intolerance of uncertainty and cognitive avoidance are positively correlated with psychological responses and anxiety [23,61,62].

People could cope with stressors better and improve their mental health by means of rational-emotive behavioral interventions and cognitive behavioral therapies to reduce anxiety and improve psychological abilities, including emotion regulation and stress management [28,29,63,64]. The emotion dysregulation model of anxiety suggests that the lack of emotion regulation has a positive correlation with anxiety [65,66]. Therefore, to intensify protective effects of positive psychological responses, psychological interventions for the

XSL•FO
RenderX

public might be an effective approach, and these should be provided as soon as possible during public health emergencies.

This study also found that excessive consumption of information about COVID-19 might be closely linked with anxiety. Consuming information about the pandemic for more than 1 hour a day was observed to be associated with anxiety. Our results are consistent with other studies showing that anxiety is associated with increased use of smart phones, leading to excessive exposure to COVID-19 news [19,22,67,68]. The frequency and duration of searching for health information could exacerbate stress, anxiety, and perception of health risks [69-72]. WeChat users in this study might actively search or passively receive health information about the COVID-19 pandemic via multiple media sources. Searching for health information can be regarded as a source of anxiety and negative psychological responses. Spending too much time searching for health information could be linked to increased levels of anxiety, anger, or sadness. This might be due to increased fear of being infected by a severe disease and could adversely impact people's self-esteem and reduce their tolerance of uncertainty [73-81]. Conversely, it is also possible that anxious people are more likely to overconsume information. Health professionals should provide timely suggestions for the public on how to access and absorb health information from trusted sources [77,82,83].

Moreover, sources of information about COVID-19 were found to be significantly associated with anxiety, especially information obtained via social media was observed to have a positive correlation with anxiety. Excessively searching for health information on social media during traumatic events (eg, public health emergencies, food safety incidents, terror attacks, and natural disasters) can result in sleep disorders, distress such as anxiety and depression, and posttraumatic stress disorder [84-89]. Social media provides open platforms for the public to exchange their ideas and perspectives in a timely and prompt manner. However, it might be difficult for the public to distinguish true information from false information. Through improved dissemination of health information, coping strategies and healthy behaviors in the context of the COVID-19 pandemic could be encouraged, in addition to focusing on the prevention of negative psychological responses and improvement on positive psychological responses [90].

Limitations

Several limitations should be acknowledged. First, the data were collected using a self-administered web-based questionnaire via smartphones, which may have resulted in information bias and misclassification bias. It is possible that participants did not provide accurate information in the study in order to either be included in the study or to move quickly through the survey. To minimize the bias as much as possible, a pilot study was conducted to acquire participants' perception of the questionnaire. Therefore, the collected questionnaire had been filtered with data cleaning, checking for consistency and logicality of the answers, adjusting invalid and missing values. Due to the severity of the COVID-19 pandemic and the necessity of timely acquisition of data, the survey was distributed via WeChat rather than conducted using a face-to-face approach. Additionally, this survey among WeChat users used a convenience sampling method during the first 2 months of the COVID-19 pandemic. Therefore, generalizability of the results may be limited to the whole population of China. As the survey was shared within academic WeChat groups, it is possible the results reported in our study are from a population that has a higher education level than the general population, and this may have affected anxiety levels either positively or negatively, because the participants likely had a stronger understanding of the pandemic. Future studies should be carried out with random sampling. Finally, the results may be limited by residual confounding from unmeasured confounders such as regional economic disparity, allocation of health resources, and an individual's social status. To minimize the potential errors induced by unmeasured confounders, the survey was conducted across 3 municipalities and 22 provinces via WeChat, one of the most popular social platforms in China.

Conclusions

The COVID-19 pandemic has adversely affected the mental health of the public and resulted in a high prevalence of anxiety among them, especially during the early stages of the pandemic. Certain behaviors such as cannot stop searching for information on COVID-19, being concerned about the COVID-19 pandemic, spending more than 1 hour a day consuming information about the COVID-19 pandemic, and using social media and commercial media as the primary source of information about the COVID-19 pandemic were found to be associated with anxiety. In contrast, positive psychological responses such as being confident and being rational were found to be negatively correlated with anxiety. Prompt measures and guidance from public health authorities on choosing reliable and trusted sources of information might decrease the negative effects of overconsumption of COVID-19–related information and improve the overall mental health of the public.

Acknowledgments

This survey was conducted using a web-based WeChat platform developed by the Department of Environmental Health, China Medical University, which was approved by the Public Behavior Research Project of Prevention and Control of COVID-19, China Medical University (grant number: 121-1210120025). The researchers also appreciate all of the study participants for their time to complete the survey.

Authors' Contributions

Abstract

Although the SARS-CoV-2 virus has already undergone several mutations, the impact of these mutations on its infectivity and virulence remains controversial. In this viewpoint, we present arguments suggesting that SARS-CoV-2 mutants responsible for the second wave have less virulence but much higher infectivity. This suggestion is based on the results of the forecasting and mechanistic models developed by our study group. In particular, in May 2020, the analysis of our mechanistic model predicted that the easing of lockdown measures will lead to a dramatic second wave of the COVID-19 outbreak. However, after the lockdown was lifted in many European countries, the resulting number of reported infected cases and especially the number of deaths remained low for approximately two months. This raised the false hope that a substantial second wave will be avoided and that the COVID-19 epidemic in these European countries was nearing an end. Unfortunately, since the first week of August 2020, the number of reported infected cases increased dramatically. Furthermore, this was accompanied by an increasingly large number of deaths. The rate of reported infected cases in the second wave was much higher than that in the first wave, whereas the rate of deaths was lower. This trend is consistent with higher infectivity and lower virulence. Even if the mutated form of SARS-CoV-2 is less virulent, the very high number of reported infected cases implies that a large number of people will perish.

mathematical modelling of epidemics; COVID-19; SARS CoV-2; pandemic; lockdown in Europe

Introduction

The novel coronavirus SARS-CoV-2 has already undergone several mutations. A study claimed that a specific mutation had created a more “aggressive” form of the virus [1]. However, it was later argued that, during epidemics in general, a virus spreads to new areas and creates new localized epidemics that grow exponentially [2]. This finding implies that a mutated virus spreading in these new uninfected areas will rapidly increase its mutation frequency; this will occur even if the mutation is neutral or detrimental to the virus itself. This study also showed that the observations reported by Tang et al [1] could be explained by the abovementioned process and that there was *no* evidence for the emergence of a more aggressive form of the virus [2]. Another study analyzed a set of mutations in the spike protein of SARS-CoV-2 and concluded that a specific mutation had enhanced the capacity of the virus to spread from China to Europe, North America, and Australia [3]. These authors concluded that this was the result of the fact that this mutation had made the virus more “transmissible,” allowing it to outcompete other virus strains that did not possess this mutation. However, this conclusion was challenged by several scientists. In particular, a more formal analysis of the effect of this mutation by another research team suggested that it actually has reduced transmissibility [4]. It has now been firmly established that the second wave was caused by a new mutated form of SARS-CoV-2, called D614G—the name refers to the substitution of the amino acid aspartic acid (D) by glycine (G) in a region of the viral genome that encodes the relevant spike protein. In particular, a study conducted in Houston, Texas, United States, found that D614G is the fully dominant form of the second wave of the COVID-19 pandemic, exhibiting a

XSL•FO
RenderX

prevalence of 99.9% [5]. The study also found that people infected with the new SARS-CoV-2 strain had higher loads of the virus in their upper respiratory tracts, which suggests that the D614G strain may be more infectious; however, no definitive conclusion regarding its infectivity has been reached. The high prevalence of the new strain was also established in a study in the United Kingdom involving the analysis of 25,000 whole-genome SARS-CoV-2 sequences [6], but no conclusions were reached regarding its infectivity or virulence. Therefore, the crucial question of establishing whether the new strain D614G was indeed more infectious and/or less virulent remained open [7].

In the framework introduced by Holmdahl and Buckee [8], epidemiological models are broadly divided into two categories: *forecasting* and *mechanistic*. The former models fit a specific curve to the data and then attempt to predict the dynamics of the quantity under consideration. The main limitation of these models is that they remain valid only if the epidemiological situation remains unchanged. For example, they can be used during a lockdown period but will not make accurate predictions after the lockdown is lifted. In contrast to forecasting models, mechanistic models can make predictions even when the relevant circumstances change. Their main limitation is the difficulty of determining the parameters specifying such models.

Our group has developed both forecasting and mechanistic models. In this paper, we present the implications of our models to argue that the mutated virus D614G was more infectious but less virulent.

The Prediction of the Effect of Easing Lockdown Measures by Using a Mechanistic Type Model

The generic weakness of mechanistic models, namely the difficulty in determining the parameters of the given model, was partially bypassed in a previous study [9]. Indeed, this study showed that the death data *uniquely* determine the parameters specifying a given ordinary differential equation characterizing the number of deaths. Furthermore, a robust numerical algorithm was presented for obtaining these parameters. The abovementioned equation was obtained from the manipulation of a susceptible-exposed-infected-recovered (SEIR) type model. Using this methodology, predictions were made about the dynamics of the COVID-19 epidemics in Greece, Andalusia, and Portugal, following the easing of lockdown measures. One of the above parameters obtained from the death data during the lockdown period corresponds to the number of contacts of the asymptomatic individuals. By changing this parameter (doubling, tripling, etc), while keeping all other parameters unchanged, the effect of relaxing the lockdown measures could be *quantified*: if the contacts of the asymptomatic people double, nothing much happens; but if they triple, then the situation dramatically deteriorates. The numbers of reported infected cases during the second wave was within the range of our prediction made in May 2020; fortunately, the number of deaths reported was lower, suggesting less virulence.

Cumulative Number of Deaths and Cumulative Number of Reported Infected Cases

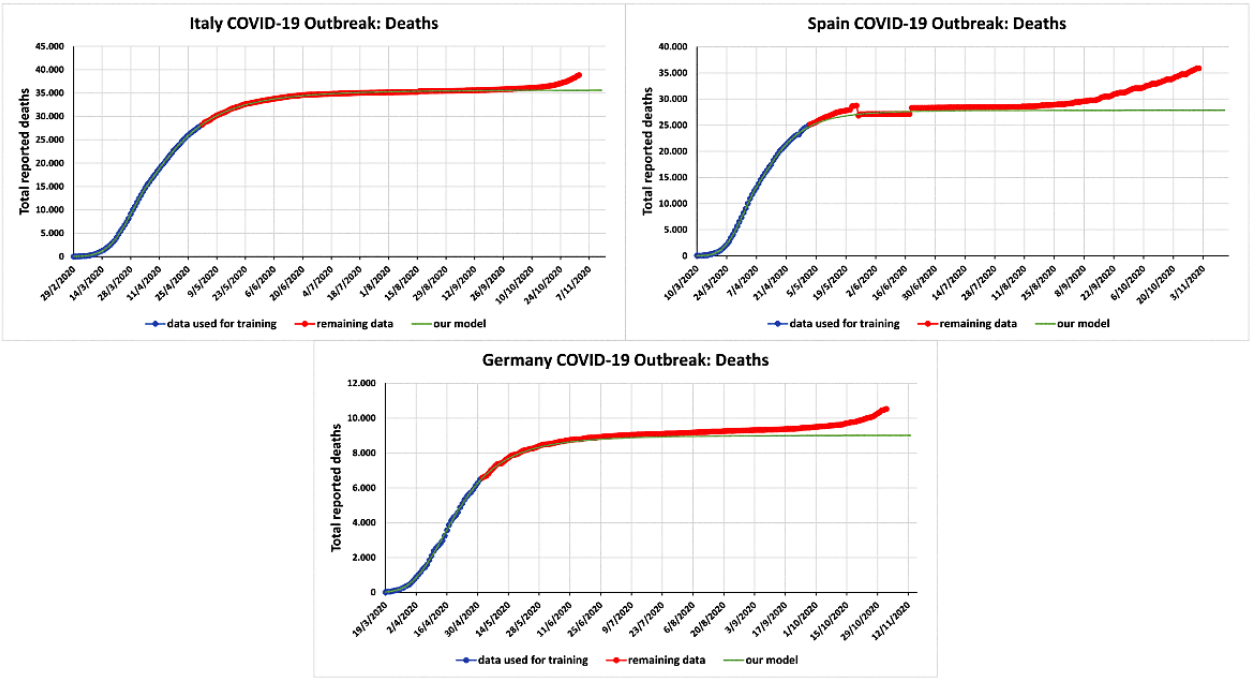
It is correctly noted in a previous study [10] that the forecasting models are "not well suited for long-term predictions." However, we have introduced a forecasting model that *can* provide *highly accurate long-term predictions* both for the number of deaths caused by COVID-19 and the number of reported infected cases. Our success was based on replacing the usual logistic formula used in epidemiology by slightly more general formulas, namely, what we have called rational and birational formulas. Interestingly, these formulas are, in a sense, optimal, since elaborate "deep learning" algorithms could *not* improve the predictions obtained by using these formulas [11].

By training a formula to use data for the accumulative number of deaths in a given country until May 1, 2020, we were able to make predictions that were valid well beyond the end of the first wave, namely, for a period of more than 3.5 months. As shown in Figure 1, in Italy, there was no deviation between the curve depicting the number of deaths and the curve of our predictions, whereas in Germany, a small deviation began to occur in the second week of August 2020. In Spain, a larger deviation began to occur in the first week of August 2020 [12]. Our predictions for the number of reported infected cases were equally accurate [11].

These graphs show that following the easing of the first lockdown, the number of deaths did not increase in several European countries for approximately two months. Figure 1 presents three graphs depicting the total number of deaths caused by the COVID-19 epidemics in Italy, Spain, and Germany. These graphs compare the red curves indicating *real data* from the period of May 2 to November 2, 2020, with the green curves indicating the *predictions* made with an explicit mathematical formula introduced previously [11]. This formula contains 4 explicit constants that were determined by using data up to May 1, 2020. The green curves depicting this formula are indistinguishable from the red curves depicting the real data until mid-August 2020, despite the fact that the lockdown was lifted in the above countries by mid-June 2020.

XSL•FO
RenderX

Figure 1. Actual versus predicted cumulative number of reported deaths due to COVID-19 for Italy, Spain, and Germany. The constants of our mathematical model were determined using data up to May 1, 2020, which are depicted in light blue. The red curves correspond to the actual data up to November 2, 2020, which are the data during the period of our predictions. Our predictions are depicted in green.



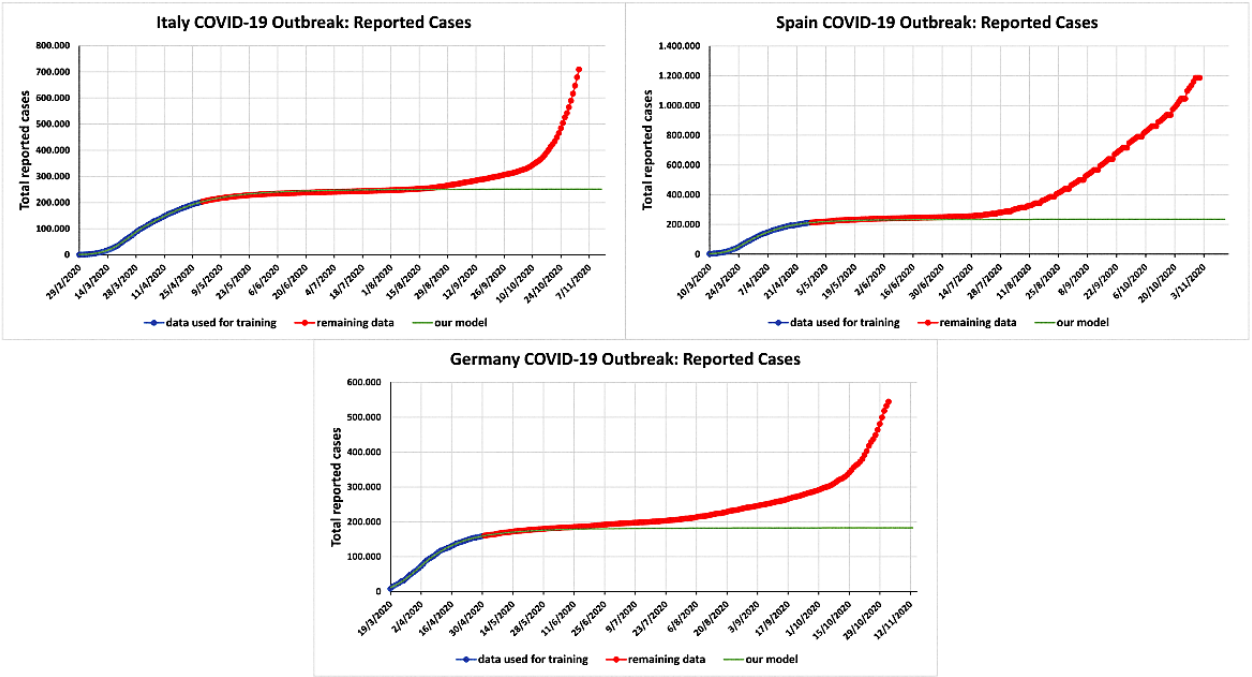


Figure 2 presents analogous curves for the number of reported infected cases. Comparing the red curves depicting the real data with the green curves depicting our predictions, it follows that until August-end for Italy, mid-July for Spain, and June-end for Germany, in 2020, the effect of the elimination of several restrictive measures had only a slight effect on the numbers of reported infected cases (compared with the numbers that would have occurred during the lockdown).

Figure 2. Actual versus predicted cumulative numbers of reported infected individuals with COVID-19 in Italy, Spain, and Germany. The prediction fits were obtained using data up to April 29, 2020, for Italy; April 27, 2020, for Spain; and April 30, 2020, for Germany. The relevant constants were determined with the data shown in light blue. The red curves correspond to the actual data up to November 2, 2020, which are the data during the period of our predictions. Our predictions are depicted in green.

Estimates for the Number of Reported Infected Cases and Deaths in Israel

We have applied our formulas to the cumulative number of deaths and reported infected cases for the third wave of COVID-19 in Israel. For the number of deaths, the rational formula predicted a plateau on April 8, 2021, with 3234 deaths and a total of 6060 deaths overall. The plateau is defined *as the point at whichthe rate of deaths for the given wave is 5% of the maximum rate.* For the number of reported infected cases in Israel, the rational formula predicted a plateau on April 16, 2021, with 497,992 cases for the third wave and a total of 825,399 cases overall. In Israel, the rate of infections of the third wave reached a maximum on January 20, 2021.

Higher Infectivity and Less Virulence

The predictions reported previously [13] were based on the assumption that *the characteristics of the virus remained unchanged.* The initial period following the easing of lockdown measures, when the number of deaths in the abovementioned countries did *not* increase and the number of reported infected cases was small, provided hope that the virulence and infectivity of the mutated form of the virus was much lower. However, the subsequent increase in the number of confirmed cases and deaths suggests an alternative explanation: the results reported previously [13] showed that if the easing of the restrictive measures leads up to doubling of the contacts of asymptomatic persons, the situation still remains essentially the same as it was during the lockdown period. Moreover, apparently, immediately after the lockdown period, the population at large continued to observe social distancing and other protective measures. Unfortunately, following this period of high vigilance, the population, especially younger individuals, thought that the danger was over and began enjoying the summer without observing the necessary protective measures.

A possible explanation for the observation that the number of deaths in the second wave was lower than the number expected given the very high number of infected individuals includes a number of factors. First, better medical practices and treatment are available. Second, older individuals and those with comorbidities are careful and avoid social contact. Indeed, the SARS-CoV-2 infection in younger individuals rarely leads to death. By extending the algorithm developed [13] into two subpopulations consisting of younger (below 40 years) and older (above 40 years) individuals, a previous study [9] on the epidemic in Greece found that if the number of contacts between asymptomatic “younger” persons increases, the number of reported infected cases increases but the number of deaths does not. In contrast, an increase in the number of contacts involving “older” persons leads to a dramatic increase in the number of deaths. Third and most importantly, it is possible that the mutated virus D614G was less virulent.

By directly computing the rate of change in the number of deaths in the second wave by using real data, it becomes clear that this rate is lower than the rate in the first wave, thereby supporting the suggestion that the mutated virus is less virulent. However, analogous computations for the rate of the change of the number of reported infected shows that this rate is much higher for the second wave, suggesting a much higher infectivity.

Concluding, it is worth noting that the period immediately following the easing of lockdown measures provides a very useful lesson. By using the well-publicized measures of social distancing, environmental hygiene, hand washing, and appropriate use of masks, it is possible to control the COVID-19 epidemic without imposing a strict lockdown.

Abstract

Background: Due to widespread SARS-CoV-2 infection, an emergency homeschooling plan was rigorously implemented throughout China.

Objective: This study aimed to investigate the experiences and attitudes of elementary school students and their parents (two generations from the same family) toward online learning in China during the pandemic.

Methods: A 16-item questionnaire was distributed at the 10-day and 40-day marks after the start of the first online course to 867 parent-child pairs and 141 parent-child pairs, respectively. The questionnaire was comprised of questions pertaining to course and homework completeness, effectiveness, reliability, and abundance as well as the students' enthusiasm for taking part in online classes and their satisfaction with the courses.

Results: Our findings indicate that 90.7% (786/867) of students exhibited high or moderate enthusiasm for participating in online classes. However, most students performed poorly in online learning classes and after-school homework. With regard to satisfaction, parents' and students' average scores were 7.35 and 7.25, respectively (10-point scoring system). During the second stage of this study, parents' positive evaluations for online learning declined, including those for the effectiveness and reliability of the courses. Furthermore, the proportion of students who completed the courses and homework on time decreased; this difference proved statistically significant (P=.047). The parents' and students' overall satisfaction with online learning also declined during the second stage (parents: 7.21; students: 7.23); however, the difference in overall satisfaction between the two stages was not statistically significant (parents: P=.53; students: P=.60). Several of the parents (315/867, 36.2%) indicated that assisting with and supervising the students' online learning resulted in increased stress. Further, 36% of parents expressed dissatisfaction with or provided suggestions for online learning; most parents and students hoped to return to face-to-face classes (parents: 823/867, 94.9%; students: 811/867, 93.5%). Finally, our results presented the following six main issues that parents were the most concerned about: (1) disappointment regarding timely interaction in courses; (2) apprehensiveness about students' understanding of the course; (3) the increased burden of annoying adult responsibilities; (4) concern about children's eyesight; (5) the idea that teachers' explanations were not detailed enough; and (6) concerns about the decline of students' interest in and attention toward online courses.

XSL•FO
RenderX

Conclusions: Online learning can prevent the spread of infectious diseases while still allowing elementary school students to attain knowledge. However, in our study, children's completion of the courses and homework were not satisfactory. Furthermore, their parents often experienced stress and had many concerns and complaints. Measures such as increasing the interactivity of the courses and prohibiting teachers from assigning tasks to parents could improve the effectiveness of these courses and the mental health of parents and students.

KEYWORDS

attitude; elementary school students; parents; online learning; COVID-19

Introduction

Due to widespread SARS-CoV-2 infection, the Chinese government postponed the opening of schools after the Spring Festival to prevent further infections [1]. Face-to-face socializing was also prohibited. China's Ministry of Education estimated that more than 270 million students were confined to their homes, including 17.67 million elementary school students [2].

The Ministry of Education stipulated that even though schools were closed, teaching must continue during the lockdown period [3]. Accordingly, online teaching has been rigorously implemented in China [4]. Since mid-February 2020, schools and teachers of all levels have made considerable efforts toward creating and delivering online courses via internet-based methods or television broadcasts [5]. Consequently, this has resulted in the largest online learning campaign in human history.

Previous research has shown that online education has great potential for addressing the availability and efficiency of education [6,7]. However, by itself, online education is not more effective than a classroom-based approach, and its effectiveness depends on how well instructional designs are integrated into effective learning principles [8]. Differences in content quality, interactivity, and platform availability may affect learning satisfaction [9,10], but it is not clear which aspects are the most important for online education in primary schools in China. Previous studies on problems related to online learning have focused primarily on college students [11-14]. However, few studies have focused on elementary school students' experiences and satisfaction with online learning. Another limitation that has been mentioned in previous studies is that researchers only assess online learning satisfaction from students' perspectives. However, parents' opinions also influence students' satisfaction with learning and can inspire students to learn [10]. This is worrisome, as several factors (concentration, self-discipline, and related factors) can result in a host of problems during online education [15,16].

This study aimed to investigate the experiences and attitudes of Chinese elementary school students and their parents toward online learning during the COVID-19 pandemic. Furthermore, this study evaluated differences in parents' satisfaction with online education between the 10-day and 40-day marks after the start of the first online course.

Methods

Ethical Approval

The study protocol was approved by the Research Ethics Committee of Chaohu Hospital of Anhui Medical University (approval number: 202001-kyxm-07). The enrolled participants received detailed explanations about this study and signed electronic informed consent forms (parents' consent for students' participation). All participants' personal information was kept confidential, including their names and internet protocol addresses.

Survey Questionnaire

The survey questionnaire was designed to assess the online learning experiences and attitudes of Chinese elementary school students and their parents (Multimedia Appendix 1) based on the concerns of parents of elementary school students and previous questionnaires [17]. Each questionnaire was completed by 1 student and 1 parent. In order to prevent selection bias from affecting the study outcomes, each parent was selected at random and chosen by their family. The questionnaire consisted of 16 items and focused primarily on obtaining basic information, including children's grades and the equipment that was used during online classes. Thereafter, a broader selection of information was gathered, including participants' levels of enthusiasm for online learning, the completion of online classes, the completion of assigned homework, the pressure on parents, and related factors. Items 1-12 were answered by parents and items 13-15 were answered by elementary school students. Item 16 was an open comment that was directed at parents; it was designed to obtain their opinions on online learning. To measure satisfaction, we used a 10-point scoring system (ranged from 1 to 10 with intervals of 1); 1 represented the lowest degree of satisfaction, and 10 represented the highest degree of satisfaction. The questionnaire was written in Chinese and was not translated into any other language. Primary education in China is compulsory for all children who reach a certain age (6-7 years). Primary school students are usually between the ages of 6 and 13 and are in grades 1-6. With regard to our questionnaire, primary school students only had to answer three simple questions, which they understood and correctly answered.

We pretested the questionnaire with 5 parent-child pairs of primary school students (not part of the research team) and 7 psychologists. They pretested the questionnaire to determine the feasibility and understanding of the questions and words and to provide feedback. The content validity of the final version of the questionnaire was 0.86. The Cronbach α of the

XSL•FO
RenderX

questionnaire was .73, which was within the appropriate, acceptable Cronbach α range (.70-.95) [18,19]. On the basis of the Kendall sample size calculation method [20], the minimum sample size had to be 10 times the number of items in the questionnaire plus 20% of the number of invalid questionnaires. Therefore, since the scale was composed of 16 items, the minimum sample size of this study had to be 192. Our study obtained 1008 valid questionnaires and therefore met the sample size requirements.

Survey Protocol

The questionnaire was produced and distributed by the authors. The relevant data were subsequently collected with the web-based survey tool Questionnaire Star (Ranxing Information Technology Company, Limited), a professional, web-based survey evaluation platform [21]. Questionnaire Star can be used to design questionnaires, collect data, create custom reports, and analyze results. We sent a questionnaire link to potential participants via WeChat (TenCent Holdings Limited), which is the most widely used social media platform in China.

Eligible participants included any Chinese elementary school students who participated in online education during the COVID-19 pandemic and their parents. The questionnaire survey was conducted during two separate phases in this study. A 16-item questionnaire was distributed at the 10-day and 40-day mark after the first online course. In the first phase, the questionnaire was sent to 867 parent-child pairs (867 elementary students and their parents). In the second phase, the questionnaire was sent to 141 parent-child pairs.

Statistical Analysis

Participants' responses were proportionally expressed and recorded with a Likert scale that was divided into "good," "average," and "poor" responses or "yes" and "no" responses. Continuous variables (ie, satisfaction scores) were compared with the Student *t* test. Categorical variables were compared with either chi-square tests or Fisher exact tests. Data were analyzed using PASW (Predictive Analytics SoftWare) Statistics 20 (IBM Corporation). *P* values of <.05 were considered statistically significant.

Data Availability

All the data that support our findings are presented in the manuscript. The data sets used and analyzed during this study can be made available from the corresponding author upon reasonable request.

Results

Factors Affecting Students' and Parents' Perceptions of Online Learning

The total number of participants included 867 parent-child pairs (1 parent for each child)—867 elementary school children and 867 respective parents—during the first stage of this study. During the second stage (30 days after the first interview), only 141 parent-child pairs (1 parent for each child) were included in this study. The majority of students (304/867, 35.1%) were grade 4 students (Table 1).

With regard to the equipment used in online classes, lower-grade students were more likely to choose a television. However, grade 6 students' following equipment choices exhibited relatively similar ratios: mobile phone (8/31, 25.8%), tablet (7/31, 22.6%), PC (8/31, 25.8%), and television (8/31, 25.8%; Table 1).

Table 1 shows the enthusiasm of primary school students in grades 1-6 who participated in online learning courses. The results revealed that most students (24/31, 37.4%) had enthusiasm for engaging in online learning courses. Surprisingly, 22.6% (7/31) of grade 6 students were not enthusiastic about taking online learning courses. This was statistically significant when compared to the enthusiasm of students in other grades (*P*=.006; Table 1).

With regard to completeness, two subitems were developed and pertained to online learning courses and the accompanying homework. Surprisingly, many of the students did not do well in the online classes or the after-class homework (Table 1). Notably, the degree to which online classes were completed was higher in both grade 1 (23/46, 50%) and grade 6 (13/31, 41.9%) than those in other grades; the difference proved statistically significant (*P*=.047; Table 1). Grade 6 students completed the largest amount of homework, while nearly half of the overall students performed well (15/31, 48.4%) (Table 1).

In this study, we designed the following three subcategories of evaluation through which the parents of elementary school students could evaluate the quality of online courses: effectiveness, reliability, and abundance. The results show that the majority of elementary school students' parents indicated that the reliability (649/867, 74.9%), effectiveness (334/867, 38.5%), and abundance (564/867, 65.1%) of online courses were good. However, the parents' views were inconsistent among the different grades. As such, more than 10% of grades 1 and 6 students rated the effectiveness of online classes as poor (5/46, 10.9%; 5/31, 16.1%). Furthermore, 16.1% (5/31) of the parents of grade 6 elementary students believed that the abundance of online courses was insufficient.

Parents' Perceived Pressure From and Satisfaction With Online Learning

This study assessed the pressures that parents had to deal with during their children's online education. This study also measured parents' satisfaction with online learning during the COVID-19 outbreak (Table 2).

As indicated in Table 2, the parents of lower-grade students were under higher levels of pressure than parents of higher-grade students. The parents of grade 1 students (high pressure: 21/46, 45.7%) were generally the most stressed about their children's online lessons (Table 2).

With regard to satisfaction, most of the parents (675/867, 77.9%) were satisfied with the online learning courses; they scored above 6 points on the satisfaction scale (10-point scoring system; Table 2). In accordance with their parents, most of the students (641/867, 73.9%) were satisfied with their online learning courses; they also scored above 6 points on the satisfaction scale. Grade 6 students and their parents were the least satisfied with online learning, followed by grade 1 students and their parents. Interestingly, although the difference was not statistically significant (*P*=.053), grade 6 students reported higher satisfaction scores than their parents.

The results indicated that most of the parents (823/867, 94.9%) and students (811/867, 93.5%) hoped to return to face-to-face learning in their future studies (Table 2). Interestingly, 16.1% (5/31) of grade 6 students wanted to continue attending online classes in the future.

The Attitudes of Elementary School Students and Their Parents During the Follow-up

This study was divided into two stages. The first stage of the investigation commenced 10 days after the online course began, while the second stage started 40 days after the course began. There were no significant differences in the elementary students' and parents' equipment use (P=.35), enthusiasm (P=.73), stress (P=.96), or satisfaction (students: P=.60; parents: P=.53) between the two phases.

With regard to completeness, fewer students completed their courses (11/141, 7.8%) and after-class homework (11/141, 7.8%) during the second stage compared to those in the first stage (completed course: 238/867, 27.5%; completed homework: 228/867, 26.3%). This difference proved statistically significant (completed course: P<.001; completed homework: P<.001; Table 3). Furthermore, the parents indicated that the quality of the online courses in the second stage (effectiveness: 130/141, 92.2%; reliability: 133/141, 94.3%) was lower than that in the first stage (effectiveness: 807/867, 93.1%; reliability: 838/867, 96.7%). The difference in the number of participants who believed that courses were reliable proved statistically significant (P=.01; Table 3).

Parents' and students' satisfaction levels for the online courses decreased during the second stage (parents' satisfaction: mean 7.21, SD 2.41; students' satisfaction: mean 7.13, SD 2.45) when compared to those in the first stage's survey (parents' satisfaction: mean 7.35, SD 2.35; students' satisfaction: mean 7.25, SD 2.43); however, the difference between the two stages was not statistically significant (parents' satisfaction: P=.53; students' satisfaction: P=.60; Table 3).

Parents' Open Comments Concerning Elementary School Students' Online Education

In the open comments, participants (parents) indicated that online classes effectively used their time and network so that classes were not suspended during the COVID-19 pandemic. In terms of deficiency, parents mentioned the following six main issues: (1) disappointment regarding timely interaction in online courses; (2) worry about students not understanding the course; (3) the increased burden of annoying adult responsibilities; (4) concern regarding children's eyesight; (5) concern that teachers' explanations were not detailed enough; and (6) concern about the decline of students' interest and attention toward online courses. We summarize the details in Textbox 1.

Textbox 1. Summary of parents' open comments. In total, 73% (736/1008) of parents answered the open questions.

Top question

- In total, 18.7% (188/1008) of parents thought that the interactions during the classes were inadequate.
- These parents stated that because online educational videos were taped in advance, there was a lack of question-and-answer interactions between teachers and students.
- These parents suggested that measures should be taken to ensure that teachers are aware of children's questions so that they can respond to specific questions or correct children's mistakes.

Second highest ranked question

- In total, 15.2% (153/1008) of parents were concerned that children could not understand the content of online educational videos.

Third highest ranked question

- In total, 13.6% (137/1008) of parents complained that teachers' demands, including monitoring children's online studies, checking homework, and regularly providing feedback on students' learning, greatly increased their workload, stress, and annoyance.
- A few parents were poorly educated and could not check their children's homework.

Fourth highest ranked question

- In total, 12.4% (125/1008) of parents were worried that prolonged exposure to electronic screens would lead to reduced eyesight in their children.

Fifth highest ranked question

- In total, 12.1% (122/1008) of parents thought that the online class durations were too short and that the teachers' explanations were not detailed enough.
- Only 2 parents felt that the online class durations were too long.

Sixth highest ranked question

- In total, 3.7% (37/1008) of parents claimed that online teaching lacks a learning and competitive atmosphere and that student's initiative and enthusiasm were not high.

Discussion

Principal Findings

The COVID-19 pandemic has radically changed many aspects of our lives. Furthermore, social distancing and restrictive movement policies have markedly derailed traditional educational practices [22-24]. Consequently, there is a pressing need to innovate and implement alternative education and assessment strategies [25,26]. However, the COVID-19 pandemic has provided an opportunity for the greater implementation of digital learning in elementary education that requires students to stay at home [27]. The convenience and flexibility provided by online classes seem to contribute to these classes' proliferation and popularity [28].

Although previous studies have asserted that learners gain slightly less knowledge in online environments [29-31], our survey results (in the study's first phase) showed that 93.1%

XSL•FO
RenderX

(807/867) of parents believed that the online courses were effective and were able to convey knowledge. Conversely, a study from Ghana found that only 40 (18.7%) of their respondents agreed that they were able to learn effectively at home, while 174 (81.3%) respondents disagreed with that statement [32]. These differences may be related to the different preparation times, study content, and equipment in online courses among different countries. There is an abundance of content for online learning courses in China, as the educational content of online courses was prepared early after the onset of the pandemic. Furthermore, the courses were designed so that students could use a variety of devices to participate, including students from families that do not have internet connections; they can still access the courses through their televisions. These measures have considerably increased the effectiveness of online learning in China. However, it is worth noting that during the second survey stage, the proportion of respondents who thought that online courses were effective decreased. This may have been due to long online lessons, which make it difficult for children to concentrate, thereby reducing their productivity. The number of participants in the second stage only consisted of about one-quarter (141/867, 16.3%) of the participants in the first stage. The reason for this may have been that parents' enthusiasm for the web-based survey declined during the second stage.

Satisfaction is a vital factor for determining the quality of online learning [33-35], as it reflects students' pleasure and fulfillment with the different aspects of learning services [36]. This study indicated that most parents (675/867, 77.9%) were satisfied with the online learning courses; they scored above 6 points on the satisfaction scale. In accordance with their parents, most students (641/867, 73.9%) were satisfied with the online learning courses; they also scored above 6 points on the satisfaction scale. Parents' and students' satisfaction with the online courses decreased during the second stage; however, this did not prove to be statistically significant (parents' satisfaction: P=.53; students' satisfaction: P=.60).

Grade 6 students and their parents were found to be the least satisfied with online learning, followed by grade 1 students and their parents. These participants felt that the courses were ineffective and unreliable and that the content was not abundant. Therefore, for primary school students and parents, curriculum quality was closely related to satisfaction. It is important to consider that grade 6 learners are under pressure due to the junior high school entrance examinations. This is notable because online classes only teach basic knowledge and do not allow for the conduction of extracurricular classes to improve exam scores. Grade 1 students experience cognitive pressure because of their recent transition to primary school from their carefree kindergartens. Therefore, they are more likely to develop adjustment disorders, which result in poor evaluations of a curriculum's quality.

Other studies on satisfaction have indicated that there are certain factors that affect students' satisfaction with online learning environments, such as their interactions and self-regulation [37,38]. Parahoo et al [39] indicated that the interactions among students, teachers, and classmates are an important dimension of students' satisfaction with online learning. Kuo and colleagues [40] found that learner-instructor and learner-content interactions are significant positive predictors of students' satisfaction. Another study's findings support the idea that learner-instructor interactions contribute to students' satisfaction [41]. In our survey's open comment section, the most frequently reported issue was the lack of interaction during online learning. This may account for the drop in satisfaction during the second survey phase. Sun and Chen [42] noted that students' main difficulties during online learning were staying motivated, adhering to schedules, and studying regularly. Unlike the first stage of our study, only 7.8% (11/141) of students completed their courses and finished their homework on time after a 1-day online learning class. Due to the psychological characteristics of children, few elementary students are able to consistently complete their online lessons and maintain self-discipline [43].

An advantage of our study is that we were able to assess the causes of parental anxiety related to online lessons. The factor that most frequently hindered students' learning was a lack of interaction, as identified by parents' open comments. Online courses are taped in advance, so there was a lack of timely, two-way interactions between students and teachers. Our results indicated that students generally received information passively and lacked active communication during their online classes. Furthermore, students often did not understand certain questions. Consequently, students may lose interest in online classes over time. Another potential problem is that long online courses may result in students becoming addicted to their computers and televisions. Furthermore, prolonged exposure to computers, mobile phones, or televisions can cause vision loss in elementary school students [44].

Our results indicated that a lack of interactivity may be the most important factor affecting Chinese primary school students' satisfaction with online courses. The online lessons in this study were recorded in advance, and the videos were played to primary school students later, which resulted in the one-way flow of teaching information. This is worrisome because clear explanations and communication for clarifying questions are especially important for distance learners. In contrast, online education in high-income countries has exhibited some improvement and enhancement. They emphasized more on interactivity and student participation and considered this factor when planning online courses. For example, Hrastinski [45] provided the following theory in his research:

> *If we want to enhance online learning, it needs to enhance online learners' participation and interactive experience.*

Suppan and colleagues [9] used a highly interactive online learning module that was tailored to customers' timely feedback and prevented content skipping. Their results showed that their module could enhance medical students' asynchronous distance learning in terms of knowledge acquisition. Synchronous e-learning based on interactive live webcasting has also been verified to be effective and feasible [46]. These results are consistent with our conclusions.

The low homework completion rates and high pressure on parents found in our study suggest that online learning tasks may be beyond the capacity of students and parents and may

XSL•FO
RenderX

cause parent-child conflicts and emotional problems. Our data are consistent with those of another web-based survey in China, in which parents' Self-rating Anxiety Scale results showed that the degree of anxiety was higher than normal. Additionally, 17.6% of students were suspected of experiencing emotional problems during online homeschooling [47]. Another survey showed that 73.9% of primary and secondary school students' parents felt that their burden increased, and compared to these parents, the burden on parents of primary school students in grades 1-3 increased by a higher degree (79.3%) [48].

In this study, 13.6% (137/1008) of parents complained about having to supervise their children, check their homework, and frequently deliver feedback to the teachers. This considerably increased parents' workload, stress, and annoyance. Moreover, several parents were unable to help their children, as they were uneducated. According to a previous study, there has been an alarming increase in child abuse and domestic violence rates in Brazil during the pandemic. This may be related to families' financial constraints, increased parental burdens resulting from school closures, parental stress, and the difficulty of dealing with children's irritability during isolation [49]. In our survey's open comment section, a parent wrote that when he was supervising his child, the child was undisciplined in class and perfunctory in completing his homework. The parent became particularly irritable and violent and stated that he even beat the child. The reason for such conflicts may be that parents endlessly nag their children when they are supervising their children's studies and correcting homework. This often results in children feeling that their space for independence is greatly compressed, which gives rise to conflicts between parents and students [50].

In academic circles, it is generally believed that there are utilitarian education and teaching concepts in China. Teachers who believe that "practice makes perfect" require students to perform many exercises during and after class. Since online courses in primary schools are prerecorded and lack teacher-student interaction, teachers transfer their responsibility of correcting homework to parents, which increases conflict rates and stress. Our results thus offer a new strategy for solving parent-child conflicts and emotional problems during online homeschooling.

Limitations

There are several limitations to this study that need to be discussed. First, the sample size was not very large. In future studies, a larger sample size should be used to validate this paper's results. Second, this study did not compare elementary school students' tests scores from before and after online learning. Test scores can provide a more intuitive perspective on the effects of online learning. However, due to the regulations of the Ministry of Education, we were unable to obtain the scores of the elementary school students. Third, our scale does not provide demographic data, such as age, gender, or participants' household incomes. As such, it was impossible to compare the differences among participants' demographic data. This is problematic because elementary school students of different ages, genders, or income levels may have different experiences and attitudes toward online learning. Lastly, we did not investigate teachers' attitudes toward online learning. These issues need to be explored in future research.

Conclusion

To the best of our knowledge, this study is the first to evaluate experiences and attitudes toward online learning among participants of two generations in the same family during the COVID-19 pandemic. Online learning can prevent the spread of infectious diseases and allow elementary school students to gain knowledge. Most enrolled elementary school students (673/867, 77.6% at baseline; 112/141,79.4% at follow-up) were very enthusiastic about participating in online classes, and students and their parents were satisfied with these classes. Students were able to adequately complete all of their lessons and after-school homework assignments during the initial phase of online learning. However, as time progressed, the percentage of students who completed their lessons and homework on time decreased. At this later stage, students' and parents' satisfaction with online lessons decreased. However, some online learning tasks may be beyond the capabilities of elementary school students and parents and may cause emotional and behavioral problems. This study provides evidence for policy changes that aim to reduce the amount of pressure on parents and improve mental health levels, including those that prohibit teachers from assigning the task of checking homework to parents and increase the amount of interaction between teachers and students in online classes.

Acknowledgments

We thank all the participants and corresponding authors. This study was funded by grants from the National Natural Science Foundation of China (grant 81801341) and the Anhui Provincial Key R&D Programme (grant 202004j07020030).

Authors' Contributions

KZ conceived and designed this study. XZ and KZ provided administrative support. SC, CZ, SW, XZ, LZ, LW, QY, CH, and FC collected and assembled the data. CS and KZ analyzed and interpreted the data. All authors wrote the manuscript and approved of the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: To combat the global COVID-19 pandemic, contact tracing apps have been discussed as digital health solutions to track infection chains and provide appropriate information. However, observational studies point to low acceptance in most countries, and few studies have yet examined theory-based predictors of app use in the general population to guide health communication efforts.

Objective: This study utilizes established health behavior change and technology acceptance models to predict adoption intentions and frequency of current app use.

Methods: We conducted a cross-sectional online survey between May and July 2020 in a German convenience sample (N=349; mean age 35.62 years; n=226, 65.3% female). To inspect the incremental validity of model constructs as well as additional variables (privacy concerns, personalization), hierarchical regression models were applied, controlling for covariates.

Results: The theory of planned behavior and the unified theory of acceptance and use of technology predicted adoption intentions (R^2=56%-63%) and frequency of current app use (R^2=33%-37%). A combined model only marginally increased the predictive value by about 5%, but lower privacy concerns and higher threat appraisals (ie, anticipatory anxiety) significantly predicted app use when included as additional variables. Moreover, the impact of perceived usefulness was positive for adoption intentions but negative for frequency of current app use.

Conclusions: This study identified several theory-based predictors of contact tracing app use. However, few constructs, such as social norms, have a consistent positive effect across models and outcomes. Further research is required to replicate these observations, and to examine the interconnectedness of these constructs and their impact throughout the pandemic. Nevertheless, the findings suggest that promulgating affirmative social norms and positive emotional effects of app use, as well as addressing health concerns, might be promising strategies to foster adoption intentions and app use in the general population.

Introduction

Background

With the global spread of the COVID-19 pandemic, there have been numerous efforts to develop digital and mobile health (mHealth) solutions to combat the spread of infections [1,2], support quarantine and social isolation, and improve monitoring and communication surrounding the virus [3]. To this end, COVID-19 contact tracing apps were proposed as a way to (1) monitor and track infection chains, (2) provide immediate support and information in case of an infection or contact with an infected person, (3) and support persons in quarantine by monitoring health and tailoring information and preventive actions [1,3,4]. Overall, contact tracing via mobile apps aims to increase perceived safety and security of the population, and to contain infections, some apps also include additional educational information and news updates on governmental regulations [5].

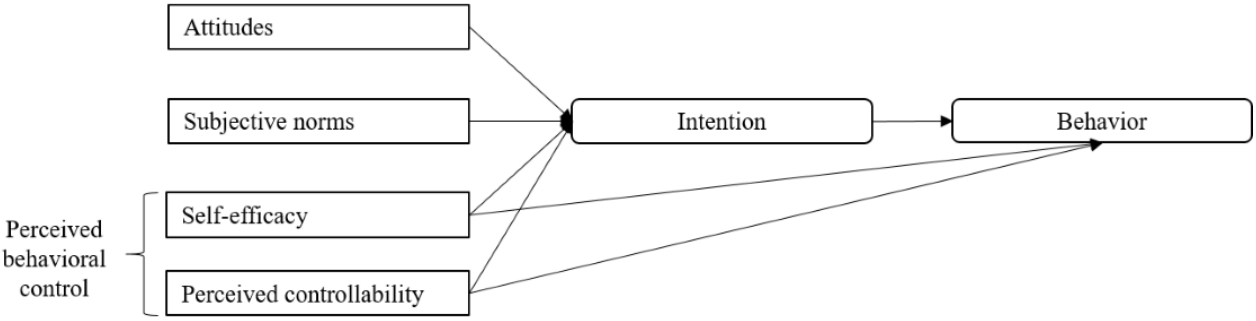
However, these developments encounter several ethical and practical challenges (eg, [1,6,7]). From a technical point of view, for instance, flawless performance of an app is essential to avoid false positives and for it to be perceived as accurate, reliable, and trustworthy (ie, efficacious) [8]. Research shows that perceived performance efficacy of a digital technology predicts behavioral compliance when confronted with false-alarm–prone systems [9]; therefore, the rate of false-positive alarms should be as low as possible for tracing apps. Furthermore, the app has to be accessible across different areas and regions (eg, rural and urban areas) to guarantee successful preventive tracing [7]. In addition, ethical questions concerning the digital divide resurface in this context [6,7,10]. Since the digital divide characterizes differences in access and reach of digital technologies (ie, primary divide) as well as capabilities and habit of use (ie, secondary divide), it challenges tracing apps as public health measures [10]. Elderly people, for example, report less use of smartphones, and they feel less competent in smartphone use [11,12]. This is particularly challenging regarding contact tracing apps, as older people represent a risk group for COVID-19 infections with a higher chance of more severe trajectories [13]. Additionally, using tracing apps also implies an agreement to share health-related data (ie, infection status) via mobile apps with governmental institutions or other citizens, raising concerns surrounding data privacy and a potential breach as well as misuse of health information beyond COVID-19 purposes (cf "surveillance creep" [3,6,7]). Since the implementation of the European Union General Data Protection Regulation in 2018, privacy concerns have repeatedly been discussed as a key variable in influencing attitudes and adoption intentions [14], particularly in the context of mHealth apps.

Hence, lively debates among journalists, scientific experts, and policymakers about the importance of weighing privacy, individual data security, and societal public health needs in digitally tracing COVID-19 infections have led to a variety of diverse developments in mHealth (eg, see [5,15]). A review conducted in May 2020 [15] described 17 tracing apps in 15 different countries with varying degrees of data processing and protection—in September 2020, the Council of Europe already listed 52 contact tracing apps worldwide [16]. Yet only 3 of these 17 reviewed apps (COVIDSafe in Australia, The e-Rouska in the Czech Republic, and VirusRadar in Hungary) were protected by respective data protection laws and provided consistent information on data storage and use policies.

In general, tracing apps tend to follow either a centralized or decentralized data processing approach or a hybrid of both, where either governmental or service institutions receive, monitor, and administer app data via a central server structure (eg, in France), or communication relies on peer-to-peer technology such as Bluetooth (eg, in Germany), to exchange randomly generated codes between app users within a certain radius (eg, a proximity of a few meters) to trace contacts. Either way, once a person's infection is validated by a health agency, a warning can be sent to stored contacts (centralized approach) or recipients of codes (decentralized approach) to inform them of a potential infection. So far, advantages and disadvantages regarding systems architecture, perceived responsibility, security, and privacy have already been discussed, ranging from personal first-hand experience [17] to systematic reviews (eg, [18]). While further differences between these approaches are beyond the scope of this paper and are discussed in detail elsewhere (eg, systems architecture [19,20]), it is important to note that these processes may further affect adoption intentions and continued app use in the population, as they are assumed to be connected to personal attitudes, such as perceived control, and privacy concerns. In fact, Trang et al [21] found that a strong privacy design, as implemented in a decentralized approach, predicted app acceptance and adoption intentions among critics of the tracing app as well as undecided participants who represented a majority of the sample. Similarly, a cross-cultural study also reported privacy and security concerns as important barriers to tracing app use [22].

Use of Contact Tracing Apps in the General Population

Mindful of these technical and ethical challenges of tracing apps, a general question therefore is whether the public uses these apps as intended. Simulation studies report that at least 56% of a population needs to use an app for it to have a public health impact [4]. However, use rates appear to be much lower in the general population so far (eg, [19,20]), with the differences being discussed in terms of data processing approaches, societal technology acceptance, and institutional or legal commitment. The Corona Warn-App (which uses a decentralized approach) was launched as the official German coronavirus contact tracing app on June 16, 2020. Until May 7, 2021, the app was downloaded 27.5 million times, which accounts for about 33.1% of the general population [23,24]. Given this large discrepancy between needed and currently reported app use, behavioral health research can help to identify predictors of app use and derive recommendations for preventive practice to increase app use and address perceived barriers in the general population. To this extent, this study draws from the literature on health behavior change as well as (mobile) technology acceptance to explore tracing app use in the general population. While we are aware of several studies that inspect barriers or motives pertaining to tracing app use (eg, [21,22]), few empirical studies are theory based in that they utilize established health behavior or technology acceptance models



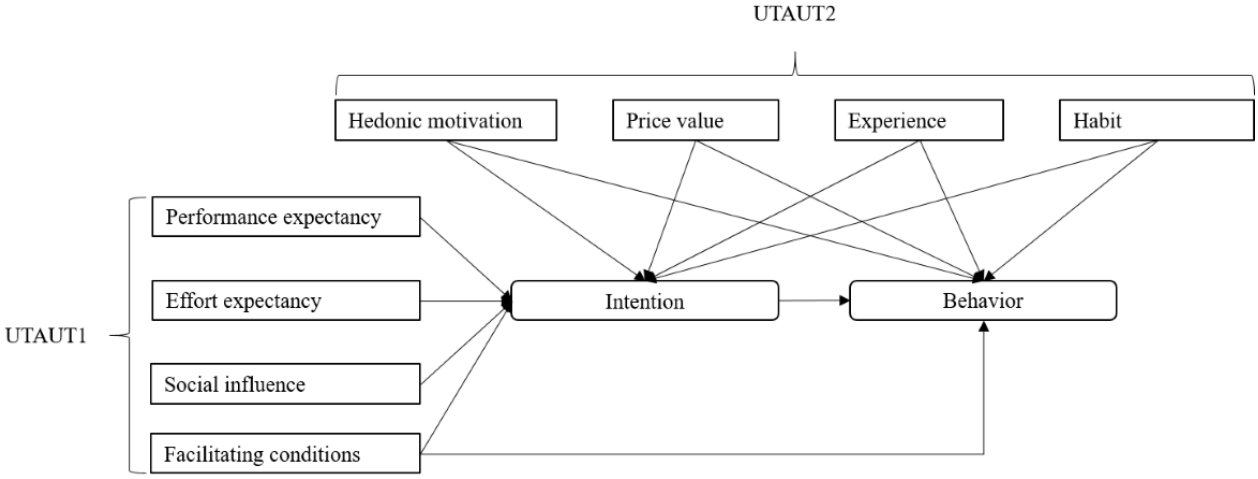
XSL•FO
RenderX

to investigate app use. So far, we have identified 3 studies based on the health belief model (HBM) [25], the protection motivation theory (PMT) [26], and the unified theory of acceptance and use of technology (UTAUT) [27]. While these studies investigated behavior change theories, they lack an assessment of social influence or social norms, even though these aspects are key factors of successful behavioral prevention during pandemics [28,29]. We believe that it is important to acknowledge the impact of social influence on contact tracing app use—as explicated in several health behavior change models.

Health Behavior Change

Ample research provides evidence of psychological processes connected to behavior change toward adaptive health behaviors in pandemics, such as keeping physical distance or practicing personal hygiene [28,30], which have been reiterated during the COVID-19 pandemic (eg, [30-32]). These processes are detailed in health behavior models like the HBM [33], Bandura's social cognitive theory [34], the PMT [35], and the theory of planned behavior (TPB) [36], which define several constructs associated with behavior change. According to the HBM, for instance, risk perception (eg, susceptibility to and fear of an illness) and perceived benefits (eg, reduced risk of infection) and barriers (eg, high costs, privacy concerns) influence behavior change tendencies. Social cognitive theory further adds the impact of efficacy expectancies [37] that comprise beliefs about the outcome of a behavior (ie, response efficacy, for instance, the belief that wearing masks significantly reduces infection risk) as well as one's ability to perform within a specific setting (ie, self-efficacy). The PMT combines these approaches by describing threat appraisals (risk perception) as well as coping appraisals (perceived benefits and barriers, response efficacy, and self-efficacy) as predictors of protection motivation and protective behavior. However, applied research points to the intention-behavior gap [38], describing a lack of implementation despite positive intentions, for instance, due to individual forgetfulness or a lack of opportunity to perform. Therefore, the TPB [36] further differentiates efficacy beliefs within the construct of perceived behavioral control (Figure 1).

Figure 1. Conceptual model of the theory of planned behavior (adapted from Ajzen [39]).



This construct comprises self-efficacy but also perceived controllability, which refers to the extent to which a person believes to be responsible for their behavioral performance within a specific setting [39]. For example, a person might report high self-efficacy regarding hand hygiene but low controllability due to a lack of soap or disinfectant available to them. Thus, the TPB assumes a direct link between perceived behavioral control and behavior as well as intentions. Other predictors of behavioral intention are attitudes and subjective norms. Attitudes are evaluative judgments of the target behavior, which might include risk perceptions and perceived benefits and barriers, and therefore connect with previously described health behavior models. Subjective norms address descriptive social influence (ie, how many people perform a target behavior) and injunctive social influence (ie, how many people suggest performing a target behavior) on individual intentions. Previous research has cemented the TPB as a popular and versatile framework for predicting health behaviors (eg, [40]) as well as use of mobile apps [41,42]. Current research on the COVID-19 pandemic underlines the predictive validity of the TPB for protective behaviors, with a particularly strong impact of subjective norms and efficacy beliefs [30,43,44]. Similarly, current research on the use of contact tracing apps also finds strong positive associations for response efficacy and moderate positive associations for self-efficacy [25-27]. Subjective norms were only measured in one study [27] and did not show significant associations with app use. However, the measure combined social norms, governmentally provided implementation support, and social support for app use as a composite measure of social influence, resulting in insufficient factorial and content validity.

Unified Theory of Acceptance and Use of Technology

While the TPB has received tremendous attention in health research, its popularity in mHealth research is rivaled by UTAUT [45]. The UTAUT itself is based on the technology acceptance model [46] and the theory of reasoned action [47], a precursor of the TPB, and it also describes psychosocial variables associated with the adoption of (new) technology [48-50]. These variables are performance expectancy, effort expectancy, social influence, and facilitating conditions in the first iteration (UTAUT1), with the addition of hedonic motivation, price value, habit, and experience in the second iteration (UTAUT2) [45,51] (Figure 2).

XSL•FO
RenderX

Figure 2. Conceptual model of the unified theory of acceptance and use of technology (UTAUT, first and second iterations) (adapted from Venkatesh et al [50]).

In contrast to the TPB, however, these descriptions are rather broad, and the model does not set strong theoretical or methodological boundaries for these variables, which has led to many publications but almost as many different iterations of the model, challenging the comparability of findings [50]. Nevertheless, the main implications of the UTAUT are that an adoption of a new technology is more likely if a person expects it to be useful, easy to access and use, recommended and supported by others, and if persons perceive themselves to be able to use it as intended. Moreover, if a person expects positive emotional reactions (eg, joy) and is familiar with similar technology use (ie, habit), this further increases the likelihood. Conversely, disadvantageous facilitating conditions, for example, information privacy concerns or low self-efficacy, can inhibit adoption intentions [25,52].

