We compared the results of our classifiers to mobility data from Descartes Labs—available at Descartes Labs [26] and described in Warren and Skillman [27]—to provide a ground truth measurement of social distancing, and to the number of confirmed COVID-19 cases in each state, as tracked by The New York Times [28]. The mobility data used geolocation services from mobile devices (eg, smartphones) to generate aggregate estimates about mobility within specific geographic areas. Descartes Labs provides data at *admin level 1* (state) mobility and *admin level 2* (county) mobility [26]. For this work, we only consider state mobility. Descartes Labs uses a normalized value of the median maximum distance traveled each day: the *m50 index*. Here, data are normalized using the median mobility per state between February 27 and March 7 (ie, a *pre–COVID-19* window). For this work, we looked at the percent change in mobility (m50 index – 100) [27], which can be interpreted as the percent change in mobility relative to the baseline period.

We used these data as a ground truth data set to validate social media tweets about social distancing and sheltering-in-place. For these comparisons, we restricted our data to those with geolocation services enabled (ie, those that used the tweet "place" to determine location), which we then aggregated by state. Here, data were aggregated to weekly data, and any weeks with fewer than 50 tweets were removed. States with fewer than 10 data points were excluded from visualization.

Results

Content Analysis and Labels

In total, 7278 tweets were read and labeled. Of these, 2202 tweets fell into the categories shown in Table 1. For each category and subcategory, the definition and an example anonymized tweet is shown. The most prevalent category by far was tweets about social distancing. Of these tweets, the vast majority were about sheltering-in-place, writ broadly, including tweets about adjusting to life at home (eg, work or school from home); tweets about entertainment, including hobbies and recipes; tweets about plans that were canceled (parties, weddings, etc); and a few tweets about a supposed "coronaboomer" phenomenon, where some suggested that the additional time spent at home would lead to an increase in babies born in 2021. In addition, we identified 53 tweets related to the mental health impacts of social distancing, including tweets about tactics to maintain positive mental health, as well as tweets describing the mental health difficulties associated with social distancing.

In other categories, we again saw a wide variety of health topics discussed. This included tweets about monitoring, of which roughly a third were about access to or experiences with COVID-19 testing; hygiene, including handwashing and cleaning protocols; and a few tweets (n=49) weighing in on COVID-19 vaccine development. Last, we also saw instances of tweets about the economic impacts of COVID-19, including on the supply chain and in terms of unemployment.

Table 1. Tweet content and relative proportion.

Category and subcategories	Definition	Example tweet (anonymized)	Tweets (N=7278), n (%)
Social distancing			
All subcategories	Discusses social distancing in either a positive or a negative way (eg, not physically seeing friends and family, not going to work, or discussing reasons why lockdowns are unnecessary)	"COVID-19 SUCKS! I can't see my family and I really miss them."	1494 (20.5)
Shelter-in-place	Discusses any aspects of shelter-in-place or stay-at-home policies; includes school or daycare (or homeschool), remote work, things to do to keep busy while staying home (eg, hobbies and recipes), canceled plans, delivery services (to avoid going out in public), and the supposed phenomenon that birth rates would increase after the pandemic ("coronaboomers")	"State going into lockdown tomorrow. I can work from home but I'm also going to catch up on my backlog Steam library!"	1117 (15.3)
Mental health	Discussions about mental health; includes suggestions of activities to maintain mental health while sheltering-in-place and documents about the mental health difficulties associated with COVID-19 and social distancing	"I'm so stressed I'm going to cry. I don't want to be where I am now, I just want to be alone for quarantine."	53 (0.7)
Voting	Decisions around voting by mail (eg, for COVID-19–related safety reasons or the opposite opinion)	"Record high cases in the past few days. It's been two weeks since the election."	12 (0.2)
Hoarding	Storing things like food, medicines, and disaster supplies	"Got a bunch of masks and gloves in case the coronavirus becomes a big deal here."	31 (0.4)
Public events	Descriptions of going to public places and choosing to not socially distance	"Airport security was super fast -- no lines at bag check."	53 (0.7)
Monitoring			
All subcategories	Behavior monitoring for illness; includes monitoring friends or family that have the disease	"I keep coming across people with sore throats and cold symptoms today. Hope it's not COVID!"	315 (4.3)
Testing	Ability or inability to get tested for COVID-19 infection; includes tweets expressing desires for improvements and increases in testing and novel testing strategies (eg, drive-through testing centers), or in combination with other tactics like contact tracing	"The complete failure in testing ramp up is really disappointing."	116 (1.6)
Remedies	Unproven treatments, advice, and/or ways to "prevent" or "cure" the disease using natural methods (eg, vitamin D)	"Anti Neo Plastons is the natural cure for Coronavirus and your body makes them naturally!"	84 (1.2)
Hygiene: all subcategories	Trying to prevent sickness by using good hygiene, including handwashing, cleaning and sanitation, and other cleanliness-related behaviors	"Just saw a kid about to use the water fountain. Their parent grabbed them and said 'NOOOOOOOO… there could be COVID!'"	94 (1.3)
Personal protective equipment: all subcategories	Using personal protective equipment to prevent illness; includes masks and gloves	"1.) Wear your mask 2.) Social distance 3.) Wash your hands! We can do this!"	164 (2.3)
Vaccine			
Provaccine	Tweets that are positive and supportive of vaccine efforts	"The work on the COVID vaccine is amazing. I can't wait to get it!"	31 (0.4)
Antivaccine	Tweets that use vaccine-averse rhetoric to describe why a vaccine will be unsafe or ill-advised	"I hope you're not in favor of the Gates vaccine. I'm not going to be tracked by a microchip!"	18 (0.2)
Economic			
Supply chain	Information or commentary about supply chain–related issues; includes information about "price gouging"	"Can we trust the food supply chain? Should we start growing our own fruits and vegetables?"	33 (0.5)
Unemployment	Includes descriptions of applying for unemployment benefits or commentary on the process; includes stimulus checks or commentary about unemployment or underemployment due to COVID-19	"I'm a driver for Uber, but I was put on medical leave after COVID-19 exposure & haven't made any money since."	53 (0.7)

A breakdown of categories by personal and impersonal labels is shown in Figure 2 (a), and subcategories are shown in Figure 2 (b). Overall, a small fraction of tweets were personal mentions; the majority of tweets were impersonal mentions related to each category (eg, mentions of articles or general opinions and suggestions that do not describe a personal behavior). This is consistent with prior work, which has found that personal mentions of health-related behavior on social media are rare [19].

Figure 2. Category distribution. Tweets are broken down by frequency of personal and impersonal labels (a) and by subcategory grouped by category (b). Categories without subcategories are not shown in (b). Only categories with at least 80 labels, and subcategories with at least 50 labels, are shown. PPE: personal protective equipment.

Because there were so few tweets in most categories, it was not feasible to build robust classifiers for most categories or subcategories. For this work, we selected for classification only the personal and impersonal classification task; the categories of social distancing, monitoring, hygiene, and personal protective equipment; and the subcategory shelter-in-place. In general, we found similar performances between random forest and logistic regression (Table 2). The exception to this trend was in the personal protective category, where the logistic regression model substantially outperformed the random forest.

For subsequent analysis, we focused on categories that achieved an F1 of at least 0.6: personal or impersonal, social distancing, and the shelter-in-place classifiers. We then applied the logistic regression models to the remaining data in our corpus of over 228 million tweets through July 2020.

XSL•FO
RenderX

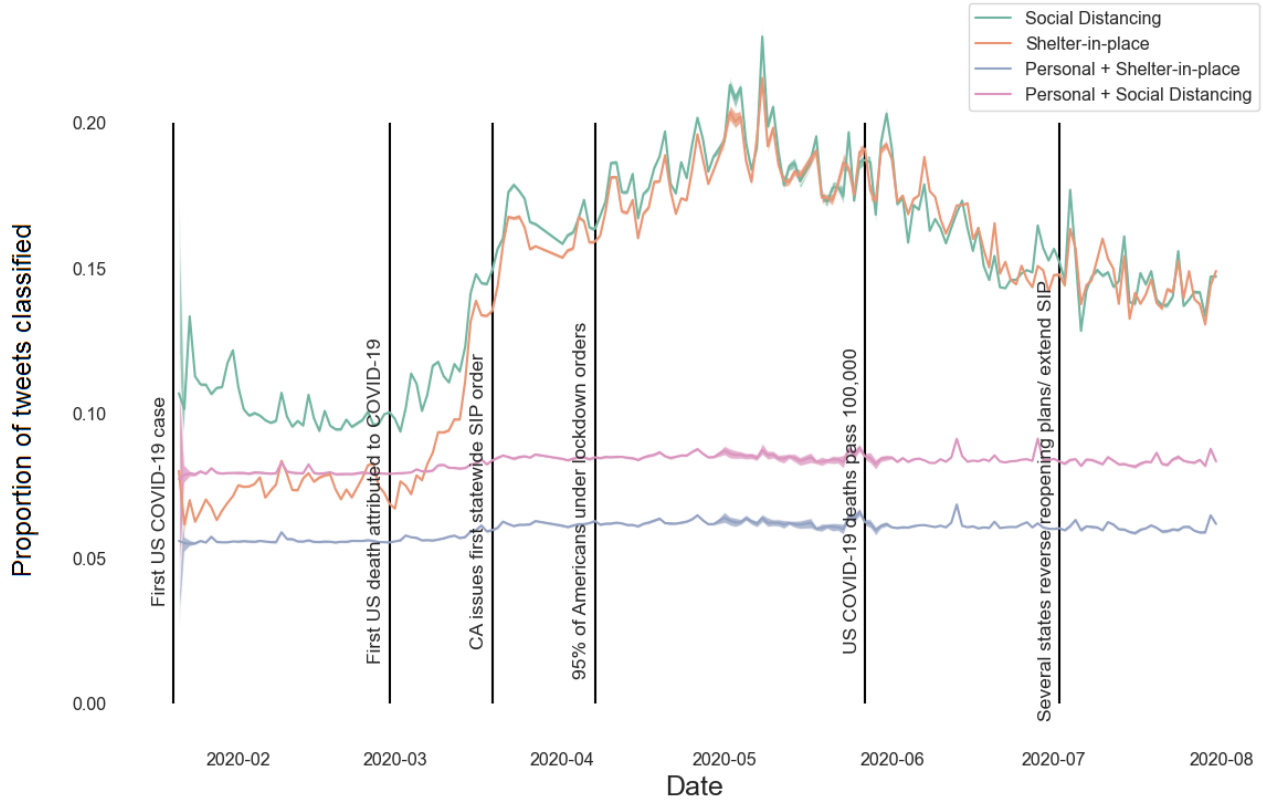

Table 2. Tweet classification results.

Classifier	Logistic regression			Random forest		
	Precision	Recall	F1 score	Precision	Recall	F1 score
Personal or impersonal	0.76	0.50	0.60	0.72	0.57	0.64
Social distancing classifiers						
Social distancing (category)	0.73	0.59	0.66	0.71	0.61	0.66
Shelter-in-place (subcategory)	0.69	0.60	0.64	0.65	0.65	0.65
Monitoring classifiers	0.72	0.17	0.28	0.32	0.13	0.18
Hygiene classifiers	0.50	0.29	0.36	0.33	0.21	0.26
Personal protective equipment (eg, masks and gloves) classifiers	0.59	0.52	0.55	0.40	0.24	0.30

Temporal Patterns

Using the full classified corpus, we compared temporal patterns in social distancing tweets, shelter-in-place tweets, and the subsets of those groupings which were also classified as personal mentions, to important real-world events that occurred during the outbreak (Figure 3). Importantly, the proportion of tweets classified as social distancing and shelter-in-place tweets followed a predictable pattern with respect to real-world events occurring during the outbreak. Social distancing tweets occurred soon after the initial US COVID-19 case as people started to discuss initial reactions to the new disease. As states began to institute shelter-in-place orders—with California leading in late March 2020 [29]—the number of tweets about social distancing and sheltering-in-place doubled. Tweets in this category stayed high throughout the summer, as a large number of Americans were under shelter-in-place orders [29]. In early April 2020, estimates of the number of Americans told to stay at home were around 95%, despite widespread variation in how stay-at-home orders were implemented [30]. As expected, the number of personal tweets was a small fraction of the social distancing and shelter-in-place tweets more broadly. There was little variation in the temporal patterns of personal tweets; all signals came from the broader set of both personal and impersonal tweets.

Figure 3. Temporal patterns in social distancing and shelter-in-place tweets. The proportion of tweets classified as general social distancing, shelter-in-place, personal shelter-in-place, and personal social distancing are shown by date. Relevant events in the outbreak are shown as vertical lines. As states increased shelter-in-place and lockdown orders, the number of tweets about social distancing and sheltering-in-place dramatically increased. Shading shows the 95% CI calculated using classifier-adjusted bootstrapped sampling while the median is a solid line. CIs are extremely small at several time points. CA: California; SIP: shelter-in-place.

State Patterns: Comparisons to Mobility Data

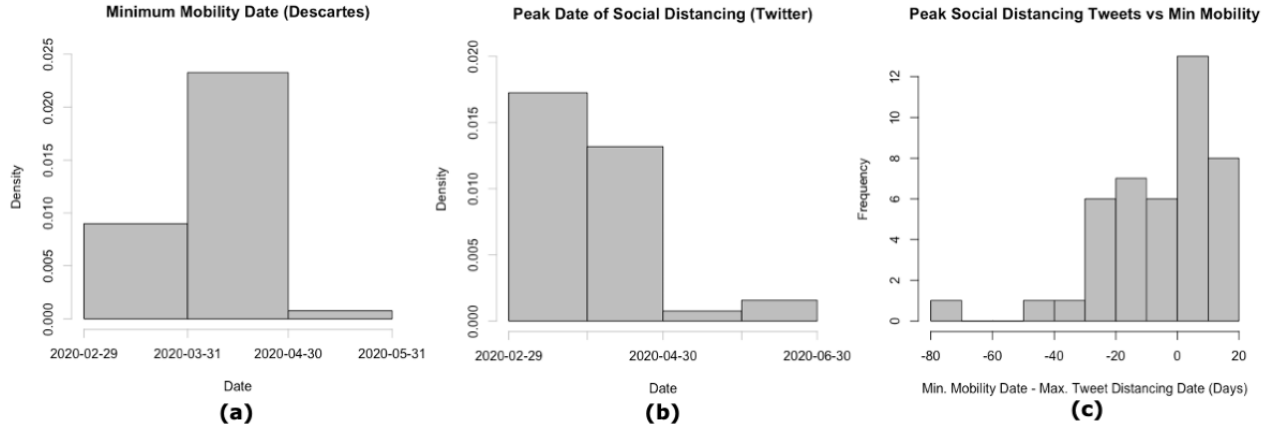
To evaluate temporal patterns more closely, we considered patterns in individual states and compared them to mobility data derived from mobile phone devices (Figures 4-6) and the actual number of confirmed COVID-19 cases (Figure 6). At a high level, it is clear that there is an inverse relationship between the proportion of tweets about social distancing and the actual movement of individuals (Figure 4), indicating that social distancing conversations on Twitter may actually be reflective of real-world behavior. However, we can also see interesting regional patterns among states. For example, some of the earliest-hit states (eg, California, Washington, and New York) showed peaks in the number of tweets about social distancing in late March 2020 compared to states that saw comparatively few cases early on (eg, Florida and Georgia, which had peaks in the number of social distancing tweets in late April 2020).

Most states observed the lowest mobility in April 2020, as seen in Figure 5 (a). The day with the highest fraction of social distancing tweets was most often in March 2020, though many states observed this in April as well, as seen in Figure 5 (b). In general, most states observed these dates within ±20 days of each other, with the majority of states observing the day of minimum mobility before the day with the most tweets about social distancing, as seen in Figure 5 (c). Further, there is a strong negative correlation between the mobility data and the classified Twitter data (Figure 6). Though patterns vary by state, the average correlation is –0.42. Some states show a notably weaker signal (eg, Arkansas, New Mexico, and Rhode Island), which could be caused in part by the relative lack of data in these states. Taken together, these suggest a reasonably strong relationship between our classified Twitter data set and the ground truth mobility data. These patterns are not as clearly reflected in the relationship to confirmed COVID-19 cases. The average correlation between the proportion of tweets about social distancing and the number of confirmed COVID-19 cases is –0.08, though the strongest, which comes from Alabama, is –0.53. This suggests that, while social distancing discussions on social media are reflective of actual social distancing practices as measured by mobility data, the link to COVID-19 transmission is likely more complicated.

Figure 4. US state patterns in mobility compared to social distancing tweets from January to July 2020. Descartes Lab data showing a rolling 7-day average of percent change in mobility (divided by 5, to improve visualization) is plotted alongside the proportion of social distancing tweets per week. Both temporal and regional patterns are clear. Further, as the proportion of social distancing tweets increased, mobility measured by Descartes Labs decreased. States without sufficient Twitter data were removed from the grid. 2-letter abbreviations are used for each state.

XSL•FO
RenderX

Figure 5. Comparison of peak social distancing tweet proportions and minimum mobility. To validate our social media findings, we compared them to mobility data provided by Descartes Labs. Dates of minimum mobility are aggregated by month (a), while dates of highest proportion of tweets about social distancing, aggregated by month, are shown in (b). The difference, in days, between the date of minimum mobility and the date of highest proportion of social distancing tweets (c) show that most states observed both peaks within 20 days of one another.



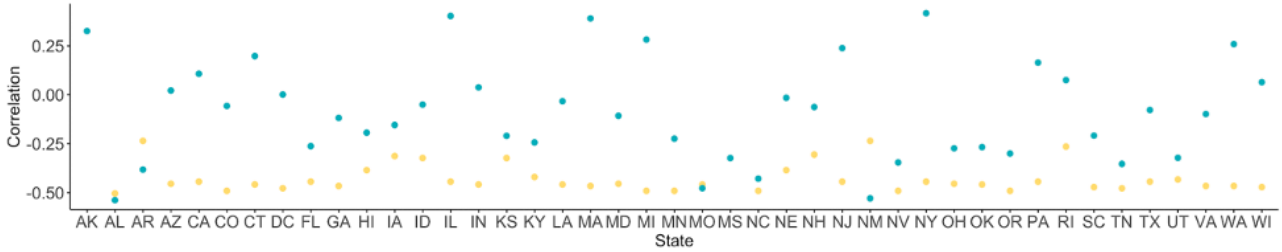


Figure 6. Correlation between confirmed COVID-19 cases or mobility and proportion of tweets about social distancing by US state. Most states have a moderate negative correlation between the proportion of tweets about social distancing and mobility data (yellow), indicating good agreement in the two signals. Some states have notably weaker negative correlations (eg, AR, NM, and RI), which could be the result of less Twitter data. Correlations between the number of confirmed COVID-19 cases and the proportion of tweets about social distancing are weak (blue), with a few notable exceptions (eg, AL). 2-letter abbreviations are used for each state.

Discussion

Principal Findings

The ongoing COVID-19 outbreak clearly illustrates the need for real-time information gathering to assess evolving beliefs and behaviors that directly impact disease spread. Historically, such information would be gathered using survey methods [5,7,31], which are time-consuming, expensive, and typically lack the ability to measure temporal and spatial variation [32]. One proposed partial solution is to use internet data (eg, search query patterns and social media data), which have been shown to correspond to disease incidence in emergent infectious disease outbreaks [23,33-35], individual risk perception [1,36,37], and risk communication [38], and have been used to identify specific health behaviors [15]. During the early stages of the current COVID-19 pandemic, social media data have been used to monitor the top concerns of individuals [39,40], characterize COVID-19 awareness [41], compare social connectedness and COVID-19 hot spots [42], monitor misinformation [40,43-45], and rapidly disseminate information [46]. Last, social media has been used as an information gathering platform during periods of uncertain information. Disease emergence is a context wherein disease risks, transmission, and treatment may be largely unclear [46]. With this context in mind, we address our findings with respect to each research question below.

What behaviors related to COVID-19 are discussed on social media websites, like Twitter? We find that there are a wide variety of behaviors discussed on social media, including mask-wearing, hygiene (eg, handwashing), testing availability and experiences, and social distancing practices. Prior work has found evidence that mask-wearing and limited mobility were behaviors adopted to reduce disease spread during SARS [5] and that handwashing would be commonly implemented by individuals during a hypothetical pandemic influenza [47]. This prior work, however, has relied on surveys to obtain data about the behaviors that individuals implement. The use of social media to complement such work would improve both the richness and the temporal and geographic scope of the data available.

Some of the identified tweets show evidence of sensitive topics. For example, we found 53 tweets related to individuals' mental health. Prior research has found that social media can be used to identify individuals with a variety of mental health concerns, including depression [48] and suicide [14]. As there is considerable work emerging about the substantial mental health impacts of COVID-19 (eg, increases in domestic violence [49] as well as depression and anxiety [50]), this could prove to be an important avenue for future work in this field.

Last, we found a small number of tweets (n=49) about vaccination related to COVID-19, of which roughly a third (n=18) showed a negative attitude. Importantly, this study was

XSL•FO
RenderX

conducted *prior* to the authorization of any vaccines in the United States. All of the tweets considered here discuss either vaccine development or a hypothetical COVID-19 vaccine. Prior research has found similarly negative tweets during the emergence of Zika [51] and the H1N1 influenza pandemic [52]. Future work analyzing these data could provide additional insight into specific reasons that populations may be hesitant to receive the COVID-19 vaccine and could inform targeted public health messaging.