Conceptually, similarities to health behavior theories are apparent, as expectancies, social influences, and facilitating conditions (eg, self-efficacy, perceived barriers) play an important role in both approaches. Hence, multiple studies have used the UTAUT approach to predict adoption of mHealth apps in general [49], and more specifically, for instance, regarding mobile health care services among the elderly [53], or the use of COVID-19 contact tracing apps [27]. In their study on the acceptance of mHealth services, Sun et al [53] directly compared the predictive value of the TPB, the technology acceptance model (as a reduced version of the UTAUT), the PMT, and an integrated model, and found that an integrated model yields the best results, including positive effects (eg, social influence) and negative effects (eg, threat appraisals) at the same time. Across studies, performance expectancy has the strongest associations with adoption intentions, followed by effort expectancies and social influence. This is in line with current evidence on tracing app use but deviates from health behavior research that reports a similar impact of efficacy beliefs, but a stronger effect of social influence [30,43,44].

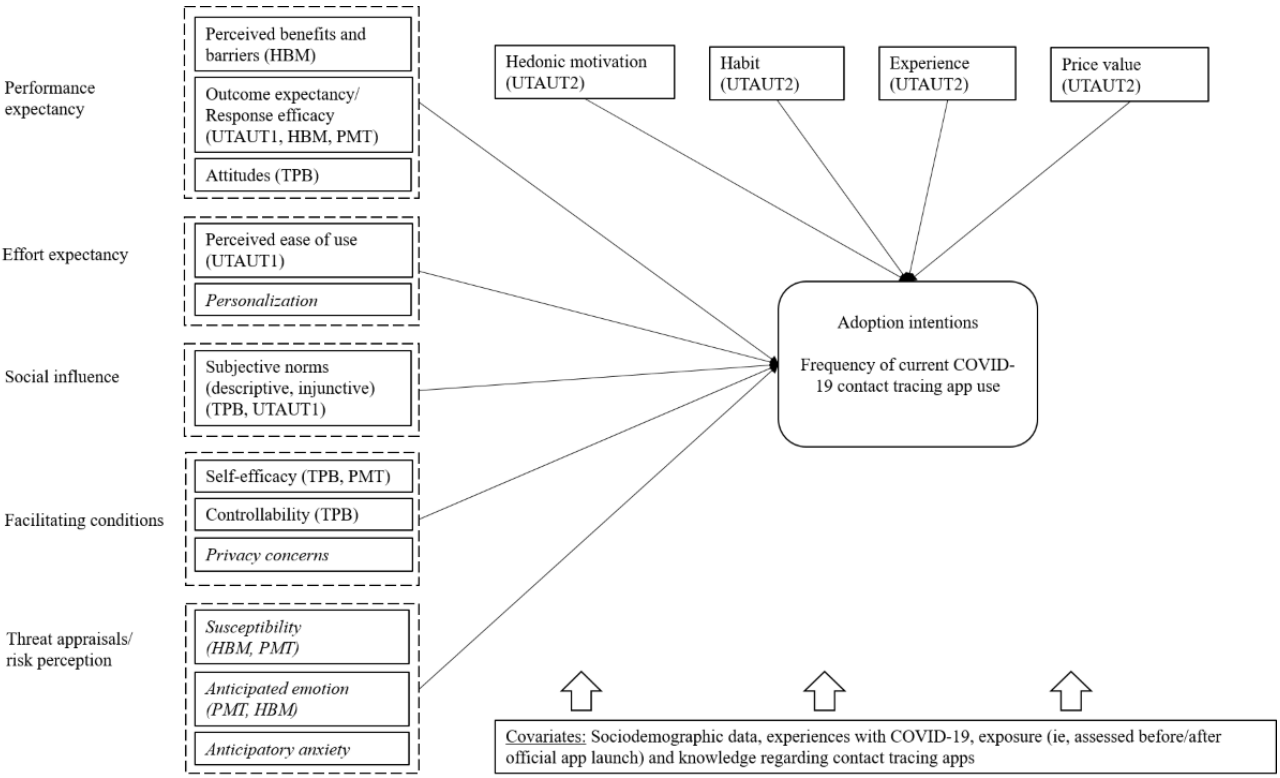
Moreover, in their comprehensive meta-analytic review of the UTAUT, Dwivedi et al [48] essentially confirm these observations, but they also point out that most UTAUT studies do not include user attitudes (ie, affective and cognitive evaluations of technology use). Instead, attitudinal assessments are often limited to expectancies. In terms of health behavior theories, this operationalization would exclude aspects of risk perception or threat appraisals (HBM, PMT), and attitudes (TPB), although attitudes were the strongest predictors of behavioral intentions in meta-analytic structural equation models of the UTAUT [48].

Furthermore, the role of social influence (ie, social norms) is not consistently defined in either the health behavior or the technology acceptance approach [54]. In fact, social norms can be categorized as descriptive and injunctive or prescriptive, and further defined as personal or societal, in that they refer to one's personal surroundings (eg, family or friends) or more general societal categories (eg, persons of the same age, the same country). In short, the reference frame defines the commitment and group orientation, which has been used by nudging interventions based on social identity models to foster technology use [55] or the uptake of vaccinations [56]. Using the general public as a reference can thus shape public behaviors (eg, wearing a mask in public), but does not necessarily affect personal beliefs as strongly (eg, private protective behaviors) [57]. In contrast, personal reference points can increase private behaviors more strongly. In the context of app use, it is therefore important to examine the differential impact of social norms.

Research Aims

In sum, this study aimed to compare the predictive value of the TPB, the UTAUT, an integrated model, and an extended model (cf [53]) regarding adoption intentions, and current use of COVID-19 infection tracing apps. By exploring both theories separately as well as concurrently, this study provides a blueprint for future research on contact tracing apps and other digital health technologies that combines health-related and technology-related perspectives.

First, we aimed to affirm previous mHealth studies on either the TPB or the UTAUT in the context of COVID-19 contact tracing apps and compared their tenability an integrative model.



Second, while both models have been successfully used to predict health technology use, there are evident shortcomings to both approaches that can be overcome by combining them.

XSL•FO
RenderX

Therefore, in this study, we included barriers like privacy concerns, which are more common in technology-focused research (eg, [27,50]), into health behavior models, while also acknowledging the importance of threat appraisals, popularized in health behavior models [53].

Third, we aimed to expand upon research on either model by considering the distinct impact of injunctive and descriptive social norms, which have often been neglected in previous research, for instance, regarding contact tracing app use (eg, [25,26]). Thus, we provide an integrative framework to test attitudinal predictors of intention and behavior concerning contact tracing app use in the general population (Figure 3).

Figure 3. Research framework combining health behavior theories (health belief model [HBM], protection motivation theory [PMT], theory of planned behavior [TPB]) and technology acceptance (unified theory of technology acceptance and use 1 and 2 [UTAUT1 and UTAUT2]) to predict adoption intentions (and frequency) of current COVID-19 contact tracing app use. Relevant variables that are not represented in TPB or UTAUT are italicized.

Methods

Recruitment

Via a cross-sectional online survey, we explored app use and associated attitudes in a convenience sample of the German population. Participants were recruited via social media (Facebook groups, coronavirus-related websites, YouTube), press outlets (local news report, Press and Media Relations Office of the University of Greifswald), and personal communications. The survey was pretested via cognitive debriefings and pilot surveys in a small sample (n=20) for clarity, readability, accessibility, and functioning. During the pretest, we observed a duration of 10-60 minutes for survey completion (depending on literacy, familiarity with surveys, etc), which we established as a guideline for data collection. The survey was subsequently implemented using SoSci Survey (SoSci Survey GmbH) [58], over a period of 3 months (May to July 2020). This recruitment period was chosen to capture a similar time frame of about 4 weeks before and after the official launch of the German Corona Warn-App. Amidst the data collection period, the Corona Warn-App was launched by the German Ministry of Health (on June 16), so we coded participation before or after this launch to control for exposure effects.

The Corona Warn-App uses a decentralized approach to infection tracking. Via Bluetooth, it measures the distance between the smartphones of app users and exchanges temporary encrypted random codes across devices. These codes are cryptographically derived several times per hour based on a random device key. If app users test positive for the coronavirus, they can choose to pass on their keys for matching with other app users who have received the random code from this device in the given time frame. If there is a match, an algorithm determines individual risk (eg, based on estimated physical distance, timing, and duration of the meeting), and subsequently informs app users about their risk status (low or increased risk). The app is available in the App Store and the Google Play Store, and it works with multiple operating systems, starting with iOS 13.5 and Android 6.

As an incentive, 50 vouchers (€15; US $18.24; exchange rate on May 11, 2021) were randomly distributed among participants. Moreover, after study completion, participants were provided additional information on COVID-19 and tracing apps, including several hyperlinks to freely available tracing apps. The study procedure was approved by the local Ethics Committee (blinded

XSL•FO
RenderX

for peer review). A list of the items is presented in Multimedia Appendix 1.

Measurement Instruments

Sociodemographic Data

We measured individual age, gender (1=female, 2=male), number of persons in one's household, current level of education (0=lower secondary education or less; 1=upper secondary education, ie, "Abitur" or higher educational achievement), current personal income (USD values based on the exchange rate on May 11, 2021; 1=€0-€500 [US $0-$608.23], 2=€501-€1000 [US $609.44-$1216.45], 3=€1001-€1500 [US $1217.67-$1824.68], 4=€1501-€2000 [US $1825.90-$2432.91], 5=€2001-€2500 [US $2434.13-$3041.14], 6=€2501 or more [US$ 3042.35 or more]; dummy coded for the analysis with the first category as a reference category), region (0=rural, ie, up to 10,000 inhabitants; 1=urban, ie, up to 100,000 inhabitants; 2=metropolitan, ie, more than 100,000 inhabitants; dummy coded with rural as a reference category), and migration background (1=father/mother/participant born in Germany, 2=father/mother/participant born elsewhere).

Health Behavior Change

Core variables of health behavior change were assessed based on the TPB, the PMT, and the HBM (Figure 1) in line with previous studies and recommendations on scale development (eg, [53,59,60]). Mean scores were used for all scales, with higher values representing more positive attitudes.

To capture subjective norms, descriptive personal norms (eg, most people who are important to me want to use such an app) were assessed via 3 items (Cronbach α=.89) and injunctive personal norms (eg, my family expects me to use such an app) via 4 items (α=.84) on a 5-point scale from 1 (strongly disagree) to 5 (strongly agree). In addition, descriptive social norms (α=.75) (eg, how many people in your age group would like to use such an app?) and injunctive social norms (α=.97) (eg, how many people in your age group should use such an app?) were assessed with 2 items each on a scale from 0% to 100%, recoded into 10 categories (0-10, 11-20, etc) for further analysis. Perceived behavioral control was reflected by its subcomponents self-efficacy (eg, I am confident that I could use such an app) via 4 items (α=.81), and perceived controllability (eg, the decision to use such an app is up to me) via 2 items (α=.69) on a 5-point scale from 1 (strongly disagree) to 5 (strongly agree). Attitudes toward app use were assessed with 4 items (eg, good-bad, helpful–not helpful) on a 7-point semantic differential, recoded to represent positive attitudes toward app use (α=.89).

We tested the factor structure of the TPB model via a principal component analysis with varimax rotation (Multimedia Appendix 2). The resulting model (Kaiser-Meyer-Olkin [KMO]=0.80) explained about 70% of cumulative variance and achieved sufficient differentiation with item loadings above .64 on each factor. The factors largely mirrored the constructs attitudes, subjective norms, and perceived behavioral control; however, items measuring injunctive and descriptive personal norms represented one factor and were thus combined into a scale of personal norms (α=.90). Moreover, the items measuring injunctive social norms (TPB_ISN1, TPB_ISN2; see Multimedia Appendix 1) were strongly associated with the factor labelled attitudes but were kept as a separate scale for theoretical reasons.

UTAUT

To capture additional constructs described in UTAUT I, we measured performance expectancies (ie, perceived usefulness) via 6 items (eg, a personalized COVID-19 tracing app improves tracing of infection chains; α=.93) as well as the perceived costs of or barriers to app use (eg, using the app can cause problems with other apps; α=.81) on a 5-point Likert scale.

We also assessed perceived ease of use (eg, learning to use the app would be easy for me) with 4 items (α=.91) on a 5-point scale from 1 (strongly disagree) to 5 (strongly agree). To further capture the constructs specified in UTAUT2, we assessed hedonic motivation (how would you feel if you used a COVID-19 tracing app) via 3 semantic differentials (happy-sad, concerned–not concerned, satisfied-dissatisfied; α=.77), price value by eliciting the perceived material benefits of not using the app with 5 items (eg, it saves time or money; α=.88), inversed to represent positive price value, and habit (eg, using an app is something that I do often) with 6 items (α=.91) on a scale from 1 (strongly disagree) to 5 (strongly agree). All scales for the UTAUT assessment were adapted from a previous study in a German sample [61] and were in line with prior UTAUT research (eg, [48,53]). To capture experience, we also asked participants how many hours per day they spent using smartphone apps (analyzed as integers).

Like the TPB model, we examined the structure of the UTAUT model with a principal component analysis with varimax rotation (Multimedia Appendix 3). The resulting model (KMO=0.90) explained about 66% of the cumulative variance and achieved sufficient differentiation with item loadings above .58 on each factor. The factors mirrored the constructs perceived barriers, perceived ease of use, price value, and habit. However, items measuring hedonic motivation were associated with perceived usefulness but were kept as a separate scale for theoretical reasons.

As potential barriers to app use, we also included data privacy concerns (eg, a good privacy policy for mobile app users should have a clear and conspicuous disclosure) measured by the App Information Privacy Scale [62], which consists of 17 items (α=.91) rated on a 7-point Likert scale, and personalization of the app (eg, the app provides information that is exactly tailored to my needs) via 3 items (α=.90), rated on a 5-point Likert scale, to complement the analysis model.

COVID-19–Related Information

We included COVID-19–related information on risk perception, namely perceived personal susceptibility to a COVID-19 infection, as well as susceptibility of one's social surroundings and one's age group (α=.88), on a scale from 0% to 100%. Values were recoded into 10 categories (0-10, 11-20, etc) for further analysis, similar to social norms. We also measured anticipatory anxiety regarding an infection (oneself, close friends/family; α=.83) on a 5-point scale from 1 (not at all worried) to 5 (very worried), and anticipated emotion as a proxy for emotional severity in case of an infection (eg, sadness, anxiety) via 5 items (α=.81) on a 5-point Likert scale. We

XSL•FO
RenderX

assessed subjective knowledge about COVID-19 tracing apps (on a scale of 0 to 100, recoded from 1 to 10), and direct or indirect experience (ie, a close friend or family) with COVID-19, including physical (eg, respiratory illness), material (eg, unemployment), and psychological (eg, depression) consequences (0=no, 1=yes).

Finally, we assessed individual intentions to use a COVID-19 tracing app within the next 3 months via 3 items on a scale of 1 (highly unlikely) to 7 (highly likely) (eg, I plan to use a tracing app within the next 3 months; α=.99). Due to the high correlation between items, they were collapsed into a single indicator with the maximum value across all three representing individual intentions. We also measured the frequency of current tracing app use from 1 (never) to 6 (multiple times per day). To compare app users to nonusers, frequency was dichotomized into 0 (nonusers) and 1 (users) for descriptive analysis. Because the survey was implemented before the official launch of the German Corona Warn-App, response options comprised a variety of available tracing apps (eg, ito App, CoroNotes, Datenspende App) and an open-ended category (other). For analysis purposes, however, all data were collapsed to reflect (the frequency of) tracing app use via single-item measures to estimate use patterns of any kind of tracing app. To make sure that participants responded within a similar frame of reference, we provided a short explanation regarding contact tracing apps before proceeding to ask app-specific questions. This explanation described the functionality of contact tracing apps as (1) monitoring and tracking infection chains, (2) delivering immediate support and information in case of an infection or contact with an infected person, (3) and possibly providing support for persons in quarantine by monitoring health and tailoring information and preventive actions (Multimedia Appendix 4). This definition is in line with current conceptualizations of contact tracing apps [1,3,4]. However, since our study preceded the official launch of the Corona Warn-App, it was impossible to precisely describe this app and its functionalities as a point of reference. We also controlled for exposure to the app via the official launch (0=completed the survey before the official launch, 1=completed the survey after the official launch of the tracing app in Germany on June 16).

Statistical Analysis

First, we provided a descriptive analysis of the sample (including missing data) and compared current app users to nonusers via *t* tests and chi-square tests. Second, we examined bivariate associations of study variables. For bivariate correlations, we report Pearson and point biserial correlation coefficients, with boundaries of r≥0.1 (weak), r≥0.3 (moderate), and r≥0.5 (strong) as effect sizes. Third, we perform 4 block-wise hierarchical regression models of adoption intentions and frequency of current tracing app use. These models comprise the TPB (model 1), the UTAUT2 (model 2), an integrated model (model 3), and an extended model (model 4) including the additional variables threat appraisals, privacy concerns, and personalization as predictor variables. Because the latter variables are not part of the core set of constructs in either TPB or UTAUT2, we aimed to test their utility beyond the integrated framework using the "additional variables" approach (eg, [48,50]). In each regression model, the first block of predictor variables consisted of covariates, the second block of model components, and the third block of additional variables (if any). By examining the changes in explained variance for each block as well as the regression coefficient of each variable, we can consecutively examine the impact of sociodemographic data, the TPB, the UTAUT2, and additional variables on adoption intentions, and app use. We reported standardized regression coefficients (beta) and R^2 as effect sizes for each model. All analyses assumed an alpha level of .05 and were conducted with SPSS Statistics 27 (IBM Corp).

Results

Descriptive Statistics

In total, 593 persons participated in the survey; however, after excluding participants who completed the entire survey in less than 10 minutes or showed monotone response patterns for >80% of the questions, 349 participants remained (age: mean 35.62, SD 14.66 years; range 18-82 years). On average, participants completed the survey in 22.65 (SD 7.93) minutes. Descriptive statistics are presented in Table 1.

Overall, missing values were low (564/31,759, 1.8%), which the Little test [63] revealed to be missing completely at random (χ^2_{2450}=2538.4, *P*=.10). Only 3 variables had more than 5% missing values, namely income (23/349, 6.6%), region (21/349, 6.0%), and an item measuring risk perception (21/349, 6.0%). Therefore, we used complete cases for descriptive statistics and applied pairwise deletion for inferential statistics, as previous studies have shown a low probability of bias in this case [64,65]. In our sample, 19% (67/349) reported current use of a COVID-19 contact tracing app, with an average frequency of several times per week (mean 4.07, SD 1.51). A comparison of current app users and nonusers (*t* tests, chi-square tests) indicates that app use was much higher after the launch and thus exposure to the official Corona Warn-App, and seemingly equally distributed across regions. App users reported significantly more positive attitudes and fewer concerns than nonusers but also had a lower relative frequency of COVID-19 experiences. Perceived controllability of app use did not differ between participants.

[a]Two-tailed *t* test or chi-square test results.

[b]Either the participant, their mother, or their father was not born in Germany.

Bivariate Correlations

Sociodemographic data were not associated with adoption intentions, but frequency of current tracing app use was negatively correlated with education (r=–0.13, *P*=.02) and urban region (r=–0.16, *P*=.005), indicating that fewer educated participants living in metropolitan or rural areas reported more frequent tracing app use (Multimedia Appendix 5).

Regarding TPB and UTAUT constructs, Table 2 shows that adoption intentions were moderately to strongly associated with most TPB constructs (r=0.38, *P*<.001 to r=0.69, *P*<.001), except for controllability (r=0.03, *P*=.63), as well as UTAUT constructs (r=0.29, *P*<.001 to r=0.64, *P*<.001) except for experience (r=0.10, *P*=.09). Perceived costs (r=–0.35, *P*<.001) were negatively linked to intentions. Overall, frequency of current app use showed similar but weaker associations. Exposure to the app was not associated with any attitudinal variable but was associated with intentions (r=0.11, *P*=.04) and frequency of app use (r=0.39, *P*<.001).

Additionally, TPB and UTAUT constructs correlated considerably with attitudes and injunctive social norms (r=0.68, *P*<.001), attitudes and perceived usefulness (r=0.80, *P*<.001), attitudes and hedonic motivation (r=0.71, *P*<.001), with hedonic motivation and perceived usefulness (r=0.69, *P*<.001) being particularly high, underlining their conceptual similarities (cf principal component analyses in Multimedia Appendices 2 and 3). Adoption intentions and use frequency were moderately correlated (r=0.46, *P*<.001).

Among additional variables (Multimedia Appendix 5), adoption intentions were mostly strongly associated with personalization (r=0.57, *P*<.001), followed by anticipatory anxiety (r=0.41, *P*<.001), data privacy concerns (r=–0.30, *P*<.001), and anticipated emotion (r=0.24, *P*<.001). Frequency of current tracing app use had similar associations and was also positively correlated with knowledge about tracing apps (r=0.28, *P*<.001).

Hierarchical Regression Models

Results of regression models testing the TPB (model 1), the UTAUT (model 2), the integrated model (model 3), and the extended model (model 4) are presented in Table 3. In each analysis, we included several covariates in the first block (ie, age, gender, and education; number of persons per household, income, and region; as well as subjective knowledge regarding COVID-19 tracing apps, COVID-19 experience, and exposure). The selection of covariates was based on previous research on technology use, and preventive behaviors during the COVID-19 pandemic. The second block contained TPB (model 1) or UTAUT constructs (model 2) or both (model 3). The third block contained additional variables (model 4). Due to high correlations between some variables, we calculated the variance inflation factor (VIF) to test for multicollinearity [66]. Accordingly, a VIF of more than 4 is often considered an indicator of multicollinearity. The VIF was below 3.00 in model 1 and model 2, but in model 3 and 4, the VIF ranged from 1.11 (COVID-19 experience) to 4.04 (attitudes). Due to its high VIF, high bivariate correlations with other constructs, and its conceptual similarities to perceived usefulness, we excluded the variable measuring attitudes from models 3 and 4.

The TPB (model 1) explained 63% of adoption intentions, with injunctive social norms (β=.35, *P*<.001), attitudes (β=.28, *P*<.001), and personal norms having the strongest association (β=.22, *P*<.001); self-efficacy having a smaller effect (β=.08, *P*=.04); and perceived controllability being not significant (β=–.02, *P*=.56). Regarding current app use (R^2=0.33), personal norms (β=.20, *P*=.004) were connected to more frequent use, but exposure to the warning app had the strongest association (β=.31, *P*<.001). Additionally, persons from more densely populated areas reported less frequent app use.

The UTAUT (model 2) explained 56% of adoption intentions and 37% of frequent app use. Perceived usefulness (β=.32, *P*<.001) and hedonic motivation (β=.35, *P*<.001) were among the strongest predictor variables of intentions and frequency of use; however, the influence of perceived usefulness was inverted (β=–.14, *P*=.049) for frequency of use. Perceived ease of use, perceived barriers, and experience were not significant. Price value was positively associated with intentions (β=.13, *P*=.02) but not frequency, while habit was associated with frequency (β=.15, *P*=.02) but not intentions.

The integrated model (model 3) explained 67% of intentions with injunctive social norms (β=.31, *P*<.001), hedonic motivation (β=.22, *P*<.001), personal norms (β=.21, *P*<.001), and price value (β=.11, *P*=.02) remaining significant. Regarding frequency, the model explained 40% of the variance with personal norms (β=.18, *P*=.007), hedonic motivation (β=.34, *P*<.001), habit (β=.14, *P*=.03), and perceived usefulness (β=–.23, *P*=.004).

XSL•FO
RenderX

Finally, the extended model with the additional constructs privacy concerns, personalization, and threat appraisals (model 4) performed marginally better regarding intentions (R^2=0.68) and frequency of app use (R^2=0.42). Anticipatory anxiety was also significantly associated with intention (β=.09, *P*.04) and frequency (β=.15, *P*=.03). In addition, privacy concerns were associated with less frequent app use (β=–.09, *P*=.046).

To summarize, the analysis showed that the TPB as well as the UTAUT proved useful in determining intentions, and frequency of use of a COVID-19 contact tracing app, although model configurations varied greatly between both outcomes (Figure 4). While most of the constructs of the TPB were significantly associated with intentions (except for controllability), neither perceived barriers, ease of use, nor experience reached significance within the UTAUT framework. Overall, perceived usefulness, subjective norms, hedonic motivation, and anticipatory anxiety were consistently associated with tracing app use across models.

Figure 4. Significant predictor variables of adoption intentions and (frequency) of current COVID-19 contact tracing app use in a German community sample. Predictors are categorized according to the theory of planned behavior (TPB), the unified theory of technology acceptance and use (UTAUT), and additional variables from other health behavior models (ie, anticipatory anxiety) or previously extended UTAUT models (ie, data privacy concerns).

Discussion

Principal Results

This study aimed to investigate the utility of health behavior theories and technology acceptance models for explaining adoption intentions and current use of a contact tracing app during the COVID-19 pandemic in the German population. The TPB as well as the UTAUT explained between 56% (UTAUT) and 63% (TPB) of adoption intentions as well as 33% (TPB) and 37% (UTAUT) of current app use. Extended models including threat appraisal, privacy concerns, and personalization features of the app explained an additional 5% for both outcomes. Overall, exposure to the app (ie, study participation following an official app launch with governmental support) was strongly associated with frequent app use and was also associated with greater acceptance and more positive attitudes (Table 1). In accordance with previous research, both models have greater predictive value concerning intentions than behavior [40], which might be connected to the intention-behavior gap [38] and related factors, such as a lack of familiarity with the app, and the unprecedented and ever-changing nature of the pandemic.

Comparison With Prior Work

A closer look at the regression models also reveals that while the main components of the TPB were significantly associated with intentions—except for controllability—this was not the

XSL•FO
RenderX

case for the UTAUT model. In fact, only perceived usefulness and hedonic motivation were highly significant and consistent, while perceived barriers, experience, and ease of use were not significant. Habit and price value played a significant role for some but not all associations. Nevertheless, the large amount of explained variance points to the model's utility in explaining adoption intentions. In general, our findings support previous research on COVID-19 contact tracing apps, as we also observed strong positive associations between response efficacy (ie, perceived usefulness in UTAUT terms) and adoption intentions, but only moderate positive associations for self-efficacy [25-27]. Presumably, high ratings of perceived usefulness or positive attitudes toward the app (ie, the app being perceived as helpful; Multimedia Appendix 1) are also associated with trust in flawless performance, a low rate of false positives, and thus a sense of security. While we did not assess these constructs directly, we assume this association based on previous research on human-computer interaction [8] as well as warning systems [9]. However, future research in this context could examine the associations between trust, perceived security, and positive attitudes (eg, perceived usefulness) more closely, for instance, by using factorial surveys that vary attributes of tracing apps (eg, rate of false alarms, sensitivity) and subsequently measure attitudes [21,67].

Interestingly, the association of perceived usefulness and frequent app use was inversed, meaning that higher perceived useful was associated with lower use frequency. Given that tracing apps are designed to inform about potential COVID-19 infections and thus serious health risks, high efficacy beliefs (or perceived usefulness) would mean that more frequent app use might increase the chance of receiving health warnings which could be perceived as a negative and undesirable event. Thus, using the app less frequent could be seen as avoiding a potential threat by reducing the information flow. This risk avoidance behavior is a common phenomenon in risk research, for example, within the risk perception attitude framework [68] that connects information avoidance to high risk perceptions as well as lower self-efficacy and control beliefs. On the other hand, if perceived usefulness is low, potential health warnings issued by the app might be taken less seriously due to a higher possibility of false positives. Since only a very frequent app use guarantees preventive efficacy of the tracing app [1,3,4], these findings are concerning. We believe that future mixed methods research can elucidate the role of perceived usefulness as a potential barrier to frequent app use as well as its interaction with other predictors, such as self-efficacy and risk perception.

Furthermore, we also observed consistent significant associations between anticipatory anxiety and (frequent) app use, although the effect was small. Conceptually, these appraisals can reflect health concerns [35,60], which are associated with vigilance toward symptoms or health problems. Since a tracing app provides an additional source of information regarding a potential illness, it can help to alleviate concerns and support vigilance [1]. Similarly, frequent app use could also increase one's sense of security and positive feelings, which is mirrored by a positive association with hedonic motivation (eg, feeling satisfied, rather happy than sad, and less concerned after using the app). A similar trade-off between mHealth use, user concerns, and perceived security has already been established (eg, [1,69]). This hypothesized association between hedonic motivation, sense of security, and technology use should therefore be tested in longitudinal studies on tracing app use.

While our study underlines the importance of attitudes and perceived usefulness, we also found a very strong connection between social norms, namely personal norms (ie, referring to one's immediate surroundings), intentions, and behavior, which is contrary to prior research on tracing app use [27]. However, as previously mentioned, Kukuk [27] compiled a measure of social influence [45] that blended subjective norms, social support, and instrumental governmental support, which might be confounded by other factors such as trust in the government. Evidently, Kukuk's measure was insufficient in capturing social norms as it showed very low factorial and content validity. Additionally, in this study, injunctive social norms (ie, referring to perceived societal expectations) were also strongly connected to adoption intentions across all models. The strong impact of social norms on behavioral prevention has already been documented for previous pandemics [28,29]. With infection prevention measures (eg, social distancing) affecting the heart of social interaction, it seems reasonable to also assume a strong impact of social norms. If one's close social network is believed to support the app, one is more likely to also engage with it, leading to a social group that protects its members by using the app because of the accelerated communication in case of an infection [5]. Thus, the (frequent) use of a tracing app can be seen as an act of social responsibility. This has implications for health communication. Promoting app use as an expression of social responsibility and putting less emphasis on the perceived usefulness might be helpful in increasing public acceptance avoid potential side effects (cf the role of perceived usefulness in this study). In this sense, the approach would be quite similar to successful nudging interventions used to foster technology use [55] or vaccine uptake [56] that are based on social norms.

Moreover, two additional components of the UTAUT were significantly associated with intentions (price value) and frequency of app use (habit). In this study, price value was not solely defined by monetary restrictions [51] because the German contact tracing apps are available free of charge. Hence, we also included other limited resources (eg, time) as a potential restriction or cost. In general, the positive association with adoption intentions was in line with previous research [50,51]; however, since our operationalization of price value also included time, it is possible that the effect disappeared for frequency of use because of a foreseeable increase in time investment. Therefore, we hypothesize a trade-off between perceived costs (ie, time investment) and benefits that might differentially affect intentions and behavior. This would also explain the observed association of habit with frequency of use but not general adoption intentions. Habit describes prior experience with a technology but also the belief that using said technology is automatic [51]. Automatic behaviors are associated with less effort because it is no longer necessary to carefully and consciously plan and monitor them (eg, [53]). Since less effort equals less time spent on (consciously) using the app, habitual use may buffer the costs of more frequent app use (ie, a greater time investment). A similar trade-off is

XSL•FO
RenderX

described for effort expectancies and performance expectancies regarding technologies [50] and health behavior models (eg, [25,60]) in that a positive balance of perceived benefits over efforts predicts intentions and behaviors. However, while effort expectancies often focus on singular behaviors instead of resources, it might be beneficial to weigh perceived resource investment and behavioral efforts when predicting intentions in future studies.

Finally, we also addressed some ethical challenges that might arise in this context, namely the age-related digital divide [10,12] and privacy concerns (eg, [1,6,7]). In contrast to previous studies, we did not find any direct link between age and intentions or behavior, but older age was positively associated with privacy concerns and negatively with personalization (Multimedia Appendix 5). The negative association with personalization might reflect a lack of competence in app use in older participants, as personalizing apps requires certain skills [11,12]. Likewise, increased privacy concerns might also be associated with increased insecurity and a lack of knowledge about procedures of privacy protection implemented in the app. To concede, this study was an online study and therefore potentially excluded people who are less interested or competent in using digital technologies. However, the possibility of an indirect negative effect of age on tracing app use via privacy concerns and lower perceived benefits (ie, personalization) is alarming and has implications for health communication research. Interventional studies are needed to test whether tailored health communication surrounding benefits and privacy concerns can alleviate concerns and lead to higher acceptance and adoption of tracing apps in older participants.

Privacy concerns were negatively associated with app use, which underscores the importance of a transparent, sound, and secure data management plan when developing and promoting mHealth apps [14]. Although the effect was rather small, it is possible that participants do indeed fear misuse of health information beyond COVID-19 purposes, providing further empirical support for current publications on the promises and pitfalls of digital health solutions during the pandemic (eg, [3,6,7]). Nevertheless, further research is necessary to explore privacy concerns and their role in determining nonuse of contact tracing apps and other digital health solutions during the COVID-19 pandemic.

Limitations

The study has several limitations. First, the sample is a German convenience sample that is not representative of the population. The survey was conducted as a self-administered online survey; the reliance on self-reports might have affected our results; hence, future studies should include objective measures (eg, smartphone data on app use). In addition, although we checked the responses for monotone response patterns, we did not incorporate attention checks into the online survey. Second, regarding the cultural context of our study, we acknowledge that the technical, legal, and cultural conditions of contact tracing apps and their implementation varies greatly across countries worldwide. Since we started our survey before the official launch of the Corona Warn-App in Germany, our results are not tailored to this app but rather tracing apps in general, which might explain why we found generally lower associations for current use than for use intentions. Hence, the findings should be replicated in larger, international samples and ideally cross-cultural studies. Third, the study is cross-sectional in nature, and it was therefore not possible to longitudinally link attitudes, intentions, and behaviors as intended in the theoretical models. While strong positive exposure effects were observed, this could also point to selection bias, where proponents of the app were more strongly motivated to participate in the survey than opponents. Fourth, the measures should be tested regarding their psychometric properties. Although the instruments were based on recommendations for behavior change research, and adapted from previous research projects, their implementation in this novel context proved challenging in some areas and requires further investigation. Fourth, other constructs like trust in the government, the app provider, or health communication about COVID-19 should be included to test their impact on attitudes and the path toward adoption of the app. For example, research on the UTAUT model (eg, [48,50]) has coined the "additional variables" approach, where factors are added to the traditional UTAUT model to inspect their incremental validity. Despite these limitations, the study was based on established theories of health behavior change and technology acceptance and implemented in an ecologically valid setting. Further, it provides some insight into urgent processes of health communication and infection prevention that can support the fight against the global COVID-19 pandemic by increasing the use of contact tracing apps in the general population.

Conclusions

This study examined the utility of health behavior change and theory acceptance models in exploring intentions and use of a contact tracing app to complement preventive measures during the COVID-19 pandemic. In general, both models provide useful information for identifying core beliefs that affect intention and behavior. Among them, subjective norms, hedonic motivation, perceived usefulness, and anticipatory anxiety were particularly important across all tested models. Thus, it seems that promulgating positive social norms and addressing health concerns in health communication might be particularly beneficial to increase tracing app use in the population. The role of perceived usefulness and tracing app use needs further investigation due to its inverse associations with intentions and behavior. Moreover, privacy concerns also emerged as a barrier to app use in this context, underlining the need for more transparency and education regarding data security in the general population. Overall, the official launch of the Corona Warn-App [23] with governmental support seemed to boost awareness and app use in the population; therefore, a concerted effort is recommended when introducing a contact tracing app as an official complementary measure of infection prevention. However, data were collected between May and July 2020 amidst the first wave of the COVID-19 pandemic, so future research needs to illustrate how living under pandemic circumstances affects acceptance and use of (preventive) technology in the long term.

Abstract

Background: COVID-19 is one of the greatest threats to human beings in terms of health care, economy, and society in recent history. Up to this moment, there have been no signs of remission, and there is no proven effective cure. Vaccination is the primary biomedical preventive measure against the novel coronavirus. However, public bias or sentiments, as reflected on social media, may have a significant impact on the progression toward achieving herd immunity.

Objective: This study aimed to use machine learning methods to extract topics and sentiments relating to COVID-19 vaccination on Twitter.

Methods: We collected 31,100 English tweets containing COVID-19 vaccine–related keywords between January and October 2020 from Australian Twitter users. Specifically, we analyzed tweets by visualizing high-frequency word clouds and correlations between word tokens. We built a latent Dirichlet allocation (LDA) topic model to identify commonly discussed topics in a large sample of tweets. We also performed sentiment analysis to understand the overall sentiments and emotions related to COVID-19 vaccination in Australia.

Results: Our analysis identified 3 LDA topics: (1) attitudes toward COVID-19 and its vaccination, (2) advocating infection control measures against COVID-19, and (3) misconceptions and complaints about COVID-19 control. Nearly two-thirds of the sentiments of all tweets expressed a positive public opinion about the COVID-19 vaccine; around one-third were negative. Among the 8 basic emotions, trust and anticipation were the two prominent positive emotions observed in the tweets, while fear was the top negative emotion.

Conclusions: Our findings indicate that some Twitter users in Australia supported infection control measures against COVID-19 and refuted misinformation. However, those who underestimated the risks and severity of COVID-19 may have rationalized their position on COVID-19 vaccination with conspiracy theories. We also noticed that the level of positive sentiment among the public may not be sufficient to increase vaccination coverage to a level high enough to achieve vaccination-induced herd immunity. Governments should explore public opinion and sentiments toward COVID-19 and COVID-19 vaccination, and implement an effective vaccination promotion scheme in addition to supporting the development and clinical administration of COVID-19 vaccines.

Introduction

The COVID-19 Pandemic

COVID-19 is an infectious disease caused by the novel coronavirus SARS-CoV-2, which was first identified in Wuhan, China, in December 2019 [1]. As of early January 2021, the cumulative number of confirmed cases was 83,862,300, while the number of deaths was 1,837,253, affecting 222 countries or regions globally [2]. In Australia, the total number of confirmed cases was 28,483, and the number of deaths was 909 in early January 2021 [3]. Both the incidence and prevalence have been rising globally, although these rates differ across countries [4]. In 2020, the pandemic had significant negative impacts on individuals, governments, and the global economy [5,6].

Patients with COVID-19 could experience either no symptoms, common signs and symptoms of infection, or respiratory distress, or die from the disease. The proportion of asymptomatic patients was estimated at 16%, with the proportion in children being nearly double that of adults [7,8]. However, over 80% of those who were asymptomatic had either unilateral or bilateral pulmonary involvement in computerized tomography scans [8]. Among those who were symptomatic, fever, cough, and fatigue were the most common symptoms [9,10]. Five percent of patients with COVID-19 developed acute respiratory distress syndrome [11]. Among them, the death rate ranged between 13% and 69% across countries [12].

The virus could be transmitted through close contact, or even droplets, between individuals, where the mucous membranes of healthy individuals are exposed to secretions produced by the carriers [13]. The reproductive number (R_0) of COVID-19 was approximately 3 but varies from 2 to 7 across countries [14,15]. This means one carrier could infect 3 individuals on average. Under public infection control measures, social distancing does not seem applicable to family households where the risk of transmission is high. A meta-analysis of 24 studies found that the intrafamily transmission rate of SARS-CoV-2 was higher than the transmission rate of severe acute respiratory syndrome coronavirus (SARS-CoV) or Middle East respiratory syndrome coronavirus (MERS-CoV) in households [16], which may contain vulnerable groups such as the elderly, those who are immunocompromised, or have chronic diseases.

Background on Vaccination

Briefly, the purpose of vaccination is to allow the immune system to memorize the features of the targeted pathogen and be able to initiate an immune response that is fast and strong enough to defeat the live pathogen in the future. Over 115 vaccines for COVID-19 are undergoing investigation and trials, and most of them target the spike protein of SARS-CoV-2 [17]. The development of a vaccine usually takes years. The relatively fast development of the COVID-19 vaccine could be ascribed to previous work on vaccines for SARS-CoV, which is 80% similar to SARS-CoV-2, as well as the immense and urgent need for vaccination [18].

Vaccination that is evidence-based and officially approved by health authorities is generally safe. The adverse effects, as well as their incidence rates, vary across types of vaccines. Previous studies have reported the incidence rates of severe adverse reactions in general populations after receiving vaccines. For example, the incident rate of febrile seizures after receiving the measles, mumps, and rubella (MMR) and varicella vaccine was 8.5 per 10,000 doses [19]. The rates attributable to influenza vaccines or 13-valent pneumococcal conjugate vaccines (PCV13) were 13 to 45 per 100,000 doses [20]. On the other hand, the incident rate of thrombocytopenic purpura after MMR injection was 1 per 20,000 doses [19]. Moreover, the incidence rates of some rare diseases such as intussusception after rotavirus vaccine injection ranged from 1 to 5 per 100,000 doses [20]. There was insufficient evidence to conclude that vaccination was the direct cause of the severe adverse effects compared with the vast majority of those who benefited from vaccinations.

Vaccination is a collective strategy that needs a high proportion of the population to be vaccinated in order to generate a protective effect. The proportion is calculated as $(R_0–1)/R_0$ [21]. If one patient could infect 3 individuals, then the proportion of the population that needs to be vaccinated would be two-thirds. This two-thirds should comprise individuals who have normally functioning immune systems. Those who are immunocompromised are contraindicated to certain types of vaccines such as live vaccines because of poor responses or severe adverse reactions [22,23]. Severe allergic reaction to a vaccine is a contraindication, although the risk is as small as 1 per 1,000,000 doses [19]. Hence, the higher the proportion of those who have normal immune systems receiving vaccinations, the better for achieving herd immunity to protect oneself and others.

Exploring Public Opinion on the COVID-19 Vaccine

In the last two decades, a prominent antivaccination movement has risen, resulting in a decline in MMR vaccination coverage and a rise in measles outbreaks in the United States, the United Kingdom, and certain major European countries [24]. A case study, which proposed an association between the MMR vaccine and autism [25], although disproven by several studies in subsequent years [26-31], fueled the antivaccine movement, and then was retracted [32]. Nevertheless, the adverse factors promoting antivaccination might be ignoring high-level evidence such as the results of randomized controlled trials of vaccines [33-35] as well as a selective adoption of unverified information by the public.

Social media has become a frequently used platform to disseminate both authorized information and misinformation. Authorized sources such as the World Health Organization [36], the US Centers for Disease Control and Prevention [37], the US Food and Drug Administration [38], and the UK Department of Health and Social Care [39] are available online. However, previous studies showed that around 30% to 60% of the information related to vaccination on social media were antivaccine content [24]. In websites that provided vaccine-related information, over 50% contained inaccurate information [40]. Although antivaxxers proposed different rationales to oppose vaccination [41], the fact is that only vaccination has a history of successfully eradicating viral diseases such as smallpox [42].

XSL•FO
RenderX

As several COVID-19 vaccine trials are progressing to or have nearly completed phase 3 in the second half of 2020, it is expected that vaccines will be made available to the public by 2021 [43,44]. In Australia, Dodd et al [45] conducted an online survey of 4362 adults in mid-April 2020 about 1 month after lockdown measures had been imposed. They found that 86% of the sample claimed that they would get the COVID-19 vaccine when available. At that time, 65% to 75% of the respondents were confident in the federal and state governments' responses. On August 19, the Australian prime minister [46] announced that the government had made an agreement with AstraZeneca: if its COVID-19 vaccine is proven to be safe and effective, Australia could manufacture it and make it free for the public. Later, the University of Oxford and AstraZeneca [47] and Johnson & Johnson [48] paused their vaccine trials in mid-September and mid-October 2020, respectively, to investigate adverse reactions among participants during the trials, which were resumed after investigations.

Significant health care–related events, such as news about vaccine efficacy [49], disease outbreak [50], or legislative decree of mandatory vaccinations [51], were found to trigger public discussions on social media. However, negative news about the vaccine, as well as antivaccine sentiment, could be hurdles to achieving vaccination-induced herd immunity. For example, information associated with the adverse effects of vaccinations were commonly manipulated by antivaxxers to fuel their movements [52]. They had even started using conspiracy theories against developing COVID-19 vaccines even before development had begun [53-55]. Therefore, online public opinion and sentiments around COVID-19 vaccination need to be explored and reviewed to promote public vaccination schemes based on factors affecting vaccination acceptance.

This study aimed to explore major topics and sentiments of tweets about COVID-19 vaccination among Twitter users in Australia. Findings from this study could help governments and health agencies plan, modify, and implement a timely promotion of vaccination to achieve vaccination-induced herd immunity.

Methods

Data Collection

Twitter, one of the world's major social media platforms, with 187 million daily active users as of the third quarter of 2020 [56], was chosen as the data source. Twitter is a common source of text for sentiment analysis [57,58] and analysis of sentiments toward vaccinations [59,60]. We used the R library package *rtweet* [61] to access the Twitter premium API (application programming interface) service and collect COVID-19 vaccine–related tweets posted between January 22 and October 20, 2020. Retweets, non-English tweets, and tweets with a geolocation outside Australia were excluded. The search terms "vacc OR vax OR vaccine OR vaccination" AND "corona OR covid" were used to search target tweets. Boolean operators "AND" and "OR" guaranteed that tweets that contained words belonging to the root of "vaccine" as well as the root of either "coronavirus" or "COVID" could be searched. As a result, 31,100 tweets were collected and used in this study. The number of tweets collected from January 22 to October 20, 2020, are shown in Multimedia Appendix 1.

Data Preprocessing

The R library packages of *qdapRegex* [62] and *tm* [63,64] were used for the preprocessing of text. The procedures included (1) removal of non-English words or common words that do not provide insights into a specific topic (eg, stop words); (2) case folding, which changes words into lower case for stemming; and (3) stemming of inflected words into roots, followed by stem completion to return complete words (tokens) for the results visualizations. The custom stop words removed were "amp" (ampersands) and the inflected words derived from "vaccine," "coronavirus," and "COVID." In addition to that, all stop words with reference to those in the package *tm*, Python libraries *spaCy* [65] and *gensim* [66], as well as stop words suggested by Sedgewick and Wayne [67] and the SAO/NASA (Smithsonian Astrophysical Observatory/National Aeronautics and Space Administration) Astrophysics Data System [68], were also removed in the corpus. Stop words in Python libraries and in other aforementioned sources were extracted and assigned to an R object for the ease of process in R. In addition, the dictionary used for stem completion was a corpus saved before the stemming procedure.

Associations Between Word Tokens

The word tokens were sorted by their counts in the corpus and plotted against their counts as shown in Multimedia Appendix 2. It was observed that the inflection point of the concave-up, decreasing curve was located at approximately 250 counts. Thus, word tokens having counts greater than 250 were included in pairwise correlation tests. The R library package *widyr* [69] was used to compute the correlations between word tokens. Then, the word pairs with Pearson correlation coefficients larger than 0.1 were plotted in a network graph. Coefficients smaller than 0.1 were considered negligible [70,71]. On the other hand, word pairs were also sorted by their counts and plotted against the counts as shown in Multimedia Appendix 3. Word pairs having counts larger than 150 were plotted in another network graph. The cutoff of 150 was adopted so that major clusters of word pairs with higher counts could be identified in the network without overly suppressing other pairs with significantly lower counts.

Latent Dirichlet Allocation Tuning and Model Building

Latent Dirichlet allocation (LDA) [72] is an unsupervised machine learning method that allows observations such as words or documents in a corpus to be explained by latent groups such as topics. LDA has been used in topic modeling of public opinions on certain vaccinations for human papillomavirus (HPV) [73] and influenza virus [74]. However, LDA topic modeling on COVID-19 vaccination was yet to be done. The corpus preprocessed was converted into a document-term matrix, and then terms that were sparse by less than 99.9% were retained for LDA modeling. The R library package *ldatuning* [75] was used to estimate the optimal number of topics in the LDA model. Four different metrics were computed in a range of topics (2-50) to identify the optimal number (Multimedia Appendix 4). The lower the metrics of

XSL•FO
RenderX

"Arun2010" [76] and "CaoJuan2009" [77], and the higher the metrics of "Griffiths2004" [78] and "Deveaud2014" [79], indicated a better number of topics to fit the LDA model. In this study, the metric of "Deveaud2014" reached its highest level and the metric of "CaoJuan2009" reached one of the lowest levels at 3 topics that were adopted as the number of topics for LDA modeling. Another R library package *topicmodels* [80] was used to estimate the two posterior Dirichlet distributions—theta distribution over the 3 topics within each tweet and beta distribution over all words within each topic. Only the top 100 words with the highest beta values were visualized using a word cloud for each topic. A larger font size and a higher level of opacity were used to indicate words with higher beta values. In each topic, the top 20 tweets, except those from news sources, with the highest theta values, which were also larger than those of the other two topics for each tweet, were reported.

Sentiment Analysis

The R library package *syuzhet* [81], which applies Stanford's CoreNLP [82] on text against an emotion dictionary, was used to score each tweet based on the 2 sentiments and 8 emotions defined in the Canadian National Research Council's Word-Emotion Association Lexicon [83,84]. There were 10 categories for scoring a tweet. The 2 sentiments were negative and positive, while the 8 emotions were anger, fear, anticipation, trust, surprise, sadness, joy, and disgust. The polarity of a tweet could be positive or negative, whereas emotion recognition aimed to identify the emotions that a tweet carried. If a tweet was associated with a particular emotion or sentiment, it would score points that reflect the degree of valence with respect to that category. Otherwise, it would have no score for that category.

Results

Overview

We first analyzed the preprocessed tweets by visualizing the word tokens with a count of >250 in the corpus as shown in the word cloud in Multimedia Appendix 5. The larger the word font size in the cloud, the higher the number of counts in the corpus. The top 10 high-frequency words were "trials," "australia," "virus," "news," "developers," "flu," "people," "years," "world," and "testing." Following that, other frequently used words included: "research," "working," "timeline," "immune," "australian," "effects," "russian," "health," "human," and "government." Based on the descriptive statistics of word counts, news about the pandemic, seasonal flu, and vaccine trials were major discussion topics among Australians. Other topics such as the effects of infection control strategies and immunity, the situation overseas, and the government's responses were also relatively prominent.

Figure 1 shows the network of word pairs with counts above 150 in the corpus. The word tokens linked with edges, where thicker and more opaque lines indicate a higher number of counts. From the graph, a group of words that were frequently used together were "trials," "human," "clinical," "news," and "australia." Moreover, the word "trials" was linked to a number of word tokens such as "phase," "australia," "testing," "volunteers," and "university"; the latter was linked to "oxford" and "queensland." Another cluster of words that were commonly used together included "flu," "years," "virus," and "people." Bigrams such as "herd" and "immune" had some associations with "flu" and "virus." There were a few word pairs, such as "antivax" and "vaxxers," which were not connected to the main network and had a relatively small number of counts at the periphery of the graph.

We further examined the correlations between word tokens. The network of correlations (r>0.10) between word tokens with a count above 250 in the corpus is visualized in Figure 2, where the edges with a larger width and higher opacity indicate stronger correlations between word tokens. A major network of words consisted of keywords associated with the development and clinical trial of vaccines such as "trials," "clinical," "human," "phase," "volunteers," "participant," "astrazeneca," "university," "queensland," and "oxford." Another noteworthy major word network was composed of keywords that were related to the Australian government's partnership with vaccine manufacturers in providing doses for the public: "deal," "federal," "government," "scotty," "morrison," "millions," and "doses." On the other hand, "flu" was the center of another cluster associated with "influenza," "deaths," "rates," "vax," and "shot." Some word pairs like "common" and "cold," "herd" and "immune," and "antivax" and "vaxxers" had distal associations with the main network. The pair "antivax" and "vaxxers" had some associations with "conspiracies" and "vax" linking with "flu" and "understand," which in turn correlated with "science" and "shared." Furthermore, "social" and "distancing" had a strong correlation, but this bigram, along with a few words that had some associations with them, did not link with the larger network of word tokens. Other similarly independent bigrams included "fast track" and "big pharma."

We built a 3-topic LDA model and visualized the top 100 probability (beta) distributions of words for each topic in word clouds (Multimedia Appendix 6). The beta values are reported in Multimedia Appendix 7, and the top 20 probability (theta) distributions of topics in the tweet samples are shown in Multimedia Appendices 8-10. Three topic themes were synthesized from the word clouds and tweets extracted.

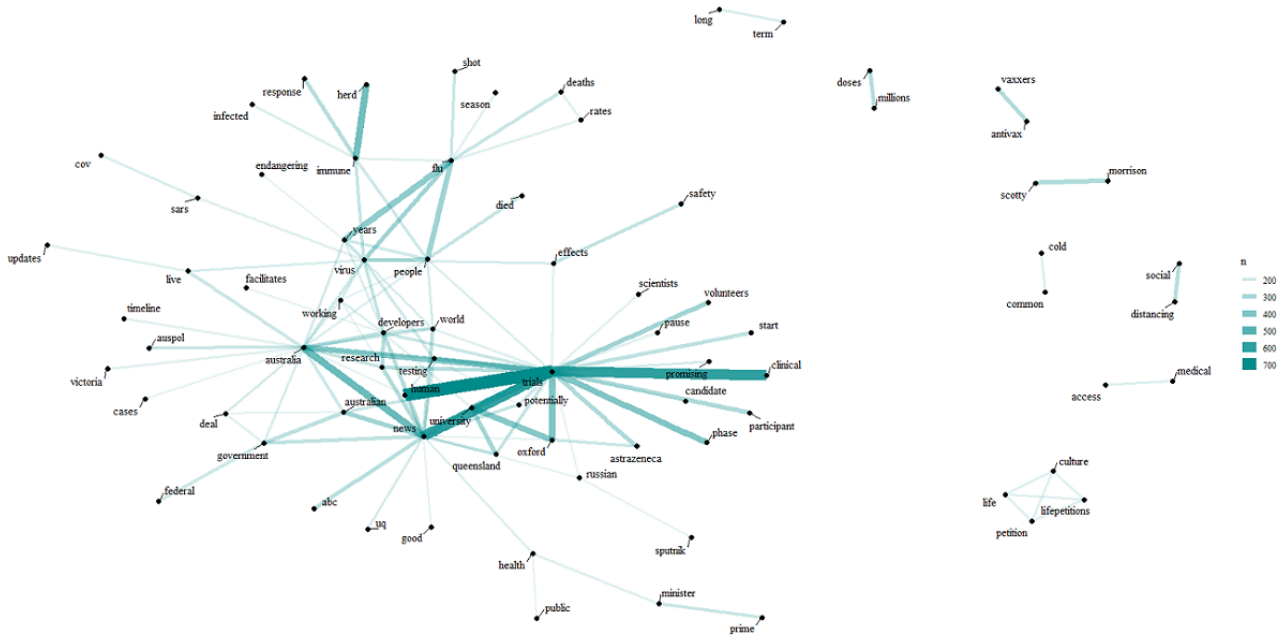
Figure 1. Network of word pairs with counts above 150 in the corpus.



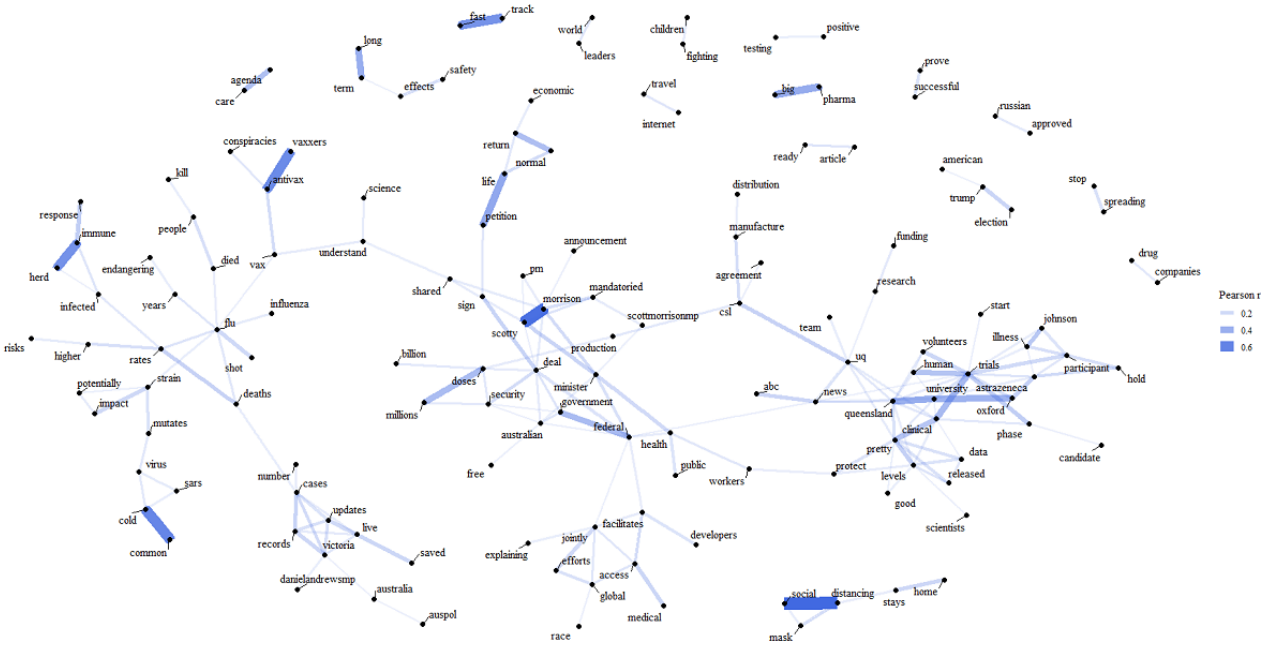


Figure 2. Network of correlations (r>0.10) between word tokens with counts above 250 in the corpus.

Topic 1: Attitudes Toward COVID-19 and COVID-19 Vaccination

The latent topic 1 centered on the public's attitudes or actions toward COVID-19 vaccination, which were associated with personal values, theories, information received, or personal experiences. Vaccine supporters accepted COVID-19 vaccination because they considered that measures should be taken to cope with the rising number of infections, deaths, health care burden, and costs due to COVID-19. They scorned those who pretended to be experts or posted misinformation such as claiming that deaths from COVID-19 were attributable to other diseases. In addition, they also supported public vaccinations by taking actions such as seeking funding sources and media to promote vaccine trials. Those who worried about the COVID-19 vaccine were skeptical about conspiracy theories such as the "mark of the beast" and microchips in vaccines. The sudden pause of vaccine trials also triggered worries among users about the safety of vaccination. Some Twitter users claimed that they would not get vaccinated because of previous experience with vaccination-related adverse effects. Nonetheless, stock prices increased when positive news about vaccine development were released. Other Twitter users disregarded COVID-19, expressing that COVID-19 had a much lower death rate than the flu, thus making it insignificant for vaccination, which they deemed would only benefit pharmaceutical firms

XSL•FO
RenderX

or be politicized. Moreover, implementing lockdowns before mass vaccination was not considered efficient in the long run. Users also thought that COVID-19 should not deserve more attention than other global problems such as climate change, aged care, or other diseases.

Topic 2: Advocating for Infection Control Measures Against COVID-19

The latent topic 2 indicated that some Twitter users were positive about the development of COVID-19 vaccines and antivirals and recognized the need for these products. Meanwhile, they also advocated following infection control measures and disproved misinformation or conspiracy theories. Some Twitter users rebutted tweets that may have been posted by antivaxxers or conspiracy theorists. For example, these users refuted skepticism over the safety of the rapidly produced vaccines, false claims about the association between the flu vaccine and COVID-19 infections and deaths, and inaccurate beliefs about vaccination coverage for achieving herd immunity differing across diseases. Some of their tweets emphasized the rising number of deaths related to COVID-19 within a rather short period compared with other pandemics in the past. They argued that although there were deaths caused by the flu, there were drugs, vaccines, and promotion campaigns targeting the flu. In comparison, deaths from COVID-19 were soaring, and even worse than the flu, without mass vaccinations or antivirals. However, COVID-19 deaths could have been preventable. With previous experiences in developing vaccines for other coronaviruses such as MERS-CoV, users believed that the COVID-19 vaccine could be successfully developed to protect vulnerable groups like patients. They believed that everyone was susceptible to COVID-19 after contracting the coronavirus without vaccination. In the future, antivirals could also be developed. Beyond vaccines and drugs, they thought physical measures such as wearing masks and social distancing should be followed, particularly at a time when mass vaccination and antivirals are not yet available.

Topic 3: Misconceptions and Complaints About COVID-19 Control

The latent topic 3 generally showed the baseless claims and conspiracy theories that antivaxxers held against the COVID-19 vaccine as well as complaints and helplessness about testing and lockdown measures, which would likely end with vaccination-induced herd immunity. Some Twitter users made claims that were unfounded or based on conspiracy theories against the COVID-19 vaccine. For example, one concluded that Australia suggested using a vaccine that had never been tested or certified to fight the virus. Some others believed that hydroxychloroquine was an effective treatment; hence, banning its use was viewed as a politicized action. Users also thought that those rejecting hydroxychloroquine should take vaccines from Bill Gates, who was falsely accused of planning to implant microchips into human bodies via vaccinations. However, other Twitter users pointed out the limitations of vaccinations such as their inability to prevent viral transmissions or treat COVID-19 and its complications. Even if vaccines are available, a high number of doses globally and tests for the virus or even antibodies are required if COVID-19 is not eradicated. Some complained that the tests led to an increase in known positive cases and in turn a prolonged lockdown, making the situation helpless without the availability of a vaccine. On the other hand, provaxxers celebrated the success in vaccine development. They criticized antivaxxers for not believing in science and accepting vaccination, as well as for disregarding the serious consequences of COVID-19 and for suggesting natural herd immunity, which would be catastrophic. For example, allowing the rampant spread of the coronavirus would lead to health care system breakdown and loss of life.

Figure 3 shows the change in sentiment scores of all tweets between January and October 2020. In each tweet, there could be both positive and negative sentiment with valences in opposite directions. Figure 3 shows that the scores increased gradually between January and March 2020. The higher the sentiment score, regardless of direction, the likelier the tweet will have stronger sentiments. However, most tweets expressed positive sentiment (score=62,498, 67%) rather than a negative one (score=27,622, 30%), while 940 (3%) tweets were neutral.

Figure 4 shows the emotion scores with respect to anticipation, joy, surprise, and trust in all tweets. The scores also rose in the first quarter of 2020. Approximately 45% of the scores were associated with these 4 emotions. Specifically, the emotion components were trust (score=22,436, 17%) and anticipation (score=19,278, 14%). Some tweets scored for surprise (score=7865, 6%) and joy (score=10,296, 8%).

Figure 5 shows the scores of negative emotions such as anger, disgust, fear, and sadness for all tweets. The scores increased in the first 3 months of 2020; approximately one-third of the scores were associated with these negative emotions. Among them, fear was the most significant one (score=18,449, 14%). Other emotions included sadness (score=11,082, 8%), anger (score=9091, 7%), and disgust (score=6337, 5%). On the other hand, nearly 22% (n=6994) of the tweets were emotionally neutral.

Discussion

Principal Findings

We found that the public opinion about COVID-19 vaccines fell under 3 latent topics among Australian Twitter users from January 22 to October 20, 2020. Topic 1 was about different attitudes and actions toward COVID-19 and its vaccination. Provaxxers recognized the consequences of the COVID-19 pandemic and supported vaccine trials. Those who were skeptical about vaccines were affected by misinformation and adverse effects, which are statistically rare. Some Twitter users gave low priority to COVID-19 and hence vaccination against it and other unrelated problems. Topic 2 showed that some Twitter users advocated for infection control measures, had confidence in COVID-19 vaccine trials, and rebutted tweets that were derived from conspiracy theories or misinformation. They argued that infections and deaths from COVID-19 had overtaken previous pandemics, and other measures such as wearing masks and social distancing should be followed when mass vaccination is yet to come. Topic 3 centered on baseless claims, conspiracy theories, complaints, and misconceptions about various measures against COVID-19, including vaccines, drugs, virus testing, lockdown, and herd immunity. The major pitfall of these tweets was that their content could not be supported with any valid scientific evidence; further, the complaints were not directly associated with any solutions. Another significant finding was that nearly two-thirds of the sentiments in the tweets related to COVID-19 vaccines were positive. Of those tweets analyzed, 17% of the emotions were linked with trust and 14% were associated with anticipation. However, 14% contained fear and 8% expressed sadness. Overall, less than one-third of the tweets' sentiments were classified as negative, and one-third of the tweets were associated with the 4 negative emotions (ie, fear, sadness, anger, and disgust).

Comparison With Prior Work

In the past decade, machine learning has been applied to explore topics and sentiments of content from Twitter users about vaccinations. Some studies have examined tweets related to vaccinations in general, while others have analyzed vaccination-related tweets focusing on a particular virus or disease, such as the influenza virus, which causes respiratory illness, or HPV, which is mainly sexually transmitted. Those studies identified both positive and negative sentiments toward vaccinations, as well as neutral sentiment. Nevertheless, the outcomes of sentiment categories and the topics identified from Twitter users varied across studies focusing on different countries, years, viruses, and thus diseases.

For example, Jamison et al [85] generated 100 topics using LDA in which nearly half were annotated as provaccination, and less than 30% were coded as antivaccination from English, vaccine-relevant tweets between 2014 and 2017. However, Raghupathi et al [60] found that both positive and negative sentiments accounted for 40% of English tweets in the first half of 2019. On the other hand, the composition of sentiments in non-English tweets could be different from of English tweets. In Italy, Tavoschi et al [51] used support vector machine to classify tweets' term frequency–inverse document frequency between 2016 and 2017, and found that 60% were neutral, 23% were against vaccination, and only 17% were provaccination. It was also found that the number of provaccine tweets became greater than the number of antivaccine tweets when news about compulsory vaccination and the soaring rate of positive cases or deaths were broadcast [86].

The topics identified were not entirely similar across studies. For instance, Jamison et al [85] summarized 5 provaccine themes and 5 antivaccine themes from 100 topics; and Raghupathi et al [60] identified 3 focus areas (eg, the search for better vaccines, the disease outbreak, and debates between provaxxers and antivaxxers regarding measles). Chan et al [74],

XSL•FO
RenderX

who studied influenza vaccination in the United States, used LDA to create 10 topics in which some shared similar attributes with the themes of Jamison et al [85], such as vaccine science, safety concerns, and conspiracy theories. Some, but not all, of the similar themes, focus areas, and topics could also be seen in the analyses of tweets about vaccination regardless of virus types such as those in the studies surrounding HPV vaccinations [73,87-90].

Added Value of This Study

This study is the first topic modeling and sentiment analysis of tweets in Australia about COVID-19 vaccinations. As COVID-19 has turned into a pandemic, it is necessary to explore and summarize public opinion and sentiments pertaining to discussions on the COVID-19 vaccine, so as to prepare for the promotion of vaccination, which needs to be strengthened. This study used a traditional natural language processing technique—LDA—to identify 3 latent topics in the tweets associated with COVID-19 vaccinations: (1) attitudes toward COVID-19 and its vaccination, (2) advocating infection control measures against COVID-19, and (3) misconceptions and complaints about COVID-19 control. Furthermore, this study discovered that positive sentiment in COVID-19 vaccine discussions was higher than negative sentiment, and trust and anticipation comprised relatively large proportions of the emotions observed, as well as fear. This study visualized results using word clouds, counts of word pairs, and correlations between words, which offer supplementary angles in interpreting the results. For example, high-frequency words and word pairs that commonly appeared together were intuitively presented.

The Australian population has been the focus of research on tweets related to vaccination in previous studies. Taking the HPV vaccine as an example, nearly one-fifth of Australian Twitter users expressed health concerns about the vaccine [88], and around one-third of the exposure to information on Twitter was associated with misinformation or adverse effects of the vaccine [89]. Our study provides new insights into topics of discussion in Australia and sentiments toward vaccination against COVID-19, which is now a global pandemic and has caused over 900 deaths in Australia [3] and over 1.8 million deaths worldwide [4] as of early January 2021. By assessing public opinion and the sentiments associated with COVID-19 vaccination, governments and health agencies can plan, tailor, and implement a timely promotion of vaccination to achieve herd immunity as soon as possible.

Implications

In the results of the previous studies, we did not see a prevalent objection or opposition, in terms of topics identified or sentiments, toward vaccination regardless of virus types. A number of topics' focus areas or themes shared a certain level of similarity across studies concerning different viruses. For instance, topics of safety, scientific evidence, and conspiracy theories were commonly found across studies. Topics like scandals associated with vaccines, misinformation, and disease outbreaks were identified in some other studies. These results indicated public concern about the benefits and risks of vaccination at the individual and social levels, and the type of virus or disease when deciding whether to receive a vaccine or not.

In our study, besides fabricated information such as microchips in vaccines and the flu vaccine causing COVID-19 deaths, some Twitter users thought that COVID-19 was not serious enough compared to other existing global crises, and that the pandemic was being politicized or commercialized. These conspiracy theories, along with other antivaccine propagandas such as encouraging natural herd immunity, indicated that the risks of deaths, complications, or sequela arising from COVID-19 to others, or to oneself, were acceptable to some members of the public.

Although the Australian opinion showed more positive sentiment related to COVID-19 vaccinations, the positive sentiment was not a leading majority compared to the negative one. This means more work needs to be done to promote vaccination so as to achieve herd immunity to protect vulnerable and minority groups. Rigorous science that is easily understandable needs to replace biased, fabricated, or outdated information in the public. Governments should build and strengthen the public's confidence in COVID-19 vaccination, if it is not mandatory, that is, required by law, beyond arranging vaccine delivery logistically and vaccine administration clinically.

Limitations

Our results represent Twitter users in the Australian public, which is a different approach from national survey statistics. However, the public opinions collected on Twitter may represent views from younger populations. Previous studies showed that around 85% to 90% of Twitter users were aged less than 25-40 years, which varied across locations such as the Netherlands [91], the United Kingdom [92] and other places [93]. Older adults' opinions require further investigations with modifications to the study design whereas younger adults' opinions on the vaccine deserve continuous attention. Goldstein et al [94] reported that those aged less than 35 years had high cumulative rates of COVID-19 infections in the community where transmissions in secondary schools or high schools were robust. A report published by the US Centers for Disease Control and Prevention [95] showed that the percent positivity of SARS-CoV-2 RT-PCR (reverse transcription–polymerase chain reaction) tests increased early among young people, followed by a rise in positivity in middle-aged and older adults. Consequently, around 20% of adolescents manifested symptoms compared with nearly 70% of the elderly [96], who are subject to a higher probability of further developments leading to death. Hence, there is an urgent need to explore younger population's opinion and acceptability of vaccination, which could have significant impact on disease control in the first place.

In addition to the study period and the country of concern, analysis methods might lead to variation in topics and sentiments toward vaccinations. For supervised learning such as support vector machine, a training set is required, which needs to be manually labeled; this might carry some subjectivity in categorizing tweets into predefined topics for training. However, the advantage is that the set could be used to validate the model performance and then test a large data set. Considering unsupervised learning such as LDA, Dirichlet multinomial

XSL•FO
RenderX

mixtures (DMM), and k-means of term frequency–inverse document frequency, the primary limitation is the subjectivity in defining the topics created [60,74]. In addition, a sound reason or calculation is needed to support the preset number of topics, which would affect the results.

Some previous studies generated a rather high number of topics (30-100) using an LDA or DMM model, and then manually grouped the topics into themes [73,85,89]. However, there was risk of bias since the content of each topic was not reported in detail, and the contents of the themes could be mixed, which is difficult to interpret. Furthermore, the manual grouping also contained the risk of subjectivity. In the current study, we adopted LDA, which was similar to the one used by Chan et al [74]. We identified 3 latent topics in which the importance of words were visualized; the frequency of word pairs and correlations between words provided additional results corresponding to the topic content.

Regarding sentiment analysis, the number of emotion categories were limited to 8 [83,97], but emotion is an abstract and broad concept that may involve as many as 27 categories [98]. Furthermore, words with spelling mistakes could not be identified and analyzed in the algorithm. With respect to each term for the development of an emotion lexicon by Mohammad and Turney [83], only 5 individuals in the public were recruited to annotate a term against each of the 8 emotions. The emotions of a term were annotated without considering possible contexts. Moreover, the interrater reliability statistics were not reported though the agreement percentages were apparently high.

Future Directions

Our study adopted an unsupervised machine learning method—LDA—for topic analysis. Future studies could investigate supervised learning to train classifiers to categorize tweets into different topics and sentiments based on a recognized theoretical framework. Such a framework could be proposed after an extensive literature review and qualitative synthesis; manual annotations should be as transparent, objective, and reliable as possible. Results from supervised learning following the same theoretical framework could be compared across the analyses of different data sets, for example, the results from different countries as shown by Shapiro et al [88]. Public opinions across countries require further study. For instance, recent online surveys of US adults found that only half claimed that they were “very likely” to get the COVID-19 vaccine [99], and one-third would not accept recommendations for vaccination [100]. In the United Kingdom, around one-third of the adult sample showed hesitancy or resistance against COVID-19 vaccination [101,102]. In the future, a spatiotemporal analysis of tweets about COVID-19 vaccination could be attempted. Similar studies have been conducted on Twitter data to study emergency department visits for influenza-like illness in New York City [103], COVID-19–related stress symptoms in the United States [104], and communicating the risk of MERS infections in South Korea [105]. Furthermore, individual reactions toward the COVID-19 vaccine in tweets could be monitored over time and tested for correlations between frequencies of identified topics or emotions, important real events, and health indicators such as vaccination coverage, infection rate, and death rate. In addition to studying the spread of misinformation and conspiracy theories on social media, future research should explore personal values that might hinder collective health care strategies and positive outcomes.

Conclusions

Our findings indicate that the Australian public possessed varying attitudes toward COVID-19 and its vaccination. Moreover, some had misconceptions and complaints about COVID-19 and infection control measures, while others advocated for pharmaceutical and nonpharmacological measures against COVID-19. Nonetheless, in our sentiment analysis, the level of positive sentiment in public opinion may not be strong enough to further a high vaccination coverage to achieve vaccination-induced herd immunity, which is essential to protect oneself and others. For those without contraindications, getting vaccinated is not merely a personal choice but is also a way of protecting the community. Governments should explore public opinion and sentiments toward COVID-19 vaccination and get the public psychologically prepared for vaccination with evidence-based, authorized, and understandable information, in addition to supporting the biomedical development, storage, delivery, and clinical administration of vaccines.

Abstract

Background: The COVID-19 pandemic has broader geographic spread and potentially longer lasting effects than those of previous disasters. Necessary preventive precautions for the transmission of COVID-19 has resulted in delays for in-person health care services, especially at the outset of the pandemic.

Objective: Among a US sample, we examined the rates of delays (defined as cancellations and postponements) in health care at the outset of the pandemic and characterized the reasons for such delays.

Methods: As part of an internet-based survey that was distributed on social media in April 2020, we asked a US–based convenience sample of 2570 participants about delays in their health care resulting from the COVID-19 pandemic. Participant demographics and self-reported worries about general health and the COVID-19 pandemic were explored as potent determinants of health care delays. In addition to all delays, we focused on the following three main types of delays, which were the primary outcomes in this study: dental, preventive, and diagnostic care delays. For each outcome, we used bivariate statistical tests (*t* tests and chi-square tests) and multiple logistic regression models to determine which factors were associated with health care delays.

Results: The top reported barrier to receiving health care was the fear of SARS-CoV-2 infection (126/374, 33.6%). Almost half (1227/2570, 47.7%) of the participants reported experiencing health care delays. Among those who experienced health care delays and further clarified the type of delay they experienced (921/1227, 75.1%), the top three reported types of care that were affected by delays included dental (351/921, 38.1%), preventive (269/921, 29.2%), and diagnostic (151/921, 16.4%) care. The logistic regression models showed that age (P<.001), gender identity (P<.001), education (P=.007), and self-reported worry about general health (P<.001) were significantly associated with experiencing health care delays. Self-reported worry about general health was negatively related to experiencing delays in dental care. However, this predictor was positively associated with delays in diagnostic testing based on the logistic regression model. Additionally, age was positively associated with delays in diagnostic testing. No factors remained significant in the multiple logistic regression for delays in preventive care, and although there was trend between race and delays (people of color experienced fewer delays than White participants), it was not significant (P=.06).

Conclusions: The lessons learned from the initial surge of COVID-19 cases can inform systemic mitigation strategies for potential future disruptions. This study addresses the demand side of health care delays by exploring the determinants of such delays. More research on health care delays during the pandemic is needed, including research on their short- and long-term

XSL•FO

impacts on patient-level outcomes such as mortality, morbidity, mental health, people's quality of life, and the experience of pain.

Introduction

Times of disaster have often been characterized by a lack of access to health care, treatment delays or interruptions, and medication shortages [1-4]. The COVID-19 pandemic has broader geographic spread and potentially longer lasting effects than those of previous disasters. Further, the care of patients with COVID-19 has overburdened health care systems, and seeking health care may put patients at risk of exposure to SARS-CoV-2. Implementing necessary infection prevention precautions for the transmission of SARS-CoV-2 (the virus that causes COVID-19) and allocating resources (eg, personal protective equipment, beds, and personnel) in anticipation of or in response to a surge of COVID-19 cases has resulted in delays in and cancellations of in-person health care services, especially at the outset of the pandemic. These delays may affect a large proportion of patients. For example, in a recent study about health care delays at the outset of the pandemic among breast cancer survivors (April 2 to April 27, 2020; N=609), 44% of participants reported breast cancer treatment delays [5]. The consequences can be significant for individuals with conditions that require timely intervention, such as cancer, other chronic health conditions, and mental health concerns. The deleterious effects of postponing preventive, diagnostic, and dental health care may include the delayed or missed diagnosis of life-threatening illnesses such as cancer, the exacerbation of illnesses, and even death. Given the potential implications for the morbidity and mortality of delaying or not accessing health care, it is important to document delays and interruptions in health care access during the COVID-19 pandemic to inform appropriate intervention efforts.

Of great interest and concern are delays in preventive and diagnostic care, particularly delays in such care for older adults. Before the pandemic, approximately 50% of all adults received the recommended preventive care in the United States [6-8]. Thus, people with pre-existing and emerging conditions may not be receiving needed health care management—a problem that was not introduced but rather amplified by the pandemic. Further, as preventive and diagnostic care are the first line of defense for diagnosing life-threatening illness, delays and interruptions may result in higher mortality and morbidity. This is of particular concern for older adults, given that age is the main risk factor for cardiovascular disease, cancer, and neurodegenerative conditions [9], and such conditions may be exacerbated by stress and isolation during the pandemic. Emerging studies on delayed and interrupted care have focused on specialties such as head and neck malignancies [10], urologic surgeries [11], and heart failure [12]. Ding and colleagues [13] documented the potentially fatal consequences of care delays for COVID-19–negative patients requiring in-person medical care for timely diagnosis. They described five pediatric patient cases with poor clinical outcomes resulting from delays in cancer diagnosis. These poor outcomes unfortunately occurred despite the fact that several patients interacted with primary care providers through telehealth visits prior to presenting at the hospital. Due to the effects of the COVID-19 pandemic on people's access to health care, the oncology community anticipates an uptick in the number of cancer diagnoses and diagnoses at higher cancer stages and an increase in cancer mortality rates overall [14]—a devastating and sobering concern. Research with a focus on older adults is needed to characterize the near- and long-term impacts of delayed and interrupted care on health and inform effective and person-centered solutions to protect severely ill but treatable patients.

To address a gap in our understanding of the effects of the pandemic on health care access, we examined the rates of delays in health care among a US convenience sample at the outset of the pandemic, with a specific focus on preventive care. Our study reflects Americans' experiences with the demand for health care. We also characterized the reasons for such delays. As we navigate the pandemic and the potential resurgences of infections, our findings can inform systems-level strategies for future public health emergencies to mitigate delays, improve effective communications for addressing uncertainty, and promote mental health interventions.

Methods

Study Design

In April 5, 2020, we launched an internet-based survey study examining the impact of the COVID-19 pandemic on mental health and well-being. Participants were invited to take part in a study that focused on "how the pandemic is affecting you" through social media (ie, Twitter and Facebook), listservs, social networks, websites (eg, Buzzfeed), and the research match website at Columbia University. Information about this study was included in the beginning of the survey; participants indicated consent by proceeding to the survey. The survey comprised multiple validated instruments as well as items that were developed to help us understand experiences that were specific to the COVID-19 pandemic. The mean completion time for the full survey was approximately 35 minutes. As this study was not funded, participants were not offered compensation. At the culmination of the survey, participants were provided with a list of resources (eg, crisis hotlines) in case they experienced distress. Participants were also asked to provide their email addresses if they consented to being recontacted for future follow-ups. Participants who provided their email addresses were surveyed again between April 26 and May 5,

XSL•FO
RenderX

2020. All study procedures were reviewed and approved by the Columbia University Institutional Review Board.

Measures

Participants were asked about any interruptions they experienced to their health care in the following item, which was developed specifically for this study: "Have you experienced any delays or interruptions in your healthcare (e.g. cancelled or delayed appointments, tests, procedures) during the coronavirus outbreak?" Response options for this item were dichotomous ("yes" or "no"), and participants who responded affirmatively were asked to elaborate with an open-ended, text-based answer. Responses ranged from no delayed care to multiple types of delayed care. Some participants included more detailed responses.

Data Coding and Analysis

To characterize and code the types of delays, we used Microsoft Excel. Three researchers (ELP, DR, and HG) coded participants' responses to the open-ended item about the types of health care delays and interruptions they experienced [15,16]. The coding process was as follows. First, one researcher (DR) reviewed a set of 25 randomly selected responses and developed a draft codebook, which primarily focused on the types of care affected. Second, the three researchers collaboratively reviewed the codebook draft and planned the logistics of the coding process. Each researcher coded the same 50 responses, identified coding uncertainties, and noted potential codebook edits. To establish interrater reliability, the three researchers discussed coding discrepancies until they were resolved with 100% agreement among all three researchers. The codebook was edited to clarify codes, add additional codes, and remove codes. Third, each researcher coded a third of the remaining responses. Any uncertainties were resolved by communication and discussion with the other two researchers. Finally, upon completion, researchers debriefed to further refine the codebook (eg, adding a dermatology code based on its frequency of appearance in the data set). All codes (n=2776) were integrated into a single spreadsheet.

Statistical Analysis

Basic descriptive statistics were used to describe the research sample. We conducted two sets of inferential procedures to determine which factors were associated with self-reported health care delays, with a focus on three outcome variables. First, we examined the determinants of experiencing any health care delays due to the pandemic (dichotomous variable; "yes" or "no"). Among those who experienced delays, we were particularly interested in the following three types of delays: dental, preventive, and diagnostic care delays. For each dependent variable, bivariate analyses were conducted to describe the associations of the outcomes with demographic characteristics or self-reported levels of worry about their general health and COVID-19. Independent samples *t* tests were used for continuous independent variables, whereas chi-square tests were used for categorical variables. All independent variables were then entered into a multiple logistic regression model; R (The R Foundation) [17] was used for the statistical inference procedures.

Results

The analytic sample for this study included 2570 participants (accounting for missing data in the delays question) from across all US states who completed the survey between April 5, 2020, and May 5, 2020. Participants' ages ranged from 18 to 84 years (mean 37.3 years, SD 12.6 years). The majority of participants were non-Hispanic White (2464/2570, 95.9%), were cisgender (ie, gender identity is consistent with the sex assigned at birth) women (2456/2570, 95.6%), were heterosexual (1680/2570, 65.4%), and had at least a Bachelor's degree (1259/2570, 50%). Table 1 shows a summary of demographics.

Graduate or professional school	894 (34.8)
Doctorate degree (eg, MD, PhD, DrPH)	449 (17.5)

Almost half (1227/2570, 47.8%) of all participants reported experiencing delays or interruptions in their health care. Of these, 8.3% (102/1227) reported switching their care to telemedicine, and 12.6% (154/1227) reported experiencing health care access issues (eg, barriers associated with insurance coverage). Most participants (921/1227, 75.1%) who experienced delays specified the types of affected care. Some individuals solely responded with phrases such as “doctor’s appointment,” which resulted in no associated code due to the lack of the specificity of the response. Among those that specified the type of care, the three most commonly reported types of care affected included dental (351/921, 38.1%), preventive (269/921, 29.2%), and diagnostics (151/921, 16.4%) care (Figure 1). Emergency care was the least commonly reported type of care affected (12/921, 1.3%) among this sample, followed by vaccinations (14/921, 1.5%) and cancer care (14/921, 1.5%). Further, 10.2% (94/921) of the participants who responded to this item reported disruptions to the health care of others (eg, child, spouse, and parent; not included in Figure 1).

Figure 1. Types of health care impacted by the COVID-19 pandemic (n=921). Proportions do not sum to 100% because participants may have listed >1 type of care. OGBYN: obstetrics and gynecology.

In Table 2, we present the reported barriers to receiving health care services, which were based on follow-up questions that were sent to individuals who indicated an interest in participating in follow-up questionnaires. The top 3 barriers to care—each reported by about one-third of participants—included a fear of SARS-CoV-2 infection (126/374, 33.7%), provider discouragement (122/374, 32.6%), and the feeling that their health care concerns were not as important as others' concerns (118/374, 31.6%).

Table 2. Barriers to receiving health care during the COVID-19 pandemic (n=1025). Responses to the following question are presented: "Since the start of the coronavirus pandemic, have you needed to get healthcare but haven't gotten it? Why?"

Responses	Value, n (%)[a]
No	651 (63.5)
Yes	374 (36.5)
I was afraid of getting infected	126 (33.7)
My health care provider discouraged me from coming in	122 (32.6)
I felt like my concern/need wasn't as important as other people's	118 (31.6)
My health care provider is unavailable	108 (28.9)
I felt like my symptoms weren't severe enough	89 (23.8)
I have no health insurance	15 (4)
I cannot afford my copay or deductible	14 (3.7)
Other	60 (16)

[a]Proportions do not sum to 100% because participants may have listed >1 reason.

Determinants of Patient-Reported Health Care Delays

Table 3 shows the associations between the dependent variable "any health care delays" and independent variables as a series of separate bivariate tests. Several demographic factors were associated with reporting any health care delays resulting from the pandemic. On average, older age, cisgender women, White individuals, higher levels of education, higher levels of self-reported worries about general health, and higher levels of self-reported worries about COVID-19 were all associated with experiencing health care delays. We then entered all independent variables, regardless of their significance at the bivariate level, into a multiple logistic regression model. The results from the logistic regression models indicated that age (P<.001), gender

XSL•FO
RenderX

identity (*P*<.001), race (*P*=.005), education (*P*=.007), and the degree of worry about COVID-19 (*P*<.001) and general health (*P*<.001) were all significantly associated with experiencing health care delays due to the pandemic. The largest effect was observed for gender; the odds of patient-reported health care delays for cisgender men were 0.60 (95% CI 0.46-0.78) times that of cisgender women.

Table 3. Bivariate analyses[a] of the reasons for experiencing health care delays resulting from the COVID-19 pandemic (N=2570).

Independent variables	Yes	No	*P* value
Age (years), mean (SD)	38.9 (13.1)	36.0 (12.1)	<.001
Gender identity, %[b]			
Cisgender women	87.2	83.8	<.001
Cisgender men	8.3	13.4	—[c]
Transgender or nonbinary individuals	4.6	3.8	—
Race, %[b]			
White	87.8	83.9	.005

Bachelor's degree or some graduate school	38.9	35.3	—
Graduate or doctorate degree	44.1	50.2	—
Distance to nearest hospital (miles), mean (SD)	2.3 (1.0)	2.3 (0.9)	.15
Worry about general health (scale of 0-100), mean (SD)	54.5 (27.0)	50.1 (26.2)	<.001
Worry about COVID-19 (scale of 0-100), mean (SD)	76.3 (20.4)	73.6 (20.6)	<.001

[a]Bivariate tests are used to determine whether each independent variable is related to each dependent variable. Continuous independent variables are used in an independent samples *t* test to identify a significant association, while categorical independent variables are used in a chi-square test of association.

[b]Percentages are based on column totals.

[c]Not available.

We also examined delays in specific types of health care—dental, preventive, and diagnostics care. Both the bivariate tests (Table 4) and the multiple logistic regression model (Table 5) showed that the only significant independent variable that was associated with dental delays was self-reported worries about general health. Increased levels of worry were associated with fewer delays in dental care (*P*=.002). Our bivariate analyses identified two factors that were associated with experiencing delays in diagnostics (Table 4)—age and self-reported worry about general health. In the multiple logistic regression model, both factors remained significant at the .05 level of confidence. Age had a larger effect on experiencing delays in diagnostics. Every 10-year increase in age increased the odds of experiencing delays in diagnostics by a multiple of 1.36. The bivariate tests of association for delays in preventive care showed that age (*P*=.03) and race and ethnicity (*P*=.02) were significant. Neither of these factors remained significant in the multiple logistic regression model, and although there was trend between race and delays (people of color experienced fewer delays than White participants), it was not significant (*P*=.06).

Table 5. Multiple logistic regression of reasons for experiencing health care delays resulting from the COVID-19 pandemic.

Independent variables[a]	Dependent variables[b]							
	Any delays		Delays in dental care		Delays in diagnostics		Delays in preventive care	
	P value	95% CI	*P* value	95% CI	*P* value	95% CI	*P* value	95% CI
Age (years; 10-year increments)	<.001	1.12-1.28	.25	0.95-1.19	<.001	1.15-1.53	.18	0.96-1.22
Gender								
Cisgender men	<.001	0.46-0.78	.93	0.60-1.59	.17	0.27-1.20	.60	0.50-1.46
Transgender or nonbinary individuals	.36	0.80-1.81	.75	0.56-2.16	.48	0.55-3.03	.39	0.29-1.52
Race								
People of color	.07	0.64-1.02	.70	0.70-1.68	.10	0.89-2.69	.05	0.34-0.99
Sexual identity								
Sexual minority	.01	1.04-1.46	.28	0.63-1.14	.31	0.82-1.81	.26	0.61-1.14
Education								
Bachelor's degree or some graduate school	.43	0.87-1.40	.63	0.72-1.71	.87	0.60-1.90	.32	0.79-2.09
Graduate or doctorate degree	.02	1.03-1.64	.85	0.69-1.57	.58	0.69-2.03	.07	0.96-2.39
Distance (miles) to nearest hospital	.34	0.96-1.13	.31	0.81-1.07	.68	0.80-1.16	.70	0.89-1.19
Worry about general health (10-point increments)	.01	1.01-1.08	.002	0.86-0.97	.02	1.01-1.19	.95	0.94-1.06
Worry about COVID (10-point inccrements)	.88	0.96-1.05	.35	0.96-1.12	.62	0.88-1.09	.72	0.93-1.10
Intercept	<.001	0.17-0.44	.41	0.31-1.62	<.001	0.01-0.12	<.001	0.09-0.53

[a]The reference group for all categorical variables are as follows: cisgender woman (gender), White (race), heterosexual (sexual identity), and less than Bachelor's degree (education).

[b]There were 2570 observations for any delays, 907 observations for delays in dental care, 907 observations for delays in diagnostics, and 907 observations for delays in preventive care.

Discussion

Principal Findings

In June 2020, Dr Lasic, an interventional cardiologist at Jamaica Hospital Medical Center and Lenox Hill Hospital in New York, made the following prediction: "I think the toll on non-COVID patients will be much greater than COVID deaths" [18]. To our knowledge, ours is the only study that aimed at understanding the toll on patients without COVID-19 by describing rates of multiple types of health care delays as well as characterizing people who were the most affected by these delays during the beginning of the pandemic. In June 2020, under dynamic circumstances, researchers found that 32% and 12% of adults deliberately delayed or avoided routine care and emergency care, respectively [19]. Our findings suggest that a not insignificant proportion of the US populace may be experiencing delayed or interrupted care as a result of the pandemic, which may lead to decrements in health over the long term. Across all types of delays, older people, people with higher levels of education, and people who were more worried about their health were more likely to report delays or interruptions in their care. Men and people of color were less likely to report delays or interruptions.

Our findings highlight that dental care appears to be the most impacted (reported by over one-third of participants; 351/921, 38.1%). This is unsurprising, given that many dental offices closed at the outset of the pandemic due to concerns of patient and provider safety. However, studies have shown a relationship between dental health and heart disease, between dental health and diabetes, and between dental health and prenatal outcomes [20-22]. This is suggestive of the potential, downstream, deleterious health implications of delayed or interrupted dental care. Dentists are often also on the frontlines of identifying child abuse [23] and intimate partner violence [24], of which both have reportedly increased in incidence during the pandemic [25-27]. Further, a recent study conducted in Qatar has suggested that routine oral care is associated with a reduction in the risk of COVID-19 complications (eg, hospitalization and ventilation) [28]. Several months into the pandemic (July 2020), the American Dental Association released a policy declaring that dentistry was essential care (ie, care that is integral to systemic health) [29]. Of great concern are our findings associated with the frequency of reported delays in preventive and diagnostic care, particularly delays in such care for older adults. The implications of this finding are described in the *Introduction* section.

The lessons learned from the initial surge of COVID-19 cases can help mitigate potential future disruptions. Mitigation strategies for future disruptions include effective patient prioritization and triage [30-34]. For instance, Medically Necessary Time-Sensitive Prioritization is a scoring system for surgical triage that integrates multiple factors associated with

XSL•FO
RenderX

the environment, patient risk, and ethics that are intended to be generalizable across hospital settings [35]. Additionally, the Centers for Medicare & Medicaid Services have released guidelines for the provision of non–COVID-19 care [36-38], However, considerations should also include patient life factors (eg, family support and transportation) as well as systems factors at the hospital (eg, visitation policy), local and state (eg, infection control mandates), or national levels (eg, policies). Using systems thinking perspectives is necessary for addressing complex problems [39]. Cancer care providers have also recommended balancing delays against COVID-19 risk, practicing effective social distancing, and managing the appropriate allocation of resources [32]. Key to reducing delays among patients is the relaying of accessible, clear, and actionable messaging by health care systems about how and when to safely access health care.

More research on health care delays and interruptions during the pandemic is needed. Further investigation is needed into the differences between the care of chronic illness and emergent conditions. For instance, the first pandemic surge resulted in a decline in hospitalization rates and lengths of hospital stay associated with acute cardiovascular conditions as well as other common conditions, such as acute appendicitis, bone fractures, cancer, and live births. Given the evidence on differences based on sex [40], race and ethnicity [41], sexual and gender identity [42,43], and other key factors, we need to investigate sociodemographic differences in delayed or interrupted care. Further, the significant economic effects of the COVID-19 pandemic as well as the high rates of job loss may result in the loss of insurance. Thus, more work is needed to understand how these factors affect health care. The potential impacts on patient-level outcomes such as mental health, quality of life, and pain must also be considered.

Study Limitations

There are some key limitations that need to be considered. First, this study relied on a convenience sample that is not representative in terms of race, ethnicity, education, age, and gender. Convenience samples are limited in terms of the generalizability of prevalence rates. However, they have the advantage of efficiency, which is critical in a dynamic situation, and can be useful for understanding patterns and relationships associated with a phenomenon of interest. Recent research has shown that internet-based convenience samples correlate with truly random probability samples to a surprising extent. For example, Mullinix et al [44] found a correlation of 0.75 when they conducted 20 experiments that replicated results based on national probability samples on Amazon Mechanical Turk (an internet-based survey platform). More recently, Coppock [45] conducted 15 replication experiments and similarly found that convenience and national probability samples provided similar estimates of treatment and moderator effects. However, despite the limitation of using a convenience sample, our study is unique and critical to documenting experiences at the outset of the pandemic, given that the conditions under which the data were collected are not replicable. In addition, a study conducted over the internet does not reach individuals who do not have access to the internet. However, this is perhaps the only mechanism for capturing data from a fleeting moment in time that is characterized by dynamic and uncertain circumstances.

Conclusions

The pandemic has amplified people's attention to health disparities and inequities in the United States and has created a need for inclusive and equitable research. The limitations of this study highlight pervasive gaps and challenges associated with conducting such research (and doing so efficiently, given the dynamic nature of the COVID-19 pandemic). There is an urgent need for sharing lessons learned, disseminating effective strategies for reaching more diverse populations (eg, engaging leaders of marginalized communities, understanding and addressing research hesitancy, etc), and encouraging the research community to use and improve upon these strategies in future research. Although the conditions for this study cannot be replicated, the methodological lessons learned can serve as a sort of pilot study for future crises, thereby creating more diverse and inclusive bodies of research that drive health equity forward. Without explicit discussions of research limitations, the research community cannot make progress in collecting data to inform the design of effective programs for addressing health inequities that have existed long before the COVID-19 health crisis. The impact of health care disruptions resulting from the COVID-19 pandemic may be difficult to measure in the short term. However, characterizing these disruptions and improving research methods for such characterizations is critical to informing systemic and equitable planning, mitigation, and recovery strategies for the long term.

Abstract

Background: During the COVID-19 pandemic, many ambulatory clinics transitioned to telehealth, but it remains unknown how this may have exacerbated inequitable access to care.

Objective: Given the potential barriers faced by different populations, we investigated whether telehealth use is consistent and equitable across age, race, and gender.

Methods: Our retrospective cohort study of outpatient visits was conducted between March 2 and June 10, 2020, compared with the same time period in 2019, at a single academic health center in Boston, Massachusetts. Visits were divided into in-person visits and telehealth visits and then compared by racial designation, gender, and age.

Results: At our academic medical center, using a retrospective cohort analysis of ambulatory care delivered between March 2 and June 10, 2020, we found that over half (57.6%) of all visits were telehealth visits, and both Black and White patients accessed telehealth more than Asian patients.

Conclusions: Our findings indicate that the rapid implementation of telehealth does not follow prior patterns of health care disparities.

Introduction

During the COVID-19 pandemic, many hospitals reduced in-person ambulatory care. Through payment parity and reductions in administrative barriers, including the Health Insurance Portability and Accountability Act of 1996 waivers by Health and Human Services, physicians rapidly began providing care through telemedicine [1,2].

Our large academic physicians' group in Boston, Massachusetts, similarly expanded telehealth in mid-March 2020. This sudden move, however, risked exacerbating care inequity across racial and socioeconomic groups [3,4]. Given potential barriers faced by different populations [5], we investigated whether telehealth use was consistent and equitable across age, race, and gender.

XSL•FO
RenderX

Methods

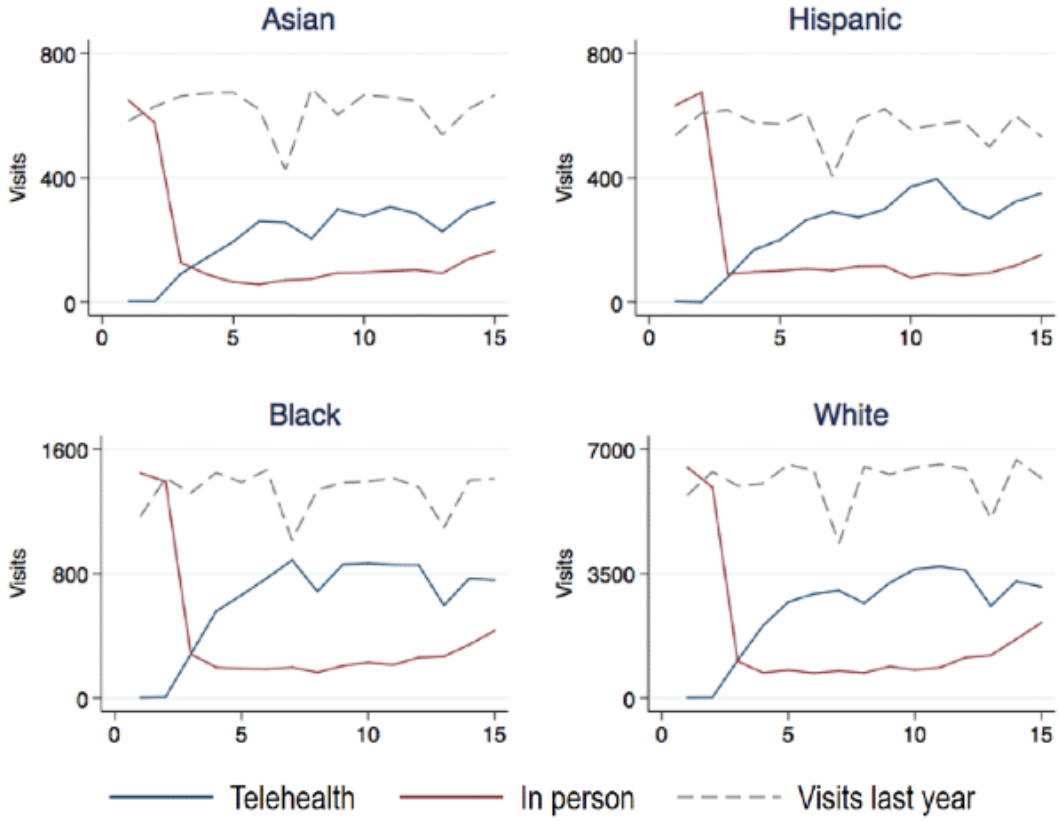
Study Population and Data Source

This study was deemed exempt by the institutional review board at the Beth Israel Deaconess Medical Center. In-person and telehealth visits to outpatient clinics staffed by our practicing faculty, between March 2 and June 10, 2020, for patients aged ≥18 years were identified and compared to visits to identical clinics during the same period in 2019.

Study Variables

Patient age (in deciles), self-identified race, and gender were extracted from the electronic health records.

Statistical Analysis



Statistical tests were performed using Stata SE (version 14.2, StataCorp). In-person and telehealth use were stratified by week and race and compared to the same period in 2019. We conducted similar comparisons by gender and age deciles and explored interaction terms to determine whether different groups of age deciles and race used telehealth more or less than other groups. We further conducted a subgroup analysis of care provided after April 27; after this date, we had more complete documentation of whether the telehealth visit was conducted using video technology or over the telephone. In this subgroup, we explored whether older adults (≥65 years old) made use of video technology at similar rates as younger patients. We similarly conducted a subgroup analysis during this period to investigate whether non-White patients used video technology at similar rates as White patients.

Results

Between March 2 and June 10, 2020, a total of 129,844 ambulatory visits were conducted, compared to 180,831 visits during the same period in 2019, which indicates a reduction of 28%. Compared to 2019, visits in 2020 decreased for all racial groups (White patients: 31%, Black patients: 23%, Hispanic patients: 26%, and Asian patients: 39%; *P*<.001).

Among visits in 2020, a total of 74,846 (57.6%) visits were conducted through telehealth. Overall, Black (n=9414 of 15,423, 61%) and White (n=37,620 of 63,397, 59.3%) patients used telehealth rather than in-person visits at higher rates; Asian patients used telehealth the least (n=3162 of 5661, 55.9%) (Figure 1). Patients with "unknown" racial designations displayed the lowest rates of telehealth use (*P*<.001).

Figure 1. Comparison of outpatient visits in 2020 with those conducted during the same time period in 2019 (dotted line), by race at a single academic health system in Boston, Massachusetts. While all racial groups experienced decreased access to outpatient care owing to the surge in COVID-19 cases from March to June 2020, Asian patients had reduced access to any care (in-person and telehealth) and a decreased rate of access to telehealth services than those of other racial groups. The x-axis represents weeks since March 2020.

Older patients accessed more outpatient care than younger patients (*P*<.001) (Table 1). Differences were observed by age and race; differences were most prominent among Asian patients (*P*<.001). Asian and Hispanic patients aged under 65 years used telehealth less than age-matched White patients (*P*<.001), but there was no difference in telehealth usage between Black and White patients under 65 years of age (*P*=.07).

XSL•FO
RenderX

In a subgroup analysis conducted among patients who sought care after April 27, we found that older adults were less likely to use video technology (19% of telehealth visits) rather than the telephone compared to their younger counterparts (26% of telehealth visits; $P<.001$). White patients used video technology significantly more (25% of telehealth visits) than those of all other races (Black patients: 16%, Hispanic patients: 23%, and Asian patients: 17%; $P<.001$).

Table 1. Overall usage of in-person and telehealth services from March 2 to June 10, 2020, at a single academic medical center in Boston, Massachusetts, among patients stratified by age and race, recorded at the time of registration (N=129,844).

Parameters	Total	In-person visits	Telehealth visits	*P* value
Age (years), n (%)				<.001
18-29	11,121 (100)	5179 (46.6)	5942 (53.4)	
30-39	19,675 (100)	10,234 (52.0)	9441 (48.0)	
40-49	15,831 (100)	6623 (41.8)	9208 (58.2)	
50-59	23,238 (100)	9437 (40.6)	13,801 (59.4)	
60-69	28,120 (100)	11,535 (41.0)	16,585 (59.0)	
70-79	20,972 (100)	7914 (37.7)	13,058 (62.3)	
≥80	10,887 (100)	4076 (37.4)	6811 (62.6)	
Race, n (%)				<.001
Asian	5661 (100)	2499 (44.1)	3162 (55.9)	
Black	15,423 (100)	6009 (39.0)	9414 (61.0)	
Hispanic	6243 (100)	2656 (42.5)	3587 (57.5)	
Other	8499 (100)	3817 (44.9)	4692 (55.1)	
Unknown	30,621 (100)	14,240 (46.5)	16,381 (53.5)	
White	63,397 (100)	25,777 (40.7)	37,620 (59.3)	
Total, n (%)	129, 844 (100)	54,998 (42.4)	74,846 (57.6)	

[a]N/A: not applicable.

Discussion

Principal Findings

Our results indicate that implementation of telehealth does not necessarily exacerbate the inequity in health care access, but it should be monitored carefully. Patients had fewer ambulatory visits of any kind during the COVID-19 pandemic; however, Asian and White patients accessed care less than Black and Hispanic patients compared to baseline. Black and White patients accessed telehealth care more than Hispanic and Asian patients. Patients with an "unknown" racial or ethnic designation upon registration had the least access to care.

Contrary to concerns that older patients might have difficulty navigating technology [6], our older patients used telehealth more often than younger patients. The potential reasons for this could be that younger patients perceived their clinical needs to be less urgent, had variable awareness of telehealth services, or experienced additional barriers [7]. However, we found that among telehealth users, patients over 65 years of age were less likely to use video technology, which may reflect concerns with technology; these concerns have been explored by other investigators [6,8]. Similarly, Black, Asian, and Hispanic patients were less likely to use video technology than White patients.

Limitations

The limitations of this study include the use of administrative data and self-reported racial designations; approximately 22% of patients in our study belonged to an "unknown" racial category, which may limit our ability to draw inferences [9,10]. Further, our documentation of telehealth early in the pandemic was unable to distinguish telephonic and video visits, which may vary across racial and age groups [6].

Conclusions

In conclusion, after a rapid increase in telehealth use at a single academic medical center in Boston, Massachusetts, we observed variable engagement of our patient population by both race and age in telehealth, but the trends did not mirror previously described patterns of health access disparity.

Abstract

Background: Identifying new COVID-19 cases is challenging. Not every suspected case undergoes testing, because testing kits and other equipment are limited in many parts of the world. Yet populations increasingly use the internet to manage both home and work life during the pandemic, giving researchers mediated connections to millions of people sheltering in place.

Objective: The goal of this study was to assess the feasibility of using an online news platform to recruit volunteers willing to report COVID-19–like symptoms and behaviors.

Methods: An online epidemiologic survey captured COVID-19–related symptoms and behaviors from individuals recruited through banner ads offered through Microsoft News. Respondents indicated whether they were experiencing symptoms, whether they received COVID-19 testing, and whether they traveled outside of their local area.

Results: A total of 87,322 respondents completed the survey across a 3-week span at the end of April 2020, with 54.3% of the responses from the United States and 32.0% from Japan. Of the total respondents, 19,631 (22.3%) reported at least one symptom associated with COVID-19. Nearly two-fifths of these respondents (39.1%) reported more than one COVID-19–like symptom. Individuals who reported being tested for COVID-19 were significantly more likely to report symptoms (47.7% vs 21.5%; $P<.001$).

Symptom reporting rates positively correlated with per capita COVID-19 testing rates ($R^2=0.26$; $P<.001$). Respondents were geographically diverse, with all states and most ZIP Codes represented. More than half of the respondents from both countries were older than 50 years of age.

Conclusions: News platforms can be used to quickly recruit study participants, enabling collection of infectious disease symptoms at scale and with populations that are older than those found through social media platforms. Such platforms could enable epidemiologists and researchers to quickly assess trends in emerging infections potentially before at-risk populations present to clinics and hospitals for testing and/or treatment.

Introduction

The global outbreak of SARS-CoV-2 led the World Health Organization (WHO) to declare a pandemic on March 11, 2020 [1]. SARS-CoV-2 causes COVID-19, which has a range of manifestations from asymptomatic infection to severe pneumonia, potentially leading to intensive care utilization and death. With over 34 million cases globally, COVID-19 has impacted health and health care in every country. Although COVID-19 spread has leveled off in some parts of the world [2], public health experts anticipate future outbreaks given that only a fraction of the population has been infected with the disease [3].

Given the need to isolate or quarantine infected individuals in order to slow community-level spread, a key component of an effective response to COVID-19 is early identification of new cases. At the beginning of the pandemic, most nations lacked capacity to confirm positive cases, typically performed using a real-time reverse transcription–polymerase chain reaction laboratory test. Over time, public health as well as hospital and commercial labs have expanded their abilities to perform COVID-19 tests. However, COVID-19 is challenging to identify because many cases are mild or asymptomatic. Between 40% and 45% of active viral cases do not exhibit symptoms [3,4]. Other individuals experience more mild symptoms, such as muscle aches, that may not prompt them to seek medical care. Individuals who do not feel sick are less likely to present to hospital or clinic for testing. Therefore, many COVID-19 cases go unreported, making it challenging for epidemiologists to track COVID-19 spread or model its future impact.

There exist several infodemiology [5,6] and digital surveillance tools to identify or estimate suspected COVID-19 cases in a population. These tools seek to capture COVID-19 symptoms, risks, and exposure information directly from consumers. Several recent studies report efforts to capture COVID-19 symptom data from consumers using internet-based surveys [7,8] or social media platforms [9,10]. Additional studies examine the use of mobile apps that allow patients to self-report symptoms; some are dedicated to COVID-19, while others are extensions of existing platforms [11-13]. Further, some studies explore the use of web search behaviors to detect potential clusters of COVID-19 [14].

Existing COVID-19 surveillance tools tend to focus on tracking COVID-19 cases in a localized geographic area. For example, a review of COVID-19 mobile apps found that more than half were official apps managed by local health authorities presumably focused in their local region [13]. Moreover, many reports on existing tools either lack details regarding users who provided information [12,14] or the population surveyed was skewed, such as in Shen et al [9] where 85% of respondents were between 19 and 40 years of age. To maximize efficacy, digital public health surveillance tools should capture data from a representative sample across local, state, and national levels to enable global outbreak identification and trend monitoring. Furthermore, public health authorities should use a variety of surveillance tools to gather data from multiple sources to triangulate disease outbreaks and trends.

In this study, we sought to examine the feasibility of using an existing web-based news platform to recruit individuals willing to self-report symptoms associated with COVID-19 as well as health behaviors via a survey. We sought to recruit a diverse set of volunteers in a manner that can be scaled during a pandemic.

Methods

Overview

We employed an epidemiologic survey to collect COVID-19 symptoms and behaviors from individuals recruited using a web-based news platform. Not knowing whether the method would be successful, we approached the project as a feasibility study. We collected data in multiple countries over 4 weeks to examine the platform's ability to capture a representative sample of the underlying population with internet access in order to detect suspected COVID-19 cases before individuals may have sought diagnosis and treatment from the health system.

Survey Instrument

The survey primarily focused on capturing symptoms associated with COVID-19. Using the best available data at the time (early April 2020), the following symptoms were included in the survey: fever, cough, itchy or watery eyes, loss of sense of taste or smell, nasal congestion or runny nose, sore throat, and shortness of breath or difficulty breathing. Our list was principally based on the list published by the US Centers for Disease Control and Prevention, which recognized three main symptoms for COVID-19: fever, cough, and shortness of breath [15]. An early systematic review, published in March 2020, that included 1576 early COVID-19 patients reported that the most prevalent clinical symptom was fever, followed by cough, fatigue, and dyspnea [16]. A later review reported the main symptoms to be fever, cough, fatigue, slight dyspnea, sore throat, headache, conjunctivitis, and gastrointestinal issues [17]. We further included anosmia (loss of the sense of smell) and ageusia (loss of the sense of taste), because early evidence [18] linking these symptoms was emerging from the literature around the time of survey development. Because these symptoms were only associated with COVID-19, and they are similar to symptoms experienced by patients with other diseases, we considered these symptoms to indicate COVID-19–like illness rather than a definitive case of COVID-19, which is confirmed through laboratory testing.

In addition to symptoms, we asked respondents to report some behaviors linked to COVID-19 risk. We specifically asked respondents to describe where they had spent time outside of their home in the past 2 weeks, more than 18 miles from home or fewer than 18 miles from home. We also asked if they had traveled outside of their home country in the previous 2 weeks.

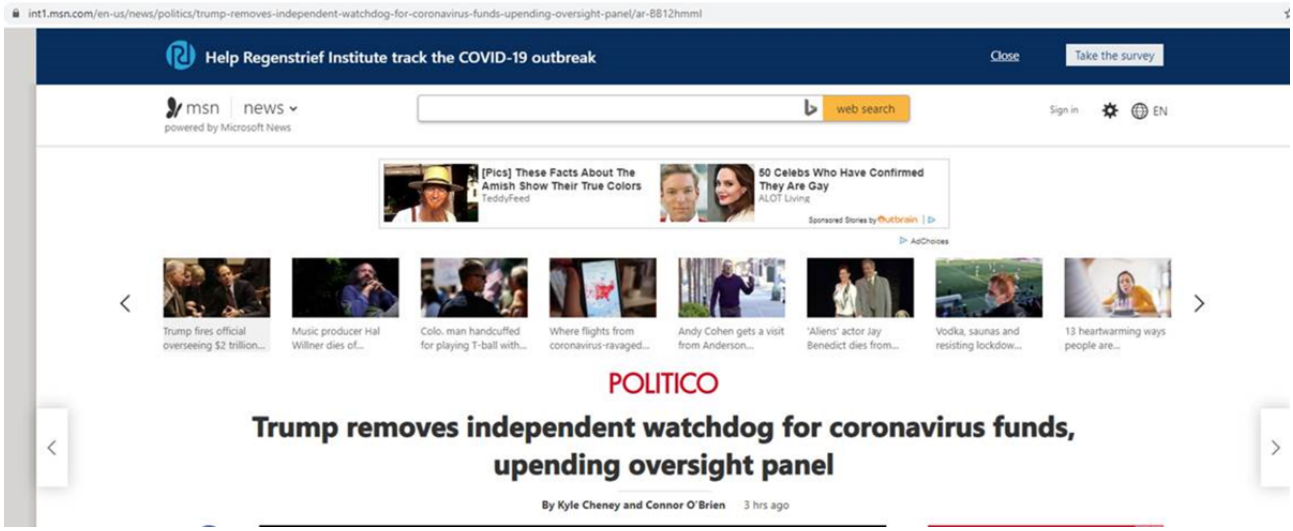
We collected minimal demographics for respondents to protect privacy. The only demographics requested were age group (eg, 40-49 years) and gender. We further asked for respondents' postal codes (eg, ZIP Code) to enable comparisons with localized outbreaks of COVID-19. We did not ask respondents to separately report their country of residence. We did not

XSL•FO
RenderX

capture race data as it is not customary to collect such information outside the United States.

We created the survey in English and subsequently translated it into 12 additional languages for release into 30 different language markets. Languages included, among others, Mandarin, French, German, Japanese, Greek, and Spanish.