How do patterns in behaviors change geospatially and temporally in the United States? As expected, the patterns in tweets classified as social distancing and shelter-in-place followed extremely similar trends. These patterns corresponded to important real-world events during the outbreak, suggesting that individuals were responding to actual events and some were describing their own personal behavior. We found, however, that tweets classified as personal mentions represented a very small subset of social distancing and shelter-in-place tweets. This is not unexpected, given that prior work has shown that personal mentions of health may be extremely uncommon [20].

How do these trends compare to other data streams, like mobility data sets, that have also shown promise in COVID-19 modeling efforts? Despite the lack of a temporal signal in tweets labeled as personal and social distancing, there was a stronger signal when comparing classified data to Descartes Labs' mobility data. We observed meaningful regional differences between states and saw that, in general, the peak number of tweets about social distancing happened within a few weeks of the actual measured minimum in mobility. This suggests that social media data may be used as a proxy for sensor data in appropriately data-rich contexts. Recent work using geotagged Twitter data to create social networks and analyze social distancing in the context of policy decisions found similar relationships and supports this finding [53].

Limitations

There are a number of limitations to consider in this work. The first is that, as mentioned above, it is known that social media data are biased in a number of ways, including demographically, and that bias differs by geographic areas [18]. Further, personal mentions of health-related information on Twitter are rare [19]. These are known limitations of using internet data and could potentially explain the variations in correlation we observed between social distancing posts and actual mobility data. Importantly, however, it is difficult to assess this without extensive prospective surveys conducted at the same time as tweet collection.

Our observed wide range in correlations between the proportion of social distancing tweets and actual COVID-19 cases in individual states is an example of the ecological fallacy. State-level COVID-19 cases represent an aggregate measure of a state's behavior, while tweets represent individual actions and observations. The available data do not allow us to probe the reasons for the variation, but a number of possible factors could be at play. Individuals' social distancing thoughts at a specific moment in time will be influenced by contextual information about other aspects of their lives. For example, people that tweet in support of social distancing may have in-person jobs or be in high-risk groups, which could motivate them to use social media platforms to voice support for public health measures. The stronger correlation with mobility outcomes is expected by this same argument because mobility is more directly representative of individual actions.

Additionally, tweeting norms could be systematically different across the country (eg, people in different states might be more or less likely to talk about social distancing based on the policies in place and the perceived threat of COVID-19). It is also possible that there are differences in which individuals use Twitter and have geolocation services enabled in different states. In an operational context, it is hugely important to combine internet data with traditional data streams in order to provide a more complete picture of an evolving scenario. Future work should focus on targeted studies to better understand potential bias.

An additional known source of bias comes from imperfect classification. Our classifiers performed similarly to other classifiers used to identify health behaviors [15], but were clearly not perfect. To account for known classifier bias, we used an adjusted bootstrapping method from Daughton and Paul [25], which generates accurate confidence intervals despite classifier error.

We validated our work using mobility data from Descartes Labs. However, there are a number of mobility data sources available [54]. Prior work indicates that these data have similar patterns [54], but it is possible that using a different source would produce slightly different validation results.

Conclusions

Behavior changes and policy decisions that occur early within an outbreak have the largest effects on disease dynamics [55,56]. Real-time conversations about health behaviors, in addition to other behavioral data sources such as mobility metrics or media consumption (eg, home television viewing [55]), could help improve overall knowledge and policy decisions in the early stages of an epidemic and could better capture dynamic changes caused by uncoordinated behavioral change. Using such data has the unique capability to inform public health decisions as an outbreak emerges, especially with respect to public health communication. The World Health Organization suggests a communication checklist to prepare for and minimize morbidity and mortality in the event of a pandemic [57,58]. The checklist emphasizes building public trust through early communication, even with incomplete information, and evaluating the impact of communication programs to assess whether recommendations are being followed. The use of social media streams as a simultaneous real-time measure of public sentiment toward messaging and a dynamic evaluation tool of communication effectiveness could be invaluable in minimizing effects from a future disease outbreak.

Acknowledgments

ARD, CDS, and DG created the labeling schema. DG, NP, TP, ARD, CWR, GF, and NYVC collected and analyzed the Twitter data. ARD, CDS, DG, IC, GN, and NM labeled the tweets. ARD and CWR built the supervised learning models, and ARD implemented the classifier-adjusted bootstrapped sampling. MB collected the mobility data and created several figures. ARD, CDS, and MB wrote the initial paper. All authors provided critical revisions to the paper. ARD led the project. Research support was provided by the Laboratory Directed Research and Development program of Los Alamos National Laboratory (project No. 20200721ER) and the US Department of Energy through the Los Alamos National Laboratory. Los Alamos National Laboratory is operated by Triad National Security, LLC, for the National Nuclear Security Administration of the US Department of Energy (Contract No. 89233218CNA000001). The Los Alamos National Laboratory Review & Approval System reporting number is LA-UR-21-20074.

Abstract

Background: Cerebrovascular disease is a leading cause of mortality and disability. Common risk assessment tools for stroke are based on the Framingham equation, which relies on traditional cardiovascular risk factors to predict an acute event in the near decade. However, no tools are currently available to predict a near/impending stroke, which might alert patients at risk to seek immediate preventive action (eg, anticoagulants for atrial fibrillation, control of hypertension).

Objective: Here, we propose that an algorithm based on internet search queries can identify people at increased risk for a near stroke event.

Methods: We analyzed queries submitted to the Bing search engine by 285 people who self-identified as having undergone a stroke event and 1195 controls with regard to attributes previously shown to reflect cognitive function. Controls included random people 60 years and above, or those of similar age who queried for one of nine control conditions.

Results: The model performed well against all comparator groups with an area under the receiver operating characteristic curve of 0.985 or higher and a true positive rate (at a 1% false-positive rate) above 80% for separating patients from each of the controls. The predictive power rose as the stroke date approached and if data were acquired beginning 120 days prior to the event. Good prediction accuracy was obtained for a prospective cohort of users collected 1 year later. The most predictive attributes of the model were associated with cognitive function, including the use of common queries, repetition of queries, appearance of spelling mistakes, and number of queries per session.

Conclusions: The proposed algorithm offers a screening test for a near stroke event. After clinical validation, this algorithm may enable the administration of rapid preventive intervention. Moreover, it could be applied inexpensively, continuously, and on a large scale with the aim of reducing stroke events.

Introduction

Cerebrovascular disease is a leading cause of mortality and disability. Further, with the worldwide aging of the population, the rise in stroke mortality is only second to that attributed to heart disease [1]. The overall care of stroke survivors comprises an immense social and economic burden due to the high incidence (~30%) of residual cognitive and physical disabilities

XSL•FO
RenderX

[2]. Hypertension, atrial fibrillation, hyperlipidemia, smoking, obesity, and diabetes comprise the major treatable risk factors that underly the occurrence of most stroke events [3]. With the exception of obesity and smoking, these conditions are often asymptomatic and therefore can be missed with treatment deferred for years, unless incidentally detected, clinically suspected, or realized during an acute vascular event. Even when subjects or physicians are aware of these conditions, treatment is not consistently initiated and is often insufficient or discontinued [4,5] due to patient or health care system neglect. Effective means now exist that can substantially lower the rate of stroke shortly after their implementation, as best exemplified by the early benefits of immediate treatment with anticoagulants for atrial fibrillation and blood pressure–lowering drugs for hypertension [6,7]. Therefore, the timely detection of an impending stroke might open a time window of opportunity for immediate medical intervention that can save lives and prevent poststroke disability. To our knowledge, the only risk calculator for impending stroke has been constructed in subjects who have already experienced a previous single stroke, aiming to predict the 90-day risk of recurrent stroke [4], but not for first-ever stroke events.

Computer-based analysis of electronic health records has the potential to provide major novel insights of benefit both to specific individuals in the context of personalized medicine as well as on the level of population-wide health care and policy [8]. However, such analysis mostly relies on traditional risk factors that have already been at the core of daily practice for several decades. The most widely accepted models for stroke prediction, such as those of the American College of Cardiology/American Heart Association cardiovascular disease risk algorithm and the Framingham risk score actually offer a more general predictive target, usually referred to as an "event," which includes an overall risk of occurrence of stroke and other vascular events such as myocardial infarction, death from coronary heart disease, congestive heart failure, incident angina, or intermittent claudication [9]. Further, although these risk profiling models provide clinically critical information in that they calculate the likelihood of an event in the near decade, they have not been constructed to evaluate the risk of an impending short-term cardiovascular threat.

An alternative approach for predicting stroke relies on identification of covert cerebrovascular disease, which often precedes stroke. Covert cerebrovascular disease is associated with subtle cognitive and motor deficits, and increased risk for stroke and further cognitive decline [10,11]. Currently, this can be diagnosed by either neuroimaging or in-person assessment using conventional cognitive screening tests; however, both tools are costly, not effective on the population as a whole, and not continuous [12].

The way that an individual interacts with their computer has been suggested to represent an as-yet unexploited means of assessing everyday cognition [13]. Computer interaction requires motor, language, and executive functions; ability to operate the keyboard and mouse; comprehend and create text; plan; and focus attention. Routine use such as querying of search engines has been shown to correlate with parts of standard cognitive tests, and may thus be used as a continuous, unobtrusive, inexpensive monitoring application [13]. More broadly, internet data have been shown to be a useful source for studying health and improving public health. This has become an active field of research, known as infodemiology, a term coined by Eysenbach [14,15]. Due to their ubiquitous nature and anonymity [16], search engine queries have been shown to be useful for screening for a variety of diseases, including Alzheimer disease [17], Parkinson disease [18], several types of cancer [19-21], diabetes [22], and eating disorders [23]. Similarly, social media postings have been shown to change prior to emergency department visits [24].

In this study, we evaluated the possibility that subjects disclosing the fact that they have experienced a stroke can be singled out from subjects without such a self-declared history via their internet-based communications prior to the occurrence of the stroke. If prestroke patients show unique alterations in communication features, this could potentially be utilized as a "last minute" alarm to seek prompt medical help, with the hope that an impending stroke can be prevented.

Methods

Data

Dataset 1 comprised all queries submitted to the Bing search engine by people in the United States during a 2-year period beginning July 2017. The data comprised the query text, the time and date, an anonymous user identifier, and data on the interaction between the user and the search results page.

To identify a "patient" cohort, we found users who queried the search engine for phrases that indicated that the user underwent a stroke, such as "I had a stroke" or "I was diagnosed with a stroke" (referred to as the "reference query"). Specifically, we defined the reference queries to be queries containing one of the phrases "I had," "I experienced," or "I suffered" *and* one of the phrases "stroke," "cerebrovascular accident," "CVA," "cerebrovascular event," "transient ischemic attack," "brain infarction," "brain ischemia," and "cerebral ischemia."

Additionally, we required that users were active for at least 10 days before and after this query, made at least 50 queries, and had no more than 3 periods of inactivity of 24 hours or more in the 60 days prior to the reference query. We also required that in the 60 days prior to the reference query, the user did not issue queries for between 1 and 10 days, which, we hypothesized, represented the time that the user was hospitalized.

We chose several populations as controls, including a random sample of people aged 60-64, 65-74, or 75 years or older, and random samples of people aged 60 years or older who queried one of the following conditions (separately): depression, migraine, B12 deficiency, heart attack, hypothyroidism, surgery, atrial fibrillation, hypertension, and Alzheimer disease. Table 1 lists the terms used to identify these conditions. Ages were determined according to information provided by users at the time of registration to Bing.

The "reference query" for the control populations was chosen as a random query from their queries (for people selected by their age) or the first query mentioning the condition of interest

XSL•FO
RenderX

(for those who queried having experienced one of the control conditions above). All control populations were filtered for the same activity levels (as described above) as the patient cohort. Dataset 2 was similar to Dataset 1, but was taken from July 2019 to June 2020 and was limited to users who were aged 60 years or more.

Table 1. Number of users in the control cohorts according to various conditions and the search terms used to identify the group.

Cohort	Terms or criteria used for identification	Users, N
60-64 years old	According to information provided at registration to Bing	108

Alzheimer disease	((I or my) AND (forgetting, misplacing, can't find, forget name)) OR Alzheimer OR dementia	75

Data Analysis

Each user was represented through the average values of several attributes and the SDs thereof, computed for all queries within a 2-day moving-window period. These attributes were chosen to represent cognitive ability [13,25,26], activity routine, and indications related to risk factors for stroke. The list of attributes is as follows: (1) number of words per query; (2) time of day; (3) the likelihood of the query string in the entire population; (3) number of new words in the query, compared to all previous queries by the user; (4) time since previous session; (5) number of queries per day and per hour; (6) time from the display of the results to the first click on a result; (7) farthest link clicked by the user; (8) use of automatic spelling correction; (9) whether the query was submitted by this user in the past; and (10) specific keywords in the query, including personal references, mention of relevant symptoms, or mention of certain medicinal drugs.

A session was defined as a continuous period of querying, followed by a break of 30 minutes or longer. Additionally, we quantified the ratio or each attribute to its values for the same user 10 days before. As noted above, we assumed that the gap in user queries just before the reference query was likely due to hospitalization following a stroke. Therefore, we defined the time of the last query prior to the gap as time zero for each user and calculated the time of each user's query relative to time zero. We refer to this as the "relative time" of a query. Patterns were augmented with the average value of each attribute within the relative time of –150 to –120 days.

Unless otherwise stated, we used all data from 30 days prior to a gap in the queries, which was followed by the reference query and up to that gap, to build a random forest model with 1000 trees to distinguish the patient cohort from each of the control cohorts. Ten-fold cross-validation at the user level was applied to reduce the likelihood of overfitting. All processes were performed using Matlab 2019. This study was approved by the Institutional Review Board of Technion, Israel Institute of Technology.

Results

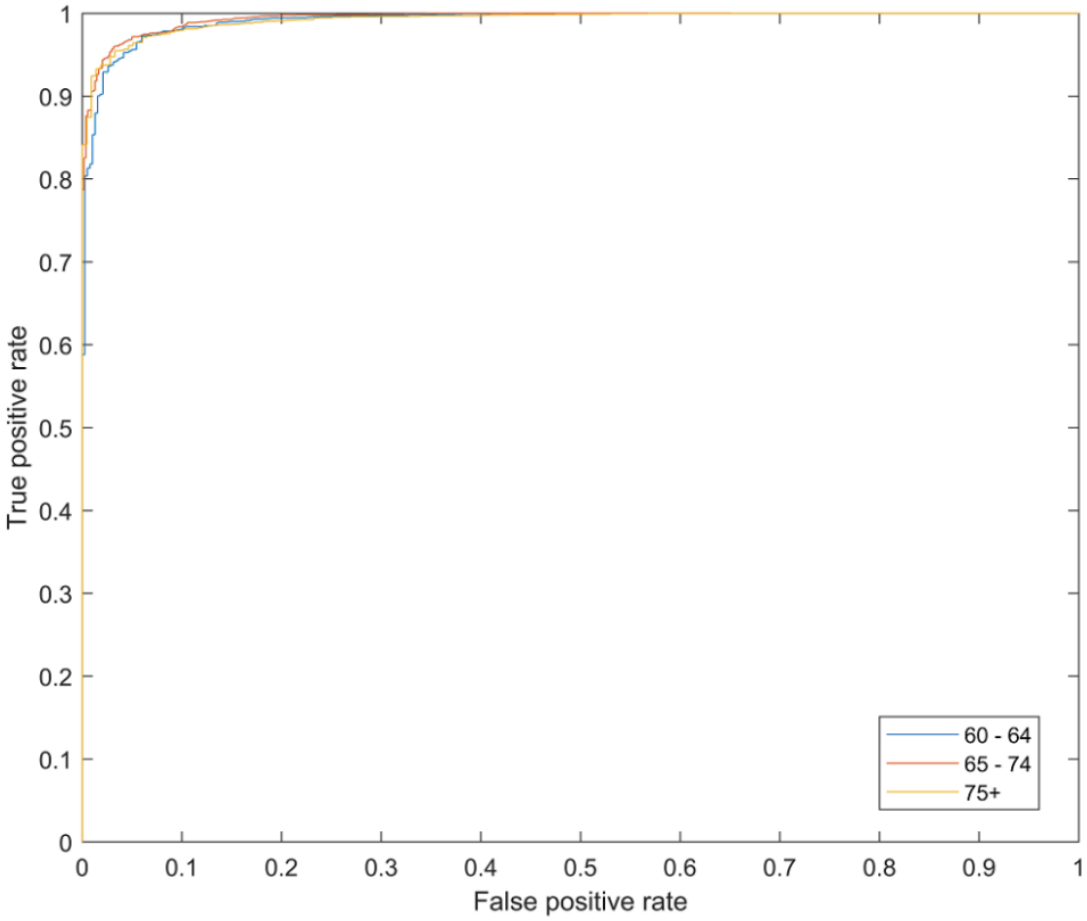
Separation of the Stroke Cohort From Control Cohorts

We identified 285 users in the patient cohort; Table 1 shows the number of users in each of the control cohorts. Figure 1 shows the receiver operating characteristic (ROC) curve [27] for distinguishing the patient cohort and the control by age cohorts. These data comprise only the queries prior to the gap preceding the reference query. The ROC curve showed that excellent differentiation between the patient and control cohorts is possible.

XSL•FO
RenderX

Figure 2 shows the area under the ROC curve (AUC) [27] and the true positive rate at a 1% false-positive rate for separating the patient cohort from each of the control cohorts. Very good performance was reached for all conditions. In addition, some cardiovascular diseases (heart attack, hypertension, and migraine) and certain mental diseases (depression) appeared to be harder to separate from stroke.

Figure 1. Receiver operating characteristic curve for distinguishing users who underwent stroke from controls for people of different ages.



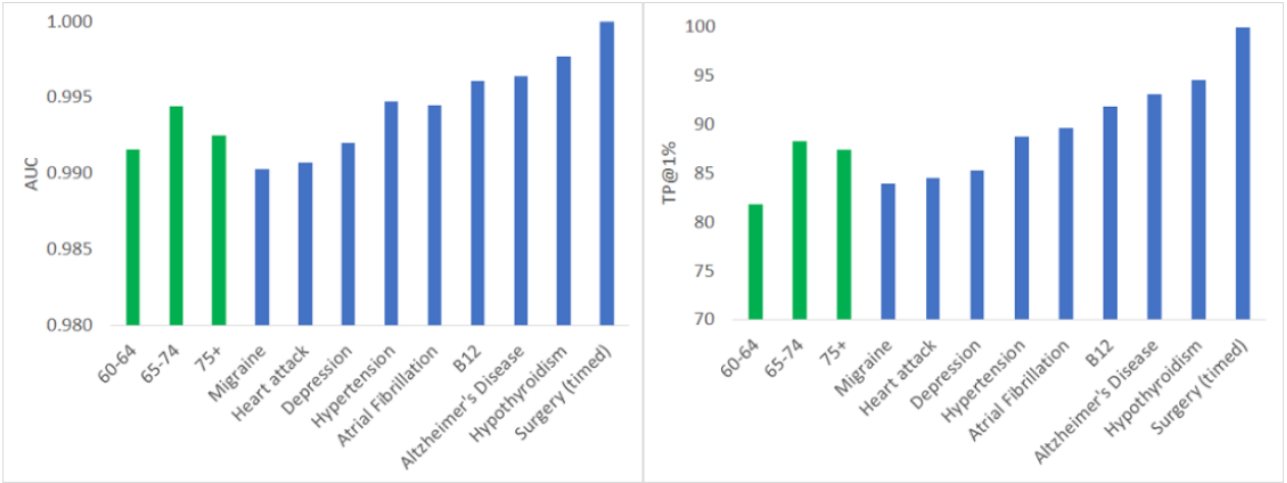


Figure 2. Area under the receiver operating characteristic curve (AUC, left) and the true positive rate at a 1% false-positive rate for separating the patient cohort from each of the control cohorts.

The best attributes for separating the stroke cohort from the other cohorts were estimated by finding the increase in prediction error if the values of that variable were permuted for the test observations, using the appropriate Matlab function (OOBPermutedPredictorDeltaError). The five most important attributes for separating the stroke cohort from each of the control conditions were (in descending order of the number of conditions in which they appeared in the top 5): average query likelihood, SD of the query likelihood, average number of queries per session, average number of spelling mistakes, and average number of repeated queries.

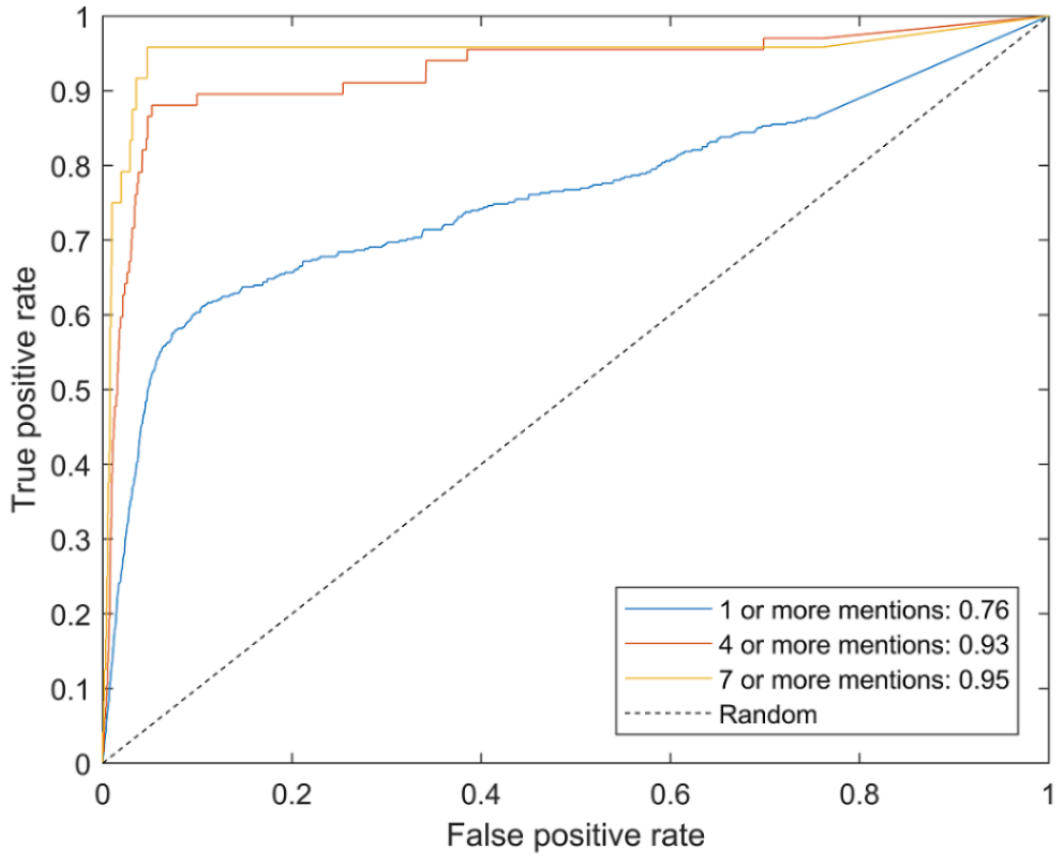
XSL•FO
RenderX

Although the model does not use specific vocabulary in identifying people at risk, it is nevertheless interesting to study the differences in the vocabulary used by the patient cohort and the control groups, and how the vocabulary changes after the stroke event.

Risk factors for stroke include high blood pressure, hypertension, diabetes, insulin, heart disease, cardiomyopathy, heart failure, atrial fibrillation, blood clot, smoking, cocaine, amphetamines, sickle cell disease, vasculitis, bleeding, overweight, stress, and cholesterol. Among people in the patient cohort, 32.2% queried one or more of these risk factors prior to day zero and 56.4% queried for these terms after day zero. Among people 60 years or older in the control cohort, the corresponding percentages were 4.3% and 4.6%.

Medical drugs used to treat survivors of stroke include plavix, clopidogrel, aspirin, dipyridamole, pradaxa, dabigatran, eliquis, apixaban, xarelto, rivaroxaban, atorvastatin, lipitor, simvastatin, simovil, rosuvastatin, crestor, pravastatin, and pravachol. Among people in the patient cohort, 12.5% queried one or more of these drugs prior to day zero and 28.2% queried for these terms after day zero. Among people 60 years or older in the control group, the corresponding percentages were 0.7% and 0.8%. We assume that some of the people mentioning the drugs in the control group and prior to the day of stroke in the treatment group did so because they received these drugs due to their being in high-risk groups for the disease.

These two results suggest that users in the patient cohort did indeed undergo a stroke at the estimated date.



Prospective Cohort

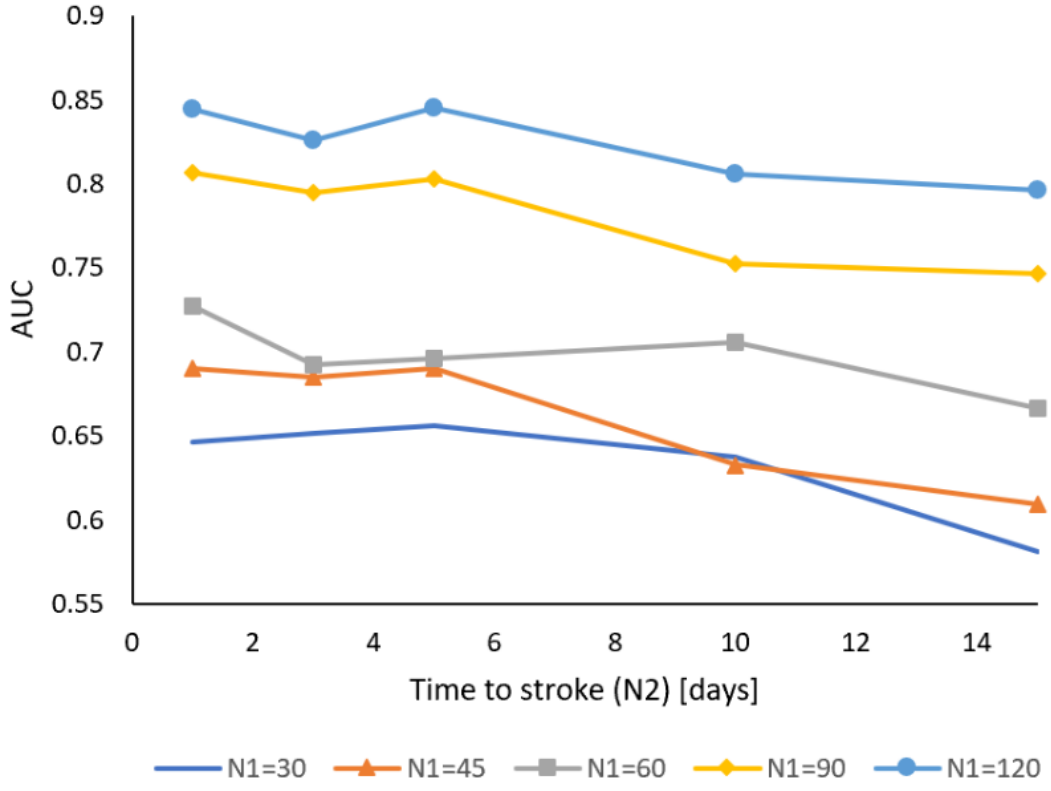
We repeated the same analysis with a prospective cohort comprising users in Dataset 2. Since relatively few people had mentioned that they experienced stroke and were over 60 years of age, our labels were whether or not a user asked about stroke more than a given number of times. This is a weaker proxy than experiential queries, but is nevertheless known to be a good proxy [28]. The control group consisted of all other users.

Our classification model was constructed using data from Dataset 1. Data for the prospective cohort comprised queries until 14 days before a gap followed by the first mention of a stroke.

Figure 3 shows the ROC curve for the resulting experiment, demonstrating the ability to detect people who will, in future, ask multiple times about stroke.

Figure 3. Receiver operating characteristic curve for the prospective cohort; the area under the curve (AUC) values for the different settings are presented in the legend.

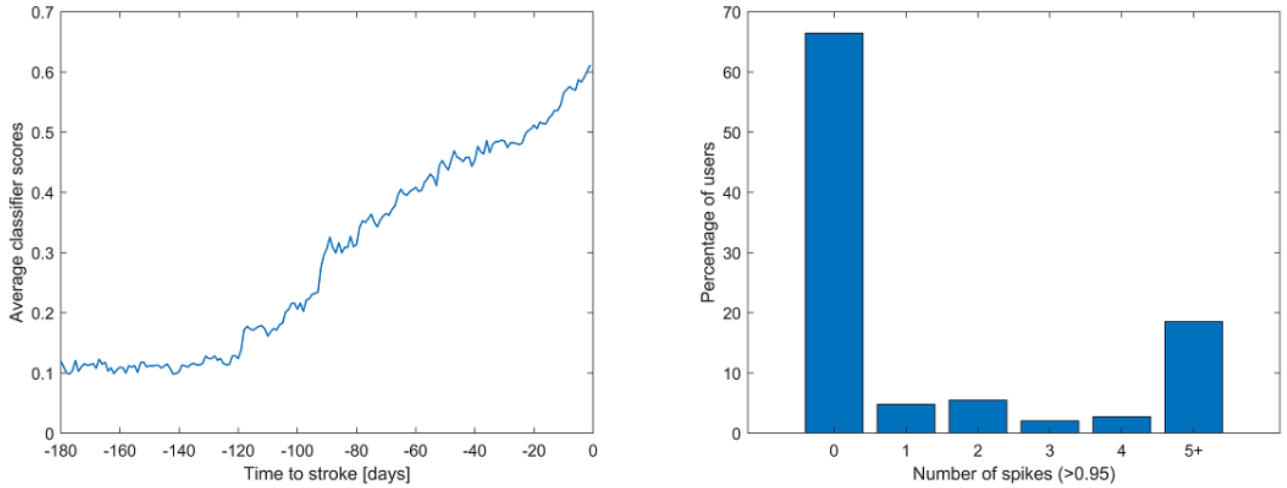
Temporal Change Prior to the Indication of Stroke



We used the attributes derived for people in the patient cohort from Dataset 1 to examine the ability to localize stroke in time. Toward this end, we considered two time constants, N_1 and N_2, to define the negative examples as data from before N_1 days prior to time zero and positive examples as data from N_2 days prior to time zero until time zero, essentially training a classification model to predict if a user will undergo a stroke in the next N_2 days.

XSL•FO
RenderX

The model was a random forest model with 1000 trees. Ten-fold cross-validation stratified by users was utilized in the estimation of model performance. Figure 4 shows the AUC as a function of N_1 and N_2. Relatively accurate classification could be obtained for the stroke localization task, especially for times close to the event. For example, Figure 4 shows that separation between data coming from 120 or more days before the stroke and data coming from 14 days before the event can be classified with AUC≥0.8. Moreover, two effects are visible. First, as the separation between N_1 and N_2 increases (N_2 is larger), performance is improved. Second, the closer to the date of estimated stroke, the better the prediction. We hypothesize that the signal of stroke becomes stronger closer to the time of the stroke and thus negative training data taken close to the date of stroke confuse the model. Second, by limiting the positive examples to those near the actual stroke date, the data contain stronger indications of impending stroke, making the classification more accurate.



To further investigate this hypothesis, we examined times close to the estimated stroke time with respect to the predicted classifier scores (with N_1=90, N_2=5). Figure 5 shows the average classifier scores (in the range of 0 to 1) as a function of the time relative to the estimated stroke time. The classifier scores began to rise around 120 days before the estimated stroke day. In addition, Figure 5 shows the number of days during the prior 120 days and until the day before the estimated stroke day on which users had a score of over 0.95. A significant percentage of users had 5 or more days on which their scores were extremely high. Taken together, these findings suggest that significant alterations can be recognized prior to the date of estimated stroke.

Figure 4. Area under the receiver operating characteristic curve (AUC) as a function of N_2, the number of days ahead for which the prediction is made. Different curves show different values of N_1, the time prior to stroke that is taken as nonstroke dates.

XSL•FO
RenderX

Figure 5. Average classifier scores as a function of the time to estimated stroke date (left) and the number of times that each user had classifier scores greater than 0.95 (right) in the period between 120 days prior to the estimated stroke date and the day before.

Discussion

Principal Findings

Our findings suggest that among internet users, stroke events are preceded by alterations in communication patterns that have been previously shown to reflect aspects of cognitive function [29]. We used an unusual break in the query stream prior to the first mention of a stroke as the likely time of the clinical cerebrovascular event. Assuming that our presumed time of stroke correctly approximates the time of the real event, the internet-derived signal of an impending stroke tends to gain strength as the time of the stroke approaches. If monitored continuously, not only the signal per se but also its persistence and intensification with time might comprise a useful aid in attempted identification of an impending stroke. We expect that these or similar changes in pattern will be present in subjects at risk for stroke prior to a clinically verified stroke. Clearly, following the present hypothesis-forming analysis, the usefulness of the prediction model described here must be validated, and perhaps improved in a clinical setting among internet users who underwent a documented stroke.

Since stroke is mostly a condition affecting the older population segments, the complexity of multiple confounding morbidities comprised a real challenge to our study. We therefore included four types of control groups: (1) subjects not mentioning any health problems; (2) subjects mentioning acute nonvascular medical conditions (ie, surgery); (3) subjects who mentioned an acute vascular event, acute myocardial infarction with risk factors that are nearly identical to those of stroke; and (4) a variety of chronic conditions, which are relatively common in older subjects and may affect cognition, including hypertension, depression, vitamin B12 deficiency, and hypothyroidism. The model developed in this study performed well against all comparator groups, but showed better distinction from surgery and acute myocardial infarction, with more limited power to separate the stroke signal from that generated by hypertension. However, even in the weakest comparisons, the performance via the ROC analysis was very high, with an AUC in excess of 0.985 for all comparators. To place this performance in the proper context, the revised Framingham Stroke Risk Score, which is based on traditional risk factors and predicts a 10-year risk of stroke, offers an AUC of ~0.71 at best [3].

This study cannot uncover the mechanism underlying the evolution, prior to stroke, of escalating cognitive signals that can be detected via examination of an internet communication pattern. A recognizable stroke could be preceded by showering of microemboli from the arterial tree or the heart; worsening of brain small-vessel disease by uncontrolled hypertension and/or hyperlipidemia; or former smaller, clinically unrecognized microstrokes such as in the case of paroxysmal atrial fibrillation or in situ thrombi with cycles of partial resolution and expansion, all subtly impairing cognitive function prior to a major event. Such putative mechanisms would be hard to verify/exclude in the absence of solid clinical, biochemical, and imaging information.

There appears to be a three-fold advantage to an internet-based app for predicting impending stroke such as that presented here. First, it has the potential of serving as an alarm signal, which becomes gradually more intense as the time of the actual stroke approaches, beginning at 120 days to a few days before the stroke. This offers a time window of opportunity to act swiftly, identify specific underlying conditions that predispose to stroke, and apply preventive measures. This concept potentially generates a concrete and immediate alarm, vastly remote from calculating a general “sometime in the next decade” warning, which is often ignored. Second, if indeed validated in the clinical setting, its predicted overall performance and accuracy are considerably higher than those of solidly established traditional tools. Lastly, this algorithm can be applied in an inexpensive manner on a large scale and ongoing basis, similar to a computer virus detection program that runs in the background, reducing costly screening, morbidity, and mortality [17].

Limitations

This study has important inherent limitations. First, the assumption that subjects who declared that they had a stroke indeed experienced some form of true cerebrovascular event lacks actual clinical documentation. However, we provide indirect evidence that the identification was likely correct, including a period of “internet silence” suggesting

XSL•FO
RenderX

hospitalization; queries for risk factors and relevant drugs, which increased substantially in the stroke cohort after the event; increase in classifier scores leading up to the estimated stroke time; and the attributes used to separate the stroke cohort from the controls. Moreover, many other people who underwent a stroke event did not identify themselves as having experienced it. Those people would not have been included in our cohort and might therefore introduce a bias toward specific populations [30].

Second, since the terms used to trap the occurrence of stroke were selected by lay people, the precise nature of the event is impossible to determine, neither is the ratio among various forms of cerebrovascular events such as true stroke vs transient ischemic attack. The requirement for a minimal period of internet "absenteeism" as an inclusion criterion would likely, but not completely, exclude very minor events. As is the case for the occurrence of stroke itself, the existence of the comparator conditions such as acute myocardial infarction completely depends on wording in queries and lack actual medical evidence.

Third, our analysis only applies to presumed stroke survivors who could return to use the internet. Therefore, it does not apply to individuals who did not survive the stroke or had an unfortunate clinical course that precluded further internet communications after the stroke; thus, our analysis was likely not applied to the most severe forms of stroke. Although it is possible that subjects that suffered fatal or severely disabling stroke would have no prestroke warning fingerprints in their communications, it is equally reasonable to assume that their prestroke signals could be even stronger. Moreover, the actual use of drugs is likely higher than their mention in communications and could also refer to people other than the subjects under study themselves.

We also note that the identification of people in the control condition, although supported by precedent [28], does not preclude people who queried for events that happened in the past, because they were asking about other people or those who were asking out of general interest. However, as the cited literature suggests, they are a reasonable proxy for such a condition cohort.

Conclusions

We have developed an internet-based detection model that retrospectively identified subjects who later developed stroke according to self-reports. The usefulness of this system in real-life patients awaits validation in a clinical setting where this model must be tested against accurate diagnoses, information on stroke risk factors, comorbidities, drugs, and outcome. We put forth the vision, which requires much testing but deserves further pursuit, that consenting internet users at some risk for stroke would request continuous surveillance, much like standard computer antivirus programs, to detect an impending stroke so as to allow its prevention.

Abstract

Background: Telemonitoring could offer solutions to the mounting challenges for health care and could improve patient self-management. Studies have addressed the benefits and challenges of telemonitoring for certain patient groups.

Objective: This paper will examine the nationwide uptake of telemonitoring in chronic care in the Netherlands from 2014 to 2019 by means of an annual representative survey among patients and health care professionals.

Methods: Between 2014 and 2019, approximately 2900 patients with chronic diseases, 700 nurses, and 500 general practitioners (GPs) and medical specialists received a questionnaire. About 30 questions addressed topics about the use of eHealth and experiences with it, including data about telemonitoring.

Results: Between 2014 and 2019, the use of telemonitoring remained stable for all groups except medical specialists. In medical specialist departments, the use of telemonitoring increased from 11.2% (18/161) in 2014 to 19.6% (36/184) in 2019 (χ^2_4=12.3; *P*=.02). In 2019, telemonitoring was used by 5.8% (28/485) of people with chronic disease. This was 18.2% (41/225) in GP organizations and 40.4% (44/109), 38.0% (78/205), and 8.9% (29/325) in the organizations of nurses working in primary, secondary, and elderly care, respectively. Up to 10% of the targeted patient group such as diabetics were regarded by health care professionals as suitable for using telemonitoring. The main benefits mentioned by the patients were “comfort” (421/1043, 40.4%) and “living at home for longer/more comfortably” (334/1047, 31.9%). Health care professionals added “improvement of self-management” (63/176, 35.8% to 57/71, 80.3%), “better understanding of the patient’s condition” (47/176, 26.7% to 42/71, 59.2%), “reduction of workload” (53/134, 39.6% of nurses in elderly care), “better tailoring of care plan to the patient’s situation” (95/225, 42.2% of GPs), and “saves time for patients/caregivers” (61/176, 34.7% of medical specialists). Disadvantages mentioned by professionals were that “it takes time to monitor data” (13/130, 10% to 108/225, 48.0%), “it takes time to follow up alerts” (15/130, 11.5% to 117/225, 52.0%), and “it is difficult to estimate which patients can work with telemonitoring” (22/113, 19.5% to 94/225, 41.8%).

Conclusions: The uptake of telemonitoring in Dutch chronic care remained stable during 2014-2019 but increased among medical specialists. According to both patients and professionals, telemonitoring improves the quality of life and quality of care. Skills for suitably including eligible patients and for allocating the tasks of data monitoring and follow-up care within the team would help to further increase the use of telemonitoring.

KEYWORDS

eHealth; telemonitoring; self-management; telemedicine; telehealth

Introduction

Added Value of Telemonitoring

Telemonitoring could broaden access to health care and offer solutions to the mounting challenges for the health care system such as an ageing population, which is creating a demand for long-term care, rising expectations from patients who are better informed about health issues, and the pressure on national health care budgets due to these demands [1-4]. Telemonitoring uses technology such as videoconferencing, email, remote electronic monitoring equipment, social network apps, and internet portals to allow monitoring and self-monitoring of health data by patients and health-related education and long-distance interventions by health care professionals (HCPs) [5-7]. Several studies have addressed the benefits of telemonitoring, for example, better access to health care and the cost-effective delivery of health care. Telemonitoring could reduce face-to-face consultations and clinic visits. In addition, telemonitoring improves the quality of care and clinical outcomes through continuous and reliable monitoring of data, immediate assessment, triage, and interventions. Telemonitoring could also improve patient empowerment, self-management, and compliance [4,8-16].

Implementation of Telemonitoring

Implementation and actual use of telemonitoring in daily practice require well-thought-out action plans, for example, for selecting appropriate interventions or for tailoring the design to the needs of the user group. In addition, telemonitoring should be seamlessly integrated into the health care processes and should avoid disrupting the HCPs' existing workflow. It was also recommended that telemonitoring should be part of "blended care" as both patients and HCPs prefer face-to-face encounters [17,18]. Implementation programs for telemonitoring should tackle barriers to actual use. Some studies found barriers that are related to "users" of telemonitoring such as lack of digital skills, resistance to change, and lack of direct personal benefit. Mentioned examples of barriers that were related to the context were lack of privacy (or fear of it), security, patient safety, a properly working internet connection, proper technological infrastructure, regulations, funding, and task allocation [4,19].

Telemonitoring in the Netherlands

In the Netherlands, an enabling factor related to the context of telemonitoring is the availability of 4G mobile networks and high-speed broadband Internet access, even in rural areas [20]. Currently, 90% of Dutch people use the internet daily. In particular, over the last 5 years, older people, the less well-educated, those born outside the country, and low-income households have caught up [21]. In terms of policy, several national documents, studies, and guidelines for eHealth have been developed during the last 10 years addressing privacy and patient safety in the use of eHealth [22,23]. In 2012, the Dutch National Implementation Agenda for eHealth was launched, followed by the eHealth Governance Covenant 2014 - 2019 [24] and a framework on the use of eHealth by HCPs [23]. As regards funding, telemonitoring is covered by the Dutch health insurance system; in particular, the funding of follow-up consultations improved in 2019. Still, HCPs do not have the funds to upscale telemonitoring [25].