Subject Recruitment



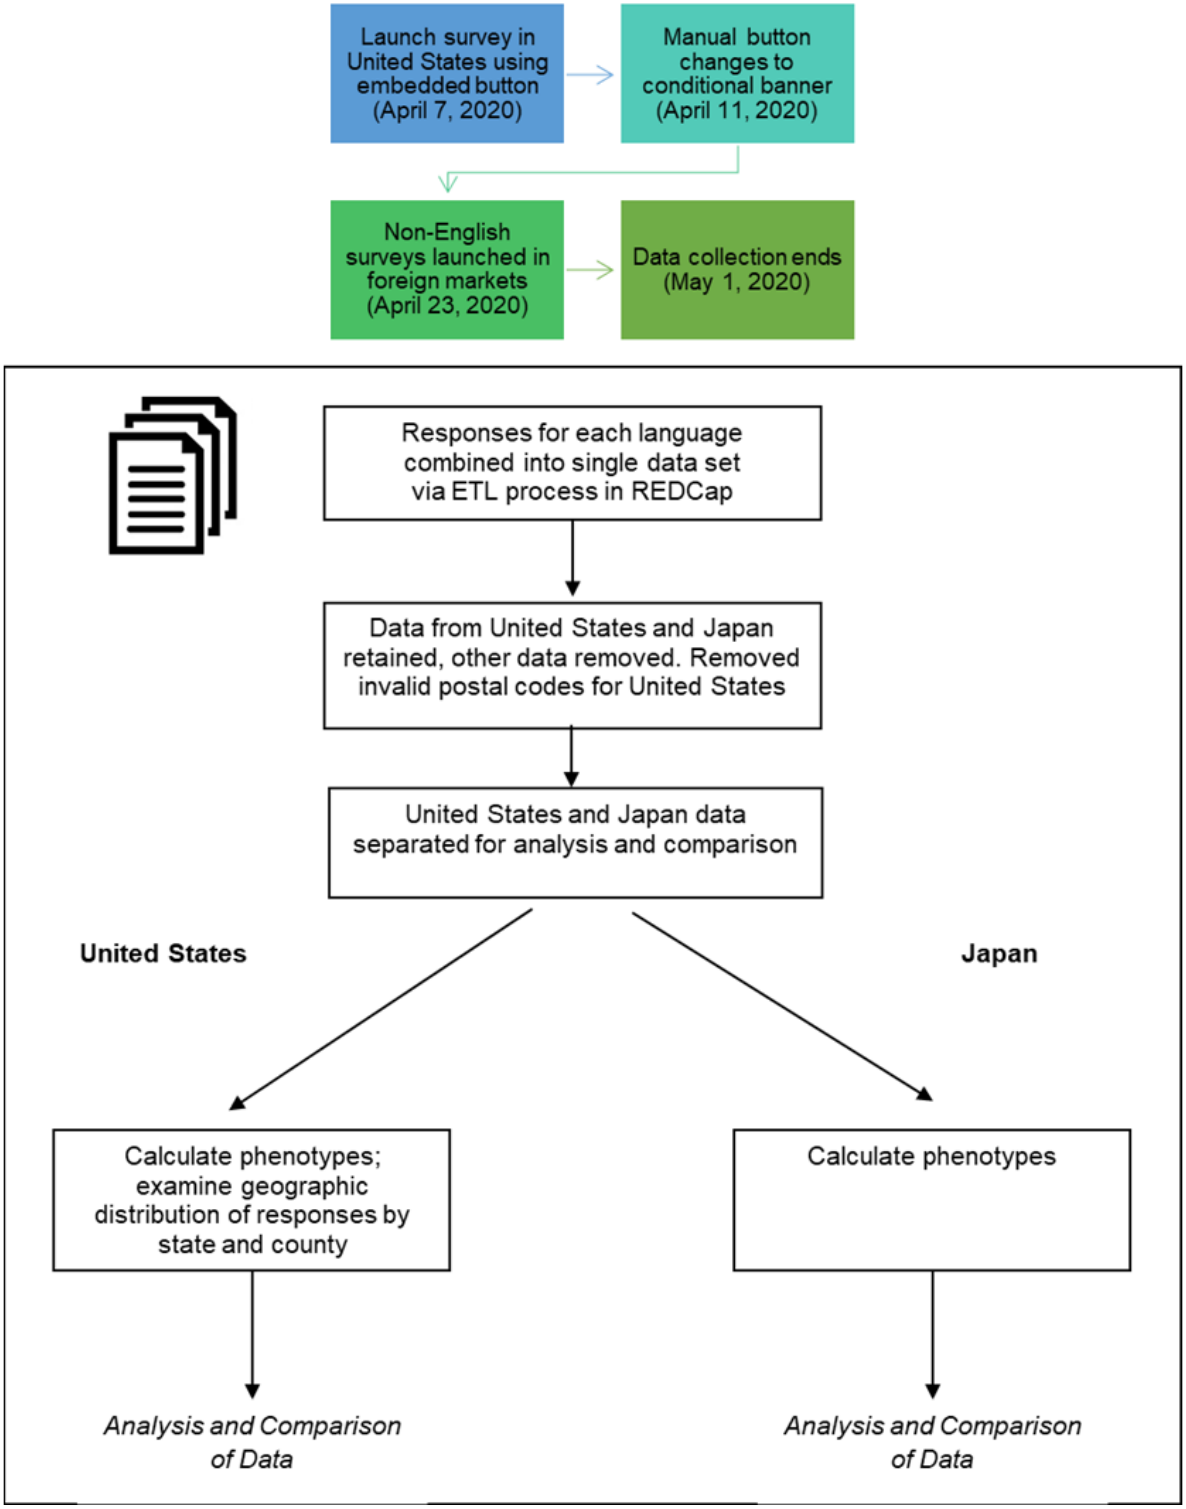
To recruit participants, we placed banner ads on the Microsoft News platform. Microsoft News delivers news from multiple, popular publishers across web and mobile experiences. The service is used by nearly a half billion monthly users, making it one of the largest audiences of news readers in the world [19].

The Microsoft News team embedded a link to the Regenstrief Institute survey on its news sites in 31 global language markets to reach a large, general population sample for the survey. Each language market directed users to a survey in that language. Initially, Microsoft News editors manually embedded a promotion button calling for survey participants that linked to the survey. Editors randomly embedded the link in approximately 150 pieces of news content daily that were delivered to readers across the United States. Editors placed a button on news content at randomized time windows (eg, 5:36 AM Pacific Time [PT]; 2:12 PM PT) to limit the time window in an effort to deter malicious tampering (eg, bot attacks) during a 1-week survey pilot period. Unique URLs for each language-specific survey were also used to prevent bot attacks. Editors also attempted to avoid placing the button on COVID-19–related content to prevent oversampling people reading about COVID-19. Moreover, editors tried to ensure the button was placed at a low profile (ie, "below the fold" of the news article).

By April 10, 2020, COVID-19–related content accounted for 80% of US news traffic. This challenged the manual embedding process, placing an unmanageable burden on the Microsoft News editorial team. Therefore, in consultation with the research team, Microsoft News switched to a conditional banner method on April 11, 2020.

The conditional banner ad methodology involved automatically rendering the ad (Figure 1) at the top of all news articles, but with the condition that a user would only see the banner twice in 30 days. The conditional banner provided a gating effect so that Microsoft News readers could only be served a total of two conditional banners calling for participants to complete the survey during any single month. For example, if a reader visited a travel article and a politics article during the month, the reader had two opportunities to see the banner ad but would not see it again until the next month. Furthermore, once a reader clicked on a conditional banner ad, which took them to the survey, they would not receive another conditional banner ad calling for participants until the next month. We offered users two banner ads per month until they completed the survey or until the survey closed. Although Microsoft News tracked whether a user saw the banner ad more than once, user identifiers were not provided to the research team, so we could not identify individuals or link their multiple responses.

Figure 1. Screenshot of the Microsoft News platform showing the banner ad placed at the top of the screen that recruited participants to take a survey about COVID-19 symptoms and behaviors.



Importantly, Microsoft News readers who clicked on the banner ad always saw an initial screen on the survey site that prompted them for their explicit consent to participate, informed them of the risks of participating, and gave them a chance to leave the survey and either return to Microsoft News or access COVID-19 information resources (eg, WHO site). No user data were captured until participants consented. The Regenstrief Institute monitored referring websites to confirm that nearly all respondents came to the survey from Microsoft News.

Data Collection

Surveys were developed and rolled out in two phases. We first generated and published the US-based English survey. The US-based English survey was published beginning on April 7, 2020. Beginning April 11, 2020, the conditional banner ad replaced the manually embedded button. Non-English surveys were published on April 23, 2020. All surveys closed on May 1, 2020. Figure 2 depicts the overall flow for collection and analysis of data.

XSL•FO
RenderX

Figure 2. Overview of data collection and analysis processes. ETL: extract, transform, load; REDCap: Research Electronic Data Capture.

Survey responses were collected and managed in collaboration with Research Technologies, a Pervasive Technology Institute Center at Indiana University (IU) [20], using Research Electronic Data Capture (REDCap) tools [21,22]. Data from each language-based survey were stored in separate tables on the REDCap server, then extracted into a combined data set for analysis using REDCap-ETL (extract, transform, load) and the IU REDCap-ETL Gateway [23,24]. The language of the respondent was captured as a distinct field in the combined data set.

REDCap is a secure, web-based software platform designed to support data capture for research studies, providing (1) an intuitive interface for validated data capture, (2) audit trails for tracking data manipulation and export procedures, (3) automated export procedures for seamless data downloads to common statistical packages, and (4) procedures for data integration and interoperability with external sources. REDCap-ETL extracts

XSL•FO
RenderX

data from REDCap, transforms the extracted data, and loads the transformed data into a database. The IU REDCap-ETL Gateway enables high-throughput data transfer between REDCap and multiple endpoints by allowing REDCap-ETL to scale to many simultaneous runs using the job scheduler of a high-performance computer.

Analytical Methods

We used descriptive statistics to summarize responses overall and by country to examine patterns. We further employed ecological methods to compare prevalence by country as well as association methods to examine differences in responses by country. Moreover, we employed correlation methods to compare symptom responses to standard outbreak measures. More than 85% of responses were received from residents in the United States and Japan. Therefore, we only included these responses in the analysis.

We first examined patterns regarding the limited demographics captured in the survey. Descriptive statistics provide a sense for the representativeness of the respondents. We calculated summary statistics for respondent demographics after removing all entries that did not provide informed consent, indicated by failing to click *Next*. In all demographic categories, we restricted our summarization to those individuals who did not select *prefer not to say*.

We next summarized responses based on respondents' reported symptoms and behaviors that might contribute to COVID-19 exposure. We asked respondents to indicate the presence of one or more current symptoms, including symptoms believed to be associated with COVID-19 infection and those not shown to be associated. The symptoms believed to be more common among patients testing positive for COVID-19 include fever, cough, shortness of breath, loss of sense of taste or smell, and sore throat [7,17,18,25].

Symptoms associated with COVID-19 were grouped into various phenotypes for COVID-19–like illness. We defined four different COVID-19 phenotypes for analysis, summarized in Table 1. We examined a variety of phenotypes to explore symptom combinations associated with COVID-19. We examined multiple phenotypes since evidence suggests that many COVID-19 patients experience more than one symptom, but a specific set of symptoms is not yet definitive. Phenotype 3 is the broadest definition for a potential case, as individuals could report any of the symptoms previously known to be associated with COVID-19 infection. Phenotype 4 is the most restrictive phenotype, as it requires indication of fever or loss of taste or smell plus one of the other symptoms associated with infection. All phenotypes were informed by available evidence [26] indicating which symptoms or combinations are associated with infection.

Table 1. Phenotypes for suspected COVID-19 cases.

Symptoms	Phenotype 1	Phenotype 2 (one or the other)		Phenotype 3	Phenotype 4 (both must apply)	
	Individual reports *at least* 2 of the following	Individual reports *any* 1 of the following	Individual reports *at least* 2 of the following	Individual reports *any* 1 of the following	Individual reports *at least* 1 of the following	Individual reports *any* 1 of the following
Fever	✓		✓	✓	✓	
Cough	✓	✓		✓		✓
Loss of sense of taste or smell	✓		✓	✓	✓	
Sore throat	✓		✓	✓		✓
Shortness of breath or difficulty breathing	✓	✓		✓		✓

To visualize the distribution of respondents in the United States, we restricted the data to valid US ZIP Codes. The text field used by respondents to enter their postal code was unrestricted, given the lack of global conventions for representing residential area. Invalid ZIP Code entries were ignored when generating maps of US respondents. States were assigned based on published ZIP Code values associated with each state. To map ZIP Code values to US counties, we leveraged a crosswalk between county Federal Information Processing System codes and ZIP Code.

Chi-square tests of independence were used to examine whether responses differed significantly between the United States and Japan. We further compared responses between respondents indicating that they received testing versus those reporting that they did not receive laboratory testing for COVID-19. We employed correlation to compare the proportion of respondents meeting various phenotype definitions in a given state to existing surveillance per capita metrics reported in the same state during the study period. First, we correlated phenotypes with the per capita testing rate in each state, since individuals with symptoms are theoretically more likely to seek out testing. Second, we correlated phenotypes with the reported per capita case rate, which represents the positive case volume in a given state. These metrics were obtained from The Atlantic application programming interface [27], which are aggregated from a variety of sources.

Ethics Approval

This study was approved by the Institutional Review Board at IU as exempt research.

Results

We received a total of 87,322 valid responses. Of these, 47,424 (54.3%) were from the United States and 27,936 (32.0%) were from Japan. Table 2 summarizes responses and the demographics of respondents. Responses from Japan are skewed toward male gender (21,220/27,936, 77.0%), whereas the US

XSL•FO
RenderX

responses are more balanced (male: 25,787/47,424, 57.0%). With respect to age, more than half of the respondents from both countries were over 50 years of age. Chi-square analysis found the rates of responses in Japan were significantly different from those in the United States.

The distribution of respondents in the United States is depicted in Figure 3 as well as in Multimedia Appendix 1. The raw counts of respondents from each state and ZIP Code (Figures S1 and S2 in Multimedia Appendix 1) show broad geographical distribution of responses across the nation. Higher numbers of responses were generally observed in areas with higher populations. When normalized by state population, responses were greatest in the northern states, especially the extreme northeastern states and the states in the Upper Plains region.

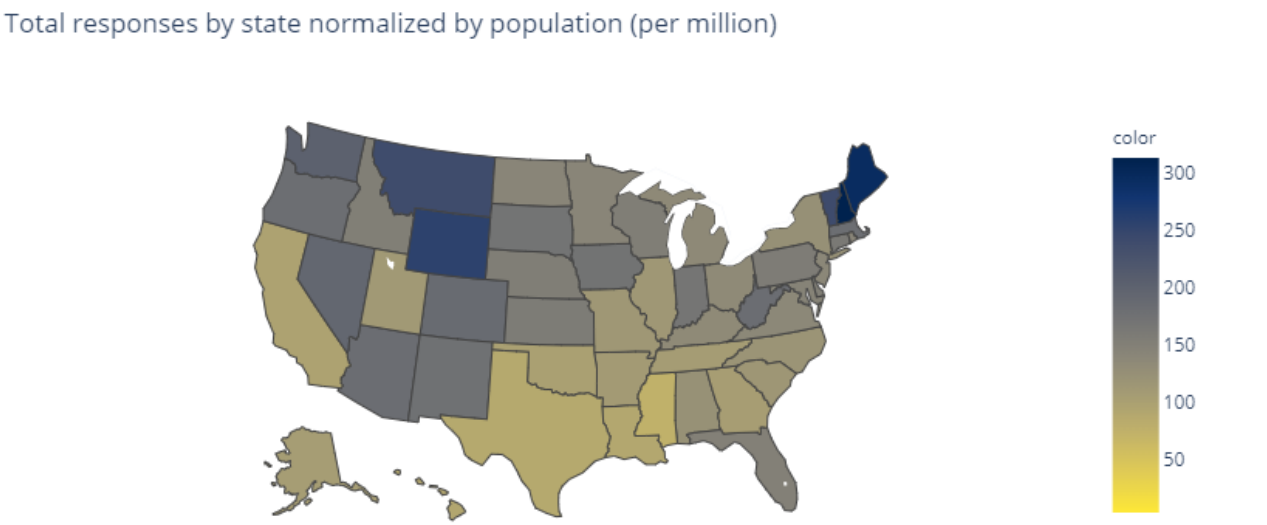


Table 2. Demographics of all respondents (who completed the consent portion) of a web-based questionnaire about COVID-19 symptoms recruited through the Microsoft News platform.

Demographic	All respondents, n (%)[a]	Respondents from the United States, n (%)[a]	Respondents from Japan, n (%)[a]	*P* value[b]
Age (years) (all: n=83,901; United States: n=45,050; Japan: n=27,536)				
80+	2672 (3.2)	2202 (4.9)	252 (0.9)	<.001
70-79	12,150 (14.5)	8402 (18.7)	2343 (8.5)	<.001
60-69	23,632 (28.2)	14,438 (32.0)	6233 (22.6)	<.001
50-59	23,174 (27.6)	10,635 (23.6)	9539 (34.6)	<.001
40-49	12,580 (15.0)	5040 (11.2)	5850 (21.2)	<.001

Responses over time are summarized in Figure 4, stratified by the location of the response. Cumulative responses increased rapidly in the days immediately after the survey launch followed by a continued, steady increase in the weeks after the launch. The Japanese survey was launched 16 days after the English survey, yet responses followed a similar pattern with respect to rapid increase following the launch.

Figure 4. Cumulative responses over time, stratified by location of respondent, to a survey on COVID-19 symptoms. The survey was offered in Japan 16 days after it was introduced in the United States.

In Table 3 we summarize the responses with respect to COVID-19 symptoms, phenotypes, and behaviors. Most respondents (56,551/87,322, 64.8%) reported no symptoms. Among those reporting at least one symptom (30,771/87,322, 35.2%), a total of 19,631 respondents (63.8%) reported at least one of the following symptoms associated with COVID-19: fever, cough, loss of sense of taste or smell, sore throat, shortness of breath, or difficulty breathing. These respondents met the inclusion criteria for Phenotype 3. Higher proportions of respondents in the United States reported COVID-19–like symptoms than respondents in Japan across all symptoms and phenotypes (42.2% vs 25.2%; $P<.001$).

Among the 19,631 respondents meeting criteria for Phenotype 3, 7670 (39.1%) reported at least two symptoms associated with COVID-19 (Phenotype 1). A total of 15,341 out of 30,771 individuals with symptoms (49.9%) reported either cough or shortness of breath, or they reported at least two symptoms from the set of fever, sore throat, or loss of taste or smell (Phenotype 2). Examining the more specific symptoms of fever and loss of sense of taste or smell, 4820 out of 30,771 individuals with symptoms (15.7%) reported at least one of these symptoms in combination with one of the other symptoms (Phenotype 4). Reported symptoms met phenotype definitions at higher rates among respondents from the United States compared to respondents from Japan ($P<.001$).

Compared to respondents who did not report symptoms, those reporting at least one of the symptoms associated with COVID-19 (Phenotype 3) in the United States were more likely to report getting tested ($P<.001$). Similar rates were observed in Japan. Overall, higher proportions of respondents in the United States reported getting tested than did those in Japan ($P<.001$). In both countries, individuals meeting the inclusion criteria for one of the phenotypes more frequently reported that they had traveled more than 30 km from their home within the past 14 days. Chi-square analysis found that the rates of responses in Japan were significantly different from those in the United States.

[a]*P* values were based on chi-square analysis.

In Table 4, we compare respondents who reported that they were tested for COVID-19 versus those who reported no testing. Overall, few respondents (1967/87,322, 2.3%) indicated that they were tested for COVID-19. Examining symptom combinations and phenotypes revealed that individuals who reported symptoms were more likely to report being tested for COVID-19. Among those tested for COVID-19, nearly half (939/1967, 47.7%) reported at least one symptom compared to individuals who were not tested (18,197/84,498, 21.5%; $P<.001$). The most prevalent symptom combinations among individuals tested for COVID-19 included cough and nasal congestion or runny nose (404/1967, 20.5%), cough and shortness of breath or difficulty breathing (372/1967, 18.9%), as well as fever and cough (318/1967, 16.2%). Nearly two-thirds (55,084/84,498, 65.2%) of individuals who reported no symptoms also reported not being tested.

The proportion of respondents in each state meeting a given phenotype definition positively correlated with the proportion of individuals tested in that state (Figures S1-S4 in Multimedia Appendix 2). For example, the proportion of individuals who reported symptoms corresponding to Phenotype 3 were significantly ($P<.001$) positively ($R^2=0.26$) correlated with the per capita rate of individuals tested for COVID-19 (Figure S3 in Multimedia Appendix 2). The proportion of respondents meeting a given phenotype definition showed slight correlation with the reported case rate ($R^2\leq0.04$) (Figures S5-S8 in Multimedia Appendix 2), yet these correlations were not statistically significant ($P\geq.05$). For example, the proportion of individuals who reported symptoms corresponding to Phenotype 4 were nonsignificantly ($P=.23$) positively ($R^2=0.04$) correlated with the per capita rate of individuals testing positive for COVID-19 (Figure S8 in Multimedia Appendix 2).

Discussion

Principal Findings

In this study, we recruited tens of thousands of respondents within 3 weeks to an online survey asking questions about symptoms associated with a novel infectious disease quickly spreading across the globe using banner ads on an online news platform. A principal finding is that an internet news platform is feasible for quickly collecting large-scale data from individuals across local, state, and national areas. Furthermore, this recruitment method reached an older population at greater risk of complications from COVID-19, distinguishing our study from prior research. Whereas many infodemiology studies recruit subjects from social media platforms where users are primarily under 40 years of age, the news platform we leveraged draws primarily from populations at least 50 years of age. Both findings have implications for future surveillance efforts in public health.

At time of the survey, Japan's epidemic curve had started to flatten, with daily increases in new cases between 3% and 5%, whereas the curve in the United States continued its upward trajectory, with daily increases between 10% and 20% (Figure 5 [26,28]). On April 30, 2020, the United States reported a daily rate of new infections of 8.26 per 100,000 population. On the same date, Japan reported a daily rate of 0.19 new infections per 100,000 population. In this study, rates of reported symptoms in Japan were significantly lower than in the United States, providing face validity for respondents' self-reported data. This further builds the case for an online news platform as a reliable method for recruiting survey respondents.

Figure 5. COVID-19 epidemic curves for the United States and Japan through May 1, 2020 [26]. The plot shows cumulative confirmed COVID-19 cases. The number of confirmed cases is lower than the number of actual cases; the main reason for that is limited testing. The source of this data is the European Centre for Disease Prevention and Control, Situation Update Worldwide, last updated August 31, 2020, 10:34 AM (London time). Official data were collated by Our World in Data [28].

The survey data further yielded interesting insights about the pattern of symptoms reported by respondents. First, nearly two-thirds of those reporting at least one symptom reported at least two symptoms. Emerging evidence suggests that symptom combinations may be predictive of COVID-19 infection [26]. The fact that most individuals reporting COVID-19–like symptoms reported more than one symptom provides further evidence that exploring specific phenotypes might be fruitful for future research. Second, the constellation of symptoms involving loss of taste or smell with fever appears more often among individuals who reported that they received testing for COVID-19. Several studies report loss of taste and smell as common among COVID-19 patients [18,26,29], suggesting that these symptoms cause individuals to seek out medical care or indicate an association with infection. Moreover, those reporting at least one symptom were significantly more likely to report having been tested for COVID-19 than those without symptoms, and those reporting symptoms were significantly associated with testing rates. Yet the rates of individuals reporting symptoms were not significantly associated with positive case rates, which were admittedly hindered due to limited testing infrastructure in the United States at the time of the survey [30]. These findings are novel, given the data were captured from community residents rather than individuals hospitalized from COVID-19, which is the population most prior studies used to report common symptoms reported by individuals infected with SARS-CoV-2.

Implications of Findings

Based on these findings, we encourage further study of online news platforms as a tool for reaching broad and diverse populations by public health agencies during emerging outbreaks. Although the news platform was male dominated

XSL•FO
RenderX

and skewed older with respect to population, we recommend its use in combination with other epidemiologic methods, including infodemiology, random selection, and contact tracing. Only by using multiple methods will public health organizations successfully achieve diverse representation in the total set of data used to inform disease tracking efforts. Surveying only young, healthy populations is not sufficient for ascertaining prevalence of diseases like COVID-19. Yet inclusion of younger population data is important to understand disease spread during a crisis. It is possible that other news platforms may have younger audiences or cater to specific audiences that would improve diversity. Capturing data across platforms and methods to integrate findings would benefit future infodemiology research.

The methods used in this study go beyond the typical methods used in public health to ascertain symptoms among individuals who present at clinical or public health sites. Relying on data from individuals who present physically for treatment or testing alone is not sufficient to generate population-level information about the epidemiology of an emerging infectious disease, as only some individuals present for care or testing. Recall that approximately 40% of individuals with COVID-19 are asymptomatic [3], and many experience mild symptoms that do not require clinical intervention. Moreover, we received responses from individuals in small towns and rural communities, areas that are often medically underserved, thereby limiting patients' ability to present for care. Furthermore, rural areas often lack robust laboratory testing infrastructures, a broad challenge that COVID-19 illuminated. Finally, the methods used here allowed for at-scale collection of data in a way that respects individuals' privacy, as respondents did not need to provide any data that might otherwise be used to link back to medical records or sensitive information.

Internet-based survey methods are needed to gather data quickly during a crisis to inform where the disease might be present or where it might be headed next. Modeling efforts at the start of the COVID-19 pandemic were limited by a paucity of input data as well as a priori assumptions that drive model parameters. Having intelligence on symptoms from a broad population as well as behaviors (eg, those travelling >30 km from home) could better inform model development. Moreover, understanding which populations have received testing, and which ones do not appear to have access to testing, can inform deployment of test kits by national and/or state public health agencies. Finally, identification of symptom hot spots could help drive deployment of personal protective equipment as well as health care workers.

Limitations and Future Directions

Despite the promise of the methods described in this study, there remain many challenges for using internet news platforms and other infodemiology methods to inform public health action. Given limited testing infrastructure in many states, analysis of survey data in comparison with later waves of the pandemic might better show how survey data correlate with standard epidemiologic metrics, such as testing rates, case rates, and mortality. Furthermore, the descriptive nature of this study prevented examination of potential sampling bias in respondents. We observed some skewing related to gender and age. Further exploration of the methods for ad placement would be necessary to establish news platforms as a reliable method for infodemiology.

The study was further limited by the location data being restricted to postal codes. Postal code structures are not standardized globally. Some postal codes repeat in the world, which prevented accurate mapping of some responses to a correct country or province. Furthermore, some entries in the postal code field were unintelligible. It is also possible that some of the Japanese responses occurred outside Japan, as postal code information was self-reported rather than verified with location services within the web browser or mobile device. Moreover, the survey did not ask whether those tested for SARS-CoV-2 virus tested positive or negative. Therefore, we considered individuals reporting symptoms to have a COVID-19–like illness, recognizing that COVID-19 symptoms are similar to several respiratory diseases, such as influenza. The symptom list was further restricted to the best available evidence at the time of survey development.

In the future, we plan to expand our work to extend the survey to additional audiences and in combination with other methods for reaching broader audiences. We further plan to update the symptom list and capture additional details about an individual and their health history that could be correlated with COVID-19 cases and/or known risk factors for infection as well as hospitalization and death. In addition, because severely ill patients may not be able to complete an online survey, we will also explore whether our survey might be adapted to allow respondents to report information on family members who may be experiencing COVID-19–like symptoms.

Conclusions

News platforms can be used to quickly recruit study participants, enabling collection of infectious disease symptoms at scale and with populations that are distinct from those found through social media platforms. Such platforms could enable epidemiologists and researchers to quickly assess trends in emerging infections potentially before individuals present to clinics and hospitals for testing and/or treatment.

Acknowledgments

The authors would like to thank the REDCap support team, part of Research Technologies at IU, especially Andrew Arenson, for their assistance with configuring our REDCap surveys as well as their support with data management. We further acknowledge the Regenstrief Institute, Inc for its support of this nonfunded research project during the pandemic and the assistance provided by Megan Hall and Cindi Hart, RN, in creating the REDCap surveys. From the Microsoft team, we thank Jeri Condit, Dr Ahmed

XSL•FO
RenderX

Elshafei, and Carmen O'Toole for their support in developing and implementing the survey. We also appreciate the support of Fred Cate, Vice President of Research at IU.

Authors' Contributions

The study was conceived by authors BD, MG, and SG. The coauthors SM, JF, and AW contributed significantly to the acquisition, analysis, and interpretation of data as well as the rigor of the methodology and analysis. The primary author BD drafted the manuscript, and all coauthors significantly contributed to revising the manuscript. All authors reviewed and approved the final version of the manuscript.

Conflicts of Interest

MLG, SM, and JMLF are employees of the Microsoft Corporation. The other authors have no conflicts to declare.

Abstract

Background: The COVID-19 pandemic has created unprecedented challenges for first responders (eg, police, fire, and emergency medical services) and nonmedical essential workers (eg, workers in food, transportation, and other industries). Health systems may be uniquely suited to support these workers given their medical expertise, and mobile apps can reach local communities despite social distancing requirements. Formal evaluation of real-world mobile app–based interventions is lacking.

Objective: We aimed to evaluate the adoption, acceptability, and appropriateness of an academic medical center–sponsored app-based intervention (COVID-19 Guide App) designed to support access of first responders and essential workers to COVID-19 information and testing services. We also sought to better understand the COVID-19–related needs of these workers early in the pandemic.

Methods: To understand overall community adoption, views and download data of the COVID-19 Guide App were described. To understand the adoption, appropriateness, and acceptability of the app and the unmet needs of workers, semistructured qualitative interviews were conducted by telephone, by video, and in person with first responders and essential workers in the San Francisco Bay Area who were recruited through purposive, convenience, and snowball sampling. Interview transcripts and field notes were qualitatively analyzed and presented using an implementation outcomes framework.

Results: From its launch in April 2020 to September 2020, the app received 8262 views from unique devices and 6640 downloads (80.4% conversion rate, 0.61% adoption rate across the Bay Area). App acceptability was mixed among the 17 first responders interviewed and high among the 10 essential workers interviewed. Select themes included the need for personalized and accurate information, access to testing, and securing personal safety. First responders faced additional challenges related to interprofessional coordination and a “culture of heroism” that could both protect against and exacerbate health vulnerability.

Conclusions: First responders and essential workers both reported challenges related to obtaining accurate information, testing services, and other resources. A mobile app intervention has the potential to combat these challenges through the provision of disease-specific information and access to testing services but may be most effective if delivered as part of a larger ecosystem of

XSL•FO
RenderX

support. Differentiated interventions that acknowledge and address the divergent needs between first responders and non–first responder essential workers may optimize acceptance and adoption.

(J Med Internet Res 2021;23(5):e26573) doi:10.2196/26573

Introduction

The COVID-19 pandemic has presented unique obstacles to first responders as well as to other essential workers who ensure that health and other basic needs of the public continue to be met [1,2]. Health systems may be uniquely positioned to support these individuals given their expertise and position embedded within local communities. Efforts to understand the challenges of first responders and essential workers and to evaluate support of these groups by health systems during a pandemic response are needed.

The definition of a "first responder" varies between state and federal agencies but commonly encompasses emergency medical personnel, firefighters, and law enforcement officers [3]. Their duties can lead to adverse mental, physical, and social consequences [4]. Although academic attention has focused on the intense mental and emotional strain on health workers, such as during the severe acute respiratory syndrome (SARS) epidemic [5,6] and the COVID-19 pandemic [7-9], nonmedical first responders also face adverse mental health consequences [10,11]. Other adverse effects include worker absenteeism [12,13], an exacerbation of predisaster socioeconomic inequalities [14], and an increased risk of contracting the disease itself in an outbreak setting [15,16].

Less is known about the impact of disasters on essential workers not otherwise considered to be first responders, defined by their work in food and agriculture, construction, transportation, and other sectors of the economy deemed essential [17,18]. COVID-19 has spurred research in this population, with documented increased rates of depression and anxiety [19] and substance abuse [20] during the pandemic. Most concerning, the relative economic vulnerability of essential workers, including their need to leave home to work, further exacerbates existing socioeconomic and racial disparities seen in COVID-19 morbidity and mortality [17,21-23].

Certain factors can mitigate the stress experienced by first responders and essential workers [20]. Knowledge about a disease process may be protective, as essential workers without a health care background appear to experience a higher level of distress than workers who have training in disease processes [24]. Open, reliable information channels—even in a setting with many unknowns—may also be protective [25]. To date, documented efforts to support these workers have focused on prioritized access to testing [26], mental health support [18], and other health resources [27,28], but not necessarily on access to information.

Dissemination of this information occurs through formal and informal networks during a pandemic response [29]. However, the challenges brought on by the COVID-19 pandemic have highlighted a pre-existing disconnect between the health system and public health infrastructure [30,31]. Without these partnerships, first responders and essential workers cannot benefit from the expertise of the health systems located right in their communities. Given the uncertainties inherent in an unfolding pandemic, additional channels that draw upon health system expertise may be needed.

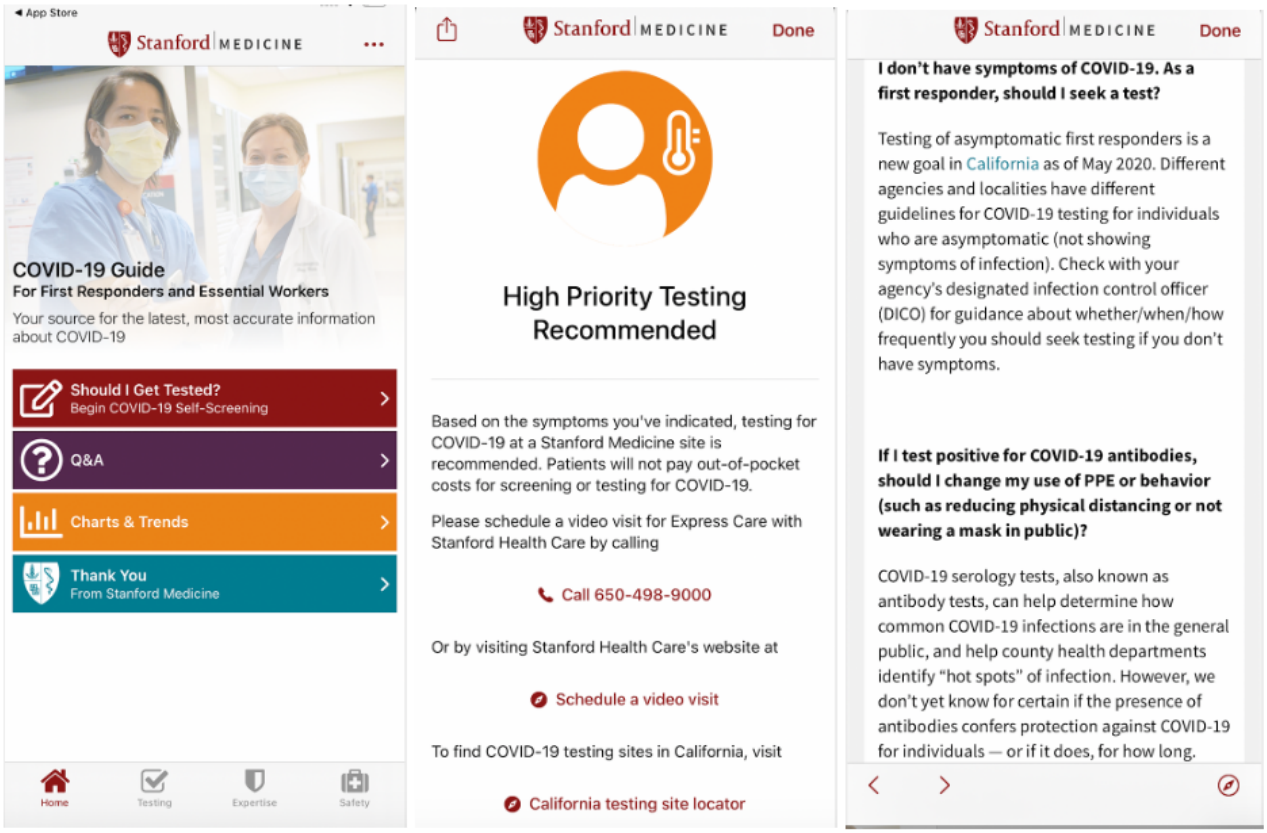
To this end, digital technologies, including mobile apps, appear to provide unique support in the context of social distancing efforts during a pandemic [32-34]. Formal evaluations of digital efforts to support first responders and essential workers are lacking; however, optimizing these upstream interventions may help mitigate health disparities and other adverse effects associated with their roles during a pandemic.

Methods

We conducted a qualitative user needs assessment and implementation evaluation (outcomes including adoption, appropriateness, and acceptability) [35] of an academic medical center–sponsored app-based intervention designed to support the information and testing needs of first responders and essential workers early in the COVID-19 pandemic. We further used app download data to triangulate [36] our understanding of the adoption of the app among the target populations using a convergent [37] mixed methods approach.

Setting

In April 2020, a quaternary academic medical center, Stanford Health Care (SHC, Palo Alto, California, United States) in partnership with a large technology company (Apple, Cupertino, California, United States) launched the *Stanford Medicine COVID-19 Guide for First Responders and Essential Workers* app (COVID-19 Guide App) with the goal of providing evidence-based information related to COVID-19, screening guidance, and access to testing services to support 1.1 million first responders and essential workers in the San Francisco Bay Area [38-40]. The dissemination effort by the institution included emails to local first responder and essential worker representatives, facilitated in part through previously established partnerships between SHC emergency physicians and emergency medical services (EMS) and fire organizations within the community developed through the institution's EMS Fellowship. This study was conducted by an interdisciplinary evaluation group led by the Stanford Medicine Evaluation Sciences Unit. First responder interview participants were recruited from Bay Area county police, fire, and EMS departments and among physicians connected to the health system's EMS physician fellowship. Essential worker interview participants were



XSL•FO
RenderX

recruited from local grocery stores, gas stations, care facilities, and civil infrastructure support businesses.

Intervention

The COVID-19 Guide App includes a screening questionnaire that provides testing recommendations with links to access further testing and care, COVID-19 resources from Stanford Health Care physicians and scientists, and foundational information on viruses and prevention (Figure 1) [38].

Figure 1. Example user displays of the Stanford Medicine COVID-19 Guide for First Responders and Essential Workers app.

Sample

First responder participants were drawn from police, fire, and EMS departments in Alameda, San Mateo, San Francisco, and Santa Clara counties through email and telephone call outreach to local departments. All fire personnel are cross-trained in EMS, although not all EMS personnel have fire training [41]; participants from both groups were recruited. Emergency medicine physicians who partnered with local fire and police departments through the EMS Fellowship [42] at Stanford School of Medicine were also interviewed using a convenience sampling approach. Snowball sampling was leveraged across all categories to connect with additional participants in harder-to-reach groups. Interviews were conducted until thematic saturation within each professional subgroup was reached.

Essential workers were recruited using a convenience sampling approach in which researchers sought interviews in person at local businesses. When a paucity of Spanish-speaking essential workers was recognized, we shifted to a telephone-based convenience sampling approach targeted at this population to better reflect demographics of the region [43] until thematic saturation for both English- and Spanish-speaking essential workers was reached. Pre-existing experience with the app was not a requirement for participation, and the interview protocol itself accommodated both prior experience and no prior experience with the app (Multimedia Appendix 1).

Qualitative Data Collection

From May to September 2020, 30-minute semistructured interviews using a protocol grounded in the Consolidated Framework for Implementation Research were conducted by multiple authors (SV, NS, AA, MF, CBJ) (Multimedia Appendix 1) [44]. Interviews were conducted with two or more researchers present, with rare exceptions for note-taking, training, and analytic purposes. First responder interviews were conducted by telephone and videoconference; essential worker interviews were conducted by telephone and in person. For Spanish speakers, a professional interpreter was enlisted to interpret interviewer questions and interviewee responses. First responder interviews were tracked confidentially, recorded, and transcribed verbatim using Rev [45]. Essential worker interviews were not recorded to protect the anonymity of these more vulnerable interviewees in their work-based settings. For these interviews, near-verbatim field notes were taken, and two or more researchers who were present at each interview contributed to the field notes in a debrief discussion immediately following the interview.

XSL•FO
RenderX

Quantitative Data Collection

Descriptive quantitative data, including the total number of downloads at the conclusion of the evaluation on September 1, 2020, were drawn from the app administrator account. User characteristics, including demographic and use data, were not available due to restrictions in data use agreements.

Qualitative Analysis

Interview transcripts were analyzed using an inductive rapid analytic process in which two researchers coded all interviews (SV, AA) [46,47]. We used an inductive-deductive approach to identify a priori themes related to access to information and testing services and emergent themes. Excerpts were presented in a matrix format following rapid analytic procedure methodology [48]. The matrix was populated with notes and quotations (AA) and reviewed by qualitative team members (SV, AA, MF) to reach consensus and compare themes across worker subgroups [49]. The Implementation Outcomes Framework guided the evaluation and presentation of implementation outcomes (appropriateness, acceptability, and adoption) [50].

Throughout the assessment, early findings were reported back to operational leads to inform ongoing improvement using the Lightning Report Method described in 2019 by Brown-Johnson et al [51]. This project was reviewed by the Stanford Institutional Review Board and did not qualify as human subjects research (Protocol ID 56126). All participants gave verbal consent to be interviewed, and first responders gave consent to be audio-recorded.

Results

Participant Characteristics

A total of 27 interviews were conducted with 17 first responders (63%) and 10 essential workers (37%) (Table 1). The number of participants within each subcategory was comparable, including 5 police (29%), 7 emergency medical technician (EMT) (41%), 4 EMT with fire training (EMT/Fire, 59%), and 5 physician police/EMS advisor (PoliceMD/FireMD, 29%) interviewees in the group of 17 first responders and 5 food and agriculture (50%) and 5 transportation and civil infrastructure (50%) interviewees in the group of 10 essential workers. The food and agriculture subgroup included 4 grocery workers and 1 dining supervisor, while the transportation and civil infrastructure subgroup included 3 gas attendants, 1 bus driver, and 1 electrician. First responders tended to be male (16/17, 88%), 30-49 years old (11/17, 65%), and White (10/17, 59%), and most reported working in their field for more than 10 years (10/17, 59%). The essential workers were 50% male (5/10), of varying ages, mostly Hispanic/Latino (7/10, 70%), and had worked in the field for either less than 5 years (4/10, 40%) or more than 10 years (5/10, 50). The primary language of half of the essential workers (5/10, 50%) was Spanish, whereas all first responder interviews were conducted in English.

Implementation Outcomes of the COVID-19 Guide App

Implementation outcomes of the COVID-19 Guide App differed between the first responder and essential worker groups. Perspectives on the app varied by group, with moderate to low adoption, mixed appropriateness, and mixed acceptability seen in first responders, and low adoption, high appropriateness, and high acceptability seen in essential workers.

Adoption

The COVID-19 Guide App received 8262 views from unique devices, from which 6640 individuals downloaded the app (80.4% conversion rate) from the launch date of April 7, 2020 to the end of the evaluation period on September 1, 2020. Assuming all downloads were in the target demographic within

XSL•FO
RenderX

the Bay Area, this suggests a 0.61% adoption rate of the region's 1,093,781 first responders and essential workers [39,40].

In the qualitative interviews, 2 participants had used the app and were able to share their experience directly. The majority were not familiar with the app but shared their perspectives based on a short description of the app.

Moderate to low adoption was described in the first responder group. First responder interviews shed light on the underlying reasons limiting widespread adoption. Physicians largely felt their involvement in the app development occurred "fairly late in the game" (FireMD 1, 2), perhaps due to the poor visibility of the emergency fellowship program within the institution (FireMD 1, 4).

In the essential worker group, on the other hand, none of the interviewees reported direct experience with the app, although their attitudes toward a theoretical app that provided COVID-19 testing were positive (see the *Acceptability* section below).

Appropriateness

First responders reported mixed perceptions of the appropriateness of the COVID-19 Guide App. All interviewees reported owning smartphones, with most using mobile apps for work. Despite the seeming appropriateness of an app-based solution for this group, some reported that the features of this app were less relevant for first responders. Although some thought the screening features and link to testing resources were personally helpful (PoliceMD 3, EMT/Fire 2) or useful for patients (EMT/Fire 7), others felt these features were already covered by other processes in their organization. Some reported frustration with the app's inability to link a positive symptom screen to a scheduled test due to technical and privacy limitations; instead, the app would "take [them] to the end of a little pathway that would be like, 'You should call your [department infection control officer] to get tested.' No [kidding]." (FireMD 2).

Conversely, essential workers reported high appropriateness of the COVID-19 Guide App. Similar to first responders, all essential workers owned smart phones, and an overwhelming majority used mobile applications for work, indicating an ability to access and navigate mobile applications.

Acceptability

First responders expressed mixed acceptability of the app. A few participants who had directly used the app had positive perceptions (EMT/Fire 3, Police 1), sharing benefits of "quick answers" that were "super easy to access" (EMT/Fire 3).

Additionally, first responders also noted the need for a succinct, trusted data source (EMT/Fire 2), such as this app, particularly one that "agreed" with county information (Police 3, FireMD 4, PoliceMD 1). Indeed, brevity and trusted branding was seen as highly valuable and missing after a midimplementation shift to incorporate an outside partnership to produce content: "…Now it's just too hard to filter what is coming as sort of medical recommendation versus what almost seemed like an ad" (FireMD 4).

Although no essential workers reported direct experience with the app, their attitudes toward a theoretical app that provided COVID-19 testing and disease information were overwhelmingly positive: "I'm looking forward to this app" (Grocery 1).

Like first responders, essential workers reported a desire for succinct, up-to-date, and trustworthy information (Grocery 4, Food Services 5). Essential workers noted that ideally, information would be presented in multiple languages to address reported widespread misinformation, particularly in non–English-speaking communities (Gas 2, Electrician 4). This information would also ideally be delivered through social media channels by physicians or nurses, as trust in the health system was reportedly higher than in media or government.

Challenges Faced by First Responders and Essential Workers

First responders and essential workers experienced a number of related challenges, described in the following qualitative themes: a need for personalized information with no clear playbook, parsing information takes time, misinformed beliefs fuel conflict, priority testing gets them back to work, fear of bringing an amorphous enemy home, and a lack of resources to fight the pandemic. First responders faced additional challenges related to the need for interprofessional coordination and a double-edged "culture of heroism" that could both protect against and exacerbate mental and health vulnerabilities (Table 2).

Table 2. Impact of the COVID-19 pandemic on first responders and essential workers.

Challenges	Illustrative quotations	
	First responders	Non–first responder essential workers
Need for personalized answers with no clear playbook	• "When COVID hit, I was taken out of my primary role… and put into a COVID response detail" (Police 1) • "And early on it was a lot of questions [from EMS[a]] 'this patient … didn't tell us she had a fever but when they got to the hospital, she had a fever and she turned out to have been on the Princess Cruise' [early COVID-19 outbreak] …it was tough because there wasn't a clear playbook for so many different situations." (Fire MD 4)	• "Before, food was served in a dining room…now residents eat in their own rooms. We set up dining carts to bring food to residents, which is exhausting." [paraphrased] (Food Services 5) • "I want information in Spanish" (Gas 2) • "I think it would be helpful to have more knowledge on herbal treatments for COVID… I prefer to use this" (Electrician 4)
Parsing information takes time	• "I pretty much rely on my division chief to disseminate information, because he spends all day reading and looking at case studies and such." (EMT[b]/Fire 7)	• "We are being bombed by so much information everywhere, so it is hard to know what is true." (Bus Driver 5)
Misinformed beliefs fuel conflict	• "The amount of misinformation has been pretty surprising. So, I don't know that our fire departments are affected more heavily than anyone else, but there's a lot of suspicion and a lot of misinformation." (FireMD 2) • "We've had a couple people who have come up and said, 'COVID-19 is a conspiracy. It's not real.'…. just acting as though we're propagating this lie, which, as firefighters, we're not used to [such] conflict with our community members…It's a little bit disappointing to see people, A: deny it and B: be confrontational with us." (EMT/Fire 3)	• "We have to deal with [people not complying with mask policies] every single day… A lot of people have the mask on but around their neck" (Bus Driver 1) • "I don't trust information from the government. I don't think it is accurate or reliable. The number of sick people is overexaggerated… they are trying to scare people." (Food Services 5) • "A German doctor is leading the work around chlorine dioxide to balance pH which improves immunity…there are some websites that are against chlorine dioxide but many that show that it works, so it is a matter of perspective what you believe" [paraphrased] (Electrician 4)
Priority testing gets them back to work	• "But yeah, there hasn't been much else as far as support, like where we could get tested, information on how we get tested." (EMT 1) • "I didn't want anybody [in law enforcement] to get sick at work from it, and I didn't want community members to get sick from my teams. So I would just err and put them off from work until we heard back, but the priority testing… is really the only option I have [to get them back to the field]" (Police 2)	• "[My employer] didn't give us a place to get tested… I wish that we had more access to testing for drivers… We drive every day, for 5 days a week and we take care of all kinds of people" (Bus Driver 5)
Fear of bringing an amorphous enemy home	• "[Police officers] have a lot of anxiety about bringing it home to their families and that sort of thing." (PoliceMD 3) • "The thing that obviously is concerning to people is the last thing we want to do is bring this thing home, right? Especially those of us who have small kids …and spouses." (Police 4)	• "It's been very tough. I need to work even though I don't feel comfortable doing so" (Grocery 4) • "At first, I couldn't breathe. The first two weeks, I was panicked. What happens if I die? I stopped reading the news, and it's getting much better now." (Gas 1)
Lack of resources to fight the pandemic	• "I think what we're having that's been a disappointment is the lack of PPEs[c]. And then the people that have been price gouging with the PPEs… And then we get them, and they're not N95s. So… we can't use them in the field." (EMT 6) • "…I mean our city fire departments are getting… [mixed] messages of 'you're heroes, but the city's not going to make nearly as much money this year as they normally do, so we're going to slash your budget.'" (FireMD 2)	• "We have coworkers that already died, we have coworkers they already have COVID. Now they give us a set of masks, a little thin piece of material. Come on." (Bus Driver 5)

XSL•FO
RenderX

Challenges	Illustrative quotations	
	First responders	Non–first responder essential workers
Need for interprofessional coordination (first responders only)	• "And I can say that we've [transported] 13 positive COVID cases. I've only been notified on two of them." (EMT/Fire 5) • "Where to park, where to go, what the entrance point is, what's the exit point [at the hospital], is there a priority line? If law enforcement comes in, and they need to do something, do they have to wait in the general line and wait behind 10 people, or are they going to be let in a different way or checked in quickly, or given priority?" (Police 4)	Did not emerge in this group
Double-edged culture of heroism (first responders only)	• "There's a certain expectation that we hold ourselves to when we come to work and put a uniform on. Regardless of the environment or whatever's presented…we just do our best to protect ourselves. Are some of us fearful of it [COVID-19]? Sure, but it doesn't create necessarily anxiety." (Police 5) • I think that because [police officers] tend to be the typical first responders, they hold things in … so they don't deal with anxiety about these sorts of issues…They only reach a crisis point before they admit it, is what tends to happen." (PoliceMD 3) • "…I think that it was tricky because I felt like we were testing pretty much anybody we wanted to at Stanford if we had a suspicion, but it was harder to tell a firefighter, 'Hey, you probably should get tested. You had a high risk exposure.'" (FireMD 1)	Did not emerge in this group

[b]EMT: emergency medical technician.

[c]PPE: personal protective equipment.

Need for Personalized Answers With No Clear Playbook

First responders and essential workers reported that throughout the pandemic, they found themselves adjusting to new protocols and professional responsibilities, which came with many uncertainties.

First responders wanted to know how standard work protocols should change in the setting of the COVID-19 pandemic, particularly in the setting of limited personal protective equipment (PPE) resources (FireMD 1). These protocol questions impacted standard procedures, such as transporting evidence from an out-of-state crime scene involving suspects with confirmed COVID-19 (PoliceMD 5), as well as human resource and personal health concerns, such as contemplating how to manage COVID-19 risk for pregnant staff and officers (Police 3). In the absence of any precedent, professionals were forced to make challenging decisions with limited information.

Essential workers also wanted personalized information (Gas 2, Electrician 4, Gas 1), though these needs were not typically related to altered professional responsibilities but were instead related to language, personal preferences, and need for increased financial support. Both groups wanted more local dynamic information about COVID-19–positive cases (Gas 3, Police 4, EMT/Fire 5).

Parsing Information Takes Time

Members of both groups acknowledged an overabundance of COVID-19 information through the media, internet, social media, and their professional settings. This aspect was particularly challenging given the dynamic nature of the available evidence (EMT/Fire 3, Police 2). Although the first responders appreciated county-level dashboards, professional daily emails, and Incident Command Center communications that made this information easier to digest (Fire/MD 4, EMT/Fire 5, Police 3, Police 5), others acknowledged significant time spent by either themselves (Gas 2, Grocery 3, Police 1) or someone in their work setting to digest the information (EMT/Fire 7).

Although first responders received their information largely from professional networks, essential worker information sources leaned toward social media (Electrician 4) and other websites (Grocery 2). The quantity of data led to skepticism:

> *Is there any [accurate data]? I feel so in the blind. I feel like there's information flying from every direction and so much of it is unreliable.* [EMT/Fire 7]

Misinformed Beliefs Fuel Conflict

The lack of reliable data sources seemed to fuel mistrust and misinformation. Both groups expressed an explicit distrust of media (EMT 4, Bus Driver 5) and government (Food Services 5). Workers also reported encountering community members

XSL•FO
RenderX

through their work who were misinformed, many of whom were reported to believe that the pandemic was a conspiracy (EMT/Fire 3). Lapses in community cooperation with mask requirements created novel conflict on the job, including the need to address "hostile" behavior in the community (Gas 1, EMT/Fire 3).

Priority Testing Gets Them Safely Back to Work

Both groups acknowledged some challenges in scheduling testing both through the app and in general through a work referral or on their own. Once a test was scheduled, however, experiences were positive. Interviewees emphasized that prioritizing testing was critical for enabling first responders and essential workers to return to their duties. In first responder organizations in which testing access was straightforward, this was thought to be due to designated COVID-19 support within the organization (Police 5, Electrician 4, EMT/Fire 5).

By contrast, essential workers reported frustration with accessing testing (Bus Driver 5). In the majority of cases where testing support was not available through work, participants sought alternate options through their primary care providers or the county (Bus Driver 5, Grocery 4, Gas 2); however, 1 participant was unsure of how to access testing at all (Gas 3).

Fear of Bringing an Amorphous Enemy Home

The stressful effects of the pandemic were salient across several interviews in both groups. These concerns centered on the amorphous nature of the disease (EMT/Fire 2), a need to go to work despite not feeling safe (Grocery 4), and fear of bringing the virus home to family (PoliceMD 3, EMT 4, Grocery 4, Food Services 5). Early high mortality rates documented in other countries contributed to widespread "paranoia" (EMT/Fire 5, Electrician 4), and reading the news worsened anxiety for some (Gas 1, Grocery 1).

The nature of a pandemic also meant that the workers' families were affected, demanding their attention on top of their existing professional duties (FireMD 4). The prolonged and unpredictable nature of the pandemic was described as a "roller coaster" (EMT/Fire 7) with a "hurry up and wait" pace (EMT/Fire 2). One responder had "never been so scared and so bored in my life" (EMT/Fire 2). The mental suffering that resulted from the COVID-19 pandemic impacted both first responder and essential worker communities, although open discussions related to mental health were described as "muted" (Bus Driver 5). Although no first responders acknowledged wanting additional mental health support (see "Culture of Heroism" below), at least one essential worker acknowledged she did not have the support she needed (Food Services 5).

Lack of Resources to Fight the Pandemic

A lack of resources emerged as a dominant theme in conversations for both first responders and essential workers. Several participants noted insufficient quantities of PPE, to the point that police officers were reported to "go begging" at one point to obtain a sufficient supply (PoliceMD 3). Public budget cuts and subsequent staffing shortages were also cited as major challenges (Police 4). Although some workers belonged to unions, which made some efforts to support workers, their impact was perceived to be limited (Bus Driver 5, Grocery 4).

The broader economic impact of the pandemic also shifted the workers' financial situations. Although some felt that the essential nature of their jobs made them more secure (Grocery 1, 2), this sentiment did not extend to everyone, as essential workers reported being furloughed (Bus Driver 5) or felt insecure in their position (Gas 1, 2). Finding financial support in the case of illness was a major challenge (EMT 1), particularly for workers who were new or did not have sick days (EMT/Fire 7). For this reason, some cited a reluctance to get tested because they were unable to take two weeks off work (EMT 6). Essential workers, more than first responders, cited financial insecurity as a major ongoing challenge (Grocery 4, Food Services 5).

Need for Interprofessional Coordination (First Responders Only)

Some themes emerged that were specific to first responders, including the need for interprofessional coordination. Health system support of first responders was felt to be critical, given their role as "the tip of the spear" (EMT/Fire 5). Specific areas for coordination with health systems included follow-up information regarding a transported patient's health status. When these communication channels fail, "anxiety increases significantly," as first responders wonder about potential exposure (EMT/Fire 5).

Another challenge emerged relating to hospital entry to respond to a crisis while bypassing the COVID-19 fever checkpoint (Police 4). In this case, the participant pointed out that because the other professional organizations already screen their workers before they start their shifts, the health system should be able to skip this step. Finally, coordination of COVID-19 information across health systems and counties up the Incident Command System was also cited as a challenge (Police 3, FireMD 4, PoliceMD 5).

Double-Edged Culture of Heroism (First Responders Only)

Several first responders shared their ongoing willingness to face the pandemic despite unfavorable circumstances because they had made a commitment to serve when choosing their profession (EMT 1, 4; EMT/Fire 3, 14; Police 1, 4, 5). Some described an underlying desire to be helpful (EMT/Fire 2) and an expansive view of their own roles in the community (Police 4). The role of choice in their profession was reported to protect against the adverse mental health effects of their roles, as with the attitude that "this is what I signed up for" (EMT/Fire 3).