Annual Nationwide Representative Study Among Health Care Professionals

Since 2013, the nationwide uptake of eHealth in general by patients and HCPs has been investigated annually and reported in what is known as the "eHealth-monitor." This investigation was commissioned by the Dutch Ministry of Health, Welfare and Sport. The aim of the annual eHealth-monitor was to investigate the implementation of eHealth and to boost its implementation in subsequent health care policy. Every year, about 30 questions addressed topics on the use of eHealth and experiences with it, including telemonitoring. The findings from the perspectives of nurses, general practitioners (GPs), medical specialists, and patients with a chronic disease increased the understanding of the implementation of telemonitoring and the uptake of telemonitoring in daily practice. To our knowledge, our study is the first scientific paper on the nationwide uptake of telemonitoring for all patient groups in chronic care over a long period of time. We analyzed data on the actual use of telemonitoring by patients and HCPs in daily chronic care. In addition, opinions on and experiences with telemonitoring were analyzed.

Methods

Study Design

Since 2013, data for the eHealth-monitor has been collected annually using various nationwide panels. Written and online questionnaires on eHealth were sent to GPs, medical specialists, nurses (practice nurses and practice assistants working in elderly care, GP care, and hospital care), and people with chronic diseases. All participants were approached in March. Nonresponders initially received 1 written or 2 online reminders. For this study, data from respondents on questions about telemonitoring between 2014 and 2019 were used.

Study Population

People with chronic diseases may be included in the representative National Panel of people with Chronic illness or Disability (NPCD) [26]. Inclusion criteria for the NPCD are age 15 or older, diagnosed with a somatic chronic disease, aware of the diagnosis, having a life expectancy of more than 6 months, mentally capable of participating, and not permanently institutionalized. Every year, 500 new panel members are selected to replace panel members who have withdrawn or who have participated for 4 years. The questions on telemonitoring were posed in 2015, 2017, and 2019.

RenderX

Nurses are participants in a representative nursing staff panel. The nursing staff panel consists of a nationwide group of nursing staff members (nurses, caregivers, and practice assistants) in various health care settings who deliver direct patient care. The recruitment of members of the nursing staff panel takes place through a random sample of two pension funds. Together, these pension funds register all employees in the Dutch health care sector. Nursing staff were asked to participate in health care research for various purposes. People who agreed and who delivered direct nursing care to patients could join the nursing staff panel. The questions on telemonitoring were asked annually, from 2014 until 2019. For this study, the data of nurses working in primary care, secondary care, and elderly care were used. For 2014 until 2016, the data of nurses working in the curative sectors (practice nurses and nurses working in hospital care) were taken together. From 2017 onwards, these sectors were split into two samples.

General practitioners and medical specialists are participants in a representative doctor's panel. Included are all registered GPs and medical specialists of the Royal Dutch Medical Association. Inclusion criteria for participating in the eHealth-monitor were practicing in the past year and being involved in the diagnosis or treatment of patients. From these doctors, certain specializations were excluded: public and occupational health, forensic medicine, addiction medicine, and psychiatry. The questions on telemonitoring were asked annually, from 2014 until 2019.

Questionnaires

All participants were asked about their use of telemonitoring and experience with its advantages and disadvantages in the previous 12 months. In addition, HCPs were asked for which portion of patients telemonitoring was used and for which patient groups relevant (Textbox 1).

XSL•FO
RenderX

Textbox 1. Questionnaires.

Telemonitoring: Remote monitoring of a patient, in which they measure their own health values (for example, blood pressure, blood sugar level) using a meter, sensor, or other device in the home situation and in which they could also respond to some questions. The HCP receives these data digitally.

People with chronic diseases who measure health values themselves

- Which of the following statements apply to you? (multiple answers possible)
- I electronically submit my self-measured health values to my health care provider (eg, by email or automatically via computer or mobile app) (2015, 2017, 2019)
- My health care provider can see my health data on a website or in a mobile app (2015, 2017, 2019)
- My health care provider looks at my self-measured health data before or during a consultation and discusses it with me (2015, 2017, 2019)
- My health care provider keeps an eye on my self-measured health data remotely and contacts me if anything is wrong (2015, 2017, 2019)
- Can you say how desirable or necessary telemonitoring is for you? (2017)
- Could you please answer the following statements? (2019) I notice or think that telemonitoring...
  - ...makes it easier for me to live at home longer and/or more easily
  - ...takes a lot of effort for me
  - ...improves my care
  - ...makes me very tense

Nurses

- Has telemonitoring been used in your organization in the past year? (2014-2019)
- If so, what proportion of your clients/patients use telemonitoring (estimated)? (2016, 2017, 2019)
- If so, what proportion of your clients do you think telemonitoring makes sense for (estimated)? (2019)
- What advantages and disadvantages do you experience with telemonitoring or expect from it? (multiple answers possible) (2019)

General practitioners

- Could you state whether telemonitoring is applied to the following patient groups (in your practice)? If telemonitoring is not applied, could you please state whether there are plans to start within a year and whether you would like to do so? (2014-2017)
- In your practice, some of your patients with diabetes are currently being monitored by telemonitoring. Could you please estimate the proportion of your diabetes patients for whom you think telemonitoring is sensible? What proportion of your diabetes patients do use it? (2015-2017)
- Is telemonitoring of patients relevant to you or your practice, and is it used within your practice for some or all of the patients? (2019)
- Could you estimate the size of the group of patients for whom you think telemonitoring is sensible and for whom you or other HCPs actually use it in your practice? (2019)
- What advantages and disadvantages do you experience with telemonitoring or expect from it? (multiple answers possible) (2019)

Medical specialists

- Is telemonitoring of patients relevant to your medical specialty, and is it applied by your department for some or all patients? (2014-2017, 2019)
- For which group of your patients is telemonitoring relevant? (2015-2017)
- Could you estimate the size of the group of patients for whom you think telemonitoring is sensible and for whom you or other HCPs actually use it at your department? (2015-2017, 2019)
- What advantages and disadvantages do you experience with telemonitoring or expect from it? (multiple answers possible) (2019)

Data Analysis

Descriptive analyses were conducted to study the use and experiences of telemonitoring. Data from the questionnaires among people with a chronic disease and nursing staff were analyzed using Stata, version 15.0 (StataCorp). The results from the questionnaires among GPs and medical specialists were analyzed using SPSS, version 25.0 (IBM Corp).

For questions asked to people with chronic diseases, the descriptive analyses were weighted for age and gender in such a way that it resembled the distribution of age and gender within the Dutch population from age 18 years, based on data from Statistics Netherlands. We applied a weighting factor ranging from 0.65 to 2.28. The samples for nurses and GPs are fairly representative of the Dutch population of nurses and GPs regarding gender, but the response is not representative for age: GPs younger than 35 years and GPs and nurses 50 years and

XSL•FO
RenderX

older responded more often. Nevertheless, we did not use a weight factor to correct for this because applying the weight factor did not affect the results. For questions asked to medical specialists, the descriptive analyses were weighted for type of specialty. We applied a weighting factor ranging from 0.5 to 1.7.

Results

Participants

Over the years, data were used from 485-633 people with a chronic disease, 322-607 nurses working in elderly care, 220-367 nurses working in the curative disciplines (primary and secondary care), 225-396 GPs, and 184-386 medical specialists who answered questions about telemonitoring (Table 1). The mean age of people with chronic disease was 64.5 to 66.4 years. The mean age of nurses varied from 46.7 to 52.2 years. The mean ages of GPs and medical specialists ranged from 50.0 to 52.6 years and 49.4 to 53.9 years, respectively. Approximately half of the people with chronic disease and the doctors were men; among nurses, only 3.5% (21/607) to 16.1% (25/155) were men.

[a]Among general practitioners and medical specialists, the questions in 2015, 2016, and 2017 were different from those in 2019.

[b]Not available.

[c]Question was only asked to persons who measured health outcomes by themselves.

[d]Weighted by type of specialty.

Actual Use of Telemonitoring

In 2019, 5.8% (28/485) of people with a chronic disease stated that their HCP monitors the health values remotely and contacts them if anything looks wrong (Table 2). In 2015, this figure was 3.3% (20/604). Most of them had been diagnosed with cardiovascular disease or diabetes. In 2019, 38.0% (78/205) of nurses working in secondary care and 40.4% (44/109) in primary care stated that their organization uses telemonitoring. In 2014, this percentage was 34.0% (89/262) for nurses working in the curative disciplines (both hospital and general practice nurses). Among nurses working in elderly care this was 8.9% (29/325) in 2019 and 11.3% (46/408) in 2014. In addition, 18.2% (41/225)of GPs and 19.6% (36/184)of medical specialists stated that telemonitoring was used in their organizations in 2019. These percentages were 17.0% and 11.2%, respectively, in 2014. Among medical specialists, this number has grown significantly over the years (χ^2_4=12.3, P=.02). Up to 10% of the targeted

XSL•FO
RenderX

patient group, including people with diabetes, is reckoned to be suitable for using telemonitoring.

Table 2. Proportions of patients and health care professionals (HCPs) using telemonitoring, from 2014 to 2019.

Population using telemonitoring	2014	2015	2016	2017	2018	2019
Patients with a chronic disease, n (%)[a]	—[b]	20 (3.3)	—	37 (5.8)	—	28 (5.8)
Elderly care						
Nurses, n (%)[c]	46 (11.3)	70 (11.5)	—	—	—	29 (8.9)

[a]The proportion of responding patients stating they are monitored on self-reported health measures by HCP (remotely).

[b]Not available.

[c]The proportion of responding HCPs stating that telemonitoring is relevant or is used at their department, practice, or organization. Difference between years (χ^2_4=12.3; *P*=.02).

[d]Proportion of patients using telemonitoring according to the HCPs; possible answers: none, up to 10%, up to 20%, up to 50%, up to 100%, I don't know.

[e]The most often mentioned were these groups: diabetes, heart failure, chronic obstructive pulmonary disease, and asthma.

Advantages and Disadvantages of Telemonitoring

Of patients with a chronic disease, 40.4% (421/1043) agreed or totally agreed with the statement "telemonitoring improves my comfort" (353/1043, 33.8% answered "don't know"). In addition, 31.9% (334/1047) agreed or totally agreed with "telemonitoring lets me stay at home longer and/or live more comfortably" (405/1050, 38.7% answered "don't know") (Table 3).

On the other hand, 7.7% agreed or totally agreed with "telemonitoring takes me a lot of effort" (36.4% answered "don't know"). Among HCPs, the most widely experienced or expected advantage of telemonitoring mentioned was "telemonitoring improves patients' self-management" (57/71, 80.3% of nurses working in primary care; 71/124, 57.3% of nurses working in secondary care; 84/134, 62.7% of nurses working in elderly care; 135/225, 60% of GPs; 63/176, 35.8% of medical specialists) (Table 4). In addition, 59.2% (42/71) of nurses working in primary care and 46.8% (58/124) of nurses working in secondary care stated that their experience or expectation of telemonitoring was that they would get a better understanding of the health condition of the patient. Of nurses working in elderly care, 39.6% (53/134) experienced or expected telemonitoring to reduce the workload. Moreover, 42.2% (95/225) of GPs said that telemonitoring let them tailor the care plan to the situation of their patients better. Of medical specialists, 34.7% (61/176) expected or had observed that telemonitoring gave them spare time for patients and caregivers/relatives.

RenderX

Table 3. Opinions of telemonitoring from patients with chronic diseases (n=1023-1050), 2019.

I notice or think that telemonitoring:	Agreement with statement, n (%)					
	Totally disagree	Disagree	Neither agree nor disagree	Agree	Totally agree	I don't know
Lets me live at home longer and/or more easily (n=1047)	47 (4.5)	62 (5.9)	199 (19.0)	235 (22.4)	99 (9.5)	405 (38.7)
Improves my comfort (n=1043)	42 (4.0)	50 (4.8)	177 (17.0)	331 (31.7)	90 (8.6)	353 (33.8)
Takes me a lot of effort (n=1023)	83 (8.1)	249 (24.3)	246 (24.0)	61 (6.0)	12 (1.2)	372 (36.4)
Improves my care (n=1035)	41 (4.0)	66 (6.4)	234 (22.6)	241 (23.3)	82 (7.9)	371 (35.8)
Makes me very tense (n=1027)	104 (10.1)	220 (21.4)	238 (23.2)	77 (7.5)	17 (1.7)	371 (36.1)

Table 4. Experienced or expected advantages and disadvantages of telemonitoring assessed by health care providers, 2019.

Characteristic	Nurses, primary care	Nurses, secondary care	Nurses, elderly care	General practitioners	Medical specialists
Advantages respondents, n	71	124	134	225	176
Advantages, n (%)[a]					
It reduces the workload	10 (14.1)	23 (18.5)	53 (39.6)	16 (7.1)	14 (8.0)
It reduces the workload of my assistants	—[b]	—	—	56 (24.9)	18 (10.2)
It saves time for patients and or caregivers/relatives	32 (45.1)	58 (46.8)	45 (33.6)	86 (38.2)	61 (34.7)
It improves the quality of care in my organization	34 (47.9)	50 (40.3)	38 (28.4)	77 (34.2)	44 (25.0)
It improves the self-management of the patient	57 (80.3)	71 (57.3)	84 (62.7)	135 (60.0)	63 (35.8)
I have a better understanding of my clients' health condition	42 (59.2)	58 (46.8)	43 (32.1)	77 (34.2)	47 (26.7)
It lets me tailor the care plan better to my patients' situation	38 (53.5)	47 (37.9)	32 (23.9)	95 (42.2)	45 (25.6)
It lets patients ask for help in time	20 (28.2)	52 (41.9)	38 (28.4)	67 (29.8)	32 (18.2)
Other advantages	—	7 (5.6)	3 (2.2)	9 (4.0)	5 (2.8)
I do not expect or experience any advantages	—	9 (7.3)	23 (17.2)	32 (14.2)	48 (27.3)
Disadvantages respondents, n	68	113	130	225	181
Disadvantages, n (%)[a]					
It takes me a lot of time to monitor/check health values	32 (47.1)	21 (18.6)	13 (10.0)	108 (48.0)	56 (30.9)
It takes me a lot of time to follow up notifications	29 (42.6)	19 (16.8)	15 (11.5)	117 (52.0)	51 (28.2)
It takes a lot of time for my assistants	—	—	—	99 (44.0)	45 (24.9)
It ensures that patients and/or relatives contact me more often	20 (29.4)	22 (19.5)	21 (16.2)	83 (36.9)	40 (22.1)
It worries patients and/or relatives	10 (14.7)	20 (17.7)	23 (17.7)	81 (36.0)	33 (18.2)
I find it difficult to work with it	—	—	—	16 (7.1)	7 (3.9)
The system provides unreliable data	—	—	—	52 (23.1)	33 (18.2)
The application is not secure	—	—	—	20 (8.9)	7 (3.9)
I find it difficult to estimate which patients can work with it	15 (22.1)	22 (19.5)	37 (28.5)	94 (41.8)	52 (28.7)
Other disadvantages	8 (11.8)	7 (6.2)	8 (6.2)	18 (8.0)	20 (11.0)
I do not expect or experience any disadvantages	13 (19.1)	49 (43.4)	56 (43.1)	13 (5.8)	33 (18.2)

[a]Multiple answers possible.

[b]Not available.

A total of 43.4% (49/113) of nurses working in secondary care and 43.1% (56/130) of nurses working in elderly care did not expect or experience any disadvantages of telemonitoring. In contrast, 47.1% (32/68) of nurses working in primary care

XSL•FO
RenderX

expected or noted that telemonitoring takes a lot of time to monitor and check health values. Of GPs and medical specialists, 48.0% (108/225) and 30.9% (56/181), respectively, expected or experienced this. In addition, 42.6% (29/68) of nurses working in primary care, 52.0% (117/225) of GPs, and 28.2% (51/181) of medical specialists expected or experienced that using telemonitoring would take up a lot of time following up on alerts. Moreover, 19.5% (22/113) of nurses working in secondary care, 28.5% (37/130) of the nurses working in elderly care, and 28.7% (52/181) of medical specialists expected or experienced difficulties in estimating which patients could handle telemonitoring.

Discussion

Principal Findings

Our study adds new insights to current scientific studies of telemonitoring, as it investigated the actual nationwide uptake of telemonitoring for all patient groups in chronic care over a long period of time (before the COVID-19 pandemic). Findings from the perspectives of nurses, GPs, medical specialists, and patients with chronic diseases can assist the implementation of telemonitoring and the uptake of telemonitoring in daily practice. The current COVID-19 pandemic has called for rapid implementation of telemonitoring for acute and subacute diseases in 2020. Future editions of the Dutch eHealth-monitor might present the impact of COVID-19 on a rising uptake of telemonitoring [27] and on new opinions and experiences with telemonitoring. Strengths of our study include the large sample size, the external validity and reliability of the data, and the representativeness of the various groups of participants (people with chronic diseases, nurses, GPs, and medical specialists). Nevertheless, there are also some limitations. Due to the specific factors in the Netherlands that boosted the implementation of telemonitoring, our study results can only partly be extrapolated to other countries. In addition, the use of telemonitoring was only investigated by asking potential users in health care; we did not investigate data from other resources such as health care insurers or telehealth companies. As well, our quantitative approach is best suited to answering "what," "when," and "who" questions and less well-suited to "how" and "why" questions. The opinions and experiences with telemonitoring that we investigated therefore do not fully explain the factors concerning the implementation and uptake of telemonitoring. Even so, our results concerning the experiences of HCPs are underlined by qualitative studies [28-30]. Other benefits and barriers found are "an increased feeling of safety" and "insufficient familiarity with the technology" [28-30]. In addition, HCPs need to add telemonitoring to the health care process, with a precise description of the target group, task allocation for data monitoring, and support for patients from within the team [31,32].

Conclusion

The uptake of telemonitoring in Dutch chronic care remained stable during 2014-2019 but increased among medical specialists. According to both patients and professionals, telemonitoring improves the quality of life and quality of care. Skills for appropriately including eligible patients and allocating the tasks of data monitoring and follow-up care within the team would help to further increase the use of telemonitoring.

Acknowledgments

The project was funded by the Dutch Ministry of Health, Welfare and Sport. The Dutch Ministry of Health, Welfare and Sport had no role in the collection, analysis, or interpretation of data or in writing the manuscript. The authors would like to acknowledge all other people who were involved in data collection during 2013-2019; in particular, Johan Krijgsman, Ilse Swinkels, Judith de Jong, Janke de Groot, Anne Brabers, Lies van Gennip, Karlijn de Bruin, and Annemarie Lamain. In addition, the authors would like to thank the members of the advisory committee in 2019: Guus Schrijvers, Christine Aberson-Blok, Arina Burghouts, Jeroen Crasborn, Henny Mulders, Henk Herman Nap, Sjaak Nouwt, Renée Verwey, Karin Zwager-Ankone, and Nienke Zwennes.

Authors' Contributions

MWJH and HRVP were the main contributors in data analysis and in writing the manuscript. MW, MWJH, BvL, CK, and RDF were involved in developing the questionnaires. All authors were involved in the process of data management. MWJH, HRVP, MMM, MW, and BvL were involved in the data analysis. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Patients with peripheral artery disease (PAD) are at high risk for major cardiovascular events, including myocardial infarction, stroke, and hospitalization for heart failure. We have previously shown the clinical efficacy of a fourth-generation synchronous telehealth program for some patients, but the costs and cardiovascular benefits of the program for PAD patients remain unknown.

Objective: The telehealth program is now widely used by higher-risk cardiovascular patients to prevent further cardiovascular events. This study investigated whether patients with PAD would also have better cardiovascular outcomes after participating in the fourth-generation synchronous telehealth program.

Methods: This was a retrospective cohort study. We screened 5062 patients with cardiovascular diseases who were treated at National Taiwan University Hospital and then enrolled 391 patients with a diagnosis of PAD. Of these patients, 162 took part in the telehealth program, while 229 did not and thus served as control patients. Inverse probability of treatment weighting (IPTW) based on the propensity score was used to mitigate possible selection bias. Follow-up outcomes included heart failure hospitalization, acute coronary syndrome, stroke, and all-cause readmission during the 1-year follow-up period and through the last follow-up.

Results: The mean follow-up duration was 3.1 (SD 1.8) years for the patients who participated in the telehealth program and 3.2 (SD 1.8) for the control group. The telehealth program patients exhibited lower risk of ischemic stroke than did the control group in the first year after IPTW (0.9% vs 3.5%; hazard ratio [HR] 0.24; 95% CI 0.07-0.80). The 1-year composite endpoint of vascular accident, including acute coronary syndrome and stroke, was also significantly lower in the telehealth program group after IPTW (2.4% vs 5.2%; HR 0.46; 95% CI 0.21-0.997). At the end of the follow-up, the telehealth program group continued to exhibit a significantly lower rate of ischemic stroke than did the control group after IPTW (0.9% vs 3.5%; HR 0.52, 95% CI 0.28-0.93). Furthermore, the medical costs of the telehealth program patients were not higher than those of the control group, whether in terms of outpatient, emergency department, hospitalization, or total costs.

XSL•FO
RenderX

Conclusions: The PAD patients who participated in the fourth-generation synchronous telehealth program exhibited lower risk of ischemic stroke events over both mid- and long-term follow-up periods. However, larger-scale and prospective randomized clinical trials are needed to confirm our findings.