However, this "cavalier" culture also led to a reluctance to report symptoms and obtain health services (PoliceMD 3). Even physician advisors shared reluctance to tell first responders they needed testing (FireMD 1). One EMT/Fire responder noted that few first responders recognized that their own colleagues may be struggling and undergoing therapy to handle their mental stress (EMT/Fire 2).

XSL•FO
RenderX

Solutions to Challenges in the Field

Participants provided several solutions to address these challenges, some of which they thought could be delivered through an app (Table 3). To address misinformation and fear of SARS-CoV-2, several participants validated the potential benefit of succinct, accurate information delivered through an app. Others thought that sharing accurate information through social media would be most effective given the increased visibility of these platforms among essential workers. Yet others felt the need for "higher touch" strategies, possibly including holding local question and answer (Q&A) sessions (FireMD 2). The personalization of information in any solution was a recurrent theme:

> *So to me that [personalized information] seems more in line with our overall philosophy at Stanford of precision medicine. It's more like precision information because then it's filtered, it's more specific to you. You don't get confused when you're reading about stuff that doesn't apply to you.* [FireMD 4]

In the absence of precision information, many solutions were developed in the field: "Some of the crews just kind of came up with stuff on their own" (FireMD 4). Other essential workers found support in managing conflict with the public from their employers (Grocery 4) or through their own volition. One bus driver reported company instructions to call a hotline when riders were not compliant with wearing masks, but she instead refused to drive the bus: "I use my [face covering gesture] until they put it on" (Bus Driver 5).

Expanding the physician-first responder partnerships to a broader audience, particularly to the police, where only informal relationships existed, was suggested. A specific request was for a designated number or person within the health system to call when the COVID-19 status of a transported patient was under question.

Personalized information also encompassed health system–specific COVID-19–related information. Some first responders expressed a desire for health systems to be forthcoming about their own infection control practices and current rates: "That's where you just put the notion of, 'Hey, we're [health system] safe…You can transport patients to our hospitals and we won't get you contracted'" (EMT 4). First responders also wanted detailed, localized COVID-19–positivity data, expressing a desire to better understand the geographic spread of cases throughout the county (Police 4, EMT/Fire 2, 7).

XSL•FO
RenderX

Table 3. Participant-derived digital and nondigital solutions to support first responders and essential workers during a pandemic.

Challenge	Participant-derived digital and nondigital solutions	Example quotations
Need for personalized answers with no clear playbook	• Physician–first responder department partnerships (Fire MD 1, 4, Police MD 3, 5, Police 1, 3, 5, EMT[a]/Fire 7) • Physician-led Q&A[b] sessions (Fire MD 2) • Colocation of county officer (Police 2)	• "[E]specially in our early stages of our Incident Command Center, we created an entire team called a Virus Response Team… at the end of the day… they're just your everyday cop… I think it would have been helpful to have guidance from somebody a little bit more knowledgeable in the field versus just picking up the information from the distributor and figuring it out from there." (Police 3)
Parsing information takes time/misinformed beliefs fuel conflict	• Physicians coming into work huddles to provide relevant, accurate COVID-19 information (Grocery 2, 4, Police 5) • Provide information on an app (Grocery 1, 4, Gas 1, EMT/Fire 2, 3, EMT 4, Police 4, Electrician 4, Food Services 5) • Provide information and/or advertise app on social media (Electrician 4), telenovelas (Food Services 5)	• "Maybe coming and visiting. There are two huddles a day—maybe you [health workers] could pop in during those." (Grocery Worker 2) • "I think that's a large part of my role is that for the most part, the personnel in my departments know me and so if they ask me a question and I answer a question, or if I bring something up, they basically trust most of what I say. Or at least have enough kind of history with me that they at least need to think about it... So, I mean part of my role is to be kind of a sounding board for what's true and what's probably not true" (FireMD 2)
Priority testing gets them back to work	• Provide comprehensive information on testing resources in the county (Police 1, FireMD 4) • Provide priority testing for first responders and essential workers (Police 1, 4, 5; Police MD 3)	• "I think just a formalized priority testing system for law enforcement has a huge impact on the organization… these are the essential workers that if they're not at work or they are sick, it affects teams of people, and cars, and community contact." (Police 1)
Fear of bringing an amorphous enemy home	• Provide resources for first responders to help them manage stress and anxiety (Police MD 3) • Ask the public to share whether someone is sick in the presence of emergency personnel (EMT/Fire 5)	• "[M]aking sure you've got reliable sources of information and things like that [can be helpful]…because it can just help identify that yes, you're having anxiety about this. Here's some tools to help with it." (PoliceMD 3)
A lack of resources to fight the pandemic	• Share PPE[c] and other resources when possible (EMT 4, 6) • Promote consistent mask use to the public (EMT/Fire 7, 3)	• "I guess just shortages on masks…It's our company that was supposed to provide for us, but it's even hard for us to get supplies sometimes." (EMT 4) • "Wearing masks and not getting other people sick. That's kind of supporting us... I've been telling people that have been asking me the best thing they can do is to keep themselves healthy, to not over impact our system by, all the things that everyone's being asked to do by washing their hands and covering their face when they're in public. That's certainly a factor." (EMT/Fire 7)
Need for interprofessional coordination (first responders only)	• Keep first responders updated on the outcomes of patients under investigation (EMT 6, EMT/Fire 5, 7) • Keep first responders informed on the process of entering hospitals to facilitate efficient emergency response (Police 4)	• "Hospitals should have their infectious disease control departments, and they should be responsible for reaching out to people when they make positive COVID results." (EMT 6)
A double-edged culture of heroism (first responders only)	• Physician–first responder department partnerships (PoliceMD 3) • Provide resources for first responders to help them manage stress and anxiety (Police MD 3)	• "They're not that kind of group that usually shares those things, unless you have a preexisting relationship with them. That can be hard to get to." (PoliceMD 3)

[a]EMT: emergency medical technician.

[b]Q&A: question and answer.

[c]PPE: personal protective equipment.

XSL•FO

Heath Worker Partnerships at the Heart of a Community Solution

A number of participants desired a stronger connection to a health worker during COVID-19. The physician partners themselves felt they were often the best resource to support first responders during the pandemic: "we are the best conduit [through] the already established trust that we've built up through the years" (FireMD 1). These participants felt their role encompassed the development and maintenance of long-term, trusting relationships with these first responder communities (FireMD 1, PoliceMD 5). First responders corroborated the special nature of the relationship in times of crisis, as one physician partner was described as "a really good resource. He's been coming by the station now too, to talk with us and to check in on COVID related topics, as well as other [topics]" (EMT/Fire 7).

In addition to their formal physician partnerships, participants also received information through informal networks into the health care community, such as a former employee who worked in the health system at the time of the interview (Grocery 3). Those with shift-based work welcomed the idea of a health worker presence at the beginning of their shift: "That may be an opportunity…to have someone present during those briefings to talk on any new developments or anything COVID related" (Police 5, Grocery 2). The human, in-person element of this relationship was emphasized.

Discussion

Principal Findings

Digital initiatives such as the Stanford COVID-19 Guide App have the potential to equip first responders and other essential workers with accurate information and access to testing resources, although adoption may depend on targeted publicity and early involvement of stakeholders with pre-existing relationships within these communities. While first responders are often included under the broader category of essential workers during outreach efforts, our findings suggest they face both overlapping challenges—related to the need for personalized and accurate information, access to testing, and ongoing personal safety—and divergent challenges, such as the need for interprofessional coordination and a double-edged culture of heroism, seen in the first responder sample alone. Optimal strategies for supporting each group should therefore differ based on their divergent needs, channels for outreach, appetite for digital and relationship-based approaches, and relationship to the health system (Table 4).

Physician partnerships emerged as a key resource for first responder departments, and these relationships are recognized as a foundational underpinning of a pandemic response [52-54]. Formalizing and nourishing these relationships holds promise in strengthening the overall ability of the health system to support its community during a pandemic. Interprofessional coordination was also cited as a major challenge, hampered by interoperability challenges between the electronic health records of EMS and the receiving health system [55]. Given these challenges, a trusted point of contact (eg, emergency department nurse line) between EMS and the health system may be explored as an alternate solution in a pandemic setting.

Our findings also suggest that first responders see increased risk as an integral part of assuming their role and may therefore adapt more readily to a new pandemic. Conversely, non–first responder essential workers decidedly *do not* see their roles as inherently risky outside a pandemic scenario. Without the training and cultural reinforcement around managing increased risk as a part of standard work, essential workers may suffer disproportionately from the onset of an infectious disease pandemic. The contributions of these workers during a pandemic should therefore not be diminished, and prioritized health services and hazard pay may be justified [56].

Similarly, misinformation emerged as a widespread challenge among the broader community. Although first responders have at least a basic degree of medical training and serve as a source of information to laypersons during a pandemic [57], essential workers often lack this formal training. Health literacy, defined as the ability to acquire, understand and enlist health information [58] becomes essential during a pandemic as first responders and essential workers come into regular, direct contact with members of the community. The reported reliance of essential workers on social media for information is concerning given its link to the spread of unvetted information [59-61]. Efforts to build health literacy, not only through digital interventions but also through channels with widespread use among vulnerable populations, including essential workers and non-English speakers, are urgently needed.

We note that the early learnings described here must be interpreted with the context that the COVID Guide App was rapidly deployed in just under three months after the first reported COVID-19 case in the United States [62]. Balancing the accuracy of an intervention in achieving its aim with the goal of rapid deployment will no doubt remain a challenge during this pandemic and other disasters; we recommend a standing advisory board with representation from target populations that can be mobilized in the short term to inform intervention development. In the long-term, community-based participatory research and human-centered design are parallel and overlapping methodologies that emphasize user expertise and creative problem-solving, with documented success in vulnerable populations [63-65]. These tools may inform improved evolutions of community interventions.

Table 4. Digital and nondigital recommendations to support first responders and essential workers during a pandemic.

Consideration	Recommendations	
	First responders	Essential workers
High need areas	• Advice on work adaptation • Streamlined accurate and timely information • Interprofessional coordination around follow up of patient diagnostic status and logistics • Priority access to rapid testing • Steady access to PPE[a]	• Acceptable resources to access accurate and timely information • Priority access to rapid testing • Steady access to PPE • Assistance navigating financial resources
Primary channels for outreach	• Formal physician partnerships with first responder departments • Employers (eg, through county infection control officers)	• Employers • Social media • Telenovelas and other culture-specific channels
Role of an app-based intervention	Small role • Provide nonpublic up-to-date information on working with health systems directly (eg, priority building entrances, rapid testing schedule, contact information to receive outcome updates on patients under investigation)	Large role • Source of credible health information that builds health literacy (eg, topics such as "protecting yourself and your family," "viral transmission," "symptom screening")
Role of physician/health worker outreach	Large role • Provide guidance on safe work adaptations • Facilitate provision of rapid testing and follow-up medical support • Assist in the dissemination of relevant health information	Small role • Provide guidance on safe work adaptations • Present health information to local businesses
Role of local health system	Large role • Facilitate prioritized access to testing and follow-up health services • Provide follow-up information to emergency medical service workers regarding patient diagnostic status • Develop and disseminate streamlined protocols for entering and exiting healthcare buildings during a pandemic	Large role • Facilitate prioritized access to testing and follow-up health services • Directly address misinformation related to pandemic

[a]PPE: personal protective equipment.

Limitations and Future Work

Limitations of this study include a lack of systematic sampling across professions in the non–first responder essential worker population, which resulted from challenges accessing this group in the field. We are unaware of similar work reaching this vulnerable population, which suggests this sample is still of value. Further, Spanish-speakers predominated our non–English-speaking sample, which reflects local demographics but does not account for the full variety of languages spoken in the community [43]. Furthermore, qualitative data capture differed between the first responders (verbatim transcriptions) and essential workers (near-verbatim field notes). This decision was made to protect essential worker anonymity given their potentially vulnerable position near their place of work. Efforts to mitigate data loss from an absence of recordings included a dedicated note-taker and immediate debrief discussions between two or more researchers to expand data capture. Finally, our learnings are limited to our local community, as the Bay Area may not be representative of populations and resources available elsewhere.

Future work will benefit from increased attention to the variety of first languages that exist within the community, including non-Spanish languages. The incorporation of a mental health component to this digital solution, reported as a need here and evaluated in other settings [66,67], may also be an opportunity for future work. Finally, evaluating digital support systems for EMS personnel as they face an increased number of deaths in the field as a result of the pandemic [68,69]—supporting decisions related to triage and/or end of life care—is another important area for future research.

Conclusion

First responders and essential workers face shared challenges related to obtaining accurate information and testing services, and securing their personal safety. Digital interventions such as mobile applications have the potential to combat these challenges through the provision disease-specific information and access to testing services. Such solutions are likely to be most effective if delivered as part of a larger ecosystem of support, and with early and direct input from those in these professions to understand how best to meet their specific needs. Given varying challenges between first responders and non-first

XSL•FO
RenderX

responder essential workers, our results indicate that differentiated interventions may leverage shared insights while also acknowledging differences in their occupational requirements and culture.

Abstract

Background: More than 79.2 million confirmed COVID-19 cases and 1.7 million deaths were caused by SARS-CoV-2; the disease was named COVID-19 by the World Health Organization. Control of the COVID-19 epidemic has become a crucial issue around the globe, but there are limited studies that investigate the global trend of the COVID-19 pandemic together with each country's policy measures.

Objective: We aimed to develop an online artificial intelligence (AI) system to analyze the dynamic trend of the COVID-19 pandemic, facilitate forecasting and predictive modeling, and produce a heat map visualization of policy measures in 171 countries.

Methods: The COVID-19 Pandemic AI System (CPAIS) integrated two data sets: the data set from the Oxford COVID-19 Government Response Tracker from the Blavatnik School of Government, which is maintained by the University of Oxford, and the data set from the COVID-19 Data Repository, which was established by the Johns Hopkins University Center for Systems Science and Engineering. This study utilized four statistical and deep learning techniques for forecasting: autoregressive integrated moving average (ARIMA), feedforward neural network (FNN), multilayer perceptron (MLP) neural network, and long short-term memory (LSTM). With regard to 1-year records (ie, whole time series data), records from the last 14 days served as the validation set to evaluate the performance of the forecast, whereas earlier records served as the training set.

Results: A total of 171 countries that featured in both databases were included in the online system. The CPAIS was developed to explore variations, trends, and forecasts related to the COVID-19 pandemic across several counties. For instance, the number

XSL•FO
RenderX

of confirmed monthly cases in the United States reached a local peak in July 2020 and another peak of 6,368,591 in December 2020. A dynamic heat map with policy measures depicts changes in COVID-19 measures for each country. A total of 19 measures were embedded within the three sections presented on the website, and only 4 of the 19 measures were continuous measures related to financial support or investment. Deep learning models were used to enable COVID-19 forecasting; the performances of ARIMA, FNN, and the MLP neural network were not stable because their forecast accuracy was only better than LSTM for a few countries. LSTM demonstrated the best forecast accuracy for Canada, as the root mean square error (RMSE), mean absolute error (MAE), and mean absolute percentage error (MAPE) were 2272.551, 1501.248, and 0.2723075, respectively. ARIMA (RMSE=317.53169; MAPE=0.4641688) and FNN (RMSE=181.29894; MAPE=0.2708482) demonstrated better performance for South Korea.

Conclusions: The CPAIS collects and summarizes information about the COVID-19 pandemic and offers data visualization and deep learning–based prediction. It might be a useful reference for predicting a serious outbreak or epidemic. Moreover, the system undergoes daily updates and includes the latest information on vaccination, which may change the dynamics of the pandemic.

Introduction

In December 2019, the first cases of a new respiratory disease caused by a novel coronavirus were reported in Wuhan, Hubei province, China [1]. The novel coronavirus was subsequently identified and named SARS-CoV-2, and the disease caused by SARS-CoV-2 was named COVID-19 by the World Health Organization (WHO) [2,3]. Since the time the first cases were reported, many confirmed cases have been reported in various other countries. By March 11, 2020, more than 118,000 confirmed cases and 4291 deaths had been reported across 114 countries. The WHO declared the COVID-19 outbreak a pandemic [4], which continues to worsen. As of December 27, 2020, there were more than 79.2 million confirmed cases and 1.7 million deaths [5]. COVID-19 management has emerged as an urgent global issue. Many studies have investigated the factors that contribute to the spread of COVID-19. Demographic, geographic, and economic factors have influenced the spread of the disease. However, social factors, especially governmental response to the pandemic, have significantly influenced disease severity within certain countries [6-11]. Some countries have shown that implementing rigorous public health care management strategies can successfully control infection spread and maintain normal societal functioning [11].

The rapid development of artificial intelligence (AI) in the health care field offers new opportunities to medical researchers. There are many studies that employ AI techniques in disease predictions, such as Yu et al, who have established an online machine learning health assessment system for metabolic syndrome and chronic kidney diseases [12]. Lin et al utilized multicenter data to develop an end-stage liver disease mortality prediction scoring system [13]. Ayyoubzadeh et al analyzed the rate of COVID-19 incidence in Iran using Google Trends data and deep learning methods [14]. Yeung et al combined several online COVID-19 data to train and evaluate five non–time series machine learning models in predicting confirmed infection growth [15]. These studies have shown that AI is suitable for evaluating disease trends and can provide governments with information that can be used to prevent outspread. There are abundant research findings on COVID-19–related AI prediction and the utilization of mobile sensor data with cell broadcast to identify and manage potential contacts [14,16-20].

However, most of these studies have been conducted in a specific region or single country. There is public health consensus that vaccination is an effective prevention strategy. However, with regard to its efficiency and medical expenditure, long-term follow-up investigation is needed to evaluate the clinical effects of vaccines that have not undergone the standard approval process and tests of their mid- and long-term side effects on different groups [21]. Moreover, different studies have focused on different time frames in pandemic trend prediction. They have drawn the same conclusion: there is a high possibility that COVID-19 will remain a common illness or become endemic in the future, and we must learn to coexist with it. Many factors influence how the pandemic will progress (eg, herd immunity), and governmental and individual responses vary widely across nations [22,23]. Successful epidemic prevention and control measures remain the most efficient solution for public health problems. However, there is limited literature on the relationship between governmental responses and the severity of the domestic spread of COVID-19 [24,25].

Therefore, we constructed an online AI system that contains worldwide COVID-19–related data, each country's governmental responses to the COVID-19 pandemic, and each country's population data [26]. The COVID-19 Pandemic AI System (CPAIS) can be used to analyze the dynamic trend of the COVID-19 pandemic, facilitate forecasting and predictive modeling, and produce heat map visualization of policy measures in different countries.

Methods

Data Acquisition and System

The CPAIS integrated two data sets: the data set from the Oxford COVID-19 Government Response Tracker (OxCGRT) from the Blavatnik School of Government, which is maintained by the University of Oxford, and the data set from the COVID-19 Data Repository, which was established by Johns Hopkins

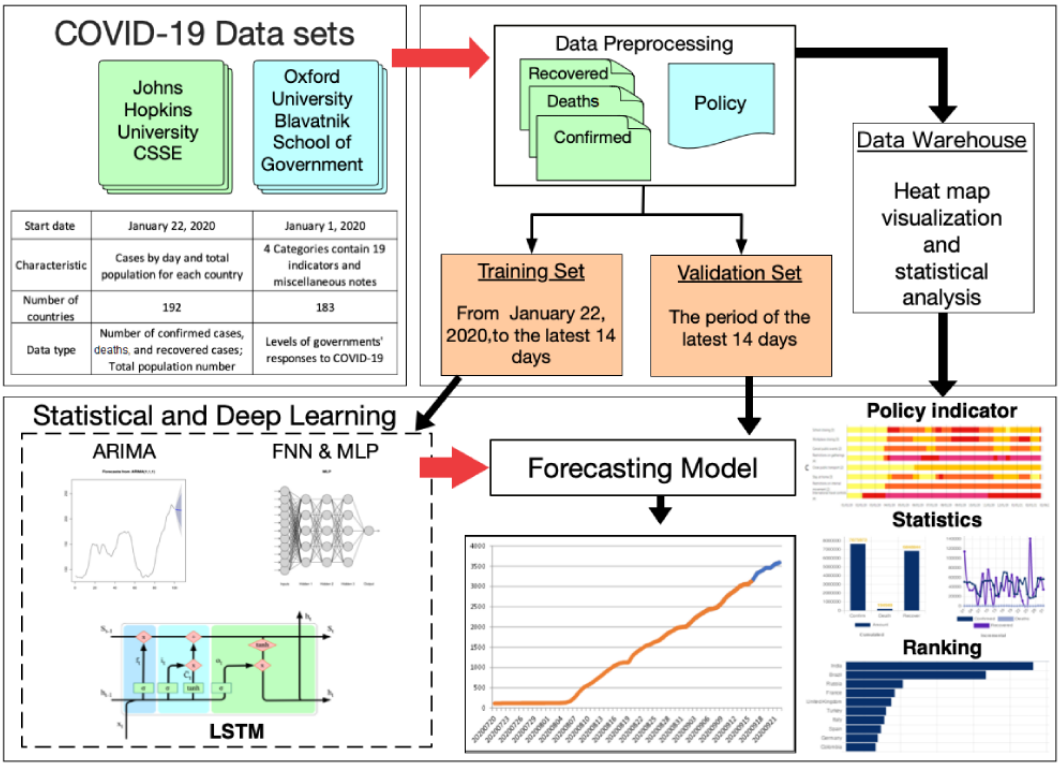
XSL•FO
RenderX

University Center for Systems Science and Engineering (CSSE). The COVID-19 Data Repository also contains each country's population data, which are obtained from the United Nations World Population Prospects [27-31]. A total of 171 countries that featured in the databases were included in the system.

The CPAIS was placed on a sever and embedded with time series deep learning models to provide forecasting analyses by the statistical program R, version 3.6.3 (The R Foundation). We used the React.js, version 16.14.0, framework; the styling language Sass (Syntactically Awesome Style Sheets), version 4; and the programming language JavaScript ES6 for front-end implementation. As for back-end implementation, we used Java 8; Spring Boot, version 2.0.2 (VMware, Inc); and R as the programming languages, and we used the MySQL (Structured Query Language), version 5.7.21, database as the storage system. In addition, this AI-based system has been programmed to update itself by auto-retrieving information from all data sets each morning at 9 AM (GMT + 8). The auto-retrieval can be summarized in the following three steps: (1) setting the crawler to fetch the data from the source databases, (2) integrating the updated data into our own MySQL database, and (3) conducting statistical analysis using the database-stored procedure.

The COVID-19 Data Repository established by Johns Hopkins University CSSE contains three categories of data concerning COVID-19 incidence—confirmed cases, recovered cases, and number of deaths—with country geolocation retrieved from 192 affected countries since January 21, 2020. For most of the countries, country-level data concerning the numbers of reported cases are available. Province- and city-level data concerning reported cases are available for some countries. To depict the COVID-19 pandemic comprehensively, we archived country-level data. The number of reported cases was updated daily using data retrieved from multiple online sources. The number of cases was retrieved from the WHO and the regional and local health departments of the affected countries, including their centers for disease control and prevention. All data were shared freely through GitHub.

OxCGRT has been collecting and documenting governmental responses to the COVID-19 pandemic based on several parameters since January 1, 2020. The data set includes 183 countries and 20 items (19 indicators and 1 free response) that characterize governmental responses. There are three types of items: (1) ordinal scale for severity or intensity, (2) numeric scale for specific numbers, and (3) text for other information types. These items can be further classified into four groups: (1) containment and closure policies (8 indicators), (2) economic policies (4 indicators), (3) health system policies (7 indicators), and (4) miscellaneous policies (1 free response). Miscellaneous policies were not included in this system because they were assessed using a free-text response format and limited data were available. OxCGRT data were retrieved from publicly available sources and regularly updated on GitHub.



Statistical Analysis and Deep Learning Techniques

Overview

Four time series models were considered for this study. Each model was applied to all the countries in our system to facilitate forecasting. With regard to 1-year records (ie, whole time series data), records from the last 14 days served as the validation set, whereas earlier records served as the training set. Using records from the last 14 days, forecasting performance was evaluated based on the following five indices: mean error (ME), root mean square error (RMSE), mean absolute error (MAE), mean percentage error (MPE), and mean absolute percentage error (MAPE) [32,33]. RMSE, MAE, and MAPE are always positive values, whereas RMSE, MPE, and MAPE are scaled measures. The hyperparameters for each model can be found in Table S1 in Multimedia Appendix 1, and the diagram of the neural networks can be found in Figure 1. R, version 3.6.3 (The R Foundation), was used to conduct statistical analysis and apply deep learning techniques.

Figure 1. The structure of the COVID-19 Pandemic AI System (CPAIS). ARIMA: autoregressive integrated moving average; CSSE: Center for Systems Science and Engineering; FNN: feedforward neural network; LSTM: long short-term memory; MLP: multilayer perceptron; NN: neural network.

Autoregressive Integrated Moving Average

An autoregressive integrated moving average (ARIMA) model is a statistical regression analysis that utilizes time series data to either understand the data set better or predict future trends. The purpose of ARIMA is to forecast future trends by examining differences between values in the series rather than by using actual values [34,35]. The three main components of ARIMA are autoregression, integration, and moving average. Autoregression refers to a model with a changing variable that regresses on its lag values. Integration represents the differences between data values and their previous values for stationary time series. Moving average incorporates the dependence between an observation and an error term from a moving average model. An ARIMA model can be comprehended by outlining each component, which serves as a parameter with a standard notation. For ARIMA models, there are three standard notations, wherein integer values serve as substitutes for the parameters to indicate the type of ARIMA model used.

The parameters can be defined as follows:

- p: the number of time lags
- d: the degree of differencing
- q: the size of the moving average window.

In this study, we used the *auto.arima* function for R, which returns the best ARIMA model based on either the Akaike information criterion value or Bayesian information criterion value. The function searches for possible models within the order constraints provided in the *forecast* package for R [36,37].

Feedforward Neural Network

A feedforward neural network (FNN) is the simplest type of artificial neural network [38]. The FNN algorithm is biologically inspired. It consists of several simple neuron-like units that are organized in layers. In FNN, information moves in one direction—from the input nodes, through the hidden nodes, and to the output nodes. The mechanism of an FNN is different from that of recurrent neural networks (RNNs) in that connections between the units do not form cycles or loops in FNNs [38,39]. In this study, we used the *nnetar* function for R, which constructs FNNs with a single hidden layer and lagged inputs for the purpose of forecasting univariate time series. Also, in the *forecast* package, the function fits into a single hidden-layer neural network for forecasting, with the *nnet* function included in the *nnet* package for R [40,41].

Multilayer Perceptron Neural Network

Like FNNs, multilayer perceptron (MLP) neural networks are common deep learning feedforward networks. An MLP neural network is also a supervised learning algorithm used for classification. The main difference is that between the input and output layer, there can be multiple nonlinear layers, called hidden layers, which are the true computational engine of the MLP neural network. MLP neural networks use a learning technique called back-propagation for training. Their multiple layers and nonlinear activation distinguish MLP neural networks from a linear perceptron [42-44]. In other words, MLP neural networks are designed to solve nonlinearly separable problems. Specifically, the units of MLP neural networks apply a sigmoid function as an activation function. In the back-propagation technique, the difference between the output values and the *ground truth* answer are calculated using predefined error

XSL•FO
RenderX

functions. The error is fed back through the network. Using this information, the algorithm can adjust the weights of each connection to significantly reduce the value of the error function. In this study, the *mlp* function fits MLP neural networks for time series forecasting executed using the *nnfor* package [45-47].

Long Short-term Memory

Long short-term memory (LSTM) networks are a special type of recurrent deep learning neural network that learns order dependence in sequence prediction problems. LSTM was introduced by Hochreiter and Schmidhuber in 1997, and it is now widely used in a variety of studies and projects [48,49]. A typical RNN makes use of sequential information. These networks are described as *recurrent* because they use their internal state to process the variable length sequences of inputs. It is difficult for a standard RNN to carry forward information from prior time steps to later ones if a sequence is too long, because it may exclude important information from the beginning. Therefore, LSTM has an advantage in that information can be remembered for long periods of time. Unlike traditional FNNs, LSTM has feedback connections, whereby the output from the previous step is supplied as input in the current step [50]. A common LSTM unit includes a cell, an input gate, an output gate, and a forget gate. The cell recalls values over an arbitrary time interval, and the three gates regulate the flow of information in and out of the cell. In this study, we used the *keras* R package to recall TensorFlow for conducting the LSTM analysis [51]. TensorFlow was developed by the Google Brain team and released in 2015. It is a free open-source software library for machine learning techniques, particularly deep neural networks [52].

Data Visualization of Time Series Data Sets

Heat maps can be generated to depict variations in policy measures for the COVID-19 pandemic across time. Gradient color bars represent changes in measures across different levels and the support received in the form of financial assistance and investments. The time schedule presented along the horizontal axis will be updated daily. Cumulative and monthly records are represented using histograms and line charts, respectively. This system also provides a download option to interested countries and comparable services with dynamic rankings of the total number of confirmed cases and deaths and declining trends for the COVID-19 pandemic. The following simple regression formula is used to examine declining trends with dynamic time intervals:

$$y_i = \alpha + \beta x_i$$

where β is the slope that represents an increasing or decreasing trend.

Results

In this study, the CPAIS was developed to explore variations, trends, and forecasts related to the COVID-19 pandemic across several counties. A drop-down list for country selection is available. The framework of the CPAIS—from data acquisition and preprocessing to deep learning model application, forecasting, and data visualization—is presented in Figure 1. It includes a combination of two data sets, construction of databases for deep learning prediction and statistical analysis, four statistical or deep learning models for forecasting, and front-end functions for data visualization.

The numbers of confirmed cases, recovered individuals, and deaths in 15 countries are listed by month in Table 1. The number of confirmed monthly cases in the United States reached a local peak in July 2020 and another peak of 6,368,591 in December 2020. Regarding the United States, the number of recovered cases after December 14, 2020, is not recorded in the COVID-19 Data Repository database. The total population for each of the 15 countries in 2020 is also mentioned in the table. The dynamic heat map with policy measures is shown in Figure 2, which depicts changes in COVID-19 measures for each country, with Australia used as an example. A total of 19 measures were embedded within the three main policy sections (ie, containment and closure policies, economic policies, and health system policies). Economic policies have the least number of measures, and only 4 of the 19 measures are continuous measures related to financial support or investment.

Deep learning and statistical learning models were used to enable COVID-19 forecasting. The function facilitates 14-day forecasting using four powerful algorithms (Figure 3). ARIMA is the statistical learning model with time series regression; the other models are deep learning neural network algorithms with a single hidden layer, multiple hidden layers, or recurrent techniques. The performance of forecasting for each model for the 15 countries listed in Table 1 is shown in Table 2. A small error value indicates a perfect fit for the data, but the comparison between the different countries was not meaningful because they had different baselines based on their populations. For most of the countries, LSTM demonstrated better forecast accuracy with fewer errors than the other models. The performances of ARIMA, FNN, and the MLP neural network were not stable because their forecast accuracy was only competitive with LSTM for some specific countries. For example, LSTM demonstrated the best forecast accuracy for Canada. The RMSE, MAE, and MAPE were 2272.551, 1501.248, and 0.2723075, respectively. ARIMA (RMSE=317.53169; MAPE=0.4641688) and FNN (RMSE=181.29894; MAPE=0.2708482) demonstrated better performance for South Korea.

Figure 4 presents descriptive statistics for specific countries. On the website, three countries can be simultaneously compared, and the period can be customized. Users can select the countries that are of interest to them and compare the COVID-19–related data. For each respective country, a line chart showing the number of confirmed cases, recoveries, and deaths per month is generated. In addition, a global comparison is also provided on the website.

Users can rank 171 countries based on five different parameters: (1) the number of confirmed cases, (2) confirmed cases by percentage of population, (3) the number of confirmed deaths, (4) confirmed deaths by percentage of population, and (5) declining trend. Figure 5 shows an example of how the top 20 countries can be ranked using confirmed cases by percentage of population. With regard to customization, the ranking

XSL•FO
RenderX

function is flexible. The selected countries and specific time period can be changed by the user.

Discussion

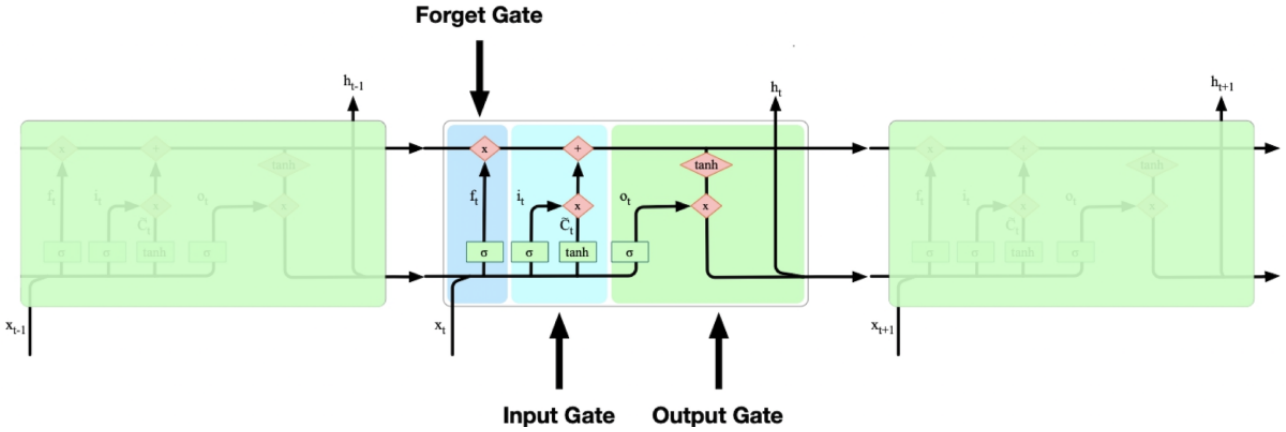
Principal Findings

A combination of data on COVID-19 incidence and policy measures can be used to examine the relationship between the progression of the COVID-19 pandemic and governmental epidemic prevention efforts. The CPAIS can help users determine whether policy measures are successful in preventing COVID-19 transmission. According to a report published by the Lowy Institute for International Policy [53], a ranked comparison of the performance of countries in managing the COVID-19 pandemic shows that New Zealand, Vietnam, and Taiwan are the top three countries with the highest average scores on their six indicators. Besides, New Zealand and Taiwan successfully controlled the COVID-19 outbreak without international financial support (Figures S1-S3 in Multimedia Appendix 1). Specifically, New Zealand had immediately implemented infection control and closure policies with a flexible adaptation on measures; in addition, Taiwan had enforced strict guidelines regarding international travel that not only contributed to infection control but also rendered the strict measures described in the containment and closure policies unnecessary. Furthermore, both countries had taken great efforts to maximize the implementation of testing and contact tracing policies during 2020. In this regard, both countries are outstanding examples. The vivid heat maps in the CPAIS illustrate time-dependent fluctuations in the measures and help users monitor variations in, and the effects of, policy measures in each country.

Several time series AI learning techniques have been used for forecasting purposes. Both statistical learning and deep learning models demonstrated efficacious performance for different countries. Although the values are not absolute, they are comparable between countries with different total populations. When compared to the results of a past study [19], performance for the same model and country was better in this study because more extensive time series data were included in our system. In addition, 14-day COVID-19 trend forecasting can serve a useful alert that will help governments and experts reduce the incidence of COVID-19. Furthermore, different AI learning techniques have unique advantages.

According to the Wold decomposition theorem [34,54,55], the autoregressive moving average model is theoretically sufficient to describe a regular stationary time series. It is possible to change a nonstationary time series into a stationary one, such as by using differencing. As noted earlier, ARIMA models have three components: autoregression, integration, and moving average. They are applied to data with evidence of nonstationarity in the mean, whereby an initial differencing step can be applied one or more times to eliminate the nonstationarity of the mean function in the trend. We used the *auto.arima* function for R to choose the best model according to either the Akaike information criterion, corrected Akaike information criterion, or Bayesian information criterion value; the *auto.arima* function also conducts the model search within the order constraints provided. FNN is similar to ARIMA because the fitted model is analogous to an autoregression(p) model, where p is the order but with nonlinear functions for nonseasonal data in this study. Therefore, it is denoted as a neural network autoregression(p,k) model called *NNAR*, where k represents the

XSL•FO
RenderX



number of hidden nodes. That is why, for some countries, ARIMA and FNN yielded similar outcomes for forecast accuracy. Differences between the two models still exist; the error can be reduced only for FNN by increasing the number of iterations, but the iteration time will be increased as a result.

The capabilities of neural networks are attributable to the hierarchical or multilayered structure of the networks. The data structure can include features at different scales or resolutions and combine them into higher-order features. After repeating the learning process for a sufficient number of training cycles, the network will transition to some state where the error term is small enough. Generalization and tolerance are the two main characteristics. First, neural networks permit generalization because they can classify both unknown and known patterns with the same distinguishing features. Second, neural networks are highly fault tolerant. Because of their distributed nature, they will continue to function even if a significant fraction of neurons and interconnections fail. In general, increasing the number of hidden nodes may enhance the performance of prediction, and increasing the number of networks to train may result in an ensemble forecast.

The core idea of LSTM lies in the cell state—the horizontal line that runs down the chain with information flowing alongside (Figure 6). In addition, LSTMs have the ability to remove or add information to the cell state, controlled by the gates, which are a pathway through which information can be allowed to pass. They consist of a sigmoid neural net layer and a pointwise multiplication operation. LSTM networks are powerful in promptly forecasting series data since there can be lags of unknown duration between events in time series. Hence, when compared to other traditional RNNs in this study, LSTM networks do not have the vanishing gradient problem. Thus, LSTM has the advantages of being relatively insensitive to time intervals and of making fewer errors in prediction when compared to other methods.

In the CPAIS, long-term cumulative records of confirmed cases, recoveries, and deaths are included. In addition, daily figures for these metrics are provided for each month. Thus, short-term trends can be examined using this system. Users can compare three or more countries and visualize the relative incidence of COVID-19 within a specific time duration. Short-term and long-term trends can be simultaneously viewed. In previous studies [14,19,20], only a limited number of countries were included for forecasting. Our system contains 171 countries and provides information about policy measures. Further, data visualization, statistical and deep learning for incidence forecasting, and customized ranking are possible. Based on their objectives, users can select country names and time periods. Similar cultural backgrounds, neighboring geographical characteristics, and high-frequency trading may also serve as attractive features. In particular, a declined ranking is calculated by our system to explore the effectiveness of COVID-19 management strategies implemented in 2020. Thus, the CPAIS is a comprehensive AI-based service that is available on the internet. It relies on big data and offers data visualization, deep learning–based prediction, and customized comparison. This system can be used to investigate COVID-19 progression trends.

Figure 6. Diagram of the long short-term memory neural network with three functional gates.

Limitations

To the best of our knowledge, this is the first web-based machine learning system that can explore variations, trends, and forecasts related to the COVID-19 pandemic across 171 countries. This pilot system still has several limitations. First, this database relies heavily on the source databases and shares similar limitations with the source databases. For example, the source databases did not consider the number of COVID-19 patients that were traveling internationally, and this may result in inaccurate analysis for a small number of countries. However, we think that the number of COVID-19 patients who were traveling internationally is small, as most countries imposed COVID-19–negative tests or proof of vaccination before allowing the traveler into the country. Second, the CPAIS cannot be updated daily if the source databases are not updated. For example, at present, the number of recoveries in the United States was last updated on December 14, 2020. So the number of recoveries in the United States may not be accurate. Finally, since the main purpose of this platform is to consolidate raw data retrieved from various databases and associated measures of pandemic policy implementation, we remind the reader to use text mining, local reports, and information retrieved from the medical system of a given country for further assessment.

Conclusions

In general, the CPAIS collects and summarizes information about the COVID-19 pandemic and offers data visualization

XSL•FO
RenderX

and deep learning–based prediction. It may be a useful and consequential reference resource for any serious outbreak or epidemic that may occur in the future. In addition, information about the vaccine is also stored in our system. It may be used to evaluate the efficacy of the vaccine in different countries in the future. Moreover, the 2-week machine learning forecasts may serve as warning signs and highlight current trends in the epidemic that have been made apparent by AI techniques. To conclude, the CPAIS can be used to summarize several factors that can influence the effectiveness of epidemic prevention and predict the next serious outbreak.

Acknowledgments

This study is supported by the Ministry of Science and Technology Grant (MOST 110-2314-B-038-025) and Higher Education Sprout Project by the Ministry of Education (MOE) in Taiwan (DP2-110-21121-01-A-09). No funding bodies had any role in study design, data collection and analysis, decision to publish, or preparation of the article.

Conflicts of Interest

None declared.

Abstract

Background: There are many alternatives to direct journal access, such as podcasts, blogs, and news sites, that allow physicians and the general public to stay up to date with medical literature. However, there is a scarcity of literature that investigates the readership characteristics of open-access medical news sites and how these characteristics may have shifted during the COVID-19 pandemic.

Objective: This study aimed to assess readership and survey data to characterize open-access medical news readership trends related to the COVID-19 pandemic and overall readership trends regarding pandemic-related information delivery.

Methods: Anonymous, aggregate readership data were obtained from 2 Minute Medicine, an open-access, physician-run medical news organization that has published over 8000 original, physician-written texts and visual summaries of new medical research since 2013. In this retrospective observational study, the average number of article views, number of actions (defined as the sum of the number of views, shares, and outbound link clicks), read times, and bounce rates (probability of leaving a page in <30 s) were compared between COVID-19 articles published from January 1 to May 31, 2020 (n=40) and non–COVID-19 articles (n=145) published in the same time period. A voluntary survey was also sent to subscribed 2 Minute Medicine readers to further characterize readership demographics and preferences, which were scored on a Likert scale.

Results: COVID-19 articles had a significantly higher median number of views than non–COVID-19 articles (296 vs 110; U=748.5; P<.001). There were no significant differences in average read times (P=.12) or bounce rates (P=.12). Non–COVID-19 articles had a higher median number of actions than COVID-19 articles (2.9 vs 2.5; U=2070.5; P=.02). On a Likert scale of 1 (strongly disagree) to 5 (strongly agree), our survey data revealed that 65.5% (78/119) of readers agreed or strongly agreed that they preferred staying up to date with emerging literature about COVID-19 by using sources such as 2 Minute Medicine instead of journals. A greater proportion of survey respondents also indicated that open-access news sources were one of their primary sources for staying informed (86/120, 71.7%) compared to the proportion who preferred direct journal article access (61/120, 50.8%). The proportion of readers indicating they were reading one or less full-length medical studies a month were lower following introduction to 2 Minute Medicine compared to prior (21/120, 17.5% vs 38/120, 31.6%; P=.005).

Conclusions: The readership significantly increased for one open-access medical literature platform during the pandemic. This reinforces the idea that open-access, physician-written sources of medical news represent an important alternative to direct journal access for readers who want to stay up to date with medical literature.

KEYWORDS

COVID-19; internet; medical news; text summaries; readership trends; news; media; open access; literature; web-based health information; survey; cross-sectional; trend

Introduction

On March 11, 2020, COVID-19 was declared a pandemic by the World Health Organization roughly 11 weeks after the report of the first detected COVID-19 case [1]. With its high transmissibility and global impact, COVID-19 has attracted tremendous interest from researchers, clinicians, and the general population worldwide. Within the first 3 months of the disease's discovery, bibliometric analyses indicated that there was already a greater number of peer-reviewed COVID-19 studies published than the combined number of articles on SARS (severe acute respiratory syndrome) and MERS (Middle East respiratory syndrome) published during these diseases' first year of discovery [2,3]. This has also resulted in significant interest from the mass media, as a substantial increase in COVID-19–related news was observed in the early months of 2020 [4]. Prior literature has found that overall news consumption increases significantly during a national crisis, and this appears to be the case for the COVID-19 outbreak, as there is evidence suggesting that information-seeking behavior increased following the declaration of the pandemic [5-7].

Compared to the past, many alternatives to direct journal access and mainstream media now exist for clinicians and the general public who want to stay informed about medical news and research, including, but not limited to, social media, blogs, journal newsletters, open-access medical news sites, and podcasts. Although there is evidence that suggests that differences in the use of these alternative sources can have subsequent downstream effects on consumers' health behaviors, there is little data on the characterization of the consumption of these sources both prior to and following the start of the pandemic [8]. Specifically, there is a notable scarcity of investigations examining the readership trends and characteristics of open-access medical news organizations.

To further characterize the consumption of medical literature during the COVID-19 pandemic, this study sought to investigate readership trends for one physician-run, open-access medical news organization and readership preferences regarding the delivery of COVID-19–related research and information.

Methods

Readership Data

Aggregate, anonymous data for this retrospective observational study was obtained from 2 Minute Medicine Inc [9]. 2 Minute Medicine is a free, open-access medical news organization that publishes daily, physician-written texts and visual summaries of new medical research. It has published over 8000 summaries since 2013. Articles published on the website from January 1 to May 31, 2020, were included in our analysis. In that time span, 40 articles were published about COVID-19–related research, and 145 articles were published about non–COVID-19 medical research. Overall daily website traffic, average view times, the average number of actions, and average bounce rates were longitudinally characterized for the study period.

Web-Based Survey Data

A web-based survey was sent to 4221 readers who opted into the website's free, daily electronic mailing list. Nonidentifying demographic data, including age, sex, respondents' level of education, and respondents' field of work or study, were gathered. Survey items were created with the intention of directly addressing identified gaps in literature regarding respondents' perspectives and the relative use of alternative sources, as secondary outcome validation was beyond the scope of this study. Descriptive data were gathered on readers' behaviors and preferences via Likert scales that ranged from 1 (strongly disagree) to 5 (strongly agree). The key statements used in the study included items such as "I prefer using open access medical news sites such as www.2minutemedicine.com to stay up to date with research related to COVID-19." Users were also asked to indicate all of the primary sources that they were using to stay informed about COVID-19–related literature, including, but not limited to, direct journal access, journal newsletters, mainstream media, social media, and open-access medical news sites such as 2 Minute Medicine. Other readership trends were also briefly investigated with the survey, as users indicated their frequency of reading full-length original journal articles both prior to and following their introduction to 2 Minute Medicine.

Ethics

This study was compliant with the Health Insurance Portability and Accountability Act and exempt from review by the institutional review board.

Statistical Analysis

All statistical analyses were performed using SPSS, version 26 (IBM Corporation). The visual inspection of a histogram, normal quantile-quantile plot, and box plot and the Kolmogorov-Smirnov test were completed to determine if the data followed a normal distribution [10]. If the data were not normally distributed, the Mann-Whitney *U* test was used to compare the average number of views (over the first 2 weeks following publication on the website), number of actions (defined as the sum of the number of views, shares, and outbound link clicks), read times (in seconds), and bounce rates (defined as the probability of readers leaving the webpage in <30 s) for each article [11]. In this study, actions, read times, and bounce rates were used as measures of reader engagement.

Results

A total of 121 responses were obtained over a 7-week period (response rate: 121/4421, 2.7%). Demographic characteristics of respondents are summarized in Table 1. The majority of

XSL•FO
RenderX

respondents reported that they worked in the health care industry (114/121, 94.2%). These respondents included undergraduate students, graduate students, medical students, medical residents, and licensed physicians, and they made up the majority of the respondents.

Table 1. Demographic characteristics of respondents.

Characteristics	Value, n (%)
Sex	
Male	66 (55)
Female	54 (45)
Age group (years)	
<20	1 (0.8)
20-29	43 (35.8)
30-39	37 (30.8)
40-49	6 (5)
50-59	7 (5.8)
60-69	10 (8.3)
>69	9 (7.5)
Did not indicate	6 (5)
Education	
Less than or equal to high school graduate	3 (2.5)
Some college or university education	13 (10.8)
Undergraduate degree	18 (15)
Master's degree	24 (20)
Doctoral or professional degree	62 (51.6)
Field of work or study	
Health care worker	116 (95.9)
Other	5 (4.1)
Licensed physician	26 (21.4)
Licensed allied health professional	13 (10.7)
Licensed pharmacist	7 (5.7)
Medical or surgical fellow	6 (4.9)
Medical or surgical resident	34 (28.1)
Pharmacy resident	1 (0.8)
Medical student	6 (4.9)
Graduate student	10 (8.2)
Undergraduate student	9 (7.3)
Pharmacy student	2 (1.7)
Unspecified or other	6 (4.9)

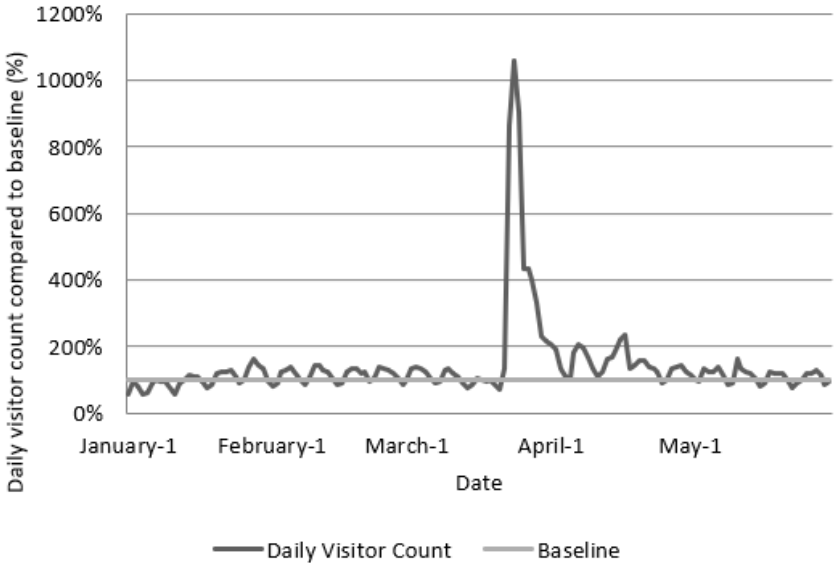
Over the study period, COVID-19 articles had a total of 68,129 views (mean 1792, SD 6491), while articles not related to the pandemic accrued 19,650 views (mean 137, SD 122). Our analysis via the Mann-Whitney *U* test revealed that COVID-19 articles published within the observed time frame had a significantly higher median number of views than non–COVID-19 articles (296 vs 110; U=748.5; P<.001). There was no difference in average view times or bounce rates between the two types of articles. Non–COVID-19 articles had a significantly higher median number of actions than COVID-19 articles (2.9 vs 2.5; U=2070.5; P=.02).

The number of daily visitors over the study period are displayed in Figure 1. The average mean daily visitor count was 1724 (SD 1549). Daily visitor counts were relatively stable from January 1 to February 29, 2020 (mean 1298, SD 292), but a significant peak in daily readership was observed in the month of March (mean 2816, SD 3134), and a peak visitor count of 12,806 daily

XSL•FO
RenderX

readers was observed on March 24. The mean daily visitor count from April 1 to May 31 was 1586 (SD 437). The average visit time per page over the study period was 168 s (SD 16 s), and this is shown in Figure 2. The lowest average daily read times were found on March 23 (116 s), March 24 (115 s), and March 25 (120 s).

Figure 1. Daily visitor traffic from January 1 to May 30, 2020 compared to the baseline average.



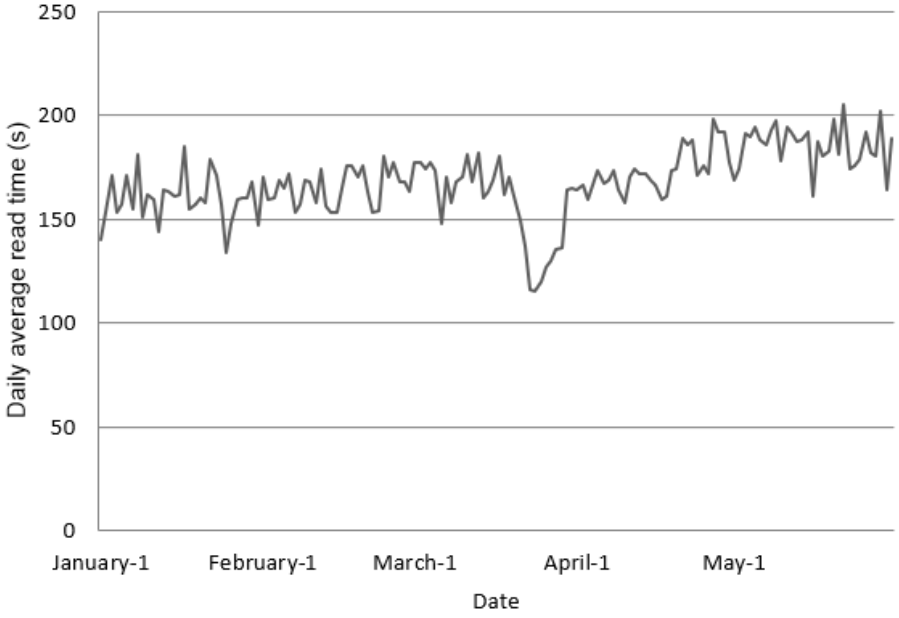


Figure 2. Daily average read times for articles from January 1 to May 30, 2020.

In terms of survey responses, on a Likert scale of 1 (strongly disagree) to 5 (strongly agree), data from 119 responses (2 respondents did not answer) revealed that 65.5% (78/119) of readers agreed or strongly agreed that they preferred staying up to date with emerging literature about COVID-19 by using sources such as 2 Minute Medicine instead of journals, as shown in Table 2.

When respondents were asked to indicate all of the sources they used to stay up to date with COVID-19 literature, a greater proportion of survey takers indicated that open-access news sources were one of their primary means of staying informed (86/120, 71.7%) compared to the proportion who preferred direct journal article access (61/120, 50.8%), as shown in Table 3. Journal newsletter updates (70/120, 58.3%), social media sources (53/120, 44.2%), and mainstream news media sources (46/120, 38.3%) were other recognized sources of information. The following five other sources were also recognized as sources of information: work or school announcements, podcasts, institutional newsletters, and search engine notifications. In terms of the impact of 2 Minute Medicine on information consumption, a Fisher exact test demonstrated that the proportion of readers who indicated that they were reading 1 or fewer full-length medical studies per month decreased after their introduction to 2 Minute Medicine (21/120, 17.5% vs 38/120, 31.6%; *P*=.005).

Research aggregator services	16 (13.3)
Other sources	5 (4.2)

Discussion

Principal Results

The results in this study show that average view counts for COVID-19–related articles were significantly higher than those of articles that covered other medical news during the pandemic (P<.001). Although this suggests people's overall interest in COVID-19–related news was greater than their interest in other medical news, there were no associated findings for measures of audience engagement, including average view times or bounce rates. Interestingly however, the average number of actions, which consisted of the number of views, shares, and outbound link clicks per article, were found to be significantly higher for non–COVID-19 medical news articles (P=.02), which had an average of nearly 3 actions. We hypothesized that this was due to these articles tending to cover subspecialties or other niche areas of medicine, thereby attracting readers that may be more heavily involved in these fields and have a higher probability of reading primary source articles.

Longitudinal trends of daily visitor counts indicated relatively stable overall site traffic for the first 3 months of 2020. A large spike in daily readership was observed between March 23 to March 26. This was followed by variable daily site traffic before it returned to relative stability in the third and fourth weeks of April. Interestingly, while prior literature has documented increased information-seeking behavior in the first 1 or 2 days following local announcements of outbreaks, this large spike in site traffic appeared to be primarily attributable to a site that published summaries covering research on hydroxychloroquine and its potential therapeutic application for treating COVID-19 [7]. Daily visitor counts dropped in the following weeks but remained above the baseline average. This is possibly indicative of readership retention. Furthermore, while average read times remained fairly stable with an SD of less than 10% over the study period, a substantial decrease in average read times coincided with this peak in visitor count; the decreased average read time was 30.3%. Although this was not confirmed in our site analysis, we believed that this decrease in average read time may be reflective of the site's larger reach to the general public compared to the normal demographic of the site's readers—health care professionals. Overall, our results indicate that secondary sources such as medical news sites may have readership data that are more heavily influenced by the gravity and popularity of individual research articles than by other potential factors, such as infection count or other trends related to the pandemic. However, this will need to be further validated in future studies. To our knowledge, these findings represent the first characterization of open-access medical news readership trends during an international health crisis.

In our review of the survey results, the survey data collected appeared to corroborate the findings of the site data comparisons. Unsurprisingly, the majority of respondents (114/121, 94.2%) to the survey, who were subscribers of 2 Minute Medicine, were primarily composed of those directly involved in health care. The survey results indicated that users preferred open-access medical news sources such as 2 Minute Medicine as their primary source of information about pandemic-related research. This is based on both the overall agreement responses on the Likert scale and the fact that a greater proportion of respondents indicated that such sources were their primary news source compared to the proportion who used journals, journal newsletters, and mainstream media as their primary news source. The transition to using sources such as open-access new sources and newsletters may be increasing in prevalence due to the explosive growth in the volume of

XSL•FO
RenderX

scientific literature being published per year [11]. The use of these alternative sources may provide readers with a means to sort through such literature and identify research with the highest impact to guide their reading. Interestingly, the use of 2 Minute Medicine appeared to influence the respondents' overall consumption of medical literature, as readers indicated that they read a greater number of articles via direct journal access following their introduction to the website. In terms of the demographic data acquired in the study, it is of note that despite people's increased interest in 2 Minute Medicine and its articles covering COVID-19–related research, the vast majority of subscribers to the website continue to be composed of respondents who are directly involved in the health care field. As such, further investigations may be needed to characterize the readership trends and preferences of the general public.

To our knowledge, this is the first study that describes open-access medical news readership trends and preferences for sources alternative to journals during the COVID-19 pandemic. During an outbreak in which an abundance of research is being published while there is high global interest in the pandemic, having a better understanding of how information is consumed by both health care workers and the general public may provide a better understanding of the behaviors associated with the pandemic. Prior literature has demonstrated that different sources of information are at variable risk of misinformation, which may have subsequent impacts on consumer behavior [12-16]. For example, a prior study conducted by Allington et al [8] found a positive correlation between the use of social media and the frequency of COVID-19–related conspiracy theories and a negative relationship between COVID-19–related health-protective behaviors and the use of social media.