Introduction

Cardiovascular (CV) diseases remain the biggest health burden worldwide [1]. Telemedicine can be used to monitor diseases and treat patients in real time. Previous studies have shown that patients with CV diseases who received telehealth medicine had better control over vascular risk factors, such as hypertension, diabetes mellitus, and dyslipidemia [2]. Furthermore, both Spyros et al [3] and Sally et al [4] reported that telemedicine was an important prognostic factor for patients with congestive heart failure in reducing all-cause mortality Relatedly, we have shown that a fourth-generation telehealth program—more specifically, an internet-based, synchronized disease management program that provides an immediate response—is associated with lower all-cause mortality among patients with CV as compared to that seen in patients who did not participate in the program [5]. However, Takahashi et al [6] found that asynchronous telemonitoring did not lead to fewer hospitalizations or emergency department visits. Meanwhile, a review article suggested that telemedicine should be carefully evaluated and applied in only those patients who would really benefit from it in terms of improved clinical outcomes [7].

Patients with peripheral artery disease (PAD) have relatively high rates of various comorbidities, including acute coronary syndrome (ACS), stroke, and congestive heart failure [8-10]. Numerous cohort studies have reported that the clinical outcomes of PAD patients are grave, with the rates of major adverse CV events and mortality being higher among PAD patients than among the general population. Moreover, PAD is an independent risk factor for mortality in patients with CV diseases [11]. Current guidelines advocate the use of antiplatelet agents and statins as primary therapies for these patients to prevent further major adverse cardiovascular events, because they are at high risk of CV events [11,12]. Therefore, it is important to treat PAD patients using innovative modalities to improve their overall prognosis. New treatment strategies that offer better CV outcomes for these patients are needed in the internet era. The costs and CV benefits of the fourth-generation synchronous telehealth program for these patients remain unknown.

The aims of this study were to elucidate the effects of the fourth-generation synchronous telehealth program for PAD patients on their CV outcomes, including stroke, ACS, and hospitalization for heart failure; and to evaluate the medical costs for these patients, including those who are treated at outpatient clinics and emergency departments or who are hospitalized.

Methods

Study Design

This was a retrospective cohort study in which data from a tertiary hospital in Taiwan was analyzed. This study was approved by the Institutional Review Board of National Taiwan University Hospital (NTUH), Taipei, Taiwan. All protocols were performed in accordance with relevant guidelines and regulations.

Patient Selection

Patients older than 20 years diagnosed with chronic CV diseases were screened at NTUH. Chronic CV diseases included coronary artery disease, myocardial infarction, heart failure, PAD, stroke, and hypertension. The patients with PAD were further selected for this study, with the PAD patients who participated in the fourth-generation synchronous telehealth program at the telehealth center of NTUH being enrolled as the study group. The patients with PAD who received usual care were enrolled as the control group. The decision of whether to participate in the telehealth program depended on the patients and/or their caregivers.

Telehealth Care Program

The fourth-generation synchronous telehealth program at our center is an integrated remote management program for chronic diseases. The internet-based platform was developed by the Graduate Institute of Biomedical Electronics and Bioinformatics, National Taiwan University, Taiwan. The details of this program have been reported previously [13]. Briefly, this telehealth program provides the following services: the collection of biometric data including single-lead electrocardiography, blood pressure, heart rate, and oximetry data, which are transferred from patients to our telehealth center daily and on demand; daily and on-demand telephone calls from nurse case managers for communication and health promotion; care and guidance from full-time nurse case managers and cardiologists who are in charge of care 24 hours per day; and long-term medication services and care management, which are discussed with the patients' primary care physician after acute events. The telehealth program bridges acute and home care and emphasizes education, prevention, and the early detection of clinical deterioration.

Usual Care

The patients in the control group received the usual care provided by the primary care physicians at our CV center according to updated guidelines including, but not limited to, the American Heart Association's guidelines for lifestyle

XSL•FO
RenderX

modification and primary prevention to reduce CV risks, guidelines for the management of stable ischemic heart disease, and the American Diabetes Association's guidelines for the management of diabetes. These patients made routine outpatient department visits (once every 3 months) to their primary care physicians. There was no contact between the telehealth center and the patients receiving usual care.

Covariates and Outcomes

The covariates were demographics (age, sex, and BMI), 10 comorbidities (hypertension, diabetes mellitus, hyperlipidemia, coronary artery disease, chronic kidney disease, myocardial infarction, stroke, heart failure, atrial fibrillation, and cancer), Charlson Comorbidity Index score, vital signs and laboratory data (mean arterial pressure, pulse rate, creatinine, and low-density lipoprotein-cholesterol), and the kinds of medication used at the time of enrollment. The outcomes were all-cause readmission, heart failure hospitalization, ACS, stroke, and the composite of ACS and stroke during follow-up. Each outcome was defined according to whether the patient was admitted with a principal discharge diagnosis during hospitalization.

Statistical Analysis

To reduce possible potential confounding when comparing the risk of outcomes between the telehealth and control groups, we employed an inverse probability of treatment weighting (IPTW) based on the propensity score [14]. The propensity score was estimated using a multivariable logistic regression model without consideration to interaction effects among the covariates, with the study group (1=telehealth, 0=control) being regressed on the selected covariates listed in Table 1 and the follow-up duration being replaced with the index date. We used the weight to estimate the average treatment effect and used a stabilized weight to mitigate the impact of extreme estimated propensity scores [15]. The balance of covariates between the groups before and after IPTW was checked using the absolute value of standardized difference between the groups, where a value less than 0.1 was considered a negligible difference [16].

The incidence of outcomes during follow-up was calculated using the incidence density ID expressed as number of events per 100 person-years. The absolute risk difference between the groups was also calculated in the IPTW-adjusted cohort. Furthermore, we compared the risk of outcomes during follow-up between the groups using the Cox proportional hazards model. The outcomes were assessed during the 1-year follow-up period, during the entire follow-up period, and before and after the 1-year follow-up period (landmark by 1 year). The average number of all-cause readmissions during follow-up between groups was compared between the groups using a Poisson model which treated the logarithm of follow-up duration as an offset variable. The accumulated medical expenditures during follow-up was compared between the groups using a linear regression model. The study group was the only explanatory factor in the aforementioned regression models. A 2-sided P value <.05 was considered statistically significant, and no adjustment of multiple testing (multiplicity) was made. All statistical analyses were performed using SAS version 9.4 (SAS Institute).

Results

Patient Demographics and Clinical Features

A total of 5062 patients were screened in this study, and 391 patients with PAD diagnosis were further selected into the telehealth and control group (Figure 1). The baseline characteristics of those patients are reported in Table 1. In the telehealth groups, the mean age was 70.8 (SD 12.5) years, and 63.6% (103/162) of the patients were male. In the control group, the mean age was 70.0 (SD 12.7) years, and 61.6% (141/229) of the patients were male. The telehealth group had more patients with stroke (53/162, 32.7% vs 65/229, 28.4%, in the telehealth group vs control group, respectively), chronic kidney disease (49/162, 30.2% vs 60/229, 26.2%), coronary artery disease (108/162, 66.7% v. 145/229, 63.3%), and hyperlipidemia (76/162, 46.9% vs 100/229, 43.7%). The Charlson Comorbidity Index score was higher in the telehealth group (mean 3.1, SD 2.0) than in the control group (mean 3.0, SD 2.1). The mean follow-up time was 3.1 (SD 1.8) years for the telehealth group and 3.2 (SD 1.8) years for the control group. After propensity score weighting, the 2 study groups were found to have well-balanced characteristics (Table 1).

Figure 1. Flow chart of enrolled patients. ACS: acute coronary syndrome; CV: cardiovascular: f/u: follow-up; HHF: hospitalization for heart failure; IPTW: inverse probability of treatment weighting; PAD: peripheral artery disease.

Prognosis of Patients With PAD Participating in the Telehealth Program

During the 1-year follow-up period, 2 of the 162 (1.2%) patients in telehealth group and 8 of the 229 (3.5%) patients in the control group had stroke, respectively. The 1-year stroke rate was significantly lower in the telehealth group (0.9 vs 3.5 events per 100 person-years; hazard ratio [HR] 0.24; 95% CI 0.07-0.80) after IPTW. The incidence of composite vascular outcome in the telehealth cohort was also lower than that in the control cohort after IPTW (2.7 vs 5.8 events per 100 person-years; HR 0.46; 95% CI 0.21-0.997). However, no significant differences between the 2 were observed in terms of all-cause readmission, heart failure hospitalization, or ACS in the 1-year follow-up period. At the end of the follow-up period, only the stroke rate was significantly lower in the telehealth group (1.4 vs 2.6 events per 1000 person-years; HR 0.52; 95% CI 0.28-0.93) after IPTW (Table 2 and Multimedia Appendix 1).

Landmark Analysis by 1-Year Follow-Up

The fitted (predicted) survival curve of stroke during the overall follow-up period was significantly lower in the telehealth group than in the control group (Figure 2A). The 2 curves remained significantly different during the 1-year follow-up period (HR 0.24; 95% CI 0.07-0.80) but were not significantly different afterwards (HR 0.73; 95% CI 0.35-1.50; Figure 2B). Similarly, the fitted (predicted) survival curve for composite vascular outcome (including acute coronary syndrome and stroke) during the overall follow-up period was not significantly lower in the telehealth group than in the control group (Figure 3A). The 2 curves were only significantly different in the 1-year follow-up after being stratified by 1-year follow-up (HR 0.46; 95% CI 0.21-0.997; Figure 3B).

Figure 3. Fitted (predicted) survival curves of composite arterial cardiovascular outcome during the overall follow-up (A) and stratified by 1-year follow-up (B) in patients who participated in the telemedicine program and who did not participate the telemedicine program.

Medical Utilization and Costs for Patients Participating in the Telehealth Program

The PAD patients in both the telehealth group and the control group had similar readmission times (mean 1.6, SD 2.0 vs mean 1.7, SD 2.2; rate ratio 1.08; 95% CI 0.97-1.20). Furthermore, no significant differences in medical expenditures between the 2 groups were observed in terms of outpatient, emergency department, hospitalization, or total costs during the whole course of follow-up (Table 3 and Multimedia Appendix 1).

Incidence Rate of All Outcomes in Patients Who Participated in the Telehealth Program

The absolute risk difference in the incidence (expressed as number of events per 100 person-years) of stroke and arterial vascular composite outcome was –2.99 (95% CI –5.29 to –0.68) and –3.14 (95% CI –6.19 to –0.09), respectively, at the 1-year follow-up. At the end of the follow-up period, only the absolute risk difference of the incidence rate for stroke was significant (Figure 4).

Figure 4. The difference of the incidence rate (expressed as number of event per 100 person-years) of all outcomes in patients who participated in the telemedicine program and who did not participate in the inverse probability of treatment weighting–adjusted cohort. ACS: acute coronary syndrome; ARD: absolute risk difference. *Composite of ACS and stroke.

Discussion

This is the first study to investigate the application of the fourth-generation synchronous telehealth program to patients with PAD in terms of various CV outcomes. Retrospectively, we found that the PAD patients who participated in the telehealth program had lower risks of both stroke and composite vascular events in the midterm follow-up but only a lower risk of stroke events over the long-term follow-up period. The vascular protection seemed most prominent in the first year, and this phenomenon then diminished in the following years with regular CV clinic visits. In the first year, 3 out of every 100 patients in the telemedicine group were free from stroke events. Otherwise, the total medical costs were comparable in both groups.

Telehealth care has been shown to reduce hospitalizations in patients with chronic conditions such as asthma, chronic obstructive pulmonary disease, and heart failure [17-20]. We have previously reported that better cost-effectiveness and clinical outcomes were noted with the use of fourth-generation

XSL•FO
RenderX

synchronous telehealth program in patients with chronic CV diseases [13]. However, some other studies failed to show better clinical outcomes in patients taking part in telehealth programs [6,7]. This difference in the results could be explained by the enrollment of different types of patients and the implementation of different versions of telehealth programs. We previously reported that PAD was the remaining prognostic factor for CV admission in patients receiving telehealth care after multivariable Cox regression [21]. However, the costs and CV benefits of the fourth-generation synchronous telehealth program for PAD patients are still not well validated. In this study, we focused on those patients with PAD who had higher risks of grave CV outcomes such as myocardial infarction and stroke [22,23]. According to a previous study, the 5-year cumulative incidence of mortality among asymptomatic and symptomatic patients with PAD is 19% and 27%, respectively [24]. In the internet era, it is important to consider the speed of medical care responses of telehealth programs, especially with respect to high-risk patient groups. The early identification of PAD patients with optimized and comprehensive treatment is critical for improving clinical outcomes, and telehealth programs could be applied to PAD-related wound care or gangrene management in place of CV systems that provide comprehensive care [25,26]. In this study, we found that patients receiving telemedicine care had significantly lower rates of stroke events in the mid- and long-term follow-up periods than did the group that received normal care. As high blood pressure is a major cause of stroke, better control of blood pressure is essential to preventing stroke attacks. Lu et al [27] showed that the implementation of home telehealth care supervised by nursing managers improved blood pressure control in patients with high blood pressure. Furthermore, it was found that a mobile phone intervention could significantly reduce systolic blood pressure among patients with high blood pressure (mean difference of 4.3 mmHg) [28]. Digital health strategies were also found to have a beneficial effect on blood pressure control [29]. These findings suggest that the stroke prevention benefits of telemedicine may be linked to the better blood pressure control exhibited by patients using the telehealth program. On the other hand, the prevalence of carotid artery stenosis is high in patients with PAD [30]. Through good medication compliance, the early management of CV risk factors, and the prompt detection of clinical arrhythmia, full-time nursing case managers and cardiologists who provide round-the-clock care are also able to reduce the risk of stroke among those patients with PAD that have carotid artery stenosis.

In this study, we found that, in the midterm, the fourth-generation synchronous telehealth programs improved the composite vascular outcome (including acute coronary syndrome and stroke) of patients with PAD. This vascular protection was most prominent in the first year and gradually diminished over the years that followed as confirmed through the regular follow-up visits at CV clinics. The telehealth program seems to bridge the transition from hospital admission to home care. Therefore, the proper timing for initiating telehealth is just as important as the timing for taking medication. The conditions of patients with CV disease deteriorated rapidly just after their discharge [31,32]. Our study supports the notion that the optimal timing for implementing a telehealth program for patients with PAD is at the time of discharge from hospital.

Those patients with PAD who took part in the telehealth program in this study had 2.99 fewer stroke events and 1.86 fewer composite vascular events per 100 patients in the first year than did the control group patients. As the prevalence and incidence of patients with PAD is high, the number of patients needed to be treated with telehealth program can be easily achieved in clinical practice. As patients participating in telehealth programs will have to pay additional fees, the costs and benefits associated with this program should be analyzed. We found that the medical costs of the telehealth program patients in this study were not greater than those of the control group, in spite of the fact that they did have better clinical outcomes in terms of stroke and composite vascular events. This finding suggests that the participation of PAD patients in the telehealth programs can also confer economic benefits. Moreover, opportunity costs other than medical ones should also be considered. Because patients with PAD suffer from grave CV outcomes, they are more likely to lose their jobs and to pay higher insurance premiums. In the United States, individuals diagnosed with PAD face higher health care–related expenditures and out-of-pocket expenses compared to healthy adults [33]. Therefore, the total expenditure of patients with PAD and stroke is likely higher than that revealed in our study.

This study had several limitations. First, the study was not randomized, which resulted in the heterogeneity of the patient population and disease severity. However, we performed IPTW matching of 2 groups with balance to minimize the possible confounding effect of clinical factors. Second, the outcome of amputation was not coded in our cohort. In addition, although we did show the composite vascular outcome in our analysis, this outcome is particularly important in patients with PAD and should be clarified in a future study. Third, the clinical outcomes were derived from the electronic billing and medical records of our hospital, and the data for patients who received care outside of our hospital were not recorded. Resources that were used but not billed might have also been overlooked when extracting data from our billing system.

Those patients with PAD who participated in the fourth-generation telehealth program exhibited a lower risk of stroke events over both short- and long-term follow-up periods than did the control group. In addition, the total medical costs of the 2 groups were comparable, with no significant difference being found. Further randomized trials are needed, however, to confirm our findings and guide clinical practice.

Acknowledgments

We thank the staff of the Department of Medical Research, NTUH for the Integrated Medical Database. We also thank Mr Alfred Hsing-Fen Lin for his assistance with the statistical analysis during the completion of the manuscript.

Abstract

With the emergence of the COVID-19 pandemic and shortage of adequate personal protective equipment (PPE), hospitals implemented inpatient telemedicine measures to ensure operational readiness and a safe working environment for clinicians. The utility and sustainability of inpatient telemedicine initiatives need to be evaluated as the number of COVID-19 inpatients is expected to continue declining. In this viewpoint, we describe the use of a rapidly deployed inpatient telemedicine workflow at a large academic medical center and discuss the potential impact on PPE savings. In early 2020, videoconferencing software was installed on patient bedside iPads at two academic medical center teaching hospitals. An internal website allowed providers to initiate video calls with patients in any patient room with an activated iPad, including both COVID-19 and non–COVID-19 patients. Patients were encouraged to use telemedicine technology to connect with loved ones via native apps or videoconferencing software. We evaluated the use of telemedicine technology on patients' bedside iPads by monitoring traffic to the internal website. Between May 2020 and March 2021, there were a total of 1240 active users of the Video Visits website (mean 112.7, SD 49.0 connection events per month). Of these, 133 (10.7%) connections were made. Patients initiated 63 (47.4%) video calls with family or friends and sent 37 (27.8%) emails with videoconference connection instructions. Providers initiated a total of 33 (24.8%) video calls with the majority of calls initiated in August (n=22, 67%). There was a low level of adoption of inpatient telemedicine capability by providers and patients. With sufficient availability of PPE, inpatient providers did not find a frequent need to use the bedside telemedicine technology, despite a high census of patients with COVID-19. Compared to providers, patients used videoconferencing capabilities more frequently in September and October 2020. We did not find savings of PPE associated with the use of inpatient telemedicine.

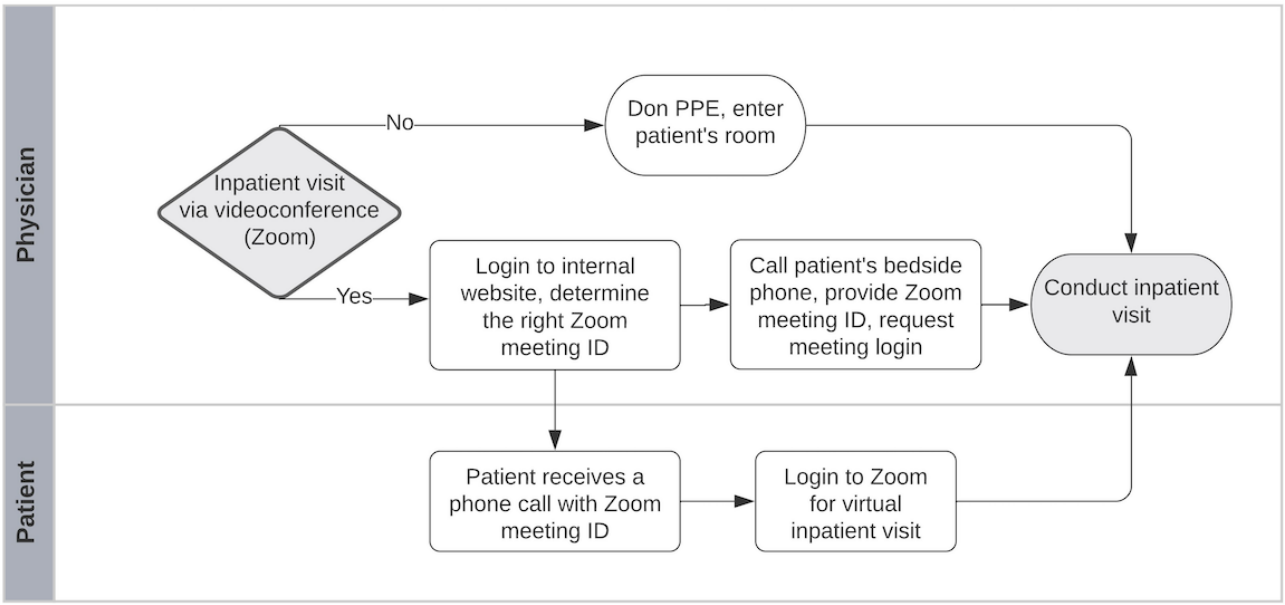
Expansion of Telemedicine and Patient iPad Program



In response to the COVID-19 pandemic, health care organizations rapidly implemented telemedicine protocols to protect health care workers and patients [1-3]. The anticipated surge in patients and shortage in personal protective equipment (PPE) were key drivers for the implementation of virtual visits and medical screening exams in the inpatient settings and emergency departments [4]. Some authors referred to the inpatient telemedicine as "electronic PPE" [4], and a few studies saw a decrease in patient contact, resulting in PPE savings [5,6]. One study among emergency department patients found telemedicine to be associated with a significant reduction in PPE use, without anticipated increase in anxiety and dissatisfaction among patients [6]. Overcoming operational barriers such as privacy, device availability, and functionality may enable organizations to conserve PPE while providing excellent patient care [7]. Although a few studies described the deployment of hospital tablets for inpatient telemedicine, the extent of long-term continuous use of this technology has not been extensively evaluated [8,9].

University of California (UC) San Diego Health is an academic medical center with multiple outpatient ambulatory sites and two hospital campuses with 808 licensed inpatient beds. Bedside iPads were implemented at one affiliated teaching hospital in 2016 followed by expansion in 2019 to include the entire inpatient population [10]. The original intent of the bedside iPads was to allow patients access to their inpatient electronic health record portal (Epic MyChart Bedside), hospitality (ordering food), comfort (controlling ambient lights and room temperature), and entertainment (streaming services) [10]. As the COVID-19 pandemic evolved and more patients required isolation precautions, hospitals limited visitations by family members. Bedside iPads, therefore, appeared to be a natural solution to connect patients with their loved ones and to conserve PPE by allowing clinicians to interact with patients remotely. The objective of this viewpoint is to describe the use of a rapidly deployed inpatient telemedicine workflow at a large academic medical center and discuss technology's potential impact on PPE use.

Inpatient Telemedicine Process Implementation

A videoconferencing tool (Zoom, Zoom Video Communications) was implemented with health care security protocols in 2019 prior to the COVID-19 pandemic. The native Zoom app was installed on all the bedside iPads to allow patients to connect with their families using video calls. Inpatient providers could also initiate Zoom calls with patients. At the beginning of the pandemic, providers could call the patient's bedside telephone to provide them with a meeting ID to join a Zoom videoconference. The patient would then join the meeting initiated by the provider (Figure 1).

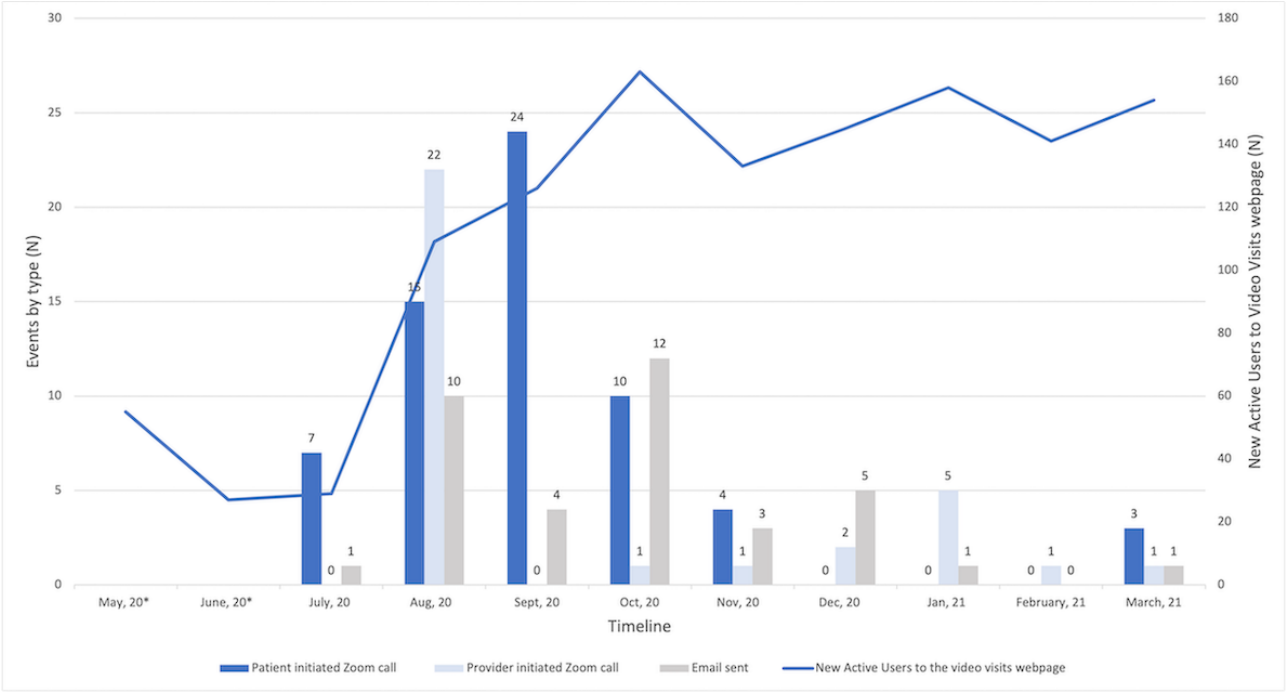
Figure 1. Process flow for inpatient video call at an academic medical center in San Diego, CA. PPE: personal protective equipment.

Although this process was adopted by many inpatient services, providers reported difficulties with retrieving telephone numbers for inpatient rooms. As a result, an internal website was created to display all available active patient iPads. From this website, providers could initiate a video call with a patient using a "Meet Now" button. The bedside iPad would then produce an audible ping alerting the patient of an incoming Zoom call. Upon discharge, the bedside iPad and Zoom ID were reset to ensure patient data privacy.

To evaluate the use of video calls in inpatient services and estimate the potential impact on PPE savings, we obtained data from the internal web server logs and Google analytics. Data from video calls to patients hospitalized for COVID-19 and other conditions were included. All available traffic data from the internal website were collected using internal servers between May and June 2020, before switching to using Google Analytics in July 2020.

XSL•FO
RenderX

We used Google Analytics to track user engagement events on patients' iPads. Engagement events included clicking on the Start Meeting, Send Email, and Meet Now links. The Start Meeting button allowed a patient to initiate a video call with their family members or a provider and was used as an indicator for a patient-initiated video call. The Send Email button allowed a patient to email video call instructions to their family members and was used as another indicator of a patient-initiated call. The Meet Now button allowed a physician to initiate a video call with a patient and was used as an indicator for provider-initiated video calls.



It was not technically feasible to track the volume of telephone calls from providers to patient rooms to determine the frequency of phone or video visits during the initial stage of Zoom implementation. It was also not feasible to track Zoom meetings conducted through the native Zoom app due to UC San Diego Health cybersecurity protocols.

We did not collect any patient identifying information and followed all data safety protocols. We relied on server and Google analytics data to determine whether patients used the bedside iPads to participate in a video call or to send an email, not the duration or content of such engagements.

Providers and Patients Underused Inpatient Telemedicine

The number of active users on the Video Visits website was determined from the internal server data for May and June 2020, and from Google Analytics for July 2020 to March 2021. There were a total of 1240 events collected from both data sources. On average, between May 2020 and March 2021, there were 112.73 (SD 49) connection events per month (Figure 2). As expected, use increased between July (n=29) and March (n=154). The lowest use was recorded in June (n=27) and the highest in October (n=163), followed by January 2021 with 158 users (Figure 2, line).

Figure 2. Users of the Video Visits webpage and engagement events (patient- and provider-initiated calls, emails), May 2020-March 2021, San Diego, CA. *The number of users of the Video Visits website was determined from the internal server data for May-June 2020 and from Google Analytics for July 2020-March 2021.

Although the number of visitors to the Video Visits site was low, the actual engagement with the system was even lower with 133 (10.7%) connections out of the total 1240 events. Of these 133 connections, patients initiated 63 (47.4%) video calls with family or friends and sent 37 (27.8%) emails with connection instructions. The highest number of calls occurred in September 2020 (n=24, 38%), and the largest number of emails were sent in October (n=12, 32%). Provider use was even lower, with providers initiating a total of 33 (52%) video calls with patients. The majority of calls were initiated in August (n=22, 67%) perhaps due to an internal awareness campaign of the available capability. Because the servers filter out automatic page refreshes, these numbers may underestimate the total number of video calls.

Inpatient Telemedicine Could Be Used to Conserve PPE

Although we implemented convenient workflows for clinicians to contact patients virtually to reduce the risk for infection, save PPE, and potentially save time to don and doff PPE, we saw minimal adoption of inpatient telemedicine. There appeared to be some seasonal variation in use, and during our study, patients initiated higher number of calls than providers (63 vs 33). The majority of our provider calls occurred in 1 month (August 2020) possibly due to an internal awareness campaign in response to a COVID-19 wave occurring at the time. Use declined to 0 to 5 calls in subsequent months, however. Our results are different from those of previous studies that found

XSL•FO
RenderX

high inpatient telemedicine use and subsequent savings of PPE [4-6,8].

No technical issues with iPads or Zoom were reported, yet the vast majority of providers saw patients in person. Inpatient physicians may prefer to see patients in person, regardless of availability and convenience of technology or potential saving of PPE. Fortunately, our academic medical center has not experienced the PPE shortages faced by our colleagues in other parts of the country [11]. As such, there was never a significant impetus to conserve PPE using all available means including inpatient telemedicine capability.

Our study had several limitations including small sample size and limited scope. Although most clinicians were comfortable with Zoom, it is possible that some were not, which would reduce technology use for inpatient visits. Patients have various comfort levels with technology, which could reduce the potential usability of inpatient telemedicine. In addition, we did not evaluate the utility of inpatient telemedicine for other health care providers such as nurses and technicians.

With the COVID-19 pandemic, telemedicine capacity was rapidly implemented in ambulatory settings [1-3]. Emergency departments also found multiple use cases for telemedicine including patient triage and expedited care for stable patients, reduced potential provider exposure to COVID-19, decreased use of PPE, reducing patient isolation, and allowing quarantined physicians to continue practicing, among others [4-6,12,13].

The utility of telemedicine in inpatient settings and its potential impact on PPE savings, however, remains to be addressed. A few studies that found inpatient telemedicine to be useful for patient care and PPE savings also reported operational barriers such as privacy and security, and limited functionality and device availability [7-9]. The availability of the technology by itself was inadequate to encourage use while PPE supplies were sufficient, and additional studies are needed to evaluate the utility of inpatient telemedicine for health care providers.

Conclusions

Similar to outpatient clinics and emergency departments, telemedicine capability could have a positive impact in inpatient settings including PPE savings. Our study found low adoption levels of inpatient telemedicine among patients and providers. Despite a high census of patients with COVID-19, our providers saw patients in person rather than relying on telemedicine. Patients' use of bedside iPads appeared to be limited for telemedicine and should continue to be evaluated to improve patient experience.

Increasing awareness of telemedicine in inpatient settings for providers and patients could help increase use for patient care. Going forward, implementation of telemedicine across all levels of care may help reduce potential provider exposure to COVID-19 and increase provider capacity.

Acknowledgments

The authors thank the UC San Diego Health Information Services Department teams for rapid implementation of inpatient telemedicine capability. Thank you to our patients and physicians who used inpatient telemedicine capability.

Authors' Contributions

LL and CAL designed the study. RH, GS, and MS obtained primary data. All authors contributed to data interpretation. RH and LL wrote the manuscript. All authors critically reviewed the manuscript for important intellectual content and approved the final manuscript.

Abstract

Background: eConsulta—that is, asynchronous, two-way teleconsultation in primary care—is one of the most important telemedicine developments in the Catalan public health system, a service that has been heavily boosted by the onset of the COVID-19 pandemic. It is vital to know the characteristics of its users in order to be able to meet their needs and understand the coverage of this service in a context where there is reduced accessibility to the health system.

Objective: This study aims to analyze the profile of the citizens who use the eConsulta tool and the reasons for their use, as well as to gain an understanding of the elements that characterize their decision to use it while distinguishing between those who used it before and those who have used it since the onset of the COVID-19 pandemic.

Methods: A descriptive, observational study based on administrative data was performed. This study differentiates between the COVID-19 pandemic era and the period preceding it, considering the day the state of emergency was declared in Spain (ie,

XSL•FO
RenderX

March 12, 2020) as the cut-off point. It also differentiates between eConsulta users who send messages and those who only receive them.

Results: During the pandemic, the number of unique users of this teleconsultation service had almost tripled, with up to 33.10 visits per 1000 inhabitants per month reported in the first three months. For the two user profiles analyzed, most users since the start of the COVID-19 outbreak were predominantly female, systematically younger, more actively employed, and with less complex pathologies. Furthermore, eConsulta users received more messages proactively from the health professionals. There was also a relative decrease in the number of conversations initiated by higher-income urban users and an increase in conversations initiated by users in rural areas.

Conclusions: The COVID-19 pandemic has helped to generalize the use of telemedicine as a tool to compensate, to some extent, for the decline in face-to-face visits, especially among younger citizens in Catalonia. Telemedicine has made it possible to maintain contact between citizens and the health care system in the context of maximum complexity.

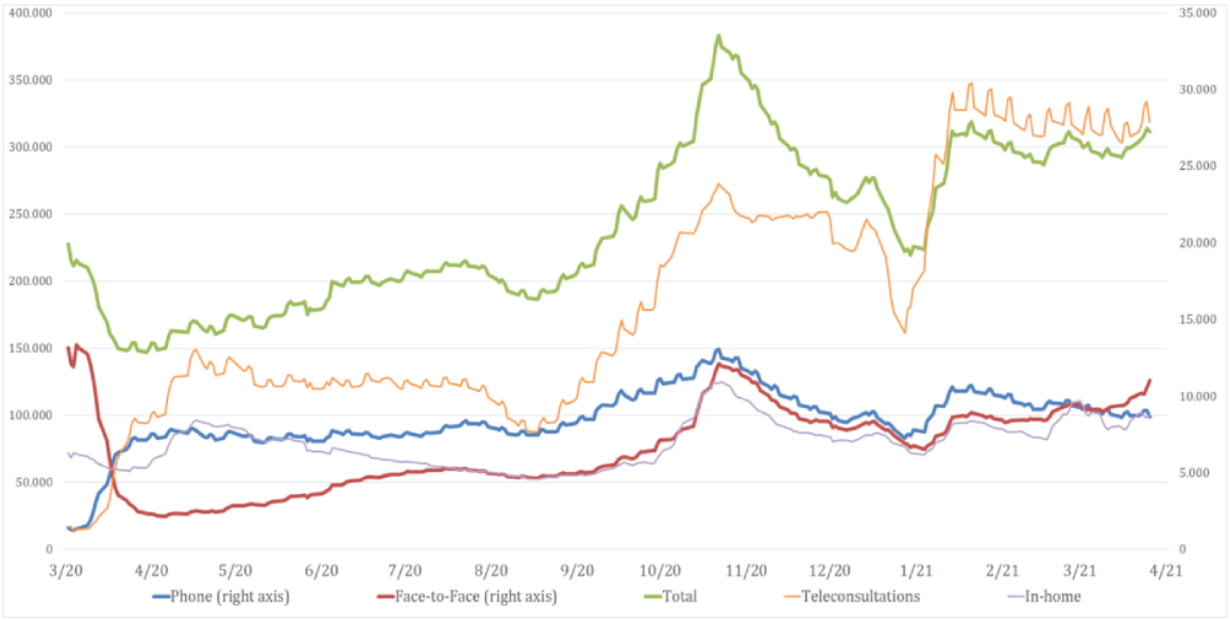
teleconsultation; primary care; remote consultation; telehealth; COVID-19; e-consultation

Introduction

The eConsulta tool, which has been in operation since 2015, is one of the most important telemedicine developments by the Catalan public health system. It is an asynchronous, two-way teleconsultation tool used by health professionals and citizens that is part of the patient portal of the public health system, a platform that also allows citizens to securely access their personal health information stored in the personal health folder and to carry out certain clinical and administrative procedures. This service was operational only in the context of primary care [1,2] until it was recently expanded to hospital care.

According to data from the Ministry of Health of Catalonia (email, March 3, 2021), from the inception of eConsulta in October 2015 up to February 22, 2021, a total of 15,569 primary care health professionals (out of about 19,000 with potential access) have carried out 4,263,665 e-consultations involving 1,061,995 citizens (out of a total population of 7.7 million. This service is a new model of care relating to health care professionals, more practical for users, and more efficient for the health system, in general [3,4]. In addition, it empowers citizens and promotes teleworking among health care professionals—an essential factor in the context of the current COVID-19 pandemic, which helps improve their work-life balance [5]. In recent years, even before the onset of the pandemic, the use of the eConsulta tool had grown significantly, among both citizens and health care professionals; however, this only represented a very small proportion in relation to the number of face-to-face visits conducted in the Catalan public primary care system [6], a situation very similar to that of other countries [7,8].



The onset of the COVID-19 pandemic and the initial need to reduce the risk of infection by preventing patients from physically visiting health centers has led to a change in the health care model that has promoted non–face-to-face care. The majority of countries have responded to this need by making significant efforts to implement both synchronous and asynchronous telemedicine approaches [9-12]. The demand for teleconsultation has considerably increased worldwide; for example, in France, the number of teleconsultations increased 50-fold during the initial weeks following the COVID-19 outbreak [13,14]. In Catalonia as well, the outbreak resulted in a very significant increase in the daily number of teleconsultations, although these numbers are well below the number of telephone consultations conducted (Figure 1).

Despite the fact that some studies question the efficiency of teleconsultations between primary care professionals and citizens [7], several studies suggest that the eConsulta tool helps to reduce the number of face-to-face visits [4,6], which may be one of the drivers of its growing use among users. With regard to the health care professionals that use eConsulta, a previous analysis found that doctors who use eConsulta are typically in the 45-64 years age group, score higher than the 80th percentile on the Quality of Care Index, have a high degree of accessibility, are involved in teaching, and work as part of a health team in a high socioeconomic urban setting [15]. With regard to eConsulta users, it is vital to analyze their characteristics in order to provide a service that is appropriate and adjusted to their needs and to also understand who is being covered by this service (and who is not) during the COVID-19 pandemic. Previous studies have shown that women use web-based consultations more frequently than men (64.7% vs 35.3%) and their average age is 39 years [7]. On the contrary, other studies have found that men send email communication for health care more often than women [16]. In Catalonia, however, there is no evidence to determine the profile of a typical citizen or their use of the eConsulta tool.

Thus, the aim of this study is to offer a descriptive analysis of the use of the eConsulta tool before and during the COVID-19 pandemic and the profile of the citizens who use it in order to gain a more comprehensive understanding of the elements that characterize their decision to use the tool and assess who is being covered through this service in a context of low accessibility to the health system.

Figure 1. Primary care daily visits in the Catalonia region of Spain, classified by type with 7-day moving average excluding weekends and public holidays (March 2020 to April 2021). Source: Primary Care Services Information Systems, Institut Català de la Salut, Barcelona, Spain (SISAP) [7].

Methods

This is a descriptive, observational study based on administrative data sourced from the Catalan Health Institute (ICS), the main provider of primary care services in the Catalonia region, serving 74% of the Catalan population. The analysis period was from June 1, 2018, to June 15, 2020. Data of all living patients, as of December 2019 (N=5,844,804), assigned to an ICS primary care team during the study period were analyzed. All these citizens could access and use the eConsulta tool with prior authorization from a health care professional. The analysis differentiates between the COVID-19 pandemic era (ie, from March 12, 2020, the day the state of emergency was declared in Spain, to June 15, 2020) and the preceding period (ie, before March 12, 2020). It also differentiates between eConsulta users who send messages and those who only receive them.

The main study variable is the use of the eConsulta service. “Use” is defined as the period when any messages are sent between a health professional and a citizen, and “nonuse” is defined as the period when no messages have been sent during the study period. The following independent variables were considered in this study: age; gender; socioeconomic level of the center; type of center (rural or urban); adjusted morbidity group (GMA) indicator, a population grouping method that allows the population to be classified into excluding groups according to their multimorbidity [17]; a binary variable identifying the low-income immigrant population; patients with advanced chronic diseases (MACA) indicator [18]; patients with complex chronic diseases (PCC) indicator; and the level of pharmacy coverage. In addition, we assessed the socioeconomic status using the validated MEDEA (Mortality in small Spanish areas and Socioeconomic and Environmental Inequalities) deprivation index, which takes into account the variables of income, occupation, and level of education, among other factors [19]. We categorized this index into quartiles, with the 1st and 4th quartiles representing the least and most deprived areas, respectively. Rural areas were categorized separately and were defined as areas with less than 10,000 inhabitants and a population density lower than 150 inhabitants/km^2.

Continuous variables are presented with mean and SD values, and variables with a nonnormal distribution are presented with median, minimum, and maximum values. Categorical variables are presented with the absolute and relative frequency of each category. For the comparison of two categorical variables, Fisher test and Chi-squared test were used; for the comparison of two numerical variables, the *t* test was used; and in cases where there were more than two variables, the analysis of variance (ANOVA) test was used. A significance level of 5% was set. Data were analyzed using R software (version 3.4.3; R Foundation for Statistical Computing).

Results

Table 1 shows the characterization of citizens who used the service, grouped according to whether they have started a conversation or only received messages, during both the pre–COVID-19 and COVID-19 periods (P<.001). The results show that the profile of the typical user who started a conversation in the pre–COVID-19 era was female (33,096/56,494, 58.6%), with a mean age of 49.84 (17.06) years, a GMA of 2, residing mostly in an urban setting (45,977/56,494, 81.4%). Moreover, the user profile for those who only receive messages was found to be slightly older (mean age: 50.71 [SD 16.16] years), more male (8606/20,104, 42.8%), and more urban (16,492/20,104, 82.0%) compared with active users. When the user profile was analyzed according to the MEDEA deprivation index, we found that since the COVID-19 outbreak, there has been a decrease in the percentage of conversations initiated by higher-income urban citizens (from 4971/20,104, 24.7%, to 19,891/89,102, 22.3%) and an increase in the proportion of users from rural areas (from 10,517/56,494, 18.6%, to 26,958/130,941, 20.6%).

Since the start of the COVID-19 outbreak, eConsulta users have been predominantly female. However, users during the COVID-19 period were systematically younger than those before the pandemic, for the two user profiles analyzed. An increase was observed in the percentage of eConsulta use (especially with regard to the number of messages received from health care professionals) in those population profiles that are more actively employed and have fewer chronic diseases. Thus, we observed a group of working-age citizens who did not used to go to the doctor and citizens who, when they have had to go, preferred the non–face-to-face channel.