Limitations

In terms of the limitations of this study, as the survey was only sent to subscribers of 2 Minute Medicine—the vast majority of whom are in the field of health care—the generalizability of our findings to the general public are unknown. The sample used for the survey also invariably skewed data to favor preferences toward open-access medical sites. This was a result of sampling bias, as respondents were active subscribers of the organization. Further studies should more broadly survey health care professionals to repeat our findings. It is also recognized that the survey used in this study lacks any validity evidence, and the wording of questions may have been framed positively toward 2 Minute Medicine, which may have introduced bias in the collection of results. Additionally, although the demographics of survey respondents were gathered, individual demographic data on site visitors were not obtained for the purposes of this study, which led to a lack of understanding of the visitors to the site itself. Finally, as survey data on the frequency of reading full-length original studies were not gathered prospectively, this study can only provide limited information regarding the interaction between open-access medical news consumption and original research consumption.

Conclusions

The results in this study indicate that readership on an open-access medical news site significantly increased as a result of the COVID-19 pandemic. Overall site traffic remained relatively stable in the first 2 months of the study period, and a substantial spike in traffic occurred in mid-March 2020. Based on the comparisons between article view counts and survey data, it appears as though open-access medical news sites may represent an important source for physicians and other health care workers who want to stay up to date with relevant COVID-19 literature. The introduction to such sites may also have subsequent impacts on overall medical literature consumption and increase the frequency of direct journal access.

Conflicts of Interest

All authors declare a financial interest (whether in compensation, equity, or both) in 2 Minute Medicine Inc, which provided the publishing platform, aggregate readership data, and readership audience for testing the hypothesis and surveying the readers.

Abstract

Background: Early detection and intervention are the key factors for improving outcomes in patients with COVID-19.

Objective: The objective of this observational longitudinal study was to identify nonoverlapping severity subgroups (ie, clusters) among patients with COVID-19, based exclusively on clinical data and standard laboratory tests obtained during patient assessment in the emergency department.

Methods: We applied unsupervised machine learning to a data set of 853 patients with COVID-19 from the HM group of hospitals (HM Hospitales) in Madrid, Spain. Age and sex were not considered while building the clusters, as these variables could introduce biases in machine learning algorithms and raise ethical implications or enable discrimination in triage protocols.

Results: From 850 clinical and laboratory variables, four tests—the serum levels of aspartate transaminase (AST), lactate dehydrogenase (LDH), C-reactive protein (CRP), and the number of neutrophils—were enough to segregate the entire patient pool into three separate clusters. Further, the percentage of monocytes and lymphocytes and the levels of alanine transaminase (ALT) distinguished cluster 3 patients from the other two clusters. The highest proportion of deceased patients; the highest levels of AST, ALT, LDH, and CRP; the highest number of neutrophils; and the lowest percentages of monocytes and lymphocytes characterized cluster 1. Cluster 2 included a lower proportion of deceased patients and intermediate levels of the previous laboratory tests. The lowest proportion of deceased patients; the lowest levels of AST, ALT, LDH, and CRP; the lowest number of neutrophils; and the highest percentages of monocytes and lymphocytes characterized cluster 3.

Conclusions: A few standard laboratory tests, deemed available in all emergency departments, have shown good discriminative power for the characterization of severity subgroups among patients with COVID-19.

Introduction

The COVID-19 pandemic has brought to light the scarcity of health care resources worldwide [1]. One of the main challenges faced by health care systems while tackling this pandemic is the lack of affordable, accurate, and simple information that can allow clinicians to predict the evolution of the patients' disease sooner, upon admission to the hospital. This information might help clinicians to make early decisions regarding arrangement and organization of medical resources, as well as early interventions to improve the health outcomes of these patients.

The exhaustive and inefficiently structured amount of health data available does not permit parametric modeling in an easy way. To overcome this issue, machine learning techniques have recently been identified as promising tools in data analysis for individual class prediction, allowing us to deal with a great number of variables simultaneously and observe inherent disease-related patterns in the data [2].

Machine learning for health care is a key discipline aimed to translate large health data sets into operative knowledge in different medical fields [3-7]. The methods of this artificial intelligence paradigm can be classified as supervised or unsupervised, based on the underlying strategy used [8]. In inductive or supervised machine learning, the method builds a general class description of the target categories from a set of previously categorized examples [8]. In general, supervised learning methods are used to design classifiers from labeled samples that predict the class of an unseen new sample [8]. In the field of medicine, these methods have been applied to find prognostic and predictive biomarkers [9]. On the other hand, in unsupervised machine learning, the goal is to find the class or classes that cover the sample [8]. These methods permit the discovery of the underlying structure and relationships among unlabeled samples [8]. Unsupervised clustering techniques can obtain groups of samples so that the intrasimilarity within each group is maximized, while intersimilarity between groups is minimized [8]. They are usually applied in medicine to identify homogeneous groups of patients based on their medical records and relationships between clinical manifestations and therapeutic responses, or to detect sets of coexpressed genes, among other applications [10,11].

There are several research reports using COVID-19 data sets, which focus on predicting the patients' mortality or severity by mainly using regression modeling from labeled clinical records [12-17]. Further, in a multicenter study, using supervised machine learning, a personalized COVID-19 mortality risk score for hospitalized patients upon admission has been proposed [18]; however, in that study [18], the reason for choosing only a subset of the recorded clinical variables to build their model was not explained. Therefore, the algorithm might have been biased, even by the expert's knowledge. In all of these studies [12-18] and in a study based on cluster analysis [19], demographics, such as age and sex, were considered as key variables in their prediction models. By contrast, these variables were deliberately excluded from the training data set in this study, in which we used an unsupervised machine learning method for data handling.

Health agencies recommend that clinical decisions should be made based on an individual's biological age rather than chronological age [20,21]. There are multiple physiological and molecular markers for estimation of biological aging that can predict life span [22]. Besides these markers, the heterogeneity of eating habits, physical and mental conditions, and therapeutics have an influence on the overall health state, making biological aging a heterogeneous process too.

Frailty and multi-morbidities, as measures of biological aging, have been found to be risk factors for mortality independent of chronological age in patients with COVID-19 [23]. New procedures for the therapeutic management of COVID-19 are required regardless chronological age [24].

Furthermore, reports about case-fatality rates for COVID-19 categorized by age groups could sentence elderly people not only to social exclusion but also to health care indifference. Considering the elderly population as a highly vulnerable group is a simple and negative stereotype that may even influence decision making in clinical resource management [25].

The prevalence and severity of COVID-19 also varies based on sex, whereby men experience higher mortality than women [26]. The severity of the disease implies that the person may need hospitalization, intensive care support, and mechanical ventilation. However, the medical treatments scheduled during hospitalization or a stay in intensive care are the same for every patient with a severe case of COVID-19, regardless age or sex [27].

Since chronological age as well as sex cannot be considered as pivotal aspects to determine an individual's health status and resilience [28], these should not be key determinants for health care or resource allocation among people suffering from COVID-19. Therefore, predictive models based on intelligent data processing that take into account a patient's age as a major determinant in health care access may be inappropriate and unethical [25].

Demographic variables (ie, age and sex) were not used in the previously published studies for building models on effective treatments based upon sex or age groups or for understanding sex or age differences [12-19]. These predictive models of severity and mortality risk for COVID-19 could be discriminating [29]. For example, consideration of the age of people in the emergency department might discriminate against older people (ie, ageism) regarding access to care, since the decision would be based purely upon the age of the patients rather than their health care needs [30].

The objective of this observational longitudinal study was to identify nonoverlapping severity subgroups (ie, clusters) among patients with COVID-19, using exclusive laboratory tests and clinical data obtained during the first medical contact in the emergency department, by means of unsupervised machine learning techniques. Age and sex were not taken into account to build the subgroups due to the ethical implications. For this purpose, we used the data set collected by the HM group of hospitals (HM Hospitales) in Madrid, Spain [31].

Methods

Data Set

This study is a longitudinal analysis of the data set collected by the HM group of hospitals in Madrid, Spain, in the context of the project Covid Data Save Lives [31]. The information from this data set comes from the electronic health records data system of the seven HM hospitals, located in the Community of Madrid in Spain [31]. This data set contains the anonymized records of 2310 patients, admitted to any of the seven HM hospitals, with a diagnosis of COVID-19 from March 1 to April 24, 2020. The data set includes different interactions within COVID-19 treatment processes, including detailed information on diagnoses, treatments, intensive care unit (ICU) admission, and discharge or death, among many other variables. The data set also includes diagnostic imaging and laboratory tests or records of previous medical care, if any. It also includes the drugs administered to each patient during admission (more than 60,000 records) with the dates corresponding to the first and last administration of each drug, which was identified by its brand name and classification in the Anatomical Therapeutic Chemical codes (ATC5/ATC7). Moreover, laboratory data are also included (398,884 records). Finally, the data set contains the records of the diagnostic and procedural information—coded according to the ICD-10 (International Statistical Classification of Diseases and Related Health Problems, 10th Revision) classification in its latest distributed version—for the patients referred, both for episodes of hospital admission (more than 1600) and for the emergencies (more than 1900) prior to those episodes, if any.

Data Preprocessing

We collected the information for each patient identifier and compiled it into one record. This included age, sex, vital signs in the emergency department, and the need or lack of need of the ICU. COVID-19 symptoms, ICD-10 codes of previous and current conditions, as well as different laboratory tests performed in the emergency department were also recorded. We also calculated, for each patient, the duration in days of the hospital stay, including ICU admission and the days from hospitalization to ICU admission. We also considered the first laboratory tests obtained from the emergency department and grouped all of the ICD-10 codes under the first three characters (ie, first letter and two subsequent numbers) of the code to reduce the number of variables and provide generalization. We codified each ICD-10 feature for inclusion in one of the following groups: *present in emergency department admission*, *not present in emergency department admission*, or *developed during hospital stay*.

Only patients with a discharge reason of *death* or *recovered* were included in the analyses. The patients with a discharge reason of *transferred to another hospital* or *transferred back to the nursing home* (about 3.6% of the total data set) were excluded, since no additional information was available after they left the hospital. We only selected the records (ie, patients) with no missing values on clinical data and laboratory tests, which left a final sample of 853 (37.2% women) patients to be included in our analyses. The mean age of the sample was 67.2 (SD 15.7) years (range 21-106). Each patient had 850 variables in his or her record, including eight variables about demographics, hospitalization stay, and outcome measures; one variable about COVID-19 symptoms; 10 variables about vital signs (eg, temperature, heart rate, oxygen saturation, and systolic and diastolic blood pressure) in the emergency department; 29 laboratory tests from the emergency department (Table 1); 168 ICD-10 codes from the emergency department; and 634 ICD-10 codes during their hospital stay.

The final sample of 853 patients was similar to the excluded sample (n=1457) in terms of age (mean 67.2, SD 15.7 years, vs mean 67.1, SD 17.0 years; $F_{1,2308}$=1.508; P=.22); discharge reason (selected deceased: 15.6% vs excluded deceased: 18.2%; $F_{1,2308}$=2.474; P=.12); ICU admission (6.8% vs 7.3%; $F_{1,2308}$=0.003; P=.96); or admission date (March 27, 2020, ± 8.3 days, vs March 28, 2020, ± 11.6 days). However, there were significant differences in terms of sex (37.2% women vs 42.2% women; $F_{1,2308}$=5.768; P=.02) and days in hospital (mean 9, SD 6, vs mean 8, SD 7; $F_{1,2308}$=4.786; P=.03). Notwithstanding, the effect size was small for both differences (η^2=0.003 and η^2=0.002, respectively).

Table 1. Laboratory tests used to characterize the patients.

Code	Description	Unit
RDW	Red cell distribution width	%
BAS	Basophils	$\times 10^3/\mu L$
BAS%	Percentage of basophils	%
MCHC	Mean corpuscular hemoglobin concentration	g/dL
CREA	Creatinine	mg/dL
EOS	Eosinophils	$\times 10^3/\mu L$
EOS%	Percentage of eosinophils	%
GLU	Glucose	mg/dL
AST	Aspartate transaminase	U/L
ALT	Alanine transaminase	U/L
MCH	Mean corpuscular hemoglobin	pg
HCT	Hematocrit	%
RBC	Red blood cells	$\times 10^6/\mu L$
HB	Hemoglobin	g/dL
K	Potassium	mmol/L
LDH	Lactate dehydrogenase	U/L
LEUC	Leucocytes	$\times 10^3/\mu L$
LYM	Lymphocytes	$\times 10^3/\mu L$
LYM%	Percentage of lymphocytes	%
MONO	Monocytes	$\times 10^3/\mu L$
MONO%	Percentage of monocytes	%
NA	Sodium	mmol/L
NEU	Neutrophils	$\times 10^3/\mu L$
NEU%	Percentage of neutrophils	%
CRP	C-reactive protein	mg/L
PLAT	Platelet count	$\times 10^3/\mu L$
BUN	Blood urea nitrogen	mg/dL
MCV	Mean cell volume	fL
MPV	Mean platelet volume	fL

Clustering

Unsupervised automatic x-means clustering [32]—the implementation in RapidMiner Studio 9.7, Community Edition (RapidMiner, Inc)—was applied to the preprocessed data set that was previously described (see Data Preprocessing section). The algorithm determines the optimum number of clusters so that the intracluster distance of patients is at a minimum, and the intercluster distance of patients is at a maximum. The x-means algorithm was used instead of the more common k-means algorithm to overcome the three major shortcomings of the latter [32]: poor computational scaling, manual selection of the number of clusters, and tendency to local minima. X-means clustering determines the optimal number of clusters by the Bayesian information criterion (BIC), also known as the Schwarz criterion, which is used to maximize the explained variance by the clusters and minimize the number of parameters (k) [32]. X-means clustering is also an improvement over k-means clustering since it tends to create clusters formed by only one sample to minimize inertia [32]. Moreover, the later use of the Davies Bouldin index to evaluate the cluster distributions is also intended to overcome this issue since it considers a mix of both inertia and distortion to quantitatively asses the cluster models (see below). In addition, the automatic selection of the number of clusters by x-means clustering avoids the possible bias in the manual selection of k [32]. This bias is also present in hierarchical agglomerative clustering, where a threshold must be set to obtain the ultimate clusters after the hierarchy is built. Despite the fact that x-means clustering is not completely deterministic, it is certainly very stable with

XSL•FO
RenderX

minimum variations between different runs [32] and is significantly more stable than k-means clustering. However, x-means clustering introduces a bias. Since it uses the BIC to evaluate the cluster models in each iteration, this criterion purposely favors the models with a lower number of clusters. This means that an alternative cluster model with a better Davies Boulding index and a higher number of clusters may have been discarded. However, a higher number of clusters with a better Davies Boulding index usually implies clusters with small numbers of samples—notice that the best index would be obtained by a model of one cluster per sample—which is not desirable at all for the clinical stratification purpose aimed for in this study.

Patients were considered here as vectors with several dimensions equal to the number of variables. In this case, the number of variables taken to apply the clustering algorithm was 842. None of the eight variables about demographics, hospital stay, and outcome measures were included. They were removed from the clustering formation because of the potential ethical controversies and biases (ie, demographics) or prospective information (ie, hospitalization stay and outcome measures). The algorithm was applied using several similarity or distance metrics between patients [33]: the Euclidean distance, the Canberra distance, the Chebyshev distance, the correlation similarity, the cosine similarity, the Dice similarity, the inner product similarity, the Jaccard similarity, the kernel Euclidean distance, the Manhattan distance, the max product similarity, the overlap similarity, the generalized divergence, the Itakura-Saito distance, the Kullback-Leibler divergence, the logarithmic loss, the logistic loss, the Mahalanobis distance, the squared Euclidean distance, and the squared loss. In spite of the fact that we could have had good similarity measure candidates a priori, based on data set characteristics such as dimensionality, the best practice was the selection based on empirical evaluation [34]. To avoid any a priori biases, we empirically tested all measures available in the software and kept the one yielding the best results.

To assess the fitness of the cluster distributions from the algorithm executions with the above metrics, the Davies Bouldin index was calculated for each one of them [35]. The Davies Bouldin index is a common measure that evaluates cluster models [35]. It quantifies the average maximum ratio of the within-cluster scatter to the between-cluster separation for every pair of clusters in a cluster model [35]. In other words, it provides a trade-off between intercluster similarity and intracluster distance [35]. With this definition, the lower the Davies Bouldin index the lower the within-cluster scatter and the higher the between-cluster separation, which is the most desirable property of a cluster model [35]. The Davies Bouldin index allowed us to quantitatively select the best cluster model among those created, one for each similarity measure considered.

Cluster Validation

From the 1457 patients excluded due to missing values (ie, not used to obtain the clusters), we performed a validation analysis with the patients who presented no missing values in the variables that statistically differed between the three clusters obtained. Subsequently, these patients were assigned to one of the clusters previously obtained by using the best distance metric determined in the clustering process described above.

Statistical Analysis

The difference in the 850 variables between all the clusters obtained was tested using a one-way multivariate analysis of variance. Pairwise post hoc comparisons between clusters were analyzed by the Bonferroni test. Significance was accepted at the 5% level (α=.05). The observed power and effect size, as partial η^2, were reported for statistically significant differences.

Results

Table 2 shows the number of clusters and the corresponding David Bouldin index of the cluster distribution of patients obtained by the x-means clustering algorithm for each of the similarity measures tested. Note that the lower the David Bouldin index, the better the cluster distribution (ie, higher intercluster distance and lower intracluster distance). The best cluster distribution (ie, lowest David Bouldin index) was obtained by using the Manhattan distance, which grouped the patients into three clusters.

XSL•FO
RenderX

Table 2. Number of clusters and the corresponding David Bouldin index.

Similarity measure	David Bouldin index	Number of clusters
Euclidean distance	0.948	3
Canberra distance	N/A[a]	1
Chebyshev distance	0.966	3
Correlation similarity	1.400	3
Cosine similarity	1.629	3
Dice similarity	N/A	1
Inner product similarity	N/A	1
Jaccard similarity	1.387	3
Kernel Euclidean distance	1.440	3
Manhattan distance	0.701	3
Max product similarity	N/A	1
Overlap similarity	5.099	4
Generalized divergence	3.445	3
Itakura-Saito distance	5.919	4
Kullback-Leibler divergence	5.677	4
Logarithmic loss	4.595	4
Logistic loss	3.445	3
Mahalanobis distance	4.595	4
Squared Euclidean distance	3.445	3
Squared loss	3.659	3

[a]N/A: not applicable; the David Bouldin index could not be calculated for these measures because they only had one cluster each.

Demographic and clinical characteristics of the patients in the three clusters are shown in Table 3. Notice that this table also shows the values of the eight variables (ie, demographics, hospital stay, and outcome measures) that were not used in the construction of the clusters (marked with a footnote in Table 3). Cluster 1 had a significantly higher proportion of deceased patients (46.6%) than cluster 2 (18.0%) and cluster 3 (10.5%). No significant difference in the percentage of ICU admissions was found between clusters. However, the patients who were admitted to the ICU in cluster 1 stayed a significantly shorter time than patients in cluster 3. No significant difference in sex was found between clusters. Patients in cluster 3 were significantly younger than those in cluster 1. In addition, patients in clusters 1 and 2 presented with a significantly higher heart rate in the emergency department than those in cluster 3. The average oxygen saturation for patients in the emergency department was significantly different between all clusters, whereby patients in cluster 1 had the lowest oxygen saturation and those in cluster 3 had the highest. With respect to previous diseases and surgical procedures, cluster 1 patients presented with a significantly higher percentage of epilepsy and emphysema than those in clusters 2 and 3. In addition, cluster 2 patients presented with a higher percentage of previous surgical procedures, as well as previous thoracic, thoracolumbar, and lumbosacral intervertebral disc disorders, than patients in cluster 3. Cluster 2 patients also presented with a significantly lower percentage of disorders of purine and pyrimidine metabolism than those in clusters 1 and 3. Finally, the percentage of patients who underwent surgical operations during their hospitalization was significantly higher in cluster 1 than in clusters 2 and 3.

Regarding laboratory tests, patients in cluster 1 showed significantly higher levels of serum creatinine, potassium, and blood urea nitrogen than those in clusters 2 and 3; cluster 1 patients also had a significantly higher value of red cell distribution width than did cluster 2 patients. In addition, patients in cluster 2 presented with significantly higher values of lymphocytes and serum levels of sodium, and significantly lower platelet counts than patients in cluster 3. In addition, cluster 3 patients showed lower values of mean corpuscular hemoglobin concentration and leucocytes, serum levels of alanine transaminase (ALT), and percentage of neutrophils than did patients in clusters 1 and 2. Cluster 3 patients had significantly higher values and percentages of eosinophils and percentages of lymphocytes than did patients in clusters 1 and 2. Finally, the laboratory tests that showed significant differences between all clusters were found for the serum levels of aspartate transaminase (AST) (cluster 1 > cluster 2 > cluster 3), lactate dehydrogenase (LDH) (cluster 1 > cluster 2 > cluster 3), C-reactive protein (CRP) (cluster 1 > cluster 2 > cluster 3), and the number of neutrophils (cluster 1 > cluster 2 > cluster 3).

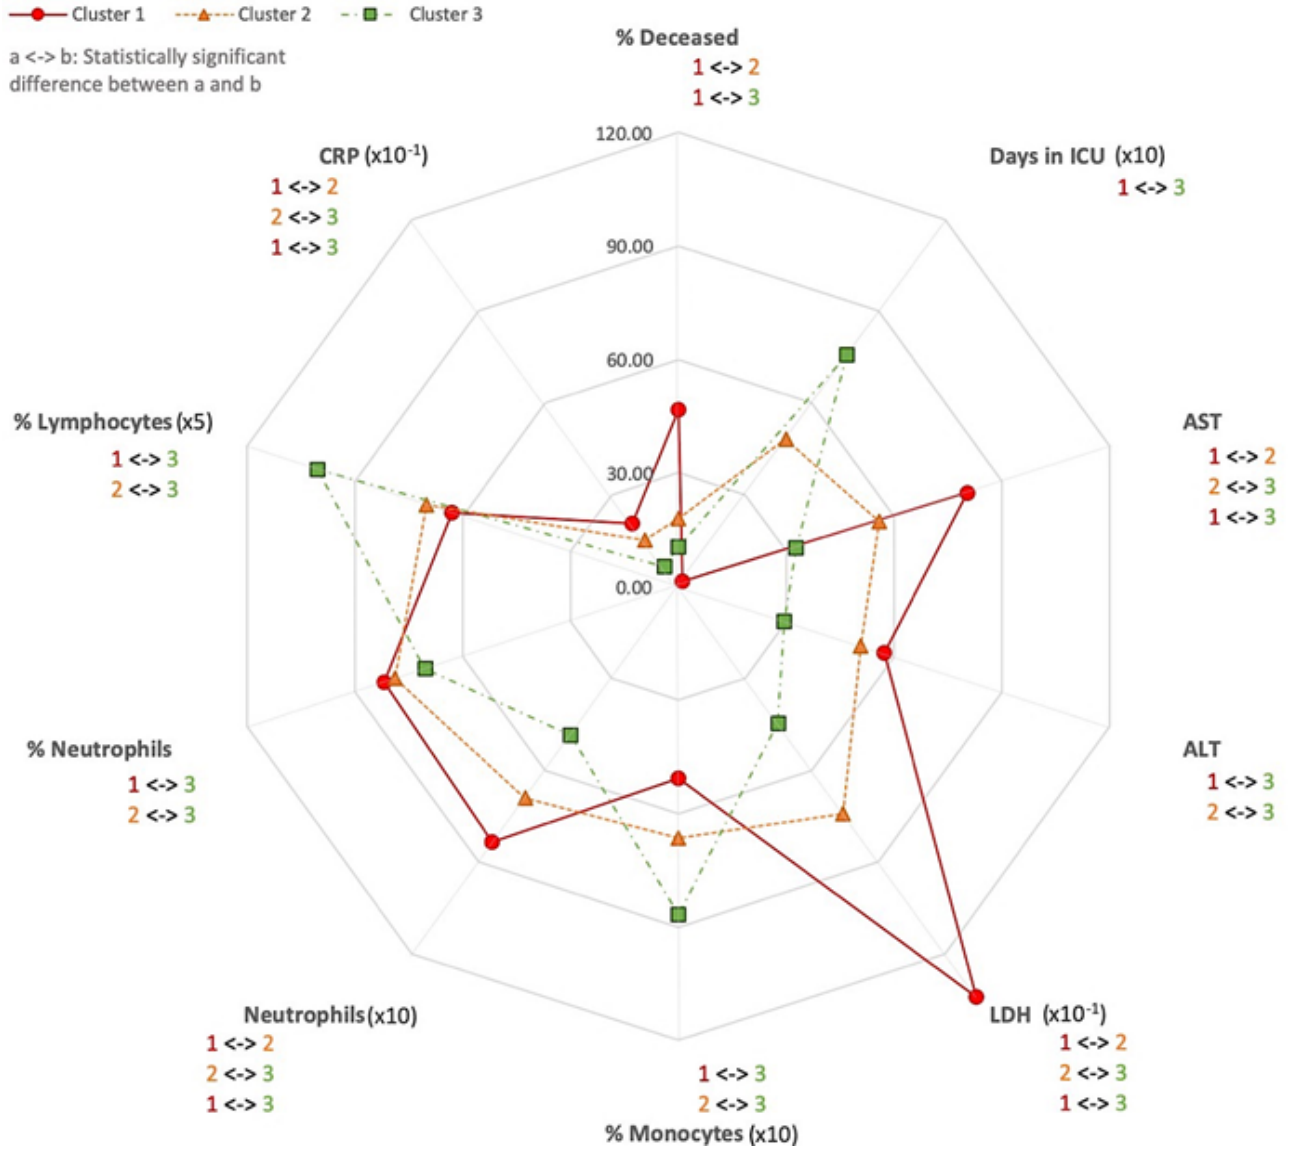
[c]These variables were not used for the cluster construction.

[d-f]Values in the same row, but in different columns, that do not share footnote letters were significantly different after Bonferroni post hoc correction; values in the same row, but in different columns, that share footnote letters were not significantly different.



For a clearer characterization of the clusters, Figure 1 shows a radar chart with the variables (ie, hospital stay, outcome measures, and laboratory tests) that showed statistically significant differences among the clusters and a medium or high effect size (η^2>0.06) [36].

A web-based cluster assignment tool, based on the results reported here, can be found online [37].

To test the robustness of the identified clusters, we performed a validation analysis using the initially excluded patients who did not have missing values in the variables that statistically differed among the three clusters (Table 3). Specifically, it was based on six variables (ie, first and last oxygen saturation measurement in the emergency department, AST, LDH, neutrophils, and CRP). For this purpose, we selected 349 patients who were initially excluded and who were assigned to one of the three previously identified clusters by the minimum Manhattan distance to the average values of the six mentioned variables of those clusters. Table 4 shows the differences in demographics, hospital stay, and outcome measures in the three clusters. Indeed, the clusters initially obtained were consistent with the clusters assigned in the validation analysis in terms of age, sex, hospital stay, and outcome measures. Specifically, cluster 1 was the one with the oldest and with the highest proportion of deceased patients. By contrast, cluster 3 was the one with the youngest and with the lowest proportion of deceased patients.

Discussion

With the application of an unsupervised machine learning approach, we could identify and segregate patients with COVID-19 into subgroups depending on the severity of disease, simply by using standard laboratory tests performed during the first medical assessment in the emergency department. We found that inflammatory (ie, CRP), hematologic (ie, number of neutrophils and percentage of monocytes and lymphocytes), and serum biochemical abnormalities (ie, AST, ALT, and LDH), mainly indicating liver dysfunction, detected upon admission to the hospital could predict the severity of the disease. From a sum of 850 variables collected in the emergency department, only four standard laboratory tests (ie, serum levels of AST, LDH, CRP, and the number of neutrophils) were enough to segregate these patients into three separate clusters. Of these, the levels of LDH had the biggest effect size, practically allowing us to differentiate the three clusters linearly. Further, the percentage of monocytes and lymphocytes as well as ALT distinguished cluster 3 patients (ie, less severe) from patients in the other two clusters. Cluster 1 was characterized by the highest proportion of deceased patients; the highest levels of AST, ALT, LDH and CRP; the highest number of neutrophils; and the lowest percentages of monocytes and lymphocytes (Figure 1). Cluster 2 included a lower proportion of deceased patients and intermediate values of the previous laboratory tests (Figure 1). Finally, the lowest proportion of deceased patients; the lowest levels of AST, ALT, LDH and CRP; the lowest number of neutrophils; and the highest percentages of monocytes and lymphocytes characterized cluster 3 (Figure 1).

Our results have several clinical implications. First, age and sex were not considered while building the clusters. Therefore, our unsupervised machine learning approach, based exclusively on the performance of simple laboratory tests at a primordial stage, would permit the establishment of a strategy for rationing of health care resources and to establish a triage protocol, which would support medical decisions in a transparent and ethical way. Second, since the analyzed data are from standard laboratory tests, this method would be especially valuable for underdeveloped and developing regions that lack medical resources and have affordability issues. Finally, we could tailor treatment to each severity group accordingly at a primordial stage (ie, in the emergency department). For example, more aggressive therapies could be considered in patients classified in cluster 1 (ie, the most severe) and not in those in cluster 3 (ie, the least severe).

Initially, SARS-CoV-2 was primarily considered a respiratory pathogen. However, with time, it has behaved like a virus with the potential to cause multisystem involvement [38,39]. Specifically, hepatic injury related to COVID-19 is only beginning to unravel. Elevated liver injury indicators, particularly AST, are strongly associated with a higher mortality risk in patients with COVID-19 [40]. Of note, high serum levels

XSL•FO
RenderX

of LDH predict higher in-hospital mortality in patients with severe and critical condition of COVID-19 [41]. Significant increased CRP levels in the early stages of COVID-19 are correlated with the severity of disease and the degree of internal tissue pathologies [42]. Further, a significant increase in the number of neutrophils with a decrease in the number of lymphocytes, monocytes, and eosinophils may indicate clinical worsening and increased risk of a poor outcome among patients with COVID-19 [43]. Taken together, the presence of elevated biomarkers of inflammation and that of liver injury in serum, as well as the number of neutrophils at admission, are indicative of multiple organ failure in patients with COVID-19 that could lead to death. Our laboratory findings are in agreement with other previous studies worldwide [44-46].

Although one previous multicenter study, based on the analyses of demographics, comorbidities, vital signs, and laboratory test results upon admission, that evaluated the prediction of disease course in patients with COVID-19 has been undertaken [18], there remains much to learn about applying machine learning techniques regarding this novel infectious disease. Comparison with that study is difficult, as they had used different variables and techniques. The accuracy of the model could be influenced by several factors, including the methods. Feature extraction methods, feature selection or classification tools, number of subjects, and demographics are also important considerations. Besides, most COVID-19 diagnostics and prognostic models that have evolved to date have a high risk of generating bias leading to inequality [47], mainly due to the high influence of demographic variables, especially age and sex, in those models and to the nonblinded nature of the supervised machine learning approach between predictors and outcome measures. In fact, our results confirmed that age and sex had a similar and low discriminant value to separate the three clusters (Table 3). Nevertheless, the results obtained in our study are in line with most previous work based on supervised machine learning techniques in COVID-19 [18,47].

The study should be interpreted within the context of several limitations. First, the patients in this study may represent a selected group of patients with COVID-19 (ie, patients with a more severe disease, since all of them were admitted to the hospital); hence, it is questionable as to what extent our results could be generalized to the entire population of patients with COVID-19. The reason for this was that the extreme circumstances in our hospitals at the peak of this pandemic permitted the hospitalization of only the most severe cases. Notwithstanding, our aim was to detect severity subgroups among patients with COVID-19 upon admission to the hospital. Second, we only kept the records (ie, patients), laboratory tests, and clinical variables from 853 patients from the data set due to the high number of missing values in the remaining 1457 patients. Despite this, the results have been robust.

In closing, to the authors' knowledge, the work presented in this paper is the first attempt to use unsupervised machine learning to identify severity subgroups among patients with COVID-19 upon admission. A few affordable, simple, and standard laboratory tests, which are expected to be available in any emergency department, have shown promising discriminative power for characterization of severity subgroups among patients with COVID-19. We have also provided an online severity cluster assignment tool for patients with COVID-19 who are admitted to the emergency department [37]. This could permit the classification of patients according to severity subgroups and, hence, initiate earlier interventions.

Abstract

Background: Persistent olfactory dysfunction is a significant complication of SARS-CoV-2 infection. Olfactory training involving aromatic oils has been recommended to improve olfactory recovery, but quantitative data are missing.

Objective: We aimed to quantify the benefit of olfactory training and visual stimulation assisted by a dedicated web application for patients who experienced olfactory dysfunction for ≥1 month.

Methods: We performed an observational, real-life, data-based study on a cohort of patients who experienced at least 1 month of persistent olfactory dysfunction between January 30 and March 26, 2021. An analysis was performed after a mean olfactory training time of 4 weeks, and at least 500 patients were assessable for primary outcome assessment. Participants exposed themselves twice daily to odors from 4 high-concentration oils and visual stimulation assisted by a dedicated web application. Improvement was defined as a 2-point increase on a 10-point, self-assessed olfactory visual analogue scale.

Results: In total, 548 patients were assessable for primary outcome assessment. The mean baseline, self-assessed olfactory score was 1.9 (SD 1.7), and this increased to 4.6 (SD 2.8) after a mean olfactory training time of 27.7 days (SD 17.2). Olfactory training was associated with at least a 2-point increase in 64.2% (352/548) of patients. The rate of patients' olfactory improvement was higher for patients who trained for more than 28 days than that rate for patients who trained for less than 28 days (73.3% vs 59%; P=.002). The time to olfactory improvement was 8 days faster for patients with hyposmia compared to the time to improvement for patients with anosmia (P<.001). This benefit was observed regardless of the duration of the olfactory dysfunction.

Conclusions: Olfactory training and visual stimulation assisted by a dedicated web application was associated with significant improvement in olfaction, especially after 28 days of olfactory training.

Introduction

Anosmia is a frequent symptom of SARS-CoV-2 infection, and its duration is usually less than 2 weeks before recovery [1-3]. However, at least 10% of patients with SARS-CoV-2 infection will experience persistent and chronic olfactory dysfunction such as diminished smell (hyposmia) or the loss of smell (anosmia), which have been shown to result in a decreased quality of life, depressive symptoms, and nutrition issues [4-6]. One treatment option that is recommended for persistent olfactory dysfunction is daily olfactory training involving high-concentration aromatic oils [7]. This showed significant results in treating postinfectious olfactory loss in a randomized, controlled, multicenter study [8]. In this trial, after 18 weeks of olfactory training, olfactory function improved in 63% of patients who experienced olfactory dysfunction for a duration of less than 12 months and used high-concentration oils, whereas olfactory function improved in 19% of patients in the control group who used low-concentration oils. Moreover, the combination of visual stimulations and olfactory training may improve recovery results [9].

No data about olfactory training for persistent olfactory dysfunction are available on patients with SARS-CoV-2 infection and persistent olfactory dysfunction, but most patients who experience hyposmia or anosmia for 30 days or more seem to have a low rate of spontaneous recovery [4].

In order to quantitatively study the time course of olfactory scores during olfactory training in real life, we developed a web application dedicated to olfactory training and visual stimulations as well as the self-assessment and follow-up of olfactory scores. We assessed the results in a real-life observational study.

Methods

The web application users were recruited via a national media campaign in France that was disseminated through social media, radio, and magazines between January 30 and February 15, 2021.

This observational, data-based study was approved by the French National Health Data Institute, which reviews the ethical conduct of human subjects research, data confidentiality, and safety. To participate, individuals were required to connect to the free covidanosmia.eu web application and provide electronic agreement. Respondents anonymously self-entered sociodemographic data and real-time polymerase chain reaction test results and confirmed a diagnosis of SARS-CoV-2–related olfactory dysfunctions. Patients were also asked to complete items about comorbidities, the duration of olfactory symptoms, and the self-assessed intensity of olfactory dysfunction by providing subjective ratings with a visual analogue scale of 0 (no smell) to 10 (no smell alteration) [10]. Patients were retained in the study analysis if they were diagnosed with SARS-CoV-2–related olfactory dysfunction that persisted for at least 1 month and reported at least 7 days of olfactory training, and if their last olfactory function assessment on the web application diary was available. The exclusion criteria were normosmia (visual scale score of >7); other causes of olfactory dysfunction such as chronic rhinosinusitis, nasal polyposis, allergic or idiopathic rhinitis, posttraumatic olfactory loss, and other acute or chronic nasal diseases (eg, acute viral infections); malignant tumors or oncology therapies (radiation therapy and chemotherapy), and a history of surgery for the nose or paranasal sinuses.

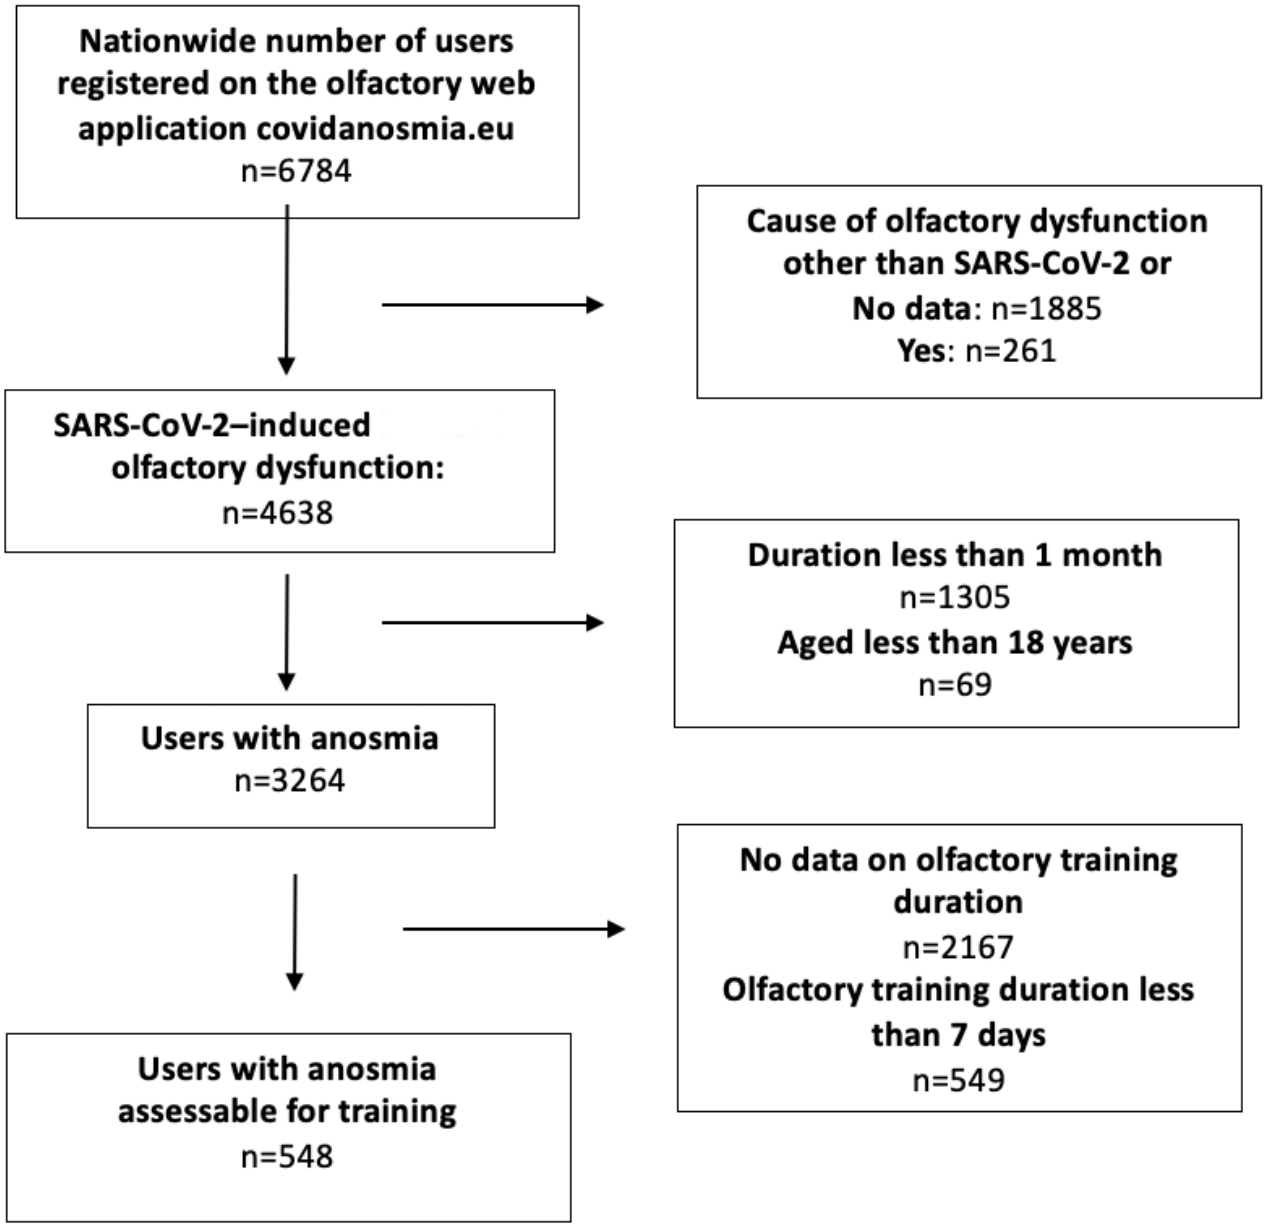
Patients had to obtain the olfactory training kit from the web application or from their pharmacist. Olfactory training was performed for a maximum period of 16 weeks. The web application provides videos, tutorials for the training, and periodic encouragements. Participants exposed themselves twice daily to odors from the following four high-concentration oils: phenyl ethyl alcohol (rose odor from *Geranium rosa*), eucalyptol (eucalyptus odor), citronellal (lemon odor), and eugenol (cloves odor). These four odorants were chosen to represent the primary odor categories created by Henning [11,12]. Participants sniffed each odor for approximately 15 seconds while blinded and repeated this process 30 seconds later once while the name and picture of the oil component was on the screen of the web application (eg, a picture of a lemon during the lemon oil sniffing process). Patients were asked to train in the morning and in the evening, resulting in a total of 4 exposures per day per odor. They were asked to keep a daily diary on the web application, in which they rated their overall olfactory abilities for each oil with subjective ratings on a visual analogue scale.

We assessed the rate of self-assessed improvement in overall olfactory function along with training times by using data that were collected anonymously from the web application diaries of patients. Improvement was defined as an increase of ≥2 points on the olfactory visual analogue scale. The analysis was performed when the mean olfactory training time of the study population was at least 4 weeks and when at least 500 patients were assessable for primary outcome assessment.

Categorical variables were summarized by using frequencies and percentages, and chi-square tests or Fisher exact tests were used to make comparisons. For quantitative variables, which were summarized with descriptive statistics, the following values were presented: N values, means, and SDs. A *t* test was used to compare groups, and the analysis of variance test was used for comparisons of more than 2 groups.

The Kaplan-Meier methodology was used to summarize time-to-event variables. Plots of Kaplan-Meier product limit estimates for time-to-event variables were drawn, and medians were presented in addition to CIs set at 95%. To compare Kaplan-Meier curves of the two groups, the log-rank test was used.

XSL•FO
RenderX



The level of statistical significance was 5% for all statistical tests (exploratory tests). To analyze predictive factors of assessment, logistic regression was used in order to calculate odds ratios, which were presented with CIs set at 95%.

All statistical analyses were conducted with SAS (Statistical Analysis System), version 9.3 (SAS Institute Incorporated).

Results

Between January 30 and March 26, 2021, the web application was used by 6755 unique individuals who completed the baseline questionnaires. Of these individuals, 548 met the inclusion criteria and were assessable for outcome assessments (Figure 1).

Figure 1. Flowchart of patients who used a web application for olfactory training.

The 548 assessable patients' median age was 42 years (range 18-84 years). Of these patients, 65.5% (n=359) were female, 32.1% (n=176) estimated having a smell sense that was more developed than average before olfactory dysfunction, 69.3% (n=380) reported that smell sense had an important role in their life, and 30.7% (n=168) did not care about their smell sense before SARS-CoV-2 infection. Of the 548 assessable patients, 111 (20.3%) experienced anosmia (level 0 on the olfactory scale), 287 (52.4%) experienced severe hyposmia (level 1 or 2 on the olfactory scale), 125 (22.8%) experienced moderate hyposmia (levels 3-5 on the olfactory scale), 25 (4.6%) experienced mild hyposmia (levels 6-7), 279 (50.9%) reported a reduction in or loss of taste, and 289 (52.7%) reported parosmia. Patients' baseline characteristics are shown in Table 1. The mean baseline olfactory function of users who were registered on the web application but underwent less than 7 days olfactory training or did not record their last olfactory function assessment on the web application diary (n=2824; olfactory function score: mean 2.23) was higher than that of the studied population (n=548 patients; olfactory function score: mean 1.9; Student test $P<.001$).

XSL•FO
RenderX

The mean baseline, self-assessed olfactory score was 1.9 (SD 1.7), and this increased to 4.6 (SD 2.8) after a mean olfactory training time of 27.7 days (SD 17.2 days; range 7-65 days).

Olfactory training was associated with at least a 1-point increase on the olfactory scale in 82.1% (450/548) of patients, at least a 2-point increase (ie, the primary outcome) in 64.2% (352/548) of patients, and at least a 3-point increase in 49.3% (270/548) of patients during the study period. The rate of olfactory improvement in patients who experienced anterior olfactory dysfunction for 12 months was 58.3%. With regard to patients whose olfactory function score increased by at least 2 points, their scores increased by a mean of 4.1 points (SD 1.9 points).

Table 1. Patients' characteristics.

Variables	Value, n (%)
Sex	
Male	189 (34.5)
Female	359 (65.5)
Smell level before smell dysfunction	
Standard	354 (64.6)
Less developed than average	18 (3.3)
More developed than average	176 (32.1)
Role of smell before smell loss	
Did not care about smell	168 (30.7)
Important role	380 (69.3)
Smell level at baseline	
0	111 (20.3)
1-2	287 (52.4)
3-5	125 (22.8)
6-7	25 (4.6)
Olfactory dysfunction duration (months)	
1-2	61 (11.1)
2.1-3	250 (45.6)
3.1-6	167 (30.5)
6.1 to ≥12	70 (12.8)
Taste dysfunction	
None	269 (49.1)
Dysfunction	279 (50.9)
Parosmia	
No	259 (47.3)
Yes	289 (52.7)

The duration of the training was associated with better outcomes, and the time to olfactory function improvement was longer in patients with anosmia (olfactory training duration for a 50% probability of improvement: mean 41 days; range 36-53 days) than in patients with hyposmia (mean 33 days; range 28-36 days; log-rank $P<.001$; Figure 2). There were no significant differences in the duration of training among patients with severe, moderate, and mild hyposmia (severe vs moderate $P=.052$; severe vs mild $P=.96$ and moderate vs mild $P=.87$).

The rate of patients' olfactory improvement (at least a 2-point increase on the olfactory scale) was higher for patients who trained for more than 28 days than that rate for patients who trained for less than 28 days (73.3% vs 59%; $P=.002$). Patients who underwent 28 days of olfactory training or more and benefited from olfactory improvement exhibited a mean improvement of 4.4 points (SD 2.0 points) on the olfactory scale, whereas a mean improvement of 3.8 points (SD 1.8) was observed in patients who underwent less than 28 days olfactory training (Student test $P=.01$).

The mean improvement in self-assessed olfactory scale scores was similar regardless of the anteriority of the olfactory dysfunction ($P=.70$; Figure 3). No other predictive factors were highlighted (Table 2).

[a]N/A: not applicable.

After a mean olfactory training time of 28 days, we observed that 17.1% (94/548) of patients had an olfactory score of ≥8. This high recovery was observed in patients regardless of the anteriority of the olfactory dysfunction (*P*=.93); 43.6% (41/94) of these patients experienced more than 3 months of olfactory dysfunction whereas 56.4% (53/94) experienced less than 3 months of dysfunction. However, patients with an olfactory training score of ≥8 had significantly higher baseline scores than users who did not achieve this score after training; the mean baseline scores were 2.9 (SD 2.0) for patients who achieved high recovery and 1.6 (SD 1.5) for those who achieved lower recovery (*P*<.001).

Discussion

This study is the first to prospectively assess the real-life benefit of olfactory training for patients who experience persistent olfactory dysfunction after SARS-CoV-2 infection. The mean duration of training was 28 days. In our cohort of 548 patients who underwent olfactory training assisted by the web application, an improvement of 2 points or more in a subjective self-assessed olfactory scale was reported by 64.2% (352/548) of patients. Beyond 28 days of training, the rate of improvement was significantly higher than the rate of improvement after <28 days of training (72.2% vs 59%; *P*=.002). The time to olfactory improvement was 8 days longer for patients with anosmia compared to the time to improvement for patients with hyposmia. Improvement was observed regardless of the

XSL•FO
RenderX

anteriority of the olfactory dysfunction. High recovery, that is, normal or subnormal self-assessed olfactory function, was observed in 17% (93/548) of patients regardless of the anteriority of the olfactory dysfunction, but high recovery occurred more frequently in patients with higher baseline olfactory scores (mean 2.9).

Our data are in line with a previous randomized trial on postinfectious olfactory loss [8]. In this trial, after 18 weeks of olfactory training, olfactory function improved in 63% of patients who experienced olfactory dysfunction for a duration of less than 12 months and used high-concentration oils, whereas olfactory function improved in 19% of patients in the control group who used low-concentration oils. We used high-concentration oils in combination—the same 4 odorants used by Damm et al [8]—in a 2-step process for each oil. The first step involved blind olfactory stimulation with a given oil like in the Damm et al [8] trial. The second step, which followed the first step and involved the same oil, was enriched via visual stimulation with a picture of the oil component on a smartphone screen, which was delivered by the web application. We chose this new approach to reinforce the olfactory trial with a mixed olfactory-visual trial, as some previous data have suggested that human olfactory perception can substantially benefit from visual cues. This suggests that there is important cross-modal integration between olfactory and visual modalities [9,12,13]. An ongoing, 4-arm, randomized trial is assessing the best modalities of training to improve olfactory training results [14]. The use of a web application is a promising method for improving olfactory training because it allows for visual stimulation, visual tutorials, the provision of encouragements, and results monitoring. Web applications have been shown to be useful during the SARS-CoV-2 pandemic for triaging patients and assessing trends of the outbreak at a large scale [15-17].

Our patients experienced persistent anosmia for 2 to 12 months, and the rapid recovery that was observed regardless of the anteriority of the anosmia suggests that olfactory improvement was a direct effect of the training. Postinfectious olfactory dysfunction that is not caused by SARS-CoV-2 is associated with moderate rates of spontaneous recovery. Hendriks [18] reported that spontaneous recovery occurs in 35% of patients over a period of approximately 12 months. In a retrospective series of 262 subjects with a mean follow-up time of 14 months, Reden et al [19] reported a 32% improvement in olfactory function, which was assessed with the objective “Sniffin’ Sticks” test, and an increase of at least 6 points in threshold discrimination identification scores. Hummel et al [7] reported a short-term recovery rate of 6% to 8% within 4 months and used the same olfactory tests and definitions for improvement as those of Reden et al [19]. More recently, Havervall et al [20] reported that the incidence rate of olfactory dysfunction after mild SARS-CoV-2 infection among seropositive health care workers was 14.6%, 10.8%, and 9% at 2, 4, and 8 months after infection, respectively, meaning that the spontaneous recovery rate is low [20].

Spontaneous recovery after persistent olfactory dysfunction in patients with SARS-CoV-2 infection is not well described. Vaira et al [4] reported a mean score of 1 on a 10-point analogue subjective olfactory scale (the same one we used) between 30 and 60 days for 138 patients who did not undergo olfactory training, and 20% of patients exhibited olfactory improvement. Our data suggest that improvement can be achieved tardily after 2 months of training. In our study, olfactory training and visual stimulation assisted by a dedicated web application were associated with 73.3% (165/225) of patients whose olfactory function improved by 2 points or more after at least 28 days olfactory training and a mean improvement of 4.4 points [4]. In another study, Lechien et al [21] reported that 15.3% of patients with anosmia and 4.7% of patients with hyposmia did not objectively recover olfaction after 60 days and 6 months, respectively. The comparison of our study with other studies is, however, limited because different olfactory tests and scale evaluations were used [21].

Our study had several limits. There were many excluded patients. Selection bias may exist because we believe that patients who do not feel improvement will more readily stop undergoing training. This could be due to confusion about how benefits are statistically better if patients follow the training regimen for more than 28 days. The mean baseline olfactory function of users who were registered on the web application but underwent less than 7 days of olfactory training or did not record their last olfactory function assessment on web application diary (n=2824; olfactory function score: mean 2.23) was higher than that of the studied population (n=548; olfactory function score: mean 1.9; Student test $P<.001$). The distribution of the olfactory dysfunction severity among patients suggests that patients with more severe olfactory dysfunction from the whole population were retained in the analysis. These data suggest that the results of olfactory training could be better in the whole population than those in the studied population.

There was no control group in this study; therefore, it remains unclear whether the incidence of spontaneous recovery distorted the results. The scale that was used to measure olfactory dysfunction and changes was subjective, as it was a self-assessment analogue scale; scores were self-reported and data about olfactory assessment were not confirmed by physicians and objective tests. However, the possibility of conducting olfactory training at home increased the number of recruited patients and resulted in higher levels of olfactory function recovery compared to those of spontaneous improvement.

Olfactory training and visual stimulation assisted by a dedicated web application was associated with significant olfactive improvement in persistent olfactory dysfunction following SARS-CoV-2 infection, especially after 28 days of olfactory training.

Abstract

Background: Several models have been developed to predict mortality in patients with COVID-19 pneumonia, but only a few have demonstrated enough discriminatory capacity. Machine learning algorithms represent a novel approach for the data-driven prediction of clinical outcomes with advantages over statistical modeling.

Objective: We aimed to develop a machine learning–based score—the Piacenza score—for 30-day mortality prediction in patients with COVID-19 pneumonia.

Methods: The study comprised 852 patients with COVID-19 pneumonia, admitted to the Guglielmo da Saliceto Hospital in Italy from February to November 2020. Patients' medical history, demographics, and clinical data were collected using an electronic health record. The overall patient data set was randomly split into derivation and test cohorts. The score was obtained through the naïve Bayes classifier and externally validated on 86 patients admitted to Centro Cardiologico Monzino (Italy) in February 2020. Using a forward-search algorithm, 6 features were identified: age, mean corpuscular hemoglobin concentration, PaO_2/FiO_2 ratio, temperature, previous stroke, and gender. The Brier index was used to evaluate the ability of the machine learning model to stratify and predict the observed outcomes. A user-friendly website was designed and developed to enable fast and easy use of the tool by physicians. Regarding the customization properties of the Piacenza score, we added a tailored version of the algorithm to the website, which enables an optimized computation of the mortality risk score for a patient when some of the variables used by the Piacenza score are not available. In this case, the naïve Bayes classifier is retrained over the same derivation cohort but using a different set of patient characteristics. We also compared the Piacenza score with the 4C score and with a naïve Bayes algorithm with 14 features chosen a priori.

XSL•FO
RenderX

Results: The Piacenza score exhibited an area under the receiver operating characteristic curve (AUC) of 0.78 (95% CI 0.74-0.84, Brier score=0.19) in the internal validation cohort and 0.79 (95% CI 0.68-0.89, Brier score=0.16) in the external validation cohort, showing a comparable accuracy with respect to the 4C score and to the naïve Bayes model with a priori chosen features; this achieved an AUC of 0.78 (95% CI 0.73-0.83, Brier score=0.26) and 0.80 (95% CI 0.75-0.86, Brier score=0.17), respectively.

Conclusions: Our findings demonstrated that a customizable machine learning–based score with a purely data-driven selection of features is feasible and effective for the prediction of mortality among patients with COVID-19 pneumonia.

KEYWORDS

artificial intelligence; prognostic score; COVID-19; pneumonia; mortality; prediction; machine learning; modeling

Introduction

Despite measureless efforts to limit the spread of COVID-19, over 100 million people have been confirmed positive for SARS-CoV-2 infection and more than 2 million people have died from the virus worldwide, as of February 10, 2021 [1]. While these numbers are rapidly increasing day by day, hospitals have been receiving requests beyond capacity and face extreme challenges concerning a sharp increase in the demand for medical resources as well as a shortage of hospital beds and critical care equipment for the timely treatment of ill patients. Additionally, the clinical spectrum of SARS-CoV-2 infections ranges from asymptomatic status to severe viral pneumonia with respiratory failure and even death, making reliable and successful patient triaging challenging [2].

Data from epidemiological studies suggest that severe illness occurs in approximately 20% of patients and that older age, coexisting medical conditions, and cardiovascular risk factors are associated with worse prognosis [3,4]. In this scenario, identification of the key patient variables driving COVID-19 prognosis is of paramount importance to assist physicians in the early prediction of the pathology trajectory and to improve patient outcomes.

To date, several prognostic models combining clinical and laboratory parameters have been proposed, but they included mainly patients from the first wave of the COVID-19 pandemic. This may cause a risk of bias, making these models unsuitable for clinical decision in daily practice [5,6].

The increasing use of electronic health record (EHR) systems has increased the availability of a large amount of data suitable for machine learning analysis. The latter has already proven its potential to support clinical decisions in many medical fields, including the COVID-19 pandemic [7,8]. Therefore, the aim of this study was to develop and validate a new scoring technique—the Piacenza score—to predict the prognosis of COVID-19 pneumonia, based on a machine learning technique with a purely data-driven selection of prognostic features collected at hospital admission.

We hypothesized that a machine learning score based on data-driven selection of features, which is different from inference statistics, could capture nonlinear relationships among clinical features without human-biased intervention and predict mortality for individual patients more accurately than the currently available risk scores.

Methods

Population and Collected Data

The study was conducted at Guglielmo da Saliceto Hospital, which serves a population of about 300,000 people in the area of Piacenza, Emilia Romagna, in northern Italy. This region has the second highest number of COVID-19 deaths in the country (6219 as of December 7, 2020).

This study retrospectively analyzed the EHRs of a cohort of 852 patients diagnosed with COVID-19 pneumonia according to the World Health Organization interim guidance and admitted to the hospital from February to November 2020. COVID-19 infection was diagnosed by a positive result on a reverse transcriptase–polymerase chain reaction (RT-PCR) assay of a specimen collected on a nasopharyngeal swab. Pregnant women, children (<18 years), and patients with a negative RT-PCR assay were excluded from the study as well as patients presenting with shock and coma.

Data collected in the EHR included patients' demographic information, comorbidities, triage vitals, and laboratory tests and outcomes (including length of stay, discharge, readmission, and mortality). Routine blood examinations at admission comprised complete blood count, coagulation profile, and serum biochemical tests (including renal and liver function, creatine kinase, lactate dehydrogenase, electrolytes, and C-reactive protein). A total of 62 patient characteristics were considered in the score design and development. The study protocol was approved by the local committee on human research.

Criteria for Discharge and Outcome

The criteria for discharge were at the discretion of the caregiver physician. In most cases, the criteria encompassed absence of fever for at least 3 days, as well as substantial clinical improvement including clinical remission of symptoms and 2 throat-swab samples negative for SARS-CoV-2 RNA obtained at least 24 hours apart. The primary outcome was 30-day in-hospital mortality.

Piacenza Score Design

The Piacenza score is a machine learning–based COVID-19 mortality risk predictor. It was implemented using a naïve Bayes approach, which is a probabilistic classifier describing the dependence from the outcome of each variable characterizing the patient, taken separately from the others. The naïve Bayes algorithm was chosen due to the following advantages: (1) it provides a probability of the final outcome, which thus

XSL•FO
RenderX

represents the mortality risk; (2) it can handle both categorical and continuous features; and (3) it can handle missing values, thus providing a mortality risk even when all variable inputs for a patient are not available. Moreover, it proved a successful approach in predicting clinical outcomes in several medical scenarios [9,10]. Other key advantages of using a naïve Bayes classifier are its easy implementation, computational efficiency, optimal scaling performance, and the fact that it achieves good results even in small data sets. Furthermore, it is not influenced by irrelevant features or outliers.

Its major limitation stands in the assumption at the core of the method: features independence. Even if this assumption is almost never satisfied, the classifier proved to reach reasonable results in many scenarios, especially in text classification. Another drawback of naïve Bayes is that if a categorical feature presents a value in the test data set, which was not observed in the training data set, then the model will be unable to make a prediction. Nevertheless, this issue can be solved with various smoothing techniques. Patients missing some features can be easily handled. In fact, only the features' probability distributions need to be computed in training a naïve Bayes classifier. Thus, no imputation was performed and all patients were included in the training phase, since not all missing data were considered for every feature. Furthermore, when applying the trained model to make inferences, the final user can insert missing data, still obtaining a reliable result.

Derivation and Test Cohorts

The EHRs of 852 patients were randomly split into derivation (70%) and test (30%) cohorts. The derivation cohort was first used to select, among the considered 62 patient features, the most significant ones, and then to train the naïve Bayes classifier using only the best predictors, while the predictive ability of the estimated model was assessed on the test cohort.

Piacenza Score Development, Optimization, and Identification of Variable Importance

The Piacenza score has been developed and tailored to (1) minimize the number of clinical variables to be ingested and (2) to maximize the overall prediction performance (ie, in terms of maximization of the area under the receiver operating characteristic curve [AUC]) and patient stratification ability. The most significant patient features were identified through the so-called forward-search approach [11].

The forward-search approach is a purely data-driven dimensionality reduction technique that is able to identify, given a large set of input features, the minimum combination of those features, which maximizes the performance metrics associated with a machine learning algorithm. The forward-search approach was employed here to reduce the number of patient variables from 62 to the 6 most relevant ones used to train the naïve Bayes classifier.

Piacenza Score Evaluation and Metrics

The test cohort was used to assess the performance of the Piacenza score. In order to increase the statistical significance of the results, bootstrapping was used to randomly generate 100 test sets from the original test cohort. Moreover, an external validation cohort has been considered to further validate the Piacenza score performance. The external validation cohort consisted of data from 86 patients with COVID-19 enrolled at Centro Cardiologico Monzino Hospital (Milan, Italy).

The performance of Piacenza score was evaluated in terms of discrimination and calibration capabilities. The discrimination ability was determined by computing the receiver operating characteristic (ROC) curve on the test cohort and the associated AUC, together with its 95% CI. As additional metrics, the negative predictive value (NPV), the positive predictive value (PPV), the accuracy, the sensitivity, the specificity, and the F1 and F2 scores were computed. These metrics were calculated for a threshold value obtained by maximizing the F2 score. The calibration ability was derived by the so-called calibration plots, which compare observed and predicted outcomes with associated uncertainties. The Brier index was used to evaluate the ability of machine learning to stratify and predict observed outcomes. The Brier index is defined as the mean-squared difference between the observed and predicted outcomes and ranges from 0 to 1, with 0 representing the best calibration.

Finally, the variable relative importance was quantified for the identified 6 most relevant patient features. The relative importance is a comparative measure of the patient feature's weight in determining the Piacenza risk score.

Usability, Flexibility, and Customization

The Piacenza score was specifically designed to be an easy, fast, versatile, fair, open, and user-friendly tool. To reach this goal, a web-based calculator of the score, via a website, was released [12]. This calculator can be used by clinicians to estimate a hospitalized patient's risk of 30-day mortality.

We added a tailored version of the algorithm to the website, which enables an optimized computation of the mortality risk score for a patient even when some variables used by the Piacenza score are not available. In this case, the naïve Bayes classifier is retrained over the same derivation cohort but using a different set of patient characteristics. Moreover, a second naïve Bayes model has been presented as a possible example of the Piacenza score's customization and flexibility. The above-mentioned model has been trained with the following 14 variables, chosen a priori by the physician for their association with mortality in COVID-19 pneumonia: age, gender, diabetes, length of symptoms before hospital admission, systolic blood pressure, respiratory rate, PaO_2/FiO_2 ratio, platelets and eosinophils count, neutrophil-to-lymphocyte ratio, C-reactive protein, direct bilirubin, creatinine, and lactate dehydrogenase. Finally, we compared the performance of the Piacenza score with the above-mentioned "clinical" naïve Bayes classifier to show the flexibility of the method, which can be easily retrained with another subset of predictors.

Website Design and Development

The website has been developed in Python (Python Software Foundation), using the Flask framework, and Hosting is managed through Docker.

The site consists of three main pages: *Home*, *Custom Analysis*, and *Multiple Analysis*. The *Home* and the *Custom Analysis*

XSL•FO
RenderX

pages require submitting a form that is dynamically composed in the backend through a Python dictionary variable. This allows us to easily change the form without changing the HTML code. The current dictionary contains the following fields characterizing the features: name, type (continuous or binary), measurement unit, information for the user, value, and mandatory flag.

On the *Home* page, once a form is submitted, the backend receives and sends the parsed data to the previously trained naïve Bayes classifier, which computes the mortality risk that is visualized on the website, typically in less than 1 second. On the *Custom Analysis* page, once a form is submitted and parsed, a naïve Bayes classifier is trained using only the specified features. Since the overall training process may be time-consuming as it also performs feature selection, the final results are automatically sent to the email address specified by the user after completing the training. The *Multiple Analysis* page allows users to compute mortality risks for many patients, without the need to manually fill in a form for every single patient. Clinicians are requested to submit a CSV (comma-separated values) file containing the values of the 6 features characterizing the Piacenza score. An example of the structure of a CSV file is provided on the website.

Comparison With Conventional Risk Models

To further assess the performance of the Piacenza score, we compared it with the 4C mortality score, which considers the following predictors: age, gender, number of comorbidities, respiratory rate, peripheral oxygen saturation (sO_2), level of consciousness (Glasgow coma scale), urea level, and C-reactive protein. The same test cohort used to test the Piacenza score was employed.

Statistical Analysis

Categorical variables were reported as count (%) and continuous variables as mean (SD). A two-sided *P* value <.05 was considered statistically significant. We used the Fisher exact test to assess differences between binary variables and the Welch two-sample *t* test to assess differences between continuous variables. The overall implementation of all codes for the machine learning score and analysis tools was performed in the Python 3.7.4 environment. The Python libraries employed were *pandas* (for data set management), *NumPy* (for numerical computations), and *sklearn* (for data set preprocessing; eg, data set splitting). The naïve Bayes classifier at the core of the Piacenza score was manually implemented (without any additional machine learning framework used) since an existing algorithm for naïve Bayes classification dealing both with continuous and categorical variables as well as missing data was not available in the *sklearn* library. The forward-search algorithm for feature selection was also manually implemented.

Results

Patient Characteristics and Events

A total of 852 patients with SARS-CoV-2 pneumonia were hospitalized during the study period, of which 242 (28%) were admitted to the intensive care unit (ICU). The mean age of the patients was 70 (SD 14) years, and 599 (70%) were male. Comorbidities were present in 602 patients (71%): mainly arterial hypertension (n=499, 59%), dyslipidemia (n=205, 24%), and diabetes (n=157, 18%). The mean time between onset of symptoms and hospital admission was 6.5 (SD 3.9) days. Fever (n=776, 91%), dyspnea (n=543, 64%), and cough (n=400, 47%) were the most common symptoms at admission. A total of 293 patients (34%) died within 30 days after hospital admission. The median time from hospital admission to discharge or death was 9 days. A comparison of clinical characteristics between survivors and nonsurvivors showed that the latter were older (*P*<.001) and had a higher prevalence of hypertension and cerebrovascular disease (*P*<.001); longer symptom duration (*P*<.001); higher respiratory rate (*P*<.001); and lower SpO_2 (*P*<.001), PaO_2/FiO_2 ratio (*P*<.001), and systolic blood pressure at admission (*P*=.02) (Table 1).

[a]*P* value refers to either the Student *t* test or the chi-square test. Italicized values are significant.

Major laboratory markers were tracked upon admission. Specifically, lactate dehydrogenase, creatine kinase, cholinesterase, creatinine, and glycemia were significantly higher in nonsurvivors than survivors (*P*<.001). Nonsurvivors had a significantly lower lymphocyte and eosinophil percentage and red blood cell count as well as lower hemoglobin, mean corpuscular hemoglobin concentration (MCHC), and hematocrit values (*P*<.001). Furthermore, nonsurvivors showed significantly higher levels of inflammatory biomarkers such as neutrophil count, C-reactive protein, and neutrophil-to-lymphocyte ratio (*P*<.001). Other differences in laboratory findings among the two groups are summarized in Table 2.

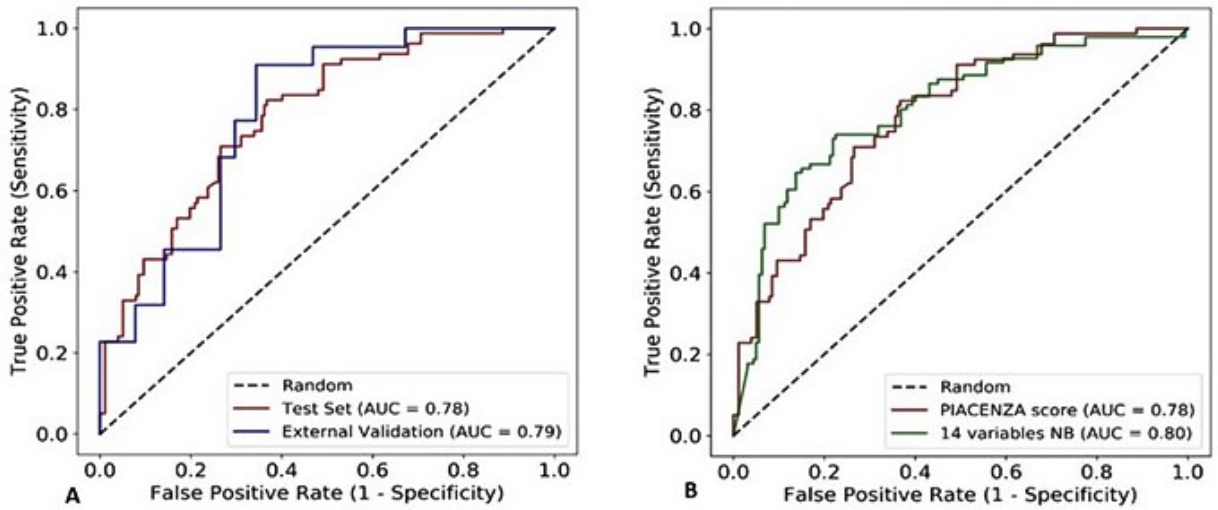
[k]PT: prothrombin time.

[l]INR: international normalized ratio.

[m]PTT: partial thromboplastin time.

[n]NLR: neutrophil-to-lymphocyte ratio.



Significant Predictors and the Piacenza Score

Using the forward-search algorithm, the following 6 most important predictors at hospital admission were identified and used to compute the Piacenza score: age, MCHC, PaO_2/FiO_2 ratio, temperature, previous cerebrovascular stroke, and gender.

The median of the ROC curve over 100 test cohorts (generated through bootstrapping) is reported in Figure 1. The corresponding median of the AUC is equal to 0.78 (95% CI 0.74-0.84) with a sensitivity of 94% and specificity of 37%. The NPV of the Piacenza score was 93% with a PPV of 40% (Table 3).

The calibration plot of the Piacenza score over the range of risk showed a Brier score of 0.19. The risk deciles are grouped into three levels: low risk (first to fifth deciles), intermediate risk (sixth to eighth deciles), and high risk (ninth and tenth deciles). A gradual and progressive increase in absolute event rates was observed across risk classes for all the Piacenza scores (death: 14% [18/125] in low-risk deciles vs 36% [27/75] in intermediate-risk deciles vs 66% [33/50] in high-risk deciles).

Figure 1. (A) Receiver operating characteristic (ROC) curves obtained by evaluating the Piacenza score (red curve) on the test cohort and on the external validation cohort. (B) ROC curves obtained by evaluating the Piacenza score (red curve) and the naïve Bayes (NB) model trained with 14 manually chosen features (green curve). AUC: area under the ROC curve.

XSL•FO
RenderX

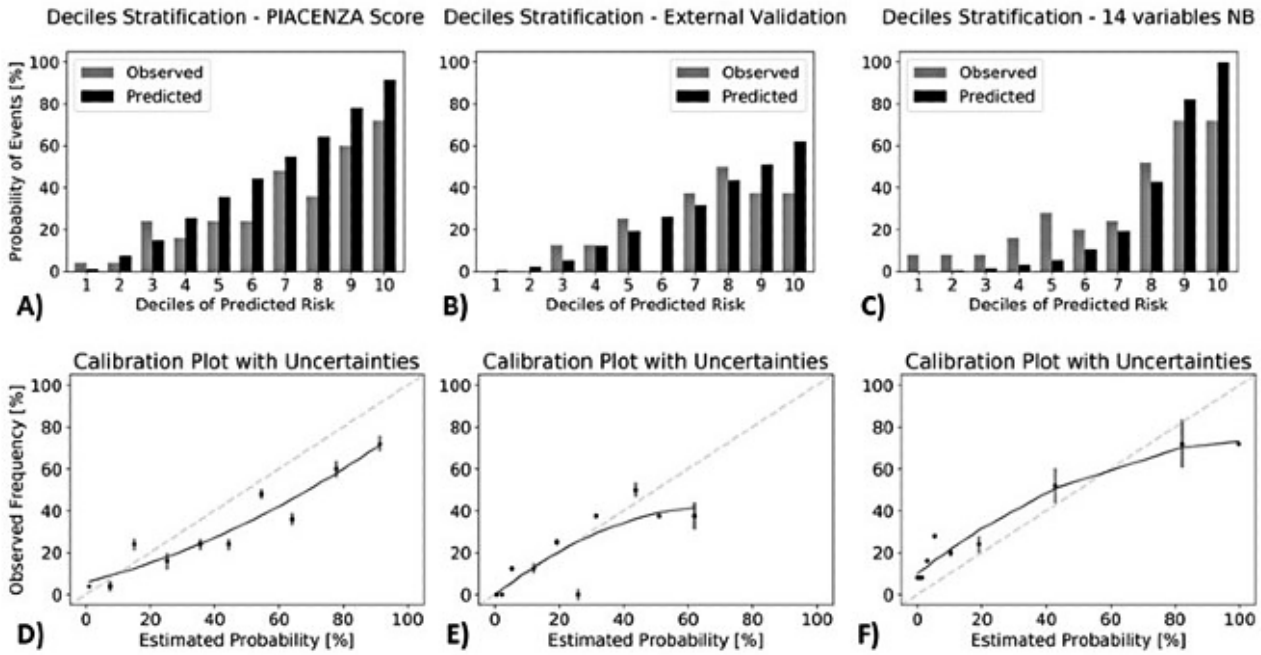


Table 3. Negative predictive value (NPV), positive predictive value (PPV; or precision), accuracy, sensitivity (or recall), specificity, F1 score, and F2 score for all scores. These metrics have been calculated for a specific threshold value on the final risk score probability chosen by maximizing the F2 score, the reason being that F2 privileges a high recall and therefore a broader confidence for correctly identifying patients at risk.

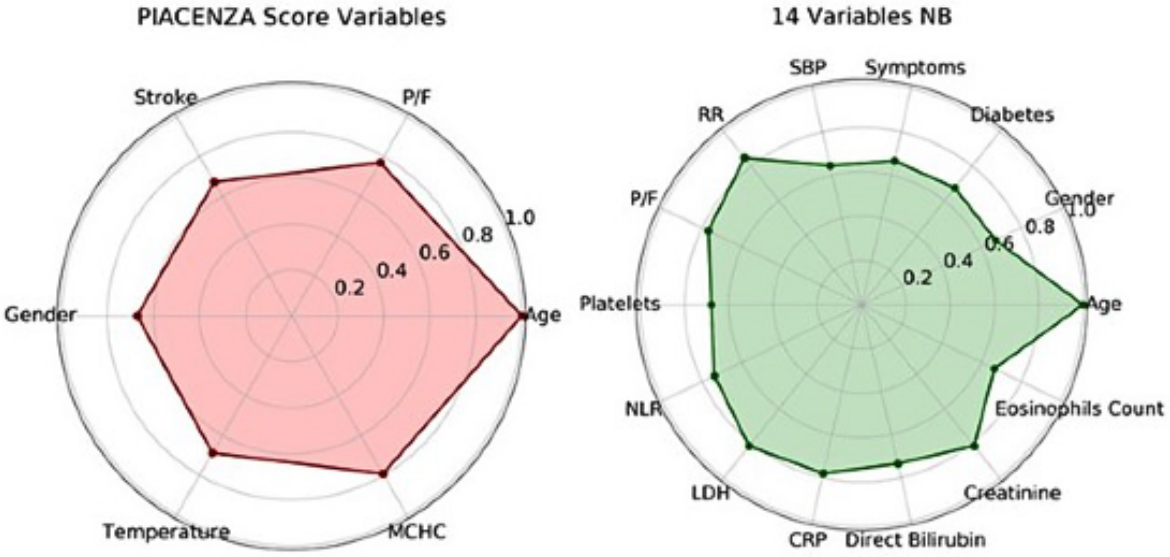
Scores	Threshold	NPV	PPV	Accuracy	Sensitivity	Specificity	F1 score	F2 score
Piacenza score	0.16	0.93	0.40	0.55	0.94	0.37	0.56	0.74
Piacenza score–external validation	0.16	0.97	0.37	0.57	0.95	0.44	0.53	0.72
Naïve Bayes model trained with 14 manually chosen features	0.04	0.88	0.54	0.67	0.88	0.55	0.67	0.78
4C mortality score	0.12	0.98	0.39	0.53	0.99	0.34	0.56	0.76

From the computed calibration plot, we can observe that the mortality risk is underestimated only in the first few deciles, while in the higher deciles the risk is slightly overestimated (Figure 2A-D).



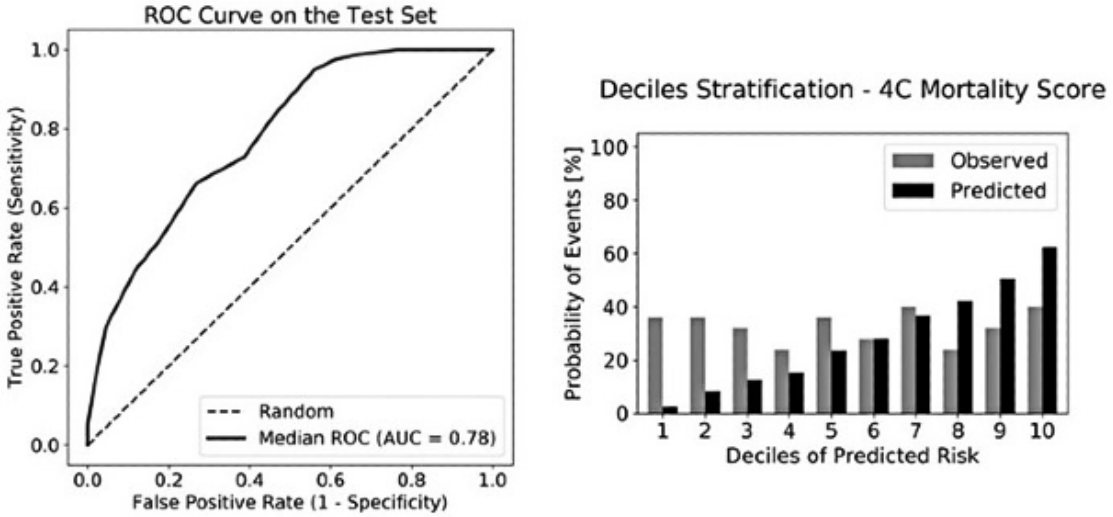
Regarding the relative importance of each features independent from the others, age was the most important feature to predict death followed by MCHC, PaO_2/FiO_2 ratio, previous cerebrovascular stroke, gender, and temperature (Figure 3).

Figure 2. Risk of observed death according to deciles of event probability based on the Piacenza score (A), the Piacenza score on the external validation data set (B), and the naïve Bayes (NB) model trained with 14 manually chosen features (C). For every single case, the corresponding calibration plots with standard deviations calculated over the deciles are also shown below each respective graph (D, E, and F).

XSL•FO
RenderX

Figure 3. Radar plot for the 6 Piacenza score predictors of death and for the 14 manually chosen features, showing their relative importance. Feature importance is scaled with respect to the most important feature. NB: naïve Bayes, MCHC: mean corpuscular hemoglobin concentration, CRP: C-reactive protein, LDH: lactate dehydrogenase, NLR: neutrophil-to-lymphocyte ratio, P/F: PaO2/FiO2, RR: respiratory rate, SBP: systolic blood pressure.

External Validation



The corresponding median of the AUC in the external validation cohort was 0.79 (95% CI 0.68-0.89) with a Brier score of 0.16 (Figure 1A), a sensitivity of 95%, and a specificity of 44% (Table 3).

The calibration plot is reported in Figure 2B and showed again a gradual and progressive increase in absolute event rates across risk classes (death: 10% [4/40] in low-risk deciles vs 29% [7/24] in intermediate-risk deciles vs 38% [6/16] in high-risk deciles).

Comparison With the 4C Mortality Score and the Naïve Bayes Model Using Manually Chosen Features

The median of the AUC was 0.78 (95% CI 0.73-0.83) with a sensitivity of 99% and specificity of 34% for the 4C score when evaluated on the test cohort. The corresponding Brier score was equal to 0.26 (Figure 4). The naïve Bayes model with 14 features chosen manually based on clinician experience achieved an AUC of 0.80 (95% CI 0.75-0.86) with a sensitivity of 88%, a specificity of 55%, and a Brier score of 0.17 (Figure 1B). The detailed performance metrics of both scores are reported in Table 3. The relative importance of the selected 14 features of the naïve Bayes model is shown on the radar plot in Figure 3.

Figure 4. Performance of the 4C mortality score (both in terms of discrimination and calibration abilities) calculated on the test cohort. ROC: receiver operating characteristic, AUC: area under the ROC curve.

The observed mortality increased gradually and progressively for the naïve Bayes model with manually chosen features—death: 14% (17/125) in low-risk deciles vs 32% (14/75) in intermediate-risk deciles vs 72% (36/50) in high-risk deciles. This was not observed for the 4C score—death: 33% (41/125) in low-risk deciles vs 31% (23/75) in intermediate-risk deciles vs 36% (18/50) in high-risk deciles. Both scores achieved a satisfactory patient stratification only in the last three deciles whereas the 4C mortality score overestimated the prediction in the high-risk deciles and underestimated it in the low-risk ones (Figures 2C-4).

Discussion

Principal Findings

In this study, we developed and validated a machine learning–based risk score—the Piacenza score—to predict mortality risk among hospitalized patients with COVID-19 pneumonia. This score is based on only 6 variables that are readily available at hospital admission.

Satisfactory performance, measured in terms of AUCs in both the testing and external validation cohorts, was achieved with excellent patient stratification. More specifically, the Piacenza score showed a higher sensitivity with a lower specificity. Likewise, it underestimated the mortality risk in the first three risk deciles; slight overestimation occurred in the other deciles. This behavior is acceptable and preferred in an acute setting since the score has been designed as a screening predictive tool capable of correctly identifying patients at low risk from those at high risk of mortality.

In crowded hospitals, and with shortages of medical resources, this simple model can help to quickly prioritize patients: if the patient's estimated risk is low, the clinician may choose to monitor the patient, whereas a high-risk estimate might support aggressive treatment or admission to the ICU. Data from China, Europe, and the United States reported a hospitalization rate of 20% to 31%, an ICU admission rates from 17% to 35%, and an in-hospital mortality rate between 15% and 40% [13]. In our study, the in-hospital 30-day mortality rate was 34% with lower survival rates for older patients with pre-existing comorbidities and with clinical signs and symptoms suggesting respiratory failure at hospital admission. In line with previous findings, we found that the most common laboratory abnormalities among patients who died were related to the inflammatory process, renal and liver damage, and procoagulation status [14,15].

In the presence of a large number of patients requiring intensive care and threatening to overwhelm health care systems around the world, several models to predict survival and guide clinical decisions in COVID-19 pneumonia were developed [16]. However, many of these models have been found to have a high risk of bias, which could reflect their development based on a small study population with high risk of overfitting and poor generalization properties to new cohorts, and without clear details of model derivation and testing [6].

The recent spread of artificial intelligence has brought novel ways to combat current global pandemics by collecting and analyzing large amounts of data, identifying trends, stratifying patients on the basis of risk, and proposing solutions at the population level instead of at the single individual level [17,18].

Comparison With Other Risk Stratification Scores

During the COVID-19 pandemic, machine learning approaches have been used to predict the outbreak, to diagnose the disease, to analyze chest x-ray and CT (computed tomography) scan images, and more recently to predict mortality or progression risk to severe respiratory failure [19,20].

Yuan and colleagues [21] developed a simple prognostic risk score based on a logistic regression classifier that included 3 laboratory markers: lactate dehydrogenase, high-sensitivity C-reactive protein, and lymphocyte percentage. This score was developed from a cohort of 1479 patients and externally validated in 2 independent cohorts, reaching an accuracy of 95% in predicting the risk of mortality. However, the model comprised only Chinese patients during the early stages of the outbreak and, more importantly, it seems to have a significant selection bias as it did not include patients with mild and moderate disease at admission [21].

The 4C mortality score, developed and validated by the International Severe Acute Respiratory and Emerging Infections Consortium, based on 8 clinical and laboratory variables, achieved an AUC of 0.78 in predicting mortality. It is easy to use and has a pragmatic design. In fact, to calculate the score, no external tool or complex mathematical equation is required, and results can be immediately retrieved at the bedside [5]. However, due to the rapidly evolving characteristics of the virus and its impact on the population, the score should be continuously updated. For example, the 4C score did not include patients from the second wave of the pandemic. At the same time, if a broad range of individuals are included, the score may become unsuitable for more specific clinical scenarios, such as patients affected by severe pneumonia.

The performance of our model is comparable with the 4C mortality score applied to the test cohort used in this paper. However, we remark that the 4C mortality score was derived based on a population of 35,000 patients, while the naïve model providing the Piacenza score was trained using information coming only from 852 patients. This is indicative of the high representativeness of the training cohort considered in our study. Furthermore, although there is a similar discriminative power between the 4C score and the Piacenza score, the latter score showed better performance in stratifying patients according to their mortality risk, which is of paramount importance in selecting the appropriate treatment and for resource allocations. We also externally tested our score, achieving good performance and confirming that our data-driven model is robust despite its reliance on variables deemed relevant in this context without actually knowing their semantics.

Characteristics of the Piacenza Score

The Piacenza score contains parameters reflecting patient demographics, comorbidity, and physiology at hospital admission. It shares some characteristics with the 4C score such as age, gender, comorbidities, and PaO_2/FiO_2 but also includes unexplored features like temperature and MCHC deriving from a substantially different selection of variables. Unlike traditional scores based on logistic regression analysis mixed with a knowledge-driven approach where a score is assigned by an expert to each of the limited number of selected variables, the proposed predictive model is purely data driven and is not affected by a clinically oriented, potentially biased choice of variables [22].

The Piacenza score is highly customizable and can be adapted as more information becomes available on disease progression and the impact of interventions like vaccines and new pharmacological treatments. In fact, the naïve Bayes algorithm, during its learning phase, generates a summary of the data set

XSL•FO
RenderX

where each variable is associated with the outcome in terms of a probabilistic dependence. This summary describes the distribution of the current data set and can be quickly and easily updated when a new observation is available, adapting itself to changes within the population. Likewise, if new data are available, they can be used to train a new version of the Piacenza score and study the possible fingerprints of COVID-19 variants.

The Piacenza score is thus highly flexible; if the some of the required variables are missing, the model can be retrained and the physician can still receive a customized result (associated with the best possible accuracy with respect to the variables provided). The retraining process can take up to 10 hours, depending on the number of features inserted. However, depending on future requests, codes can be easily optimized and run on more powerful hardware.

An example of a personalized model different from the Piacenza score is the naïve Bayes model trained with 14 manually chosen features, which showed a predictive power comparable to that of the Piacenza score. Other models differ in performance; however, as demonstrated, the variables age and PaO_2/FiO_2 ratio have the biggest contribution to the predictive power of the model. Therefore, starting with age and the PaO_2/FiO_2 ratio and adding more variables will lead to predictive performances similar to that of the Piacenza score, which represents the best combination for stratifying patients and predicting mortality.

Finally, our score's predictors were not chosen a priori (like, for example, the 4C mortality score) but as the product of a machine learning–based optimization technique, which considers the smallest possible subset of leading predictors associated with the best possible performance.

The Piacenza Score Beyond the COVID-19 Pandemic

The approach proposed in our paper is suitable for risk stratification and mortality assessment of other conditions as well, such as heart failure (HF), which constitutes a growing public health issue. In fact, although machine learning has made significant contributions to health care in just a few years, little evidence exists on the role of machine learning in predicting mortality in patients with HF and in general with cardiovascular diseases. In this context, several researchers have developed prognostic risk scores for HF such as the Seattle Heart Failure Model and the Meta-Analysis Global Group in Chronic Heart Failure [23,24]. However, these models do not necessarily predict mortality in patients with HF at the individual level and do not present the same flexibility as the Piacenza score. When dealing with cardiovascular diseases, the flexibility of the scores is of crucial importance due to the continuous and rapid changes in therapeutic strategies; this makes the above-mentioned scores less useful or not reliable in clinical practice.

Limitations

This study has room for further improvement, which is left for future work. First, given that the proposed machine learning method is purely data driven, our model may vary if a different data set is used. As more data become available, the model can be refined and performance of the Piacenza score can further increase. To this aim, we are currently looking forward to subsequent large-sample and multicentered studies. Second, the forward-selection algorithm (used to select the Piacenza score predictors and most importantly to personalize the Piacenza score on any other subset of features) may be an expensive option to be considered and may surely be optimized in further versions of the code. Finally, new variables such as d-dimer and troponin, currently not available, but which are known to be associated with a higher mortality risk in cases of COVID-19 pneumonia may be included in future analyses.

Conclusion

In conclusion, we have developed and validated robust machine learning models, which could be used to predict the prognosis of patients with COVID-19. The Piacenza score has several advantages: first, it relies on objective clinical and laboratory measurements not affected by human interpretation; second, it was tested and validated in patients belonging to the second wave of the pandemic; third, it is automatically generated through a combination of variables widely available at hospital admission and can be calculated through a user-friendly web interface; and finally, as opposed to traditional epidemiological predictive models, the Piacenza score has the added advantage of adaptive learning, trend-based recalibration, and flexibility.

Acknowledgments

No sponsor had any role in the study design, data collection, data analysis, data interpretation, or writing of the paper.

Authors' Contributions

GH, DP, MV, and MAD conceived the study. A Biagi, LR, A Botti, CM, AN, MM, and ES collected the data. MS, UM, AN, and DP managed and analyzed the data. MM, FP, LR, and EM developed the website. PA and MN provided clinical expertise. MP supervised the work. All authors interpreted the results. GH, MAD, MV, and DP wrote the manuscript, which was approved by all the authors.

Abstract

Background: Classic compartmental models such as the susceptible-exposed-infectious-removed (SEIR) model all have the weakness of assuming a homogenous population, where everyone has an equal chance of getting infected and dying. Since it was identified in Hubei, China, in December 2019, COVID-19 has rapidly spread around the world and been declared a pandemic. Based on data from Hubei, infection and death distributions vary with age. To control the spread of the disease, various preventive and control measures such as community quarantine and social distancing have been widely used.

Objective: Our aim is to develop a model where age is a factor, considering the study area's age stratification. Additionally, we want to account for the effects of quarantine on the SEIR model.

Methods: We use the age-stratified COVID-19 infection and death distributions from Hubei, China (more than 44,672 infections as of February 11, 2020) as an estimate or proxy for a study area's infection and mortality probabilities for each age group. We then apply these probabilities to the actual age-stratified population of Quezon City, Philippines, to predict infectious individuals and deaths at peak. Testing with different countries shows the predicted number of infectious individuals skewing with the country's median age and age stratification, as expected. We added a Q parameter to the SEIR model to include the effects of quarantine (Q-SEIR).

Results: The projections from the age-stratified probabilities give much lower predicted incidences of infection than the Q-SEIR model. As expected, quarantine tends to delay the peaks for both the exposed and infectious groups, and to "flatten" the curve or lower the predicted values for each compartment. These two estimates were used as a range to inform the local government's planning and response to the COVID-19 threat.

Conclusions: Age stratification combined with a quarantine-modified model has good qualitative agreement with observations on infections and death rates. That younger populations will have lower death rates due to COVID-19 is a fair expectation for a disease where most fatalities are among older adults.

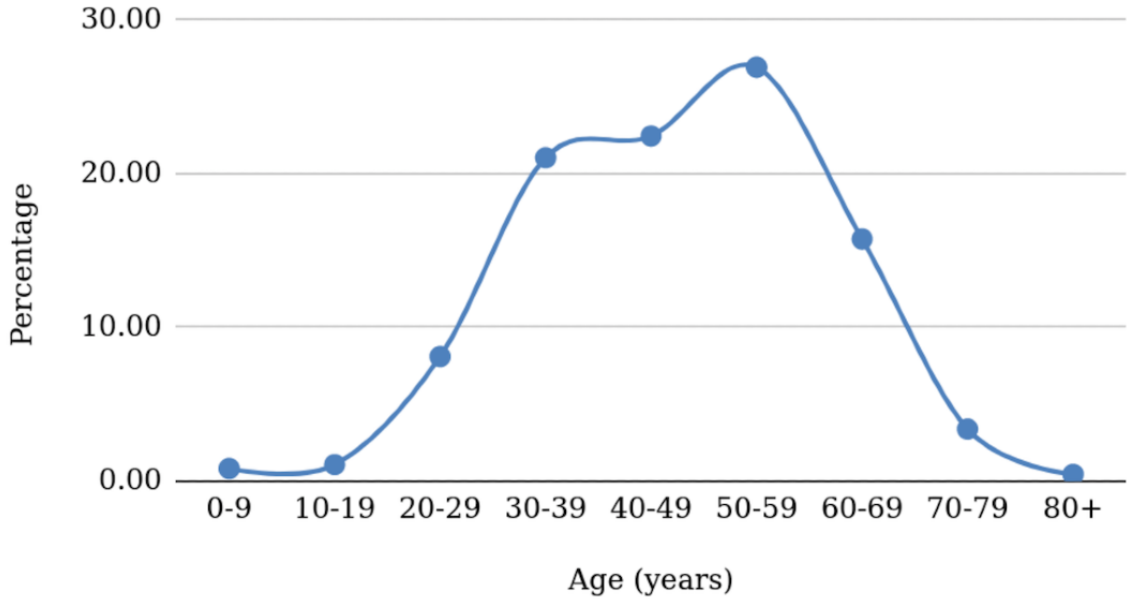
Introduction



The initial impression that came out of Wuhan, China, in late 2019 and early 2020 was that COVID-19 most affects older adult males with pre-existing conditions. Classic compartmental models like the susceptible-exposed-infectious-removed (SEIR) model all assume a homogenous population, and that everyone has equal chances of getting infected. The SEIR model is initialized by "dividing" the population into four compartments; people "progress" through being susceptible, to getting exposed, to being infectious, to getting removed, either via recovery with permanent immunity or death. Permanent immunity is a common assumption when modelling viral infections, and it is assumed here. In future, the model may be modified for temporary immunity, as soon as we get reliable data on reinfection rates. A scan of the preprints from various modeling efforts during the first quarters of 2020 gave high estimates for the peaks of the exposed and infectious groups (40% of the population, by some estimates). Even our quarantine-modified model suffered from this, and this inspired us to use age-stratified infection probabilities, which gave us a lower bound for estimates.

Methods

Estimates by Age Stratification

This calculates the "mathematical expectation" of future infections per age group, by multiplying an age group's infection probability by the population in that age group. Initially, we used the data of patients with COVID-19 in Hubei [1], stratified by ages. As data came in, we repeated the calculations with updated Quezon City data. We treat the percentages of incidence in each age group as a proxy or estimate for the corresponding probabilities of infection for people in the corresponding age group. The true probabilities are and continue to be unknown, but the scatter of the data from Hubei is consistent with the virus affecting older adults with pre-existing conditions more than other groups (Figure 1).

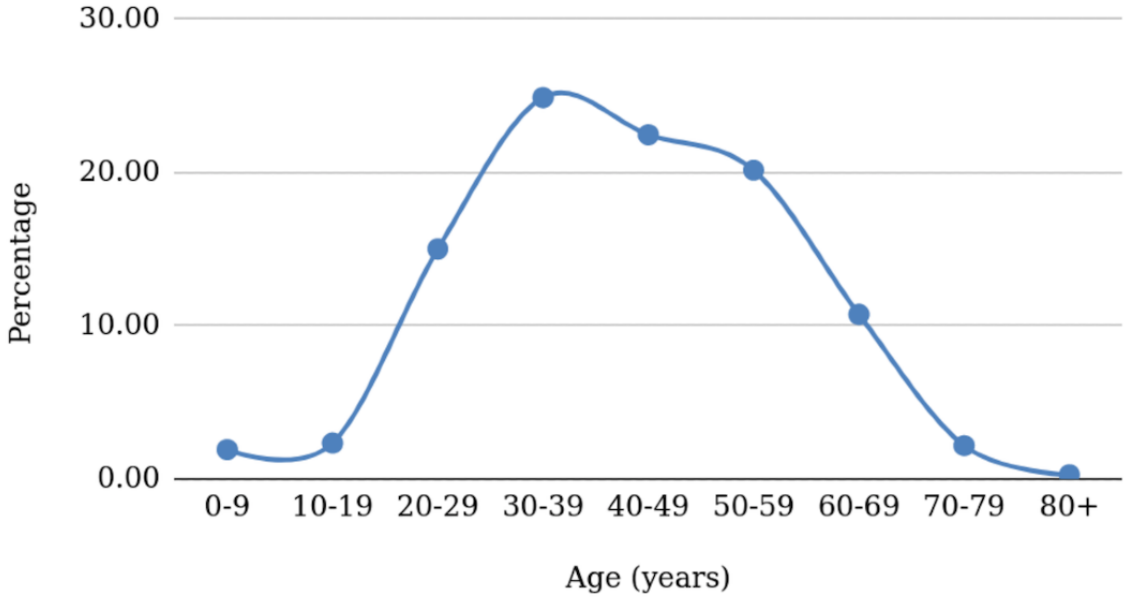


Figure 1. Projected age-stratified percentages of cases for China.

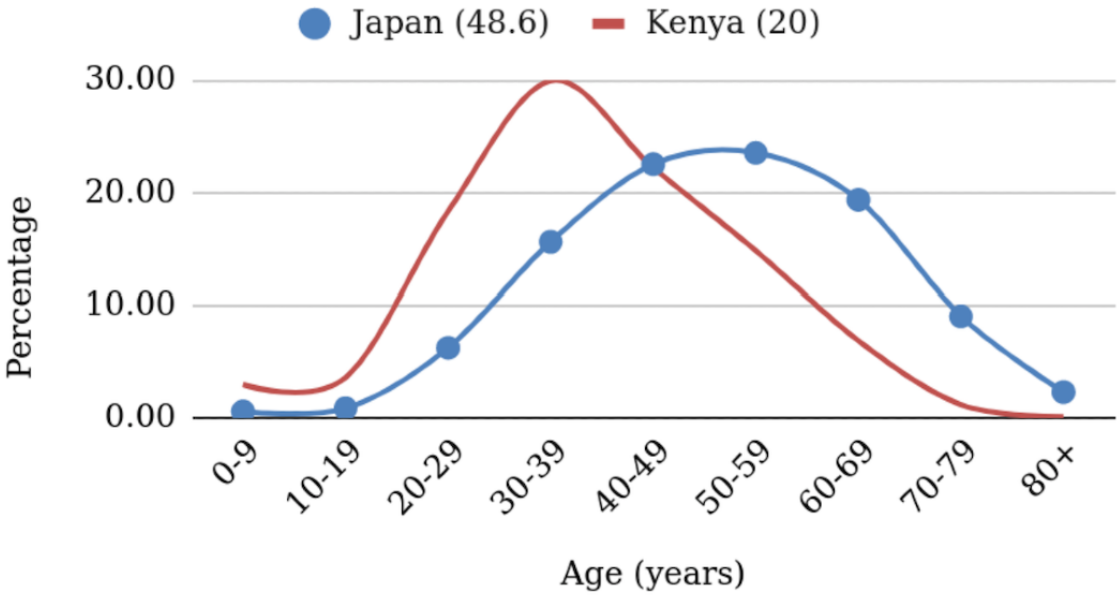
Next, we took the proxy probabilities from Hubei, and applied them to the actual age stratification of the Philippines. Due to its young population, this resulted in a "skewed to the right" distribution (Figure 2) compared to the Hubei distribution, and the true distribution for the study area will be revealed as actual cases are reported.

XSL•FO
RenderX

Figure 2. Projected age-stratified percentages of cases for the Philippines.

The Philippines has a median age of 25.7 years [2] compared to China's 38.4 years [2]. This means half of the population is aged <25.7 years, so more than half of the population will be in the "safer" age groups, with lower probabilities of getting infected, and significantly greater chances of survival if they should contract the disease. Those who do get infected account for only 10.2% of cases (see Table 1, sum of the percentages of those aged 0-29 years old). We expect this to be true for other countries with low median ages.



Using the United Nations World Population Prospects 2019 data [3], we did a similar experiment with Japan (median age 48.6 years) and Kenya (median age 20 years) [2]. We see the younger population also skewing right (Figure 3). Martinez [4] did similar calculations, but did not treat the age-stratified incidence as a proxy for infection probability.

Table 1. Quezon City, Philippines, projection of COVID-19 cases and mortality using COVID-19 data from Hubei, China.

Age group (years)	Hubei, China		Quezon City, Philippines		
	COVID-19 cases, %	Case fatality rate, %	Projected COVID-19 cases, n	Projected COVID-19 case distribution, %	Projected mortality, n
0-9	0.9	0	5164.60	1.60	0.00
10-19	1.2	0.2	7345.98	2.28	14.69
20-29	8.1	0.2	53,444.14	16.57	106.89
30-39	17	0.2	87,156.90	27.02	174.31
40-49	19.2	0.4	75,013.55	23.25	300.05
50-59	22.4	1.3	61,753.09	19.14	802.79
60-69	19.2	3.6	27,420.07	8.50	987.12
70-79	8.8	8.0	4588.82	1.42	367.11
≥80	3.2	14.8	699.83	0.22	103.57
Total	100	28.7	322,586.99	100	2856.54

Figure 3. Projected age-stratified percentages of cases for Japan and Kenya. The average age in each country is given in parentheses.

Estimates Using a Quarantine-Modified SEIR Model

The quarantine-modified SEIR equations are shown below.

The insertion of the *Q(t)* term serves to control the $S \times I$ or susceptible-infectious interactions, hence lowering exposure. *Q(t)* equal to one means no quarantine (ie, no change to the model). A *Q(t)* value of 0.4 means a 60% effective quarantine, while *Q(t)*=0.6 means the quarantine is only 40% effective; therefore, the lower the *Q(t)*, the better. We allowed *Q(t)* to vary day by day (since cases began before the quarantine), and we also estimated the success of the quarantine. Henceforth, we refer to this model as Q-SEIR. Solution was via the Euler method, and time stepping was one day. We used Excel (Microsoft Corp) worksheets for our calculations.

The model was ground-truthed to the estimated number of exposed individuals at the national level on April 1, 2020 (N=7400) [5]. From the nationally reported number of exposed individuals (patients under investigation + persons under monitoring), Quezon City represents almost 10% of cases (~740); the Q-SEIR model predicted 705 cases.

Results

Applying the Hubei infection probabilities on Quezon City with an age distribution as shown in Table 1 (from the 2015 Census, projected to 2020 at a 2% growth rate [6]) gave an estimate of 322,586 infectious individuals (accumulated, which we equate with the Q-SEIR peak), which accounts for less than 10% of the population of Quezon City. Deaths were predicted at 22,390 cases (6.94%), which lies between the World Health Organization (WHO) morbidity estimates of 5.58% [7] and the 12.47% reported in Italy [8]. These estimates were what was available as of April 2020, and will be updated in the discussion.

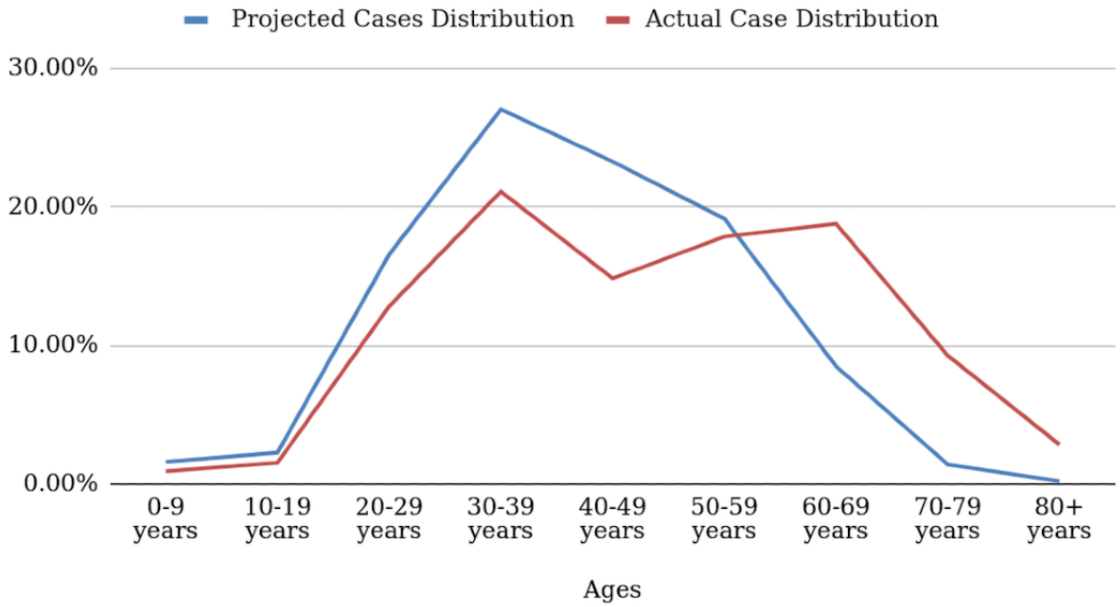
Discussion

Principal Results

Initial reports (around April 2020) estimated the Philippines' death or mortality rate to be at 4.70% (4.05%-5.43%) [8]. This high estimate may be explained by sampling bias, wherein severe cases may have been overrepresented because of a lack of testing. Those who are infectious but are asymptomatic or exhibit mild symptoms should also be equally represented in the testing guidelines (at the moment, they are not), as well as those who were infectious with no symptoms and have recovered.

We tried the calculations from [4] using the death rate, which was reported at 2.3% for China [1]. This gave a much lower number of around 2857 deaths, for a Quezon City death rate of 0.89%. This figure is surprisingly low compared to the 6.94% projected using the estimated infection probability. The latest estimate of the Philippine COVID-19 death rate is 1.82% [9].

The delay in test reporting (estimate of 5-7 days [10]) factors in the estimation of the initial E-I-R values. In addition, this delay is compounded by the incubation period and, in our opinion, moves the quarantine effect further down from the actual date of implementation (March 15, 2020). We started the Q-SEIR simulation on March 20, 2020, with no quarantine assumed because the steep jump in cases occurred on this date; 60% effective quarantine was set for April 2, 2020.



The Q-SEIR model predicted 14.00% of the population will be infectious (I) at the peak. The two methods now give us a low and high estimate for Quezon City: infectious individuals will peak between 9.95% (from age stratification) and 14.00% (from Q-SEIR) of the population, around the third week of May 2020. These figures seemed high compared to the reported incidence during the same period, but were not in any way unique (compared to modeling done in other countries). At that time, the suspicion was that actual cases were undertested/underreported by as much as 90% (ie, only 10% of

XSL•FO
RenderX

cases were being detected). Nevertheless, this range of values serves as a guide for planners in anticipating the need for personal protective equipment, mass testing, hospital beds, and other basic needs.

Figure 4 shows the scatter of cases for Quezon City projected by the Hubei data, and the actual scatter as of May 2020.

Figure 4. Projected versus actual age-stratified case distribution for Quezon City.

Limitations

Like many research groups, we were and continue to be hampered by a lack of reliable data in a usable format. Even now, we refer to multiple data sets including the Philippine Department of Health's DataDrop, WHO, and other data sources.

Comparison With Prior Work

We were one of the first groups to forward the theory of age stratification when it comes to modeling COVID-19 infections. Recently, we came across works by Balabdaoui et al [11], Undurraga et al [12], and the WHO [13]. However, we are uniquely using incidence percentages as proxies for infection probabilities with good results.

Conclusions

In conclusion, age stratification predicted the scatter of cases for Quezon City fairly well. It also predicted later observations of lower cumulative confirmed cases for the same time period (eg, 6587 cases per million compared to Italy's 58,417 cases per million as of March 28, 2021); there is a color-coded world map in [14]. Some African countries have lower median ages than the Philippines, and they have generally lighter colors than Europe and North America. The best prediction is the noticeably lower death or mortality rate of 1.82% compared to Italy's 3.05% and Indonesia's 2.7% (all as of March 29, 2021) [9]. Since COVID-19 disproportionately affects older adults more than younger populations, we expect the Philippines to have a lower mortality rate than countries with older populations (eg, Italy has a median age of 47.3 years and Indonesia has a median age of 29.7 years, compared to 25.7 years in the Philippines). Later work can use actual infection probabilities to include the effect of age stratification in the model.

Acknowledgments

VPB thanks the Alumni Engineers of the University of the Philippines Diliman for their support of the study (UPCoE Covid-19 Response). Additionally, she thanks her coauthors, RdC and JES, who worked pro bono; true heroes! Finally, the authors are grateful to the Engineering Research and Development for Technology (ERDT) Consortium, Republic of the Philippines, for shouldering publication costs.

Abstract

Background: Frontline health care workers are experiencing a myriad of physical and psychosocial challenges amid the COVID-19 pandemic. There is growing recognition that digital technologies have the potential to improve the well-being of frontline workers. However, there has been limited development of wellness interventions using mobile health (mHealth) technology. More importantly, little research has been conducted on how frontline workers perceive mHealth-based support to promote their well-being.

Objective: This study aimed to explore frontline workers' experience of conventional psychological wellness programs and their perceptions of the usefulness of mHealth apps and features for promoting well-being. It also sought to identify factors that could potentially influence uptake and retention of an mHealth-based wellness program.

Methods: We conducted semistructured interviews using purposive sampling with frontline workers involved in the COVID-19 response. Various visual materials, collated from existing mHealth app features, were presented to facilitate discussion. Interviews were audio-recorded and transcribed verbatim. Thematic analysis based on grounded theory was undertaken. Themes were subsequently mapped to key nudge strategies—those commonly used for mHealth development—to assess participants' preferences for particular features and their reasoning.

Results: A total of 42 frontline workers participated in 12 one-on-one interviews or focus group discussions. Frontline workers generally had a limited ability to identify their own psychological problems and liked the *reminders* functionality of the app to track their mood over time. A personalized goal-setting feature (ie, *tailoring*) and in-app *resources* were generally valued, while frequent coaching and messages (ie, *framing*) were seen as a distraction. The majority of participants desired a built-in chat function with a counselor (ie, *guidance*) for reasons of accessibility and protection of privacy. Very few participants appreciated a *gamification* function. Frontline workers commonly reported the need for ongoing social support and desired access to an in-app peer support community (ie, *social influence*). There were, however, concerns regarding potential risks from virtual peer interactions. Intrinsic motivational factors, mHealth app technicality, and tangible rewards were identified as critical for uptake and retention.

Conclusions: Our study highlights the potential of mHealth apps with relevant features to be used as wellness tools by frontline health care workers. Future work should focus on developing a nonintrusive and personalized mHealth app with in-app counseling, peer support to improve well-being, and tangible and extrinsic rewards to foster continued use.

KEYWORDS

COVID-19; frontline health care workers; mHealth; well-being; psychosocial

Introduction

As the COVID-19 pandemic continues to claim more lives, health systems globally have been severely strained. The consequence has been mounting pressure on frontline health care workers [1]. Being at the heart of delivering essential health services during the pandemic, frontline workers face an increased burden and risk of developing physical and psychosocial problems [2]. Studies of previous infectious disease crises, such as SARS, H1N1, and Ebola, reported that frontline workers suffered from poor emotional and social functioning, depressive symptoms, and insomnia, all in addition to the distress relating to the risk of being infected and infecting their loved ones [3-5]. Likewise, emerging literature on COVID-19 consistently indicates a myriad of physical, psychological, and social challenges faced by frontline workers, including burnout, posttraumatic stress symptoms, anxiety, and depression [6,7].

Learning from the experience of prior public health emergencies, it has been suggested that support for the mental well-being of frontline workers is a requisite strategy to ensure a healthy and resilient workforce capable of providing a sustained COVID-19 response. Many institutions worldwide have begun to develop wellness intervention plans to support frontline workers during the pandemic [8-10]. These programs have included specialized mental care clinics, employee assistance counseling, and hospital-based interactive activities [11,12]. However, with few exceptions, the majority of the psychosocial support and wellness programs have been based on in-person interventions or one-off support, without much consideration given to sustained monitoring and impact assessment.

Organizations such as NHS (National Health Service) Digital in the United Kingdom and the US Department of Health and Human Services have underlined the importance of using mobile technology to improve access to care [13,14]. There is also a growing recognition that information and communication technologies have the potential to address the many challenges faced by the public and frontline workers during public health emergencies [15]. This technology focus has led to a surge in the development of mobile health (mHealth) apps during the ongoing COVID-19 pandemic [16,17]. According to recent review studies, a total of 29 mHealth apps pertaining to COVID-19 have been developed by 19 countries [18]. Yet, all of them were exclusively designed for contact tracing and symptom management with the primary purpose of containing disease transmission.

Despite increased rhetoric and enthusiasm for wellness support for frontline workers via virtual platforms, there remain limited advances toward developing psychosocial interventions using mHealth technology for this population. More importantly, little research so far has been undertaken on how frontline workers perceive mHealth-based support to meet their psychological needs and challenges during the ongoing COVID-19 situation. In light of the dearth of literature, this study aimed to explore frontline workers' experience of conventional psychosocial wellness programs and their perceptions of the usefulness of mHealth apps and various features for promoting well-being. The study also sought to identify factors that could potentially influence uptake and retention of mHealth-based wellness support programs. Exploring frontline workers' perspectives as end users will inform future efforts to design evidence-based and user-centered mHealth interventions.

In this study, we adopted nudge theory as a way to better understand perceptions of mHealth app features designed to support psychosocial well-being. Nudge theory is a novel concept that affects the process of decision making in individuals through choice architecture [19]. The theory has been widely used to develop mHealth apps in general and has also been applied to interventions promoting mental well-being. A growing body of literature has demonstrated evidence of nudge elements that promote health behavior and optimize user outcomes with varying degrees of effectiveness in mHealth interventions [20]. For example, a study by Wiecek et al highlighted that use of *reminders* is a successful intervention component for mHealth apps to improve medication adherence, as participants are regularly "nudged" to take their medication [21]. Martin et al called for the incorporation of *gamification* in an mHealth app, as it motivates the user to adopt intended behavior through gamified activities [22]. *Social influence* has also been considered an important nudge that increases the effects of intervention outcomes by fostering a feeling of belonging to a community with a common goal [23]. Individualized *tailoring* has been found to be an effective nudge in sustaining user engagement for digital mental health interventions [24-26]. In addition, provision of app-based resources yielded a positive outcome that alleviated chronic stress of working women [27]. Taken together, nudge theory has proved to be useful in effecting behavior change for mHealth interventions. Ahead of the design of an intervention to support the well-being of frontline workers, we sought to explore their views and preferences for app features that underpin these key nudge strategies.