In addition, the analysis of the volume of use of the tool during the pre–COVID-19 and COVID-19 periods shows that the number of unique users almost tripled in the first 3 months of the pandemic (from 76,598 to 220,043, 2.87% increase; Table 2). The number of consultations in the 3 months before and after the pandemic showed a monthly increase from 5.61 to 33.10 visits per 1000 inhabitants.

Of these consultations, the proportion of conversations initiated by citizens had reduced (from 74.95% to 52.48%), whereas those initiated by professionals had almost doubled (from 25.05% to 47.52%). Furthermore, the proportion of messages sent by professionals had substantially increased. Similarly, the proportion of conversations involving a response from the professional had decreased considerably (from 1.79% to 0.47%), and the proportion of conversations involving a response initiated by the citizen (ie, patient) had slightly reduced (from 90.8% to 80.61%), as shown in Table 3.

The number of documents attached to eConsulta messages sent by citizens before and during the COVID-19 pandemic was also analyzed (Table 4 and Figure 2). A clear increase in the number of files sent, especially in terms of medical reports, was observed.

Finally, the variations in overall, face-to-face, and web-based care received by users of different age groups were analyzed. Table 5 shows that the use of telemedicine has somewhat mitigated the decline in face-to-face visits in younger age groups.

Table 2. eConsulta activity before and after the COVID-19 pandemic.

Period of analysis	Users (citizens), n (%) (N= 5,844,804)	Consultations, n

Discussion

Principal Findings

The COVID-19 outbreak has led to a significant increase in the use of teleconsultation by both citizens of the Catalonia region and health care professionals. The number of e-consultations per 1000 inhabitants has increased from 5.61, a figure that can be considered low compared to other studies [7], to 33.10 after the start of the COVID-19 pandemic. This increase is explained, first, by the fact that before the onset of the pandemic, patients needed to receive an authorization from their health care professional to be able to carry out e-consultations. After the COVID-19 outbreak, this permission was extended to all citizens. The greater use of teleconsultation is also explained by the increase in the remote provision of care processes that were performed in-person before the pandemic, enabling these citizens to receive remote assistance (ie, sick leave), remote updating of electronic prescription plans for chronic patients, or reactive prescriptions for non–face-to-face visits for acute patients and guidelines for monitoring oral anticoagulant use in patients receiving treatment, among others). The reduction in the average age and the 5-fold increase in “passive” users (ie, users who receive but do not send messages) suggest that eConsulta has been widely used for notifying results or sick leave(s) by allowing users to connect to their personal health folder.

The pandemic has modulated the way eConsulta is used and the typical user profile. There has been an increase in use by both health care professionals, with a clear increase in their initiative in sending messages and documents to citizens, and young patients without chronic diseases. This group comprises citizens, who before the pandemic were infrequent users of the system, but because of the pandemic and their acute pathologies—often related to COVID-19—have had to use the tool in order to contact the health services or receive test results. These processes have made it possible to continue to offer key and prevalent primary care processes in a non–face-to-face and safe and stable manner, by avoiding visits to health centers and contributing decisively to reducing the risk of infection during periods of strict lockdown. It should be noted that eConsulta has not been used for the purpose of COVID-19–related mass messaging by the health system and that it has only been used for the purpose of care continuity for patients.

The results of this study show that it is necessary to understand the type of use of the tool in order to make improvements in its operation and continue working on a model that improves the management of demand for primary care and, in return, its efficiency. To date, the approach based on free-text analysis using machine learning tools seems to be a suitable option to study the evolution over time of the use of the teleconsultation service [3]. This, however, would be a suboptimal solution. The planned evolution of the eConsulta tool for the coming months is precisely the structured stratification of the reasons for consultation, reported by the citizens themselves before initiating it, which will initially allow these messages to be redirected to the professional profiles (doctor, nurse, administrator, dentist, social worker, etc) that can respond in a more agile and appropriate way based on the need expressed by the citizen in their message. In this way, care is decentralized to the different

XSL•FO
RenderX

professional profiles, allowing a more efficient response to the citizen based on the reason for their consultation.

The pandemic caused by the novel coronavirus SARS-CoV-2 has changed the model of health care, and this is especially noticeable in primary care centers, where the most commonly used face-to-face model has been replaced by a mixed model in which telemedicine tools play a very significant role. Although it is clear that the pandemic has led to a reduction in the diagnosis of many diseases [22] and the control of chronic diseases [23], it is necessary to assess the effects of these changes in care (forced by the circumstances) on the health of the supported population in order to continue to guarantee quality health care. We need to emerge from this crisis with a clearer vision of how to continue to deploy telemedicine to obtain its benefits by avoiding or minimizing its drawbacks [12] and inequalities regarding access for the most vulnerable groups [24].

The acceleration of digital transformation processes in health centers has ensured the continuity of care of many basic care processes for the population during lockdown [11]. This new model of care is changing the way we interact with the health care system and the patient profile used by each channel. The results of this study show that non–face-to-face communications from the Catalan primary health care system are being used predominantly in favor of the low-risk and younger population and, therefore, preserving face-to-face and home visits for the most complex and older populations. This adaptation and flexibility of the health system's response, based on the different needs and types of patients, is beneficial and demonstrates the resilience that telemedicine tools have provided to the health system during the COVID-19 pandemic.

This study presents some limitations, as it does not evaluate the relationship between unanswered e-consultations and the type of visit, either in person or by telephone for the same user. It could be possible that the objective of many citizens who have sent an e-consultation was actually to receive a face-to-face or telephone visit in which case the e-consultation would not have replaced these other types of visits.

Conclusions

In the context of reduced face-to-face accessibility to the health system, this study has highlighted a change in the profile of the Catalan citizen using the eConsulta telemedicine tool. Since the start of the COVID-19 pandemic, this patient or user profile is similar to that of the average citizen: actively employed, with less complex pathologies, and who receives more messages proactively from health care professionals through this tool. The COVID-19 pandemic has helped to socialize the use of telemedicine, and as a result, it has helped to mitigate, to some extent, the decline in face-to-face visits in younger age groups.

Abstract

Background: Despite decades of research to better understand suicide risk and to develop detection and prevention methods, suicide is still one of the leading causes of death globally. While large-scale studies using real-world evidence from electronic health records can identify who is at risk, they have not been successful at pinpointing when someone is at risk. Personalized social media and online search history data, by contrast, could provide an ongoing real-world datastream revealing internal thoughts and personal states of mind.

Objective: We conducted this study to determine the feasibility and acceptability of using personalized online information-seeking behavior in the identification of risk for suicide attempts.

Methods: This was a cohort survey study to assess attitudes of participants with a prior suicide attempt about using web search data for suicide prevention purposes, dates of lifetime suicide attempts, and an optional one-time download of their past web searches on Google. The study was conducted at the University of Washington School of Medicine Psychiatry Research Offices. The main outcomes were participants' opinions on internet search data for suicide prediction and intervention and any potential change in online information-seeking behavior proximal to a suicide attempt. Individualized nonparametric association analysis was used to assess the magnitude of difference in web search data features derived from time periods proximal (7, 15, 30, and 60 days) to the suicide attempts versus the typical (baseline) search behavior of participants.

Results: A total of 62 participants who had attempted suicide in the past agreed to participate in the study. Internet search activity varied from person to person (median 2-24 searches per day). Changes in online search behavior proximal to suicide

XSL•FO
RenderX

attempts were evident up to 60 days before attempt. For a subset of attempts (7/30, 23%) search features showed associations from 2 months to a week before the attempt. The top 3 search constructs associated with attempts were online searching patterns (9/30 attempts, 30%), semantic relatedness of search queries to suicide methods (7/30 attempts, 23%), and anger (7/30 attempts, 23%). Participants (40/59, 68%) indicated that use of this personalized web search data for prevention purposes was acceptable with noninvasive potential interventions such as connection to a real person (eg, friend, family member, or counselor); however, concerns were raised about detection accuracy, privacy, and the potential for overly invasive intervention.

Conclusions: Changes in online search behavior may be a useful and acceptable means of detecting suicide risk. Personalized analysis of online information-seeking behavior showed notable changes in search behavior and search terms that are tied to early warning signs of suicide and are evident 2 months to 7 days before a suicide attempt.

Introduction

Worldwide, suicide is the 18th leading cause of death, resulting in nearly 800,000 lives lost annually [1]. Suicide is the 10th leading cause of death in the US, with nearly 48,000 Americans dying by suicide in 2017 and 1,400,000 suicide attempts in the same year, costing the US approximately 69 billion dollars in 2015 [2,3]. Despite the high societal and personal costs of suicide and decades of research into suicide prevention, we still cannot accurately identify who may be at risk for death by suicide or when the risk is likely to be greatest [4,5].

One of the most important challenges facing suicide prevention researchers—as well as clinical providers—is to identify warning signs for suicidal behavior [6,7], which indicate when a specific individual is at heightened suicide risk in the near term (ie, within minutes, hours, or days) [6,8]. While warning signs developed by expert consensus [6] have been widely disseminated [9-11], research on the timeliness and utility of proposed warning signs has been sparse, and some proposed warning signs have recently been found to not predict imminent suicidal behavior [12]. This is partly because warning signs such as short-term increase in alcohol use [13,14], acute negative interpersonal life events [15], intensity of affective [8], cognitive responses, suicide-related communications, and prepping one's personal affairs [12] may not be static variables (ie, they fluctuate over minutes, hours, or days) making traditional clinical risk assessment at a single health care contact imprecise [6]. Additionally, only one-third of mental health providers use suicide screens routinely [16]. An added complication is that, currently, known methods rely upon having a vulnerable individual self-disclose to and interact with systems (eg, health care, school) or individuals (eg, family, friends) in order to identify warning signs of suicidal behavior. Many people at high risk for suicide do not seek professional help because of lack of time, preference for other sources of help, or fear regarding how they will be treated in the health care system (eg, stigma and the potential trauma associated with in-patient hospitalization) [17-22]. For these reasons, methods that can identify proximal risk factors for suicide that do not depend on health care disclosure and can capture the fluctuating and individualized nature of suicide risk are needed [23].

Machine learning and natural language processing methods have recently been applied to social media data as a means of identifying suicide risk [24,25]. Social media provide a continuous stream of information about individuals' daily lives that may be useful in capturing the dynamic nature of suicide risk, and some studies have found these data can be used to infer a person's mental health as well as ongoing risk for suicide [23,26-29]. A disadvantage to using social media is that the age range of users is still very young [30,31]. Because of recent mishandling of social media data, people are also staying away from public social media platforms [32]. By contrast, 77% of the US population [33] seek information online through internet search engines. The information gleaned here is less likely to be biased, for example, by the desire to project a positive persona on social media [34], with search content focused on information gathering about personal concerns [35,36]. The use of internet search data may be an effective, private, immediate method of proximal suicide risk detection for individuals regardless of their contact with systems of care or self-reported disclosures to other persons.

The use of individualized web searches for proximal risk assessment of suicide attempts is also aligned with the Fluid Vulnerability Theory [29,37-39]. Fluid Vulnerability Theory proposes that suicide risk is a function of ever-changing interactions among multiple risk and protective factors, thus "an individual's vulnerability to suicide is variable but nonetheless identifiable and quantifiable [37]." Some risk and protective factors are static or relatively stable (eg, gender, race, genetics, trauma, dispositional optimism) whereas others are state-based and dynamic (eg, mood, life stressors, insomnia, social support). While static risk factors are known to identify who is at risk, using personalized web searches as a source of real-time real-world behavior may potentially help uncover complex interplay of real-world risk factors associated with when someone is at greatest suicide risk.

However, one limitation to using search data for suicide risk prediction is the concern about privacy and the use of data not intended for public consumption. The intent of social media is to share life events and information publicly whereas search queries are often meant for personal, nonpublic use, and thus privacy concerns about using these data are important to understand [40]. Before embarking on a scaled exploration of

XSL•FO
RenderX

these data for risk detection purposes, it is crucial to gain insight from people with lived experience of suicide about their comfort with their search data being used for suicide detection and prevention.

The purpose of this study is to examine the feasibility of using data from internet searches to identify suicide risk. The first objective of this study was to determine whether internet search behavior (frequency of search queries and queries categorized to known warning signs) were evident within 60 days of a documented suicide attempt. The second objective of this study was to determine how comfortable individuals with lived experience of suicide are with the use of internet search data for early identification.

Methods

Data Collection

Recruitment and Eligibility

Participants with a prior confirmed suicide attempt were recruited from an ongoing randomized clinical trial [41]. Inclusion criteria were (1) inpatient or emergency service admission, (2) lifetime suicide attempt and current hospital admission for suicidality or current hospital admission for a suicide attempt, and (3) consenting to study procedures. This study was approved by the institutional review board at the University of Washington. Data collection occurred from November 2017 to October 2019, and data analysis was conducted from October 2019 to August 2020.

Procedures

Participants were asked to complete a 30-minute semistructured interview about their concerns and suggestions for using internet search data as a means of preventing suicide. They were offered the option to provide a one-time confidential data download of their online Google search history. Participants who opted to participate in the study were reimbursed US $30 regardless of whether or not they agreed to share their Google search history.

Internet Search Data Collection

Google Takeout is a web-based interface developed by Google that allows users of Google apps to download their data into an exportable file. Using prior work [42], we created a web app, called gTAP [43], to allow participants to download their data without sharing personal Google account credentials. Only past Google search history was collected (Multimedia Appendix 1).

The Suicide Attempt and Self-Injury Count, a brief version of the Suicide Attempt Self-Injury Interview [44], has been widely used to determine suicide attempts in clinical trials [45-49] and was used to identify dates of suicide events and categorize events into suicide attempts and nonsuicidal acts.

Participant Survey

The interview was developed by the research team and focused on the acceptability of using internet information to detect the risk of suicide and to prevent suicide (Multimedia Appendix 2). Participants were asked to respond to the following question: “Technology companies use algorithms to predict who is at risk for suicide. Were you aware of this? Do you have any concerns or fears about how this information is collected, stored, and shared? How would you feel if they used your personal search data and/or what you have posted on social media to take action to prevent you and others in a similar situation from suicide? What do you see as the pros and cons?”

Statistical Analysis

Search Data Featurization

Participants’ web searches were used to generate behavioral (online information seeking pattern) and semantic (meaning of search content) features. For behavioral features, we generated daily summary of participants' search history such as the average number of searches per day and the time of day when searches were conducted. For semantic features, we applied distributional models of semantics [50] to derive vector representations of participants’ queries, such that queries and words relating to similar concepts would be proximal in the resulting vector space. To do so, we used semantic vectors [51-53] and publicly available pretrained word embeddings [54] (Multimedia Appendix 3 and Multimedia Appendix 4). In order to map the user search queries to 9 empirically supported warning signs [12] and suicide-method preparation (which has not been previously examined using the present approach), we developed a set of cue terms. An iterative process of cue term definition, expert review of proximal queries, and refinement of the cue term set was used to generate the final set. We calculated a proximity score between the participants' search query (web search) and vector subspace derived from the cue terms representing a warning sign, using the Gram-Schmidt orthonormalization [55] procedure to ensure mutual orthogonality. The proximity score was estimated as the length of the projection of the query into this subspace, following the quantum disjunction method [56]. We used a conservative z score threshold ≥3.5 (corresponding P=.0002) to indicate a meaningful construct-to-query association relative to all search queries for each participant. The use of a threshold of this nature is required on account of the statistical properties of high-dimensional space—all vectors in this space have measurable similarity, but only proximal neighbors in the space indicate meaningful similarity [55,57,58], which should be well above what would be anticipated by chance on account of the high probability of randomly instantiated vectors being mutually close-to-orthogonal [59,60]. Furthermore, this threshold was supported empirically by inspection of the relationships between queries that fell above and the themes of interest in a subset of the data (Multimedia Appendix 4).

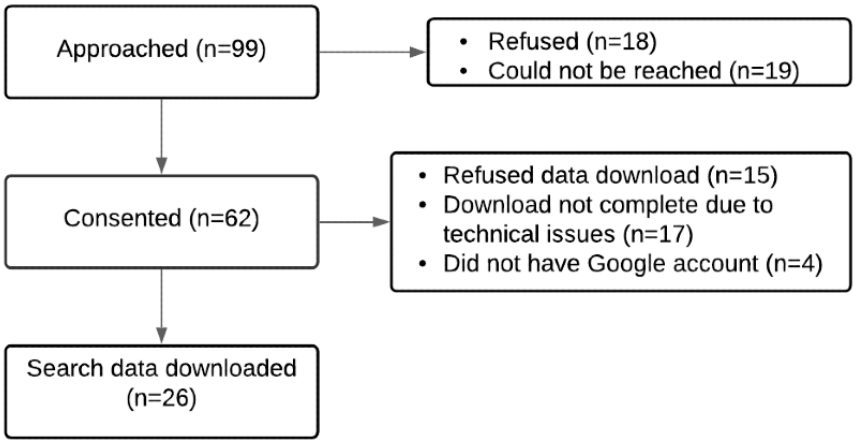
Association Analysis

Because of a small sample size and high level of heterogeneity in web search data across participants, we used an individualized analytical approach (Multimedia Appendix 4) to assess the magnitude of difference between web search data proximal (7, 15, 30, and 60 days) to the suicide attempts versus the typical (baseline) search behavior of participants. In order to show the difference between the observed search feature score prior to the time of a suicide attempt and a typical baseline of the search feature for an individual, we computed 2 versions of a standardized value for the search score at the time of the event. First, we presented the z score defined as the search score at the

XSL•FO
RenderX

observed event time (based on a chosen time window), standardized using the mean and variance associated with a patient-specific reference distribution characterizing the full range of observed search scores for an individual. This highlighted how far the observed score at the event time was from typical scores. Second, given that the reference search score distributions may be highly skewed or multimodal, we also computed the empirical reference percentile for each search feature for the event time (suicide attempt). Specifically, we used an empirical reference distribution per search feature to compute the percent of typical individual-specific search feature values that fell either above or below the corresponding search feature value for an observed attempt. A percentile calculation is a form of nonparametric standardization and is termed a *placement value* for classification problems [61]. To show either extremely low or high values, we calculated the symmetrized placement value defined as the minimum of the upper or lower tail probability for the observed attempt score. The participant-specific reference distributions were generated using a nonparametric Monte Carlo simulation [62]. All statistical analysis was performed using the R [63] statistical programming language.

Survey Data Analysis



Participants' responses to structured survey questions were summarized using summary statistics. Semistructured responses were transcribed verbatim during participant interviews and anonymized prior to analysis. We used a mixed methods approach, combining quantitative and qualitative data with the function of expansion [64], which allowed inductive qualitative data to provide the *why* to questions uncovered by the quantitative data. Qualitative data were analyzed from a constructivist perspective using thematic analysis after all interviews were completed [65]. Two coders (a psychologist and a psychiatrist) independently extracted initial themes from survey responses. Themes were reviewed by a third coder, a clinical research assistant who had performed all participant interviews. Data were iteratively reviewed (open coded) and collapsed to mutually exclusive themes (axial coding) until saturation was achieved (ie, when no new themes emerged) [66]. Triangulation [67] of quantitative and qualitative data allowed for convergence of themes and a more comprehensive understanding of willingness to use search data for prevention. Illustrative quotes and themes are provided for a qualitative data audit trail. This study was conducted in accordance with SRQR (Standards for Reporting Qualitative Research) [68].

Results

Sample Characteristics

Of 150 individuals, 99 were eligible to participate in this study and were approached, and 62 consented to participate in the qualitative interview. Of the 62 who consented, 26 (42%) were able to provide web search data. Reasons for not providing data were technical issues in downloading search data (17/62, 27%), unwillingness to share Google searches (15/62, 24%), and not having a Google account (4/62, 6%) (Figure 1). The cohort that consented to participate in the qualitative interview consisted of predominantly White individuals (43/62, 69%), and 53.2% were male (33/62). The mean age of the cohort was 34.9 years with 79% (49/62) having at least some college education. No significant differences in demographics were observed between the participants who completed qualitative interviews (n=62) and the final subset (n=26) from whom the Google search data was obtained for age (P=.18), gender (P=.58), race (P=.83), marital status (P=.94), education (P=.96), and income (P=.98) (Table 1). A total of 71 lifetime suicide attempts were reported by the full sample (n=62). The precision of the estimated attempt date varied from the exact attempt date (33/71, 46%) to within 2 weeks (11/71, 15%). To align the suicide attempt period to a proximal web search window, we only used the attempt dates that were rated as accurate within 2 weeks (n=44). Of these, retrospective web search data were available for 30 attempts.

Search Data

Summary

In total, search history data for 24,397 days were collected with 349,922 individual search queries from 26 study participants. The median time span of the search history data across participants was 1348 days (range 220-4752 days); however, the actual number of days when participants searched online was much lower than the data collection period and varied widely (median 898.5 days, range 75-2759 days) (Figure 2a). Analysis generated 11 high-level search constructs related to participants' online information-seeking behavior (ie, search behavior features) and search content proximity scores for 10 suicide warning signs (ie, semantic features) (Multimedia Appendix 3).

XSL•FO
RenderX

Figure 2. Search data characteristics across participants: (a) span (in days) of search data collected from participants (in grey) and the number of days (blue) on which participants made at least one search. (b) Median daily number of web searches performed by the participants. The error bars indicate the 25th and 75th percentile. (c) Proportions of participants' web searches stratified by time of day.

Search Behavior Features

Our analysis revealed idiosyncratic online information seeking behavior across individuals; the number of searches per day varied between 2 searches and 24 searches (median 8.5 searches). The time of day when participants conducted online searches also varied (morning: 0%-4.35%; late night: 0%-37.5%; Figure 2b,c).