Methods

Setting and Participants

This qualitative study was conducted in Singapore during the peak of the COVID-19 outbreak from April to August 2020. Singapore is a multiethnic city-state in Southeast Asia. Although the country's public health care system consists of a team of highly trained health care professionals and efficient services, the surge in COVID-19 infections placed considerable strains on the health system [28]. Mass outbreaks in foreign worker dormitories in April 2020 spurred the government's decision to impose a 2-month lockdown [29]. The evolving outbreak situation posed unprecedented risks that could compromise the well-being of frontline workers. In response, a multidisciplinary task force of the Singapore General Hospital, the largest public hospital in Singapore, swiftly rolled out a wellness program aimed at mitigating the risk of burnout and adverse stress

XSL•FO
RenderX

reactions among frontline workers. The program included operational and psychological education, provision of a written handout for family members, active support of staff who were involved in high-risk areas, and close communication between peer support leaders and clinical team members.

It is against this background that a study was conducted to explore perceptions of frontline workers (ie, doctors and nurses) about mHealth apps to improve their well-being. The study was introduced to clinical teams at the Singapore General Hospital and Community Care Facilities—large-scale institutional isolation units—at their staff meetings. Participants were identified using official websites, the study team's professional networks, and recommendations from other study participants. In this study, we defined frontline workers as those who were (1) doctors and nurses and (2) in direct contact with suspected and confirmed COVID-19 patients and provided essential health care services. Potential participants were invited to participate by email and were provided with background information. We used a purposive sampling approach to maximize the diversity of experiences and opinions. As the data collection and concurrent analyses progressed, the variation in emergent themes was explored by recruiting subsequent participants for focus groups and interviews based on profession and years of experience to improve our understanding of specific aspects of the studied phenomenon. Prior to interviews, informed consent was sought via email.

Data Collection

A semistructured interview guide was developed based on relevant literature and the study team's expert knowledge [30-32]. Major topics included perceptions of the existing wellness program available for frontline workers, perceived usefulness of mHealth apps for mental well-being, features that might be valuable for improving wellness, and factors affecting adoption of mHealth apps for wellness. In addition, self-reported demographic information, such as age, gender, ethnicity, and years of experience in health care, were collected. During the interview, various visual materials, collated from existing mHealth app features for wellness promotion, were presented to facilitate the discussion. These materials were organized according to key nudge strategies commonly used for mHealth app development [33,34]. They included, but were not limited to, the following strategies: framing, tailoring, reminders, social influence, guidance, social modeling, gamification, and resources [19]. These strategies enabled a structured way to collect participants' perspectives on the usefulness of mHealth features for improving well-being. Due to the constraints of participants' working hours, consented individuals took part in either a one-on-one interview or focus group discussion, subject to availability. For safety reasons, all interviews were conducted virtually over Zoom by two interviewers trained in qualitative research (SY and HG). Reflections and memos were written after each interview to capture insights. Interviews lasted 31 to 65 minutes. This study was approved by the National University of Singapore Institutional Review Board (NUSIRB No: S-20-115)

Data Analysis

All interviews were audio-recorded following consent and were transcribed verbatim. Thematic data analysis was undertaken using grounded theory. A grounded theory approach based on the work of Glaser and Strauss was chosen because it explored experiential aspects of psychosocial programs and how participants perceived the usefulness of key features in a wellness app. The grounded theory approach allowed for emerging constructs and themes through iterations of data collection and analysis [35,36]. Two independent coders (SY and HG) reviewed the interview materials, summarized and extracted meaningful statements, and carried out open coding and axial coding using NVivo 12 (QSR International), a qualitative data analysis software. During open coding, transcripts were analyzed to develop categories of information. This allowed for subthemes to be derived from the data instead of pre-existing ideas. During axial coding, common subthemes were grouped into unifying themes. The iterative process of independent coding and consensus meetings continued until no new emergent themes were identified. The codes were independently applied to all transcripts, and coding discrepancies were resolved by iterative discussions. Lastly, for mHealth features, themes were mapped against the nudge strategies to assess participants' preferences for particular features and their reasoning [34]. For rigor and transparency, we anchored our methodology according to the Consolidated Criteria for Reporting Qualitative Research (COREQ) checklist (Multimedia Appendix 1) [37].

Results

Characteristics of Participants

A total of 42 frontline workers participated in 12 one-on-one interviews or focus group discussions. Two one-on-one interviews and 10 focus group discussions were conducted, comprising 21 doctors and 21 nurses (for composition of participants in each session, see Table S1 in Multimedia Appendix 2). The recruitment rate was 93% (42/45). A total of 3 individuals out of 45 (7%) declined participation for reasons of lack of time and disinterest. During the peak of the COVID-19 outbreak, health care workers from a variety of clinical departments had been deployed to frontline clinical duties. Participants' clinical home departments ranged across anesthesiology, dentistry, community nursing, and cardiology, among others. Data saturation was reached after the 10th interview, with no new themes emerging from subsequent interviews. We conducted two additional focus groups beyond data saturation to ensure that the point of information redundancy had been achieved. Table 1 shows the characteristics of participants, including 21 (50%) doctors and 21 (50%) nurses out of 42; 76% (32/42) of participants were female and 64% (27/42) were Chinese. The mean age of the sample was 29.6 (SD 3.9) years, with slightly more than half of the participants (24/42, 57%) aged 30 years and below. Participants' experience in the health care sector ranged from 2 to 18 years.

Male	10 (24)
Profession, n (%)	
Doctor	21 (50)
Nurse	21 (50)
Years of experience in health care, mean (SD)	6.8 (3.6)

Experience and Perceptions of the Conventional Psychosocial Program

Table 2 shows the experience of participants regarding the existing wellness program and their coping strategies. By and large, the wellness program was perceived to be appropriate, with some participants expressing positive thoughts about the educational nature of the session. In particular, junior doctors who had never experienced an outbreak response appreciated the opportunity to learn how to protect themselves and where to find resources in the event of burnout. However, as the program comprised a one-off session delivered to a mixture of different health care teams, some expressed the need for building rapport and relationship to enhance the experience. As one participant noted, the session was felt to be a "random group meeting with strangers" (Participant #19, doctor). A minority of participants were not aware of the program's existence. The inherent absence of team spirit and social connectivity, coupled with limited awareness, seemed to discourage frontline workers from active involvement. Most participants preferred that the program session be organized according to clinical teams.

A recurring theme was that informal help-seeking appeared to be the most common avenue to ameliorate the emotional "fallout" from work for our participants. The majority indicated seeking support from family and friends when there was "emotional exhaustion." This was more apparent for participants who had limited awareness of the formal support program or felt that the current program did not meet their expectations. Importantly, participants commonly noted that they often could not recognize their own symptoms of burnout. The cumulative psychological effects of burnout at times unwittingly resulted in high anger expression and feelings of frustration. When prompted, some participants cited constant fatigue and physical exhaustion amid longer work hours as the main reason that limited their ability to self-identify psycho-emotional signs and symptoms.

XSL•FO
RenderX

Table 2. Perception of in-person wellness program and personal coping practice.

Theme and subthemes	Illustrative quotes
Experience of formal wellness program	
Greater need for building rapport and relationships	"I think the program was okay. But the group was huge, so I think sometimes people might be a bit shy to share feelings in a large group." (Participant #1, doctor)
	"The social workers gave us their contact details after the session, which was good as we can call whenever we need help. But I feel some people might not utilize them as there was no prior rapport built." (Participant #35, nurse)
Limited awareness of wellness program for uptake	"I was not aware of that [wellness program], but I do know that there are such services for the COVID-19 patients." (Participant #11, doctor)
	"I don't think there was a [wellness program], maybe I missed the email. Not too sure about that." (Participant #42, doctor)
Lacking team spirit and social connectivity among colleagues	"The session was slightly awkward as it was just out of the blue. It was like a random group meeting with strangers, I feel." (Participant #19, nurse)
	"It might be better to split the sessions into participants who are from the same team, as some people might be uncomfortable sharing in the presence of people whom they might not know." (Participant #1, doctor)
Personal coping practice	
Informal help-seeking or non–help-seeking as a prevailing practice	"Let's say on that particular day if I am feeling frustrated regarding work, I will simply talk to my family members, and they are very supportive." (Participant #4, doctor)
	"I am sure the hospital has put in place some sort of program to help us psychologically, just that I never actively sought for help." (Participant #17, doctor)
Limited ability to self-identify psychoemotional symptoms	"Sometimes when I am so tired, I just don't know what to feel anymore." (Participant #39, nurse)
	"There was this time when I had a mini rage as everything just built up. Until a senior noticed this and she came over to ask me what happened and helped me to resolve the issues." (Participant #14, doctor)

Perceived Usefulness of Features in Wellness mHealth Apps

Table 3 presents perceived usefulness of various features for an mHealth app. Across seven nudge strategies (ie, reminders, tailoring, guidance, framing, social influence or modeling, gamification, and resources), 14 themes emerged. It was commonly perceived that using *reminders* to nudge individuals to monitor their own psychological well-being would be helpful in improving self-awareness, particularly when tracking was visualized in a graphic form for easy interpretation. As one participant noted, the tracking feature would allow for "reflection on stressors" (Participant #4, doctor) by alerting users of the presence of mood deterioration. However, frequent notifications were seen as an "annoyance." In addition to the tracking feature, participants valued a personalized goal-setting feature (ie, *tailoring*), which could aid them by altering them to diet and sleep patterns. Almost all the participants desired a built-in chat with a counselor (ie, *guidance*), as it would offer greater convenience and enable ready access to professional care compared to the conventional mode of in-person counseling. However, many participants did not appreciate the artificial intelligence–driven chatbot, due to the loss of human interactivity. They expressed hesitance toward this feature, although some recognized that it might be useful for simple tasks such as requests for mental health resources.

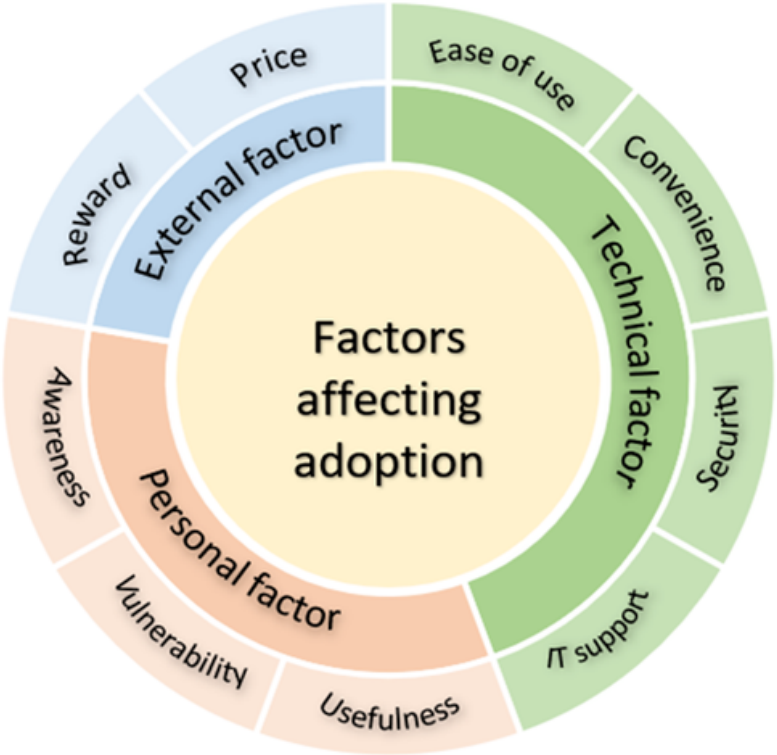
To enhance the user experience, the acceptability of a *framing* feature was explored. Given frequent changes in work protocols in light of the COVID-19 situation and its consequential work demands, occasional messages and coaching were favored compared to daily push notifications, which were seen as an "annoyance." Participants felt that the former would offer a sense of human touch without causing intrusion into private life. Under the *social influence* nudge strategy, features such as forum chats and in-app peer support groups were seen as an essential component of psychosocial support. Despite the positive perceptions of the social influence features, participants highlighted that proper safeguarding measures should be in place to ensure appropriate balance between freedom of expression and emotional manipulation, especially by users who post malicious comments. Related to this, some participants had concerns about disclosure of their personal well-being state that might inadvertently affect assessment of their work performance. This concern was more salient among junior doctors.

The *gamification* function, a widely used nudge strategy to improve self-efficacy, was not something participants were keen to use. While a minority saw a gaming strategy as entertainment, most believed that competition via scoring may be demotivating and backfire when individuals fall behind their peers and colleagues. Virtual rewards such as earning badges, intended for triggering competitive natures, were generally received in a negative light. App-based *resources*, such as mindfulness-based exercises and short wellness articles, were highly valued as a handy and useful tool in promoting a healthier lifestyle and mental well-being.

XSL•FO
RenderX

Table 3. Perceived usefulness of features in wellness mobile health apps.

Nudge strategy and categories	Theme	Illustrative quotes
Reminders (ie, timely cues)		
Mood monitoring	Regular in-app tracking of a mood trend perceived as a tool for improving self-awareness of emotions	"I think the feature can help me to record when is the day that I am feeling low or happy." (Participant #2, doctor)
Progress tracking	Regular in-app tracking of a mood trend perceived as a tool for improving self-awareness of emotions	"You can keep track of your progress and monitor your mood. Eventually, you can see a trend which might potentially help you to identify stressors in daily life. I won't mind using it." (Participant #5, doctor)
Push notification for engagement	Frequent notifications being felt as a distraction	"I do not like this idea [periodical receipt of push notifications], as I find it [to be] annoying. But as long as there is this option of turning it off, then it is fine." (Participant #11, doctor)
Tailoring (ie, context-sensing based on input)		
Tailored feedback	Feedback system aids users in making beneficial changes	"I think this feature [feedback] is a good thing. I wouldn't mind using it, as it allows me to understand better where I have done great and in which area I can work to improve my mental well-being." (Participant #3, doctor)
Personalized goal setting	Setting personalized goals are perceived to be improving general well-being	"I think being able to set goals, like exercise for half an hour a day or sleep before 11 PM, might promote healthy living." (Participant #18, doctor)
Guidance (ie, provision of practical advice)		
Artificial intelligence–based chatbot	Loss of human contact for emotional support is deemed meaningless	"If you are having some emotional issues, you probably wouldn't want to talk to a robot who might not even understand your question properly." (Participant #21, nurse)
Chat with counselor	In-app counseling providing greater convenience and access to care compared to conventional mode of interaction	"I think the chat with a counselor might be helpful, as it is pretty hard to get an appointment with them. And with the built-in feature, one can get a response almost immediately." (Participant #17, doctor)
Chat with counselor	Enabling anonymous care	"I think we do a lot of texting nowadays, so I think texting with a counselor might help, especially if the counselor does not know our identity. So privacy is guaranteed while getting your problems sorted out with a professional." (Participant #34, nurse)
Framing (ie, shaping of information that alters its perceived nature)		
Personalized messages	Personalized messages offer a sense of human touch	"A message like this [personalized message] might encourage me to check on myself more frequently. It feels like someone is concerned and telling me to take care of myself." (Participant #12, doctor)
Social influence (ie, social support and conforming to a social trend)		
Forum	Emphasis on anonymity for concerns about risk of emotional manipulation and privacy	"Although it may be useful for sharing experiences and support one another, we will definitely need moderators to watch out for potential bullying or manipulation on the forum. In a support group, you can still have other people playing the [role] as a whistleblower, but for an anonymized forum chat, there may be someone who will keep posting malicious comments." (Participant #31, nurse)
App-based peer support group	Peer support perceived as useful as a platform for seeking comfort and sharing experience with colleagues	"For people who require emotional support but choose not to share their problems in a face-to-face format, I think this is a handy feature to have." (Participant #26, nurse)
Gamification (ie, tapping into an individual's desire to progress in a game setting)		
Interactive game activities	Reservations about the effectiveness of game elements in improving wellness	"I think it might motivate people who like to play games or have the habit of playing games regularly to use the app. But it might not appeal to people who do not play games." (Participant #40, doctor)
Scoring system	Comparing scores between users may discourage usage	"Personally, I feel that comparing points [between users] will only add to the stress, because people become competitive." (Participant #27, nurse)
App-based resources		
Mindfulness-based exercises	In-app tutorials and short readings perceived as handy and useful	"This [mindfulness-based exercise] is very useful. It can potentially help me destress myself after my shift and sleep well." (Participant #29, nurse)
Self-help aids (eg, short articles and videos)	In-app tutorials and short readings perceived as handy and useful	"Some people may want to look for useful articles, and if the articles are provided in the app itself, it will be really convenient and can potentially benefit a lot of people. It would be good if they are [presented] in point form." (Participant #40, doctor)



XSL•FO
RenderX

Factors That Could Affect Adoption and Sustained Use of a Wellness mHealth App

Factors that could potentially influence the adoption of a wellness mHealth app among frontline health care workers are presented in Table 4. Three overarching factors and nine themes were identified: (1) technical factors, with the themes perceived ease of use, convenience, security, and information technology (IT) support; (2) personal factors, with the themes perceived usefulness, perceived vulnerability, and awareness; and (3) external factors, with the themes rewards and price of app. Participants noted that nonintrusiveness with a minimum set of features relevant to the needs of frontline workers would be of prime importance in prompting adoption and ensuring continued use. As one participant noted, a simple interface that requires "minimum manual input" (Participant #12, doctor) was one of the most desired features for continued use. A robust IT and security system was also brought up by participants to help them start or continue using an mHealth app.

A few participants did not consider an mHealth app as necessary for promoting their mental health and wellness, mainly because they felt that they were coping well. Nonetheless, they thought that such an app might be helpful for colleagues who require psycho-emotional support or who are keen to improve their well-being. Increasing awareness of the availability of an app would be vital to its adoption. To encourage and sustain usage, affordable pricing of the app and attractive rewards could be considered to motivate users. Cost was one of the determining factors for app adoption: the majority of participants favored a free app or were willing to pay a small amount (eg, US $10) if it lived up to their expectations. More tangible and extrinsic rewards, such as Continuing Professional Education (CPE) points and taxi credits after accruing virtual points for adherence, were also suggested as motivation to sustain usage. Figure 1 summarizes the factors that may influence adoption and sustainability of a wellness mHealth app for frontline workers.

Figure 1. Factors affecting adoption and sustained use of a mobile health app. IT: information technology.

XSL•FO
RenderX

Table 4. Factors affecting potential adoption and sustained use of wellness mobile health (mHealth) apps.

Factors and themes	Illustrative quotes
Technical factors	
Perceived ease of use	"I will use the app if it is easy to use. I think judicious use of color might catch people's attention." (Participant #12, doctor)
Convenience	"Because we are always using the phone, if you are feeling down, at least you can use the app to help you manage your emotions. I think it is quite convenient and handy." (Participant #20, nurse)
Security and privacy	"A moderator has to be present to watch out for potential bullying and malicious comments [in forum chats] so as to make people feel safe." (Participant #34, nurse)
Information technology (IT) support	"It will be good if there is a team of dedicated IT personnel to ensure the app is running well and to minimize the potential [hacking] and leaking of information." (Participant #34, nurse)
Personal factors	
Tangible benefits	"I guess for the general health care workers, it [the app] might be useful in helping them to manage their emotions better, as there are many features that I feel are quite useful, such as the virtual counseling service and peer support." (Participant #41, doctor)
Perceived vulnerability to wellness risks	"I might not use the app routinely, as I have been coping well, but for some colleagues, I can tell they are struggling with burnout. If the app is introduced to them, I feel they are likely to use it." (Participant #19, nurse)
Awareness of app	"Many people did not participate in the wellness program, simply because they were not aware or did not feel the need to. Same thing for the app; it has to be made known to us before we can decide to use it." (Participant #26, nurse)
External factors	
Rewards and incentives	"I think you need some rewards to encourage usage, apart from CPE [Continuing Professional Education] points; I think it will be great if rewards like grocery vouchers and taxi credits can be exchanged with the points we have accumulated in the app." (Participant #21, nurse)
Cost	"I stopped using [previous mHealth app] because they wanted to charge a lot. So, if your app is free, then it will be wonderful. I will totally use it!" (Participant #5, doctor)

Discussion

Principal Findings

This study sought to build on limited literature by exploring the perceived usefulness of mHealth apps and features to improve psychosocial well-being from the perspectives of frontline workers responding to the COVID-19 pandemic. Previous studies have suggested that psychological interventions could help frontline workers cope with emotional exhaustion and could ameliorate work-induced stress during public health emergencies [8,38,39] and that counseling reduces the risk of depression in frontline workers [40]. However, our study found that our current in-person counseling has limitations in its ability to monitor and manage physical and mental health issues faced by frontline workers. Our participants, who are working on the front line, commonly reported that lack of rapport and limited continuity and awareness of the program inhibited uptake and appreciation of in-person counseling and psycho-emotional education. This finding from our study reinforces that from a previous study that insufficient rapport-building led to diminished utilization of wellness support services among frontline workers [31]. These factors, together, underscore the importance of developing an optimal set of psychosocial interventions that address pertinent concerns and needs of frontline workers. Delivery of psychological interventions through digital devices can possibly help in overcoming some of the barriers identified, with the potential for wide implementation in a convenient, efficient, and cost-effective manner [41]. Current evidence indicates that mHealth-based interventions increased accessibility to counseling and psycho-education and improved resilience among health care workers [42,43]. Leveraging digital platforms to provide wellness support to frontline workers may be a viable approach. Consistent with previous research, frontline workers generally had limited ability to recognize their psychological problems [44]. Constant exposure to a high-intensity work environment and chronic fatigue appeared to impair the participants' ability to recognize their psycho-emotional signs and symptoms. Hence, assisting frontline workers to identify their symptoms early in the process could be an important strategy for mitigating the risk of developing severe mental health issues. To this end, it is encouraging to note that frontline workers in our study desired a *reminder* functionality, such as tracking of mood and psychological stress, to understand their own mental health states. Another mHealth app feature that was highly valued by the frontline workers was in-app *resources*. This finding is consistent with evidence from previous studies indicating that reminders in mHealth apps played a vital role in improving emotional well-being. For instance, regular monitoring of mood was found to be associated with timely detection and mitigation of potential stressors [45]. Routine in-app reporting of thoughts and feelings can increase emotional self-awareness, which in turn, fosters coping skills [46]. A recent randomized controlled trial demonstrated that mood tracking resulted in improved coping ability, better adaptive response, and enhanced self-care [47]. Likewise, in-app resources, such as meditation and

XSL•FO
RenderX

mindfulness exercises, were found to have a positive effect on improving subjective well-being and behavioral regulation [48]. Therefore, future mHealth interventions should incorporate key nudge strategies that are favored by frontline workers into the design to increase effectiveness.

It has been well-recognized that social support, such as being esteemed, valued, and part of a social network of mutual assistance, is strongly associated with improved mental health [49-51]. Perceived availability of social support may bolster one's ability to cope with challenges, providing an avenue for emotional expression. Our study found that informal help-seeking from family and friends or non–help-seeking (ie, ignoring symptoms) were prevailing practices for frontline workers in response to emotional exhaustion associated with COVID-19. Frontline workers commonly reported the need for ongoing social support and desired an mHealth app with features that would enable them to readily access and check in with a virtual peer support community. Indeed, having similar experiences during the pandemic, peer health care workers may be in a unique position to provide practical and emotional support. A systematic review showed that digital peer support interventions led to improved self-coping and adaptation [27]. Through candid sharing of experiences and validation of feelings, app-based peer support, embedded in a *social influence* nudge strategy, could complement existing in-person support and have a positive impact on frontline workers' psychological well-being [52]. There was, however, a common concern among our participants regarding potential risks arising from virtual peer interactions, such as the spread of misleading information, derogatory comments, and disclosure of personal mental health issues. Therefore, an appropriate safeguarding mechanism should be in place to ensure the best possible outcomes for frontline workers.

Despite several mHealth features that were valued by frontline workers, a crucial issue remains to be considered: adoption and sustained engagement. A recent study reported that nearly 70% of users abandoned mHealth apps after a single use or stopped using the apps after a month [53]. This trend could stem from various factors. Participants in our study reported that mHealth app technicality and intrinsic factors were critical for uptake and retention. This finding resonates with prior research [54] and highlights that a simple user interface would be one of the most important aspects of an mHealth wellness program for frontline workers. Communicating the benefits and relevance of the wellness app, as well as transparency of data management, would be equally important for the successful implementation of an mHealth app [55,56]. In contrast to prior literature, frontline workers were more inclined to engage with a wellness app if external incentives, such as CPE points, were offered [57]. Therefore, it may be helpful to consider incorporating app features that can be manipulated to optimize incentive effectiveness (ie, type of incentives, timing, and magnitude) to maintain engagement of frontline workers.

Strengths and Limitations

This study added important evidence to the potential for wellness interventions delivered through an mHealth app from the perspectives of frontline health care workers. Findings from this study could provide valuable insight into the development and implementation of mHealth apps for improving the well-being of frontline workers involved in the response to COVID-19. Notwithstanding its strengths, this study was limited in several aspects. The results of this study were derived from qualitative research alone, which is, by nature, prone to a degree of potential subjectivity. Despite our efforts to recruit a balanced mix of genders, almost three-quarters of the participants were female. This might have introduced potential selection bias into the study. However, we did not find any considerable gender differences in viewpoints on key topics of interest. The discussion on mHealth features during the interviews was primarily based on visual materials underpinned by nudge strategies. Thus, participants' responses might have been influenced by the mHealth features presented. Lastly, the study participants were limited to doctors and nurses; further research is needed to explore perceptions of mHealth app features to support well-being among administrative and ancillary staff as well as allied health care professionals working on the front line.

Conclusions

Emerging technologies hold considerable promise for significantly expanding the reach of wellness programs for frontline health care workers. Traditional face-to-face modes of episodic support in times of public health emergencies seem to have limited utility to monitor and address the needs of frontline workers in a timely and holistic manner. Our study highlighted the need to take into account frontline workers' preferences and values when designing mHealth-based models of care to promote their well-being. Future work should focus on developing a nonintrusive and personalized app with in-app counseling and peer support features to improve well-being as well as tangible and extrinsic rewards to foster continued use.

Abstract

Background: There is a strong demand for an accurate and objective means of assessing acute pain among hospitalized patients to help clinicians provide pain medications at a proper dosage and in a timely manner. Heart rate variability (HRV) comprises changes in the time intervals between consecutive heartbeats, which can be measured through acquisition and interpretation of electrocardiography (ECG) captured from bedside monitors or wearable devices. As increased sympathetic activity affects the HRV, an index of autonomic regulation of heart rate, ultra–short-term HRV analysis can provide a reliable source of information for acute pain monitoring. In this study, widely used HRV time and frequency domain measurements are used in acute pain assessments among postoperative patients. The existing approaches have only focused on stimulated pain in healthy subjects, whereas, to the best of our knowledge, there is no work in the literature building models using real pain data and on postoperative patients.

Objective: The objective of our study was to develop and evaluate an automatic and adaptable pain assessment algorithm based on ECG features for assessing acute pain in postoperative patients likely experiencing mild to moderate pain.

Methods: The study used a prospective observational design. The sample consisted of 25 patient participants aged 18 to 65 years. In part 1 of the study, a transcutaneous electrical nerve stimulation unit was employed to obtain baseline discomfort thresholds for the patients. In part 2, a multichannel biosignal acquisition device was used as patients were engaging in non-noxious activities. At all times, pain intensity was measured using patient self-reports based on the Numerical Rating Scale. A weak supervision framework was inherited for rapid training data creation. The collected labels were then transformed from 11 intensity levels to 5 intensity levels. Prediction models were developed using 5 different machine learning methods. Mean prediction accuracy was calculated using leave-one-out cross-validation. We compared the performance of these models with the results from a previously published research study.

Results: Five different machine learning algorithms were applied to perform a binary classification of baseline (BL) versus 4 distinct pain levels (PL1 through PL4). The highest validation accuracy using 3 time domain HRV features from a BioVid research

XSL•FO
RenderX

paper for baseline versus any other pain level was achieved by support vector machine (SVM) with 62.72% (BL vs PL4) to 84.14% (BL vs PL2). Similar results were achieved for the top 8 features based on the Gini index using the SVM method, with an accuracy ranging from 63.86% (BL vs PL4) to 84.79% (BL vs PL2).

Conclusions: We propose a novel pain assessment method for postoperative patients using ECG signal. Weak supervision applied for labeling and feature extraction improves the robustness of the approach. Our results show the viability of using a machine learning algorithm to accurately and objectively assess acute pain among hospitalized patients.

Introduction

Overview

Pain assessment is a critical public health burden and is essential to effective pain management, which is associated with many illnesses [1]. Pain is “an unpleasant sensory and emotional experience expressed in terms of actual or potential tissue damage” [2], according to the most widely accepted definition. Pain is considered to be a subjective experience that is related to each individual in early life through experiences related to injury [3]. Such pain, which is termed acute pain, usually lasts hours, days, or weeks. Acute pain is associated with soft tissue damage, a surgical procedure, or a brief disease process and fosters avoidance of the harmful action in the future and promotes healing by inhibiting activities that might cause further tissue damage [4]. Pain, as a susceptible and ambiguous phenomenon, is difficult to quantify [5], particularly when the patient's own opinion is difficult to reach due to their limited ability to communicate, as in patients under sedation or anesthesia, persons with intellectual disabilities, infants, and patients during critical illness [6]. Uncontrolled pain could cause some serious complications and may evolve into chronic pain. This could cause longer recovery in hospitals and delayed discharge, higher health care costs, and major psychological, financial, and social ramifications for patients [7]. However, overtreatment of pain can also result in adverse effects such as hospital readmission due to poorly controlled pain after discharge or long-term opioid dependence.

The current and “gold standard” pain assessment relies on patient self-reporting with tools such as the Visual Analogue Scale (VAS) and Numerical Rating Scale (NRS). Although these unidimensional models are considered powerful in acute pain assessment, they are rife with deficits given their interactive communication requirement between the patient and nurses, which is a serious problem in noncommunicative patients [8,9]. Such tools rely on nurses’ knowledge, physical assessment skills, and interviewing techniques. It is thus meaningful to develop better tools to assess pain intensity for continuous real-time pain monitoring. Such a tool not only improves the care process of noncommunicative patients but can also benefit other patient populations with timelier treatment, accurate assessment, and reduced monitoring burden on clinicians [10].

State-of-the-art objective pain intensity assessment algorithms consist of analysis of physiological and physical pain indicators, as multiparameter analysis is superior to a singular physiological parameter [11-13]. Objective pain assessment leverages using wearable devices to capture the physiological parameters. Internet-of-Things (IoT) devices, including wearable devices, play a significant role in objective pain monitoring systems [10]. As an example, Vatankhah et al [14] measured and diagnosed pain levels of human using discrete wavelet transform via electroencephalographic signals. These devices are in charge of various real-time health monitoring services as well as continuously processing and analyzing pain intensity levels to classify them automatically and objectively. However, these solutions to date have only been evaluated on healthy volunteers (stimulated pain). This was the motivation to develop a multimodal data set from postoperative adult patients in hospitals to get a better understanding of pain intensity characteristics of real patients. We call the data set UCI iHurt Database (UCI_iHurtDB) [15]. The data set is planned to be released for research purposes and, to the best of our knowledge, is the first comprehensive data set collected from patients suffering from real postoperative pain.

Electrocardiography (ECG) is useful for indicating the perception of pain among all of the physiological signals captured by wearable devices. Heart rate (HR) and heart rate variability (HRV) are the essential parameters that can be derived from ECG, as they are both coupled to autonomic nervous system activity, when internal body functions are involuntarily regulated, and they can provide a suitable proxy for examining pain intensity [16]. The most frequently used vital sign in pain studies is HR as the number of heartbeats, while HRV features with the extent to which the heart rate changes over a time interval or the extent to which it is spread over different frequencies are observed individually and selectively in some pain studies [17-19]. There are several approaches for classifying pain intensity of healthy subjects using machine learning techniques. Lopez-Martinez and Picard [18] explored traditional machine learning algorithms such as logistic regression and support vector machine (SVM) with different kernels, as well as recurrent neural network, to create a model for no pain versus pain at different intensities. Koenig et al [19] revealed that HRV is a promising measure of autonomic reactivity to nociceptive stimulation in healthy adults. Therefore, we examine HR and HRV features with their correlation with pain for future biosignal fusion in pain intensity assessment and pain detection.

XSL•FO
RenderX

To the best of our knowledge, this is the first work to study the relations between ECG physiological signal and pain intensity of postoperative patients to predict different pain intensity levels. This will promote advancements in both observational and physiological pain measurement. The technology used in this paper for objective pain assessment was developed by our group and presented in our previous work by Sarker et al [20]. The prototype device can be variably configured for inclusion in a wide range of applications. It is also validated on healthy adults under thermal and electrical experimental pain stimulus [21].

In this paper, we looked into the ECG signal as one of the physiological signals from the human body and examined HR and HRV features extracted from ECG in several categories to assess their correlation with pain intensity for future physiological data fusion in pain intensity assessment. Due to limited available self-report pain intensity labels, we explored weak supervision, which has shown that performance of the end-model can asymptotically improve with data set size, although noisy sources of supervision are used [22,23]. Thus, the contributions of this work are twofold: (1) We present UCI_iHurtDB, a freshly collected data set from postoperative patients consisting of multimodal biosignals (ECG, electromyography, electrodermal activity, photoplethysmography, accelerometer). (2) We provide a novel weakly supervised method to enhance the sparsely labeled data set. To the best of our knowledge, this is the first study using weak supervision in pain assessment.

Interpretation of ECG in Pain Studies

Interpretation of ECG in pain studies starts with the ability to detect the QRS complex as one of the morphological parts of the ECG waves, with the focus on the RR intervals (distance between adjacent R-waves). These peaks are essential in HRV analysis, where in literature they are usually referred to as NN intervals. HRV features have been traditionally calculated over a short period of 5 minutes or over a long period in 24 hours. However, in some cases such as acute physiological changes, some HRV features in less than a minute are also taken on as ultra–short-term analysis. Within each time window, HRV features can be extracted from NN intervals in several domains including (1) time domain features and (2) frequency domain features. HRV features in the time domain consist of statistical features including but not limited to SD of NN intervals, SD of average NN intervals, root mean square of successive differences (RMSSD), NN50, pNN50, and Max(HR) − min(HR). HRV features in the frequency domain are extracted by the Welch averaging method using power spectral density.

In literature, HRV analysis has been examined as one of the main ways to measure pain in different types; in Sesay et al [24], for instance, with the majority of 120 patients, it was observed that regarding acute pain after minor surgery, NRS was correlated with low-frequency (LF) band and the ratio of LF to high-frequency (HF) band but not with HF. To monitor the nociception level of patients with multiple physiological parameters, HF in a 1-minute window was calculated in Ben-Israel et al [11]. Jiang et al [17] experimented with the correlation of HRV features in the ultrashort term with acute pain. They suggested that multiple HRV features can indicate the change from no pain to pain. Werner et al [25] compared no pain among pain levels 1-4 using a random forest (RF) classifier. They reported the detection of pain using a set of features from ECG signals.

Methods

Setting

The study was approved by the University of California, Irvine (UCI) institutional review board (HS: 2017-3747). Candidates were selected from the Acute Pain Service (APS) patient list at UCI Health in Orange, California. The APS unit at the medical center serves approximately 100 patients weekly, enabling the lead Doctor of Medicine to recruit patients.

Study Description, Participants, and Recruitment

This study is a prospective observational data collection from postoperative patients likely having mild to moderate pain. All 25 participants recruited for this study met the following criteria: (1) age at least 18 years, (2) received a consult by the APS, (3) able to communicate, (4) able to provide written informed consent, and (5) healthy, intact facial skin. They were excluded if they had (1) any diagnosed condition affecting cognitive functions (dementia, psychosis), (2) any diagnosed condition affecting the central nervous system, facial nerves or muscles, (3) deformities on hand that prevent sensor placement, or (4) significant facial hair growth in the area where the sensors were going to be attached.

Potential participants were selected if they were determined to be eligible to participate in this study based on the aforementioned inclusion and exclusion criteria. Patients got both oral and written information about the details of the study. Candidates were provided at least 24 hours to consider participation in the study before finalizing the consent form, and they were recruited to participate in this study after obtaining the written consent form.

Study Design

After obtaining the written consent form, approximately 30 minutes of continuous ECG data was collected from the patients in their private room using multiple wearable sensors in two parts. In the first part, we used a transcutaneous electrical nerve stimulation (TENS) unit to obtain the baseline of the person. Patients were asked to increase the intensity of the TENS device up to the level that was tolerable for them, hold it for at least 10 seconds, and then decrease it to level 0, including additional rest between TENS challenges. In the second part, patients were engaged with soft activities such as walking, coughing, sitting, and lifting legs that may cause pain sensation. To achieve a better statistical analysis, data collection in both parts, with and without TENS unit, was repeated two to three times. Subject's self-report of pain was recorded using NRS. The NRS for pain is a segmented numeric version of the VAS to measure pain intensity in one dimension in which a respondent points to the number on the NRS, an integer from 0 to 10, that best represents their pain intensity from “no pain” to “worst pain” [26]. We expect to find solutions from multiple parameters that are robust in response to different acute pain cases or study designs.

XSL•FO
RenderX

Data Collection

To develop an algorithm for pain assessment in hospitalized patients, we tracked physiological signals such as HR, HRV, and respiratory rate from their ECG signals. The technology used in this study to capture the aforementioned signals includes the following components:

1. Biopotential acquisition system for ECG recording—ECG is a biopotential signal captured from the skin surface with a device developed by Sarker et al [20]. The system includes commercially available electrodes (eg, in 24 mm diameter), electrode-to-device lead wires, an ADS1299-based portable device, and computer software receiving streaming data from the portable device. The raw data of each channel at the rate of 500 samples per second is sent to the computer software through Bluetooth. The software visualizes the waveforms and saves the raw data into files. The common reference electrode is placed on the neutral bony area behind the ear. This device uses two channels to collect 2-lead ECG. One channel is to measure the potential between ECG - right arm and reference, and the other channel is to measure the potential between ECG - left arm and reference.
2. TENS unit device (Food and Drug Administration–cleared Class II over-the-counter HealthmateForever YK15AB electrotherapy device)—TENS units work by delivering small electrical impulses through electrodes that have adhesive pads to attach them to a person's skin.

Data Preprocessing

Data Synchronization

The ECG signals from each patient were sampled at a rate of 500 Hz. Data from two channels (left arm, right arm) were obtained. The patient's pain levels were simultaneously reported and saved as labels. For the purpose of synchronicity, the corresponding Unix timestamps were also obtained while extracting both ECG and label data. The ECG signals were trimmed from start to end to match the corresponding label timestamps. Since the sampling frequency was 500 Hz, each timestamp had 500 ECG samples associated with it.

Peak Detection

Once these clean signals were obtained, the second step in the pipeline was to extract peaks. To find the peaks, the signals were first sampled down to 250 Hz. A bidirectional long short-term memory network was used to obtain the probabilities and locations of peaks [27]. A window size of 1000 samples and stride of 100 samples was used to generate these predictions. Mean values were obtained from predictions that came from overlapping windows. The predictions that were below a particular threshold (0.05) were discarded and filtered out. Only those peaks that were in local maximum were selected. Once the peaks were obtained, the signal was resampled back to 500 Hz, and the peak probabilities and locations were obtained. This method, however, might still be susceptible to false positives that are likely generated due to the presence of noise or irregular heartbeats. Therefore, another preprocessing step that removes peaks that occur too close to each other was employed. A rolling window was used to remove peaks that occurred in a time period of 450 milliseconds or less between neighboring peaks. The final selected peaks were then appended with their corresponding Unix timestamps. This process was repeated for every patient.

Noise Removal

The third and final preprocessing step is to remove noise from the NN interval data. NN intervals are the time intervals between two successive peaks. They are obtained by subtracting two successive peak indices. All data points that are within 2 standard deviations of the mean were selected. The rest of the data points were considered outliers and were removed. Even after removing these outliers, however, there might still be anomalous (not a number [NaN]) values in noisy sections of the data. If the proportion of NaN values exceeded 50 percent, the noisy sections were discarded. Otherwise, only NaN values were discarded, and the remaining values were interpolated. The filtered NN intervals were then saved and used for feature extraction.

Feature Extraction

In the experiments conducted by Werner et al [25], they used 5.5 seconds of ECG signals and extracted 3 time domain HRV features from the ECG signal of each subject: (1) the arithmetic mean of time in between consecutive heartbeats or mean of NN intervals (AVNN), (2) RMSSD, and (3) the slope of the linear regression of NN intervals or the measure of acceleration of the heart rate. We use an open-source Python toolbox named pyHRV [28] to compute HRV features in our feature extraction process.

In addition to the 3 time domain features used by Werner et al [25], we also computed a few other time domain and frequency domain features. For classification, we conducted two separate experiments: (1) with the three above features only and (2) with additional time and frequency domain features using feature selection. The additional extracted features are mentioned below.

Time Domain Features

There were 19 time domain features extracted from the NN interval series. They include the slope of the ECG signals and 18 statistical measures. These features were computed using 5.5-second sliding windows. The definitions of these time domain features are mentioned in Table 1.

XSL•FO
RenderX

Table 1. Time domain heart rate variability features and their definitions.

Feature	Description
HR[a] (ms)	Beats per minute
AVNN (ms)	Mean of NN intervals
SDNN (ms)	Standard deviation of NN intervals
RMSSD (ms)	Root mean square of successive NN interval differences
NNXX (ms)	Number of NN interval differences greater than the specified threshold
pNNXX (%)	Percentage of successive NN intervals that differ by more than XX ms

[a]HR: heart rate.

The breakdown of the 19 aforementioned features is explained as follows: slope of NN intervals—a polynomial fit of degree 1; 5 NN interval features—total count, mean, minimum, maximum, SD; 9 NN interval difference features—mean difference, minimum difference, maximum difference, SD of successive interval differences, root mean square of successive interval differences, number of interval differences greater than (a) 20 milliseconds and (b) 50 milliseconds, and percentage of successive interval differences that differ by more than (a) 20 milliseconds and (b) 50 milliseconds; and 4 heart rate features—mean, minimum, maximum, and SD.

Frequency Domain Features

There were 13 frequency domain features extracted by estimating of power spectral density using the Welch method. These features were computed using 250-second rolling windows with a minimum threshold of 50 values per window. The definitions of these frequency domain features are mentioned in Table 2.

Table 2. Frequency domain heart rate variability features and their definitions.

Feature	Description
VLF power (s^2)	Absolute power in very low-frequency band (≤0.04)
LF power (s^2)	Absolute power in low-frequency band (0.04-0.15)
HF power (s^2)	Absolute power in high-frequency band (0.15-0.4)
LF peak (Hz)	Peak frequency in low-frequency band (0.04-0.15)
HF peak (Hz)	Peak frequency in high-frequency band (0.15-0.4)
Total power (s^2)	Total power over all frequency bands
LF/HF (%)	Ratio of LF-to-HF power

The breakdown of the 13 frequency domain features is explained as follows: total power—total spectral power over all frequency bands; 4 HF band fast Fourier transform (FFT) features—peak, absolute, relative, normalized; 4 LF band FFT features—peak, absolute, relative, normalized; 3 very low-frequency (VLF) band FFT features—peak, absolute, relative; and FFT ratio of HF and LF bands.

Feature Selection

To ensure generalization and avoid overfitting, it is important to perform feature selection. This, in turn, reduces computational complexity and the time for training and validating models. Feature selection models can be placed under three broad categories: filter-based methods, wrapper-based methods, and embedded methods. Filter-based methods statistically determine the relationship between input variables (features) and the target variable (label). They provide a metric for evaluating and filtering out features that will be used by the model. They are also computationally cheaper than the other two methods and have a reduced risk of overfitting [29]. Among the filter-based methods, Gini impurity/information gain is a widely used method to select the most informative features for a classification problem. Usually, a decision tree–based model like an RF classifier is used to output a feature importance vector. Every node of a decision tree represents a condition on how to split values present in a single feature. In this process, similar data on the condition variable end up on the same side of the split. The splitting condition is based on impurity of the features chosen in every node. During the training process, how much each feature contributed to the decrease in impurity is calculated, and features are then ranked based on this measure.

Labels

Label Distribution

Table 3 shows the distribution of NRS pain labels reported by patients during the clinical trials.

XSL•FO
RenderX

Table 3. Numerical Rating Scale distribution for 11 pain classes.

Reported Numerical Rating Scale labels	n

4	83
5	44
6	32
7	16
8	46
9	26
10	4

Since the NRS labels recorded during clinical trials were collected from real postoperative patients, there are some inherent challenges due to the distribution of data. For example, there are 83 occurrences of NRS pain label 4, but there are only 4 occurrences of NRS pain label 10 among all patients. Due to the subjective nature and the different sources of pain among our recruited patients, the imbalanced distribution of pain levels among all patients is inevitable.

To compare our pain assessment algorithm's performance with Werner et al [25], we downsampled our pain labels from 11 NRS classes (0-10) to 5 classes (0-4). Data points from NRS pain label 0 were considered as a baseline, and the remaining NRS pain labels were distributed among 4 classes. Thresholds for each downsampled class were carefully chosen in order to minimize an imbalanced class distribution. Table 4 shows the resulting distribution after downsampling the NRS pain labels. The relatively large number of occurrences of NRS pain label 4 increased the number of downsampled PL2 labels over other downsampled pain labels.

Table 4. Downsampled pain distribution with 5 classes.

Downsampled pain labels	n

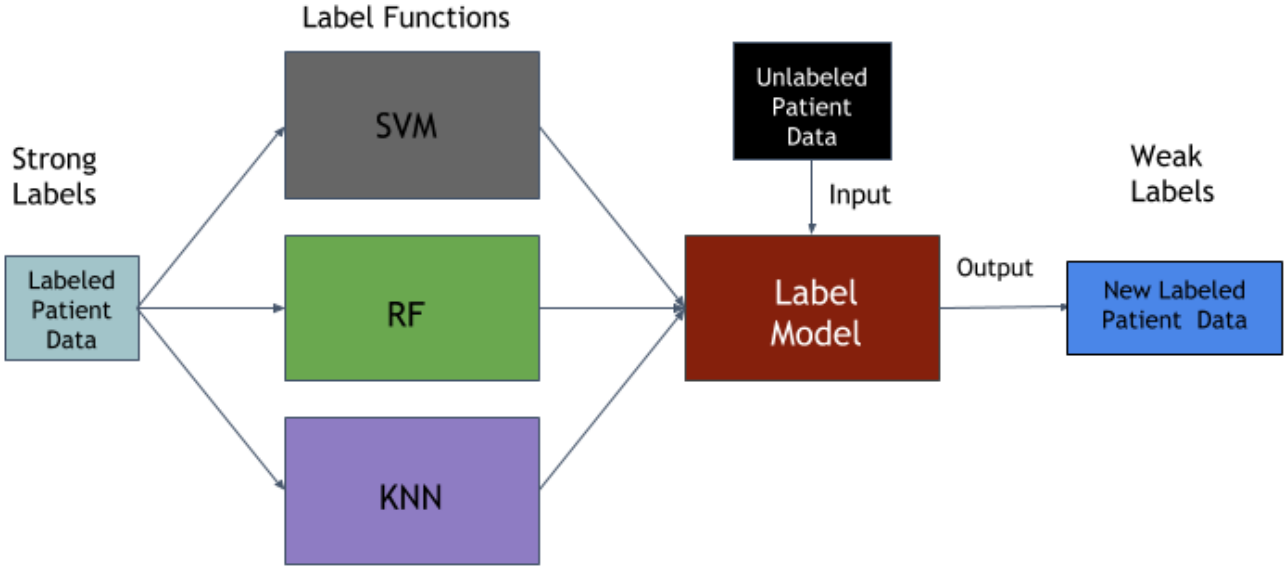
PL1[b]	89
PL2	144
PL3	92
PL4	76

[a]BL: baseline.

[b]PL: pain level.



Labeling ECG Features

Since the patients' NRS values were only reported after performing some activities, labels were stored sparsely. While combining ECG features with their corresponding labels, their timestamps were matched based on the nearest 5.5 seconds (labeling threshold). More precisely, any ECG feature window that was within 5.5 seconds of a reported NRS value was given that value as its label. However, as a consequence of this, all the feature windows that were not within the labeling threshold were not given a corresponding label.

To label the remaining unlabeled data points, we employed Snorkel [23], a weak supervision framework for rapid training data creation. Snorkel is an end-to-end system that combines weak supervision sources to label training data with limited ground truth data. Rather than hand-labeling training data, Snorkel allows its users to write labeling functions that make use of heuristics, patterns, third-party machine learning models, external knowledge bases, and more. Weak supervision is typically employed to label large amounts of unlabeled data when there are noisy, limited, or imprecise sources. This approach eliminates the burden of continuously obtaining NRS values from patients. The use of Snorkel in our labeling process allowed us to make use of more data for the purpose of training and testing our pain algorithm. This consequently led to better performance during validation. Figure 1 depicts the architecture that was used to label these unlabeled instances.

XSL•FO
RenderX

Figure 1. Snorkel labeling architecture. KNN: k-nearest neighbor; RF: random forest; SVM: support vector machine.

All the data points that were within the labeling threshold were considered "strong" labels, or labels used for training labeling functions. These strong labels were collected directly from the patients. The remaining unlabeled data points were considered "weak" data and were kept aside for the weak supervision algorithm to label. For the labeling process, only each patient's strongly labeled data was used to label their own unlabeled instances. This was done to avoid the possibility of data leakage during the validation process.

The labeling functions consist of a group of three off-the-shelf machine learning models: (1) an SVM with a radial basis function kernel, (2) an RF classifier, and (3) a k-nearest neighbor (KNN) classifier with uniform weights. Once each of these models is trained on strong labels, they are used to make predictions on the weak or unlabeled data. Their predictions are then collected and converted into a single confidence-weighted label per data point using Snorkel's *LabelModel* function. The most confident label predictions from each datapoint were considered as labels for the weak data. It is important to note that weak supervision does not compromise on the reliability of our algorithm because we use the weakly labeled data only for training our models. This way, the performance of our algorithm can be measured using only real data collected from patients.

Classification

To compare the performance of our pain algorithm with Werner et al [25], we performed binary classification on our test data using the 3 time domain features mentioned in their work. We split the binary classification problem into 4 different categories: baseline (BL) versus pain level 1 (PL1), BL versus PL2, BL versus PL3, and BL versus PL4. Since 1 of the patients had data from only one downsampled label class, they were discarded from the classification process. Consequently, we were left with data from 19 patients.

We evaluated the performance of our pain algorithm using leave-one-out cross-validation (LOOCV) with the focus on optimizing the area under the curve (AUC) score. During each iteration of LOOCV, the data of 18 of the 19 patients, including those data points that were labeled by Snorkel, were used for training. For testing, only the strongly labeled data points from the one patient left out were used. This process is repeated for all 19 patients to estimate the algorithm's performance on unseen data. Due to the presence of an imbalanced distribution of pain levels within patients, data points from some pain levels were nonexistent from their data. As a result, it was not possible to compute either precision or recall for most patients.

The following five classification methods were deployed in our experiments to identify the best performing model for our pain assessment algorithm: AdaBoost classifier, XGBoost classifier, RF classifier, SVM classifier, and KNN classifier.

We also conducted separate experiments with feature selection using the 32 features mentioned in the Feature Extraction section. To get the best set of features for classification, we run LOOCV using an RF classifier. We compute the Gini importance of each of the features at every fold and select those features that were at least one standard deviation above the mean importance score. As a result, it was possible to have different sets of features in every fold. After computing the best set of features at every fold, we consider those features that were used in most of the folds for classification. The following 8 features were used in the final feature set: (1) total spectral power, (2) absolute LF power, (3) absolute HF power, (4) mean HR, (5) relative HF power, (6) normalized HF power, (7) relative VLF power, and (8) normalized LF power.

Results

Pain Demographic Characteristics

A total of 25 patients with acute pain were engaged by APS and recruited for this study at UCI Medical Center. However, the ECG data from 2 patients were missing due to connectivity issues. Moreover, we found that 3 of the patients had arrhythmia, so we removed those 3 as well. The average age of patients was 55.6 years (SD 16.24, range 23-89); 52% (13/25) of patients were male and 48% (12/25) of patients were female (Table 5). All of the patients (n=20) were taking prescription medication

XSL•FO
RenderX

at the time of the study. The nature of the procedures for each participant included the following domains: 50% general surgery (diagnostic laparoscopy, exploratory laparotomy, and vascular), 25% orthopedics, 15% trauma (thoracic pain and rib plating), and 10% urology (cystectomy and bladder augmentation).

Table 5. Patient demographic characteristics (N=25).

Variable	Value	Range
Patients excluded due to arrhythmia, n (%)	3 (12)	N/A[a]
Patients excluded due to missing ECG[b] data, n (%)	2 (8)	N/A
Gender, male, n (%)	13 (52)	N/A
Weight (kg), mean (SD)	76.56 (17.31)	52.2-112.2
Height (cm), mean (SD)	170.9 (10.44)	152.4-193
BMI[c] (kg/m^2), mean (SD)	26.33 (6.14)	15.1-38.73
Procedure domain (n=20), n (%)		
General surgery	10 (50)	N/A
Orthopedics	5 (25)	N/A

[c]BMI: body mass index.

Pain Engagement Results

To make a fair comparison between our pain assessment algorithm and the work of Werner et al [25], we replicated their settings into our data set. The comparisons of the accuracy achieved by our algorithm on all five classifiers while using only 3 time domain features are shown in Figure 2. Similarly, Figure 3 shows the same comparison while performing feature selection. These figures show the mean accuracy across all subjects while performing 4 different binary classifications based on pain levels. The final scores are presented in Table 6 and Table 7 below.

[c]KNN: k-nearest neighbor.

[d]BL: baseline.

[e]PL: pain level.

We were able to achieve the highest accuracy on the SVM classifier for both settings, with and without feature selection. Moreover, there is no noteworthy difference in the performance of the SVM classifier in both settings. However, while comparing the other classifiers, it is evident that there is a great improvement in performance while using feature selection in the BL versus PL1 category. The performances of the AdaBoost, XGBoost, RF, and KNN classifiers have a marked increase of about 12% on average when compared to their counterparts without feature selection. However, there is a slight decrease in the AdaBoost and RF classifiers and significant decrease in the KNN performance in the BL versus PL4 category. On the other hand, there is an improvement of about 16% in the XGBoost classifier while performing feature selection in the BL versus PL4 category. We speculate that the lower accuracy scores could be due to the relatively smaller number of training examples available from the downsampled PL4. On the flip side, due to the relative abundance of training examples from PL2, there is a spike in performance for all classifiers across both feature settings in the BL versus PL2 category.

While comparing our algorithm's performance to Werner et al [25], we can see that our SVM classifier fares significantly better than their model. The SVM classifier outperforms their model by an average of 20% across both feature settings for the first three pain categories (BL vs PL1, BL vs PL2, and BL vs PL3). Conversely, there is only a slight increase in performance across both feature settings in the BL versus PL4 category.

Discussion

Strengths

To the best of our knowledge, this is the first study that uses ECG signals from real postoperative adult patients for the purpose of developing an automatic pain assessment tool. Moreover, the use of weak supervision in our data labeling process is a novel approach that has not been implemented in pain assessment studies before. It eliminates the need for constantly asking patients for their pain levels and therefore reduces the burden placed on them during the trials. The accuracy scores for this data set with the focus of optimizing it for AUC using the SVM classifier, especially in the first three pain categories, are considerably higher than the scores achieved by Werner et al for both feature settings (with and without feature selection). We also achieve comparable results for the last pain category (BL vs PL4). Furthermore, the use of feature selection in our procedure helps determine the most informative features and reduces the complexity of our pain models. We were able to identify the 8 most informative features and improve the performance of our models in the process.

Limitations

The main limitation in our algorithm is the presence of noise, in the form of motion artifacts, in our physiological data. Since we collect data from real postoperative patients in a clinical setting, they were allowed to move more freely when compared to experiments performed in a laboratory setting on healthy subjects. The presence of noise diminished the quality of our

XSL•FO
RenderX

data. Thus, this negatively impacted the performance of our algorithm.

Another limitation in our experiments is the presence of imbalanced labels in each patient's data. Since we did not collect data in a laboratory setting, most patients did not report all the different pain levels during the trials. Most noticeably, this led to a relatively smaller number of labeled examples from the highest pain level (PL4). This consequently decreased the performance accuracy for that pain category (BL vs PL4). In a controlled laboratory setting, one can design the study to force the pain intensity levels to be balanced, which is not feasible in real settings.

Furthermore, we could not find a significant difference between different pain levels in our study. We believe this is due to the fact that variations in ECG signals in response to different pain levels are much harder to distinguish in comparison to different pain levels versus baseline. Moreover, it is worth mentioning that the state of the art in pain assessment focuses on comparing baseline with other pain levels (eg, Werner et al [25]). We believe the reason is to find out if the patient has pain (baseline vs other pain levels).

Conclusions

The experiments proposed in this study show the viability of our pain assessment algorithm on data from postoperative patients. The use of weak supervision for labeling and feature extraction improves the robustness of our approach. We plan to incorporate multimodal pain assessment methods to further improve our performance and robustness.

Acknowledgments

This research was supported by the Academy of Finland project, Personalized Pain Assessment System based on IoT (313488).