Semantic Features

Of the semantic search content that we mapped to known suicide warning signs, we identified a small proportion of search queries (median 1.2%, range 0.06%-21.47%) with a proximity *z* score ≥3.5 that mapped onto 1 or more of the 10 warning signs. At times, queries meeting this threshold were observed in close proximity to a suicide attempt (within days to weeks). Table 2 provides a representative selection of highly ranked queries (based on *z* scores) for each warning sign, revealing content suggestive of premeditation, preparation, substance use, stressors, underlying mental state, and help-seeking behavior.

Table 2. Cue term sets developed to represent selected warning signs and a subset of top search queries that map to each of the warning signs.

Warning sign	Cue terms	Retrieved search queries
Alcohol use	whiskey; alcohol; aa; wine; alcoholic; beer	"aa meetings"; "how much beer to get drunk"; "wine hangover vs. hard alcohol"; "alcohol poisoning"; "alcoholics anonymous"[a]
Preparation of personal affairs	will; affairs; suicide+note	"writing a suicide note"; "living will"; "write your will online"
Suicide communication	hotline; help; suicide+communicate	"what does suicide hotline do"; "suicide crisis text line"; "suicide text line"; "emergency room si suicidal ideation"
Suicide methods (preparation)	overdose; gun; lethal	"sleeping pill overdose suicide"; "is ambien lethal"; "where can I get suicide pills"[a]; "where to buy a gun in Seattle"; "cheap guns"[a]
Burdensomeness	burden	"discussing work burdens marriage"[a]
No reason to live	hopeless; live; persist	"I don't want to live anymore"
Anger	hostile; rage; anger	"fits of rage"; "depression and rage"; "serious anger marijuana"
Anxiety	scared; fearful; afraid; anxiety; anxious; jittery;	"ocd anxiety"; "apprehensive"[a]; "social anxiety"; "marijuana for anxiety"; "why do I have so much anxiety"; "phobia of diseases"[a]
Emptiness	numb; hollow; feeling+empty	"I feel so empty"; "I like the feeling of being sad"
Interpersonal problem	conflict; divorce; fight; breakup; loss	"final divorce decree cost"; "infidelity and custody"[a]; "how much child support if spouse loses job"[a]; "divorce"

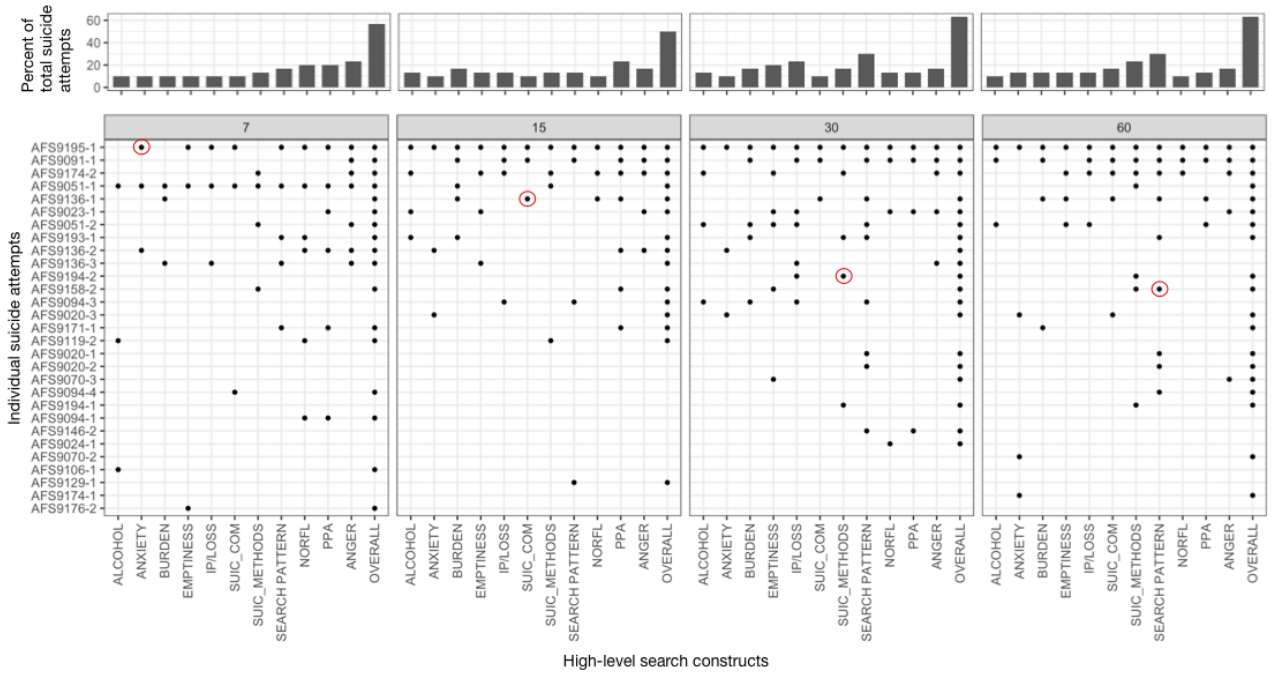
[a]Found using distributional semantic approaches (ie, queries do not contain any of the manually defined cue terms) illustrating the capacity of distributional semantics approaches to identify related concepts expressed in different terms.

XSL•FO
RenderX

Association Between Search Data Features and Suicide Attempts

On average, 58% of attempts (n=30; range 15/30, 50% to 19/30, 63%) were found to be associated ($-\log_{10}$(placement value)≥2) with at least one search feature in 1 of the 4 proximal time periods (7, 15, 30, and 60 days). Figure 3 shows the summary of individualized association analysis highlighting the specific search constructs proximally associated with suicide attempts. Notably, for 23% attempts (7/30), a prolonged association with proximal search features (from 60 days) was observed, indicating an extended period of potentially high-risk online search behavior. For the majority of attempts, we observed a high degree of variation in search constructs and the proximal time period in which they were associated with attempts. The constructs associated the most attempts (across time windows) were online search patterns (9/30 attempts, 30%), semantic similarity of search queries to suicide methods (7/30, 23%), and anger (7/30, 23%). Figure 4 shows features associated with 4 individual suicide attempts (one per proximal window) where the search behaviors of the participants were found to be markedly different ($-\log_{10}$(placement value)≥2) from their typical (ie, baseline) behavior.

Figure 3. Summary of individualized association analysis for 11 high-level search constructs over 4 suicide attempt–proximal periods: (a) 7, (b) 15 (c) 30, and (d) 60 days.



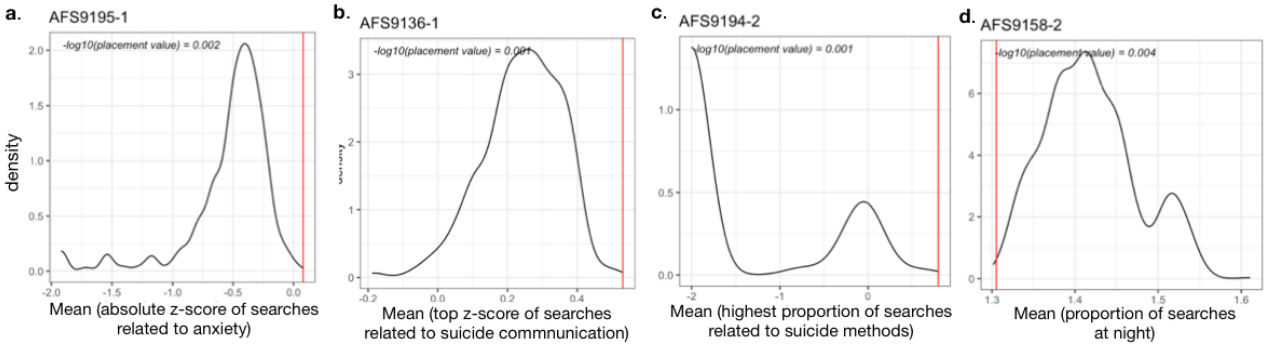


Figure 4. Baseline distributions for 4 example search features (each indicated by a red circle in Figure 3): (a) anxiety – 7-day proximal period; (b) suicide communication – 15-day proximal period; (c) suicide methods – 30-day proximal period; and (d) searches at night – 60-day proximal period. The red line indicates the value of the search feature in the corresponding time period proximal to a suicide attempt.

Perceived Acceptability and Feasibility of Internet Search–Based Prediction of Suicide Risk

Three primary themes were identified regarding the acceptability of using search history for suicide prevention: utility, accuracy, and privacy (Table 3): 68% (40/59) thought using internet search history for suicide detection and prevention could be useful; many participant (34/59, 58%) raised concerns about the accuracy of detection, in particular concerns of false positives and their potential consequences; and 32% of participants (19/59) were concerned about the intrusion of privacy.

XSL•FO

Table 3. Illustrative quotes of participant responses to use of internet history in suicide prevention.

Theme	Illustrative quotation	Respondents reporting the theme, n (%)
Useful	"It'd be a good way to help people get resources that they don't otherwise know about."	40/59 (68)
	"I think it's good. I think people would be more open online than how they are in one-to-one in-person situations."	
	"I think it sounds great. They're already using algorithms to optimize search, [so] might as well do it for something good."	
	"Potentially it could be enough to 'break the cycle' of suicidal thoughts."	
Detection accuracy concerns	"No problem with that as long as they did it right. I wouldn't want the SWAT team to show up at my door..."	34/59 (58)
	"Companies don't understand the context of the situation, try to do the right thing, but...it makes people want to shut people out because they overreact."	
	"I don't think I would mind because I know what I'm getting myself into. They should work on the algorithm before implementing it into the general population though."	
	"I like how they use trigger/key words to dump all these resources on you, but I think they need to improve it."	
Privacy concerns	"I'm chronically in private mode, because I don't want Google or tech other companies knowing I'm looking at this. If I'm ever in public, I don't want my search results to be seen by others."	19/59 (32)
	"Feels like I am being spied on."	
	"I would be a little upset about that. Seems like an invasion of privacy."	
	"[As] we become more transparent on the internet, search history or data could be used [with] malicious intentions, planting bombs for the future."	

When presented with potential prevention interventions, participants favored interventions that provided a direct link to either a crisis counselor (35/61, 57%), friends or family (33/60, 55%), peers (30/61, 49%), or to a self-guided meditation video (33/61, 54%) (Multimedia Appendix 5). Interventions that simply provided a hotline number, with suggestions to reach out, or an inspirational video were not as favorable. When asked if they had seen interventions such as Google's links to a suicide prevention hotline, only 53% (33/62) said they saw the link, and of those, only one person acted on it. Participants were allowed to voluntarily opt out of answering any questions in the qualitative survey, and if they did so for a specific question, they were not counted in the denominator of that question's response percentages. Although 62 participants consented to the qualitative interview and provided some form of response in the interview, up to 3 participants opted out of specific questions at various times for declining to answer or feeling too distressed to continue the interview.

Discussion

General

This is one of the first studies to examine and describe the nature of individualized internet search data with an eye toward suicide prevention. We found that while search queries and behavior do change prior to suicide attempts, there is considerable variation between individuals, with some participants searching online more frequently, and others seeking information online sporadically prior to attempts. Additionally, search queries over time are highly individualized, and for some attempts, changes in search behavior and queries related to risk are evident 60 days before the attempt, with a majority evident 2 weeks before the attempt. Search content associated with risk windows also varied, although some content was highly prevalent across time points such as queries expressing anger or suicide methods. Although these findings suggest that the use of internet searches for risk prediction will be complicated due to the intraindividual variation, it may still be possible to develop a personalized temporal risk profile or a digital phenotype [69] linked to suicide-related behaviors. Previous research has found that personalized models lead to more accurate prediction of clinical states [70]. In the present study, individualized risk assessment analysis identified as much as 63% of attempts (19/30) based on changes in search behavior and queries.

We found that participants felt using internet search data to predict and intervene in suicide was potentially helpful, but they also harbored some important reservations. Participants felt that any intervention based on search history or social media algorithms would need to be highly accurate and respect personal privacy. The interventions themselves should be active (link to a friend), rather than passive (suggestion to contact a hotline). Importantly, participants were particularly concerned about the use of emergency services as a means of intervention.

This study represents the first step in understanding the potential utility of online search data for suicide prevention. The next steps will require a study with a much larger sample size due to the intraindividual variation in search signal differences, in addition to interindividual variation in search terms and search behaviors prior to attempts. Expansion of the semantic feature space may also further refine predictive signals. While these results demonstrate that a personalized analytical approach can identify patterns of search behaviors that are evident up to 2 months before an attempt, larger studies are needed to assess potential representational bias and further refine high-risk signatures from online search data.

RenderX

Limitations

This study is a preliminary cohort study and thus has limitations. First, this was a small sample. Although individualized analysis of web search data indicates the potential benefits for understanding real-world risk factors of suicide and when someone may be at a higher risk, future research should explore the cohort-level predictive ability of data, including optimization of analytical parameters (eg, selection of threshold to indicate a meaningful association between web searches and suicide risk factors). Second, participants in this study were at very high suicide risk with both a lifetime suicide attempt and a recent episode requiring hospitalization. A larger prospective study of people with varying levels of suicide risk, including those without a history of suicidal ideation, is warranted to ensure that the search patterns and terms found here are unique to the imminent risk of suicide. Understanding the perspectives of other individuals on the sharing of web search data and the appropriateness of intervention will also be crucial prior to any deployment of prediction algorithms and related suicide prevention efforts. Finally, we asked participants their perspectives about hypothetical intervention scenarios based on internet search informed risk prediction. It is likely that participants' acceptability of such interventions will differ when they are faced with them during a crisis event.

Conclusion

Although this is a preliminary study, the findings are promising and suggest a potentially useful and timely method for utilizing search data for detecting the risk of suicide. If handled appropriately, this method of risk detection is seen by those with a lived experience of suicide as an acceptable method of detection. Suicide is a serious public health problem, one that has the potential to escalate during these times of health, societal and economic challenges. Methods that can quickly identify and intervene to prevent a suicide event could help prevent and reduce the public health burden of suicide.

Acknowledgments

This work was supported in part by grants from the National Institute of Mental Health (P50 MH115837, R01 MH10230f4, and R33 MH110509).

Authors' Contributions

PAA, AP, and KC designed the study. AP and TC led the search and Google Search data analyses with contributions from PH and CB. KH and TH conducted all study interviews. PAA, HH, and TH contributed to the qualitative analysis of the study and interpretation of the descriptive analyses. PAA, KC, AP, TC, and HH were involved in writing the first draft of the manuscript. PAA obtained study funding. All authors critically revised the manuscript.

Conflicts of Interest

PAA reports consulting with Verily Life Sciences on mental health and technology projects. HH was an employee of Verily Life Sciences prior to study contribution.

Abstract

Background: As one of the most essential technical components of the intensive care unit (ICU), continuous monitoring of patients' vital parameters has significantly improved patient safety by alerting staff through an alarm when a parameter deviates from the normal range. However, the vast number of alarms regularly overwhelms staff and may induce alarm fatigue, a condition recently exacerbated by COVID-19 and potentially endangering patients.

Objective: This study focused on providing a complete and repeatable analysis of the alarm data of an ICU's patient monitoring system. We aimed to develop do-it-yourself (DIY) instructions for technically versed ICU staff to analyze their monitoring data themselves, which is an essential element for developing efficient and effective alarm optimization strategies.

Methods: This observational study was conducted using alarm log data extracted from the patient monitoring system of a 21-bed surgical ICU in 2019. DIY instructions were iteratively developed in informal interdisciplinary team meetings. The data analysis was grounded in a framework consisting of 5 dimensions, each with specific metrics: alarm load (eg, alarms per bed per day, alarm flood conditions, alarm per device and per criticality), avoidable alarms, (eg, the number of technical alarms), responsiveness and alarm handling (eg alarm duration), sensing (eg, usage of the alarm pause function), and exposure (eg, alarms per room type). Results were visualized using the R package ggplot2 to provide detailed insights into the ICU's alarm situation.

Results: We developed 6 DIY instructions that should be followed iteratively step by step. Alarm load metrics should be (re)defined before alarm log data are collected and analyzed. Intuitive visualizations of the alarm metrics should be created next and presented to staff in order to help identify patterns in the alarm data for designing and implementing effective alarm management interventions. We provide the script we used for the data preparation and an R-Markdown file to create comprehensive alarm reports. The alarm load in the respective ICU was quantified by 152.5 (SD 42.2) alarms per bed per day on average and alarm flood conditions with, on average, 69.55 (SD 31.12) per day that both occurred mostly in the morning shifts. Most alarms were issued by the ventilator, invasive blood pressure device, and electrocardiogram (ie, high and low blood pressure, high respiratory rate, low heart rate). The exposure to alarms per bed per day was higher in single rooms (26%, mean 172.9/137.2 alarms per day per bed).

Conclusions: Analyzing ICU alarm log data provides valuable insights into the current alarm situation. Our results call for alarm management interventions that effectively reduce the number of alarms in order to ensure patient safety and ICU staff's

XSL•FO
RenderX

work satisfaction. We hope our DIY instructions encourage others to follow suit in analyzing and publishing their ICU alarm data.

Introduction

Background

In intensive care units (ICUs), monitoring of patients' physiologic parameters has significantly improved patient safety by alerting ICU staff through a visual or audible alarm [1] when a parameter deviates from the preset range (eg, apnea, sensor detachment). However, as one of the most digitized health care areas with a rising number of novel devices with their own alarms, the sheer number of alarms regularly overwhelms ICU staff. Some studies document more than 700 alarms per patient per day on average [2].

Being exposed to so many alarms can leave ICU staff alarm fatigued, a condition characterized by a desensitization to alarms, which can make ICU staff react inadequately (eg, responding with delay, turning down the alarm volume, turning alarms off) [3,4]. Due to the COVID-19 pandemic, this condition has been further exacerbated (eg, through the utilization of anesthesia ventilators in the ICU) [5]. Excessive alarms not only induce stress and distraction in ICU staff [6,7] but also directly impair patient recovery [8]. Ultimately, it can threaten patients' lives when ICU staff misses alarms or responds with delay. This is shown by the Joint Commission's sentinel event database, which lists 98 incidents between 2009 and 2012 that were related to alarms, of which 80 resulted in a patient's death [9]. Reporting to the database is voluntary, which likely makes this a conservative estimate. For 2020, the ECRI Institute listed an alarm-related hazard among their Top 10 Health Technology Hazards [10]. While in the United States, the Joint Commission declared it a national patient safety goal to reduce the harm associated with clinical alarm systems from 2014 onwards [11]; there is no such official endeavor in Germany.

One way to reduce harm associated with clinical alarms is alarm management, which aims to reduce the number of unnecessary alarms (that is, false, nonactionable, and avoidable technical alarms [12]) with the assumption that this reduces the overall number of alarms and thereby alleviates the staff's alarm fatigue. Traditional alarm management approaches that have been proven to reduce the overall number of alarms include the recommendation to mute alarms while examining a patient [13], introduce a delay between measuring and alarming [14], use individual thresholds for each patient instead of the monitoring device's default [15], turn off arrhythmia alarms that are not life threatening, and change electrocardiogram (ECG) leads on a daily basis [16].

To be most effective, alarm management should be adjusted to the specific conditions of each ICU [12,17]. A thorough analysis of the sociotechnical system of the ICU is necessary to sufficiently customize respective interventions. These efforts include the analysis of the alarm log data (eg, when an alarm occurred and by which device) [12,18]. Currently there is no software solution commercially available that addresses analysis of patient monitoring data.

Aim

Our aim is to develop do-it-yourself (DIY) instructions targeted at technically versed ICU staff (physicians and nurses) for self-analysis of patient monitoring alarm data, including an illustrative, complete, and repeatable analysis of device alarm data of an ICU's patient monitoring system. The application of the DIY instructions should help their users to identify patterns and trends in the alarm data and enable them to generate ideas on how the overall alarm frequency (and subsequently alarm fatigue) might be reduced.

Methods

Ethics Approval

The ethical approval for this study was granted by the Ethics Commission of the Charité – Universitätsmedizin Berlin (EA1/127/18).

Setting and Design

We conducted the study in a surgical ICU of a German university hospital. The unit consists of 21 beds in 15 rooms in which mainly patients after abdominal or neurosurgical operations are treated. The patient monitoring and alarm system used at the time of the study was the Philips IntelliVue patient monitoring system (MX800 software version M.00.03; MMS X2 software version H.15.41-M.00.04; Philips, Amsterdam, Netherlands) with bedside monitors, 3 client monitors summarizing 2-3 rooms, a central station (software version B), and 2 large hallway monitors displaying all 21 patients. Standard monitoring included oxygen saturation (SpO_2), heart rate, invasive (IBP) or noninvasive blood pressure (NIBP), and temperature. Within the Clinical Alarm Capability Maturity Model by Welch et al [19], the ICU was in the first stage at the time of this study, described as having many nonactionable alarms for unknown reasons, approaching alarm management ad hoc and not having or not consulting data to support change [19]. Accordingly, there was no hospital-wide consensus on alarm management.

We used an observational study design, which included retrospective data analysis of the patient monitoring alarm data. The DIY instructions were iteratively developed in informal interdisciplinary team meetings within the research group between February 2019 and November 2020 and adapted by the lessons learned from our own data analysis.

XSL•FO
RenderX

Data Collection and Deidentification

We manually collected clinical audit logs (which include the alarm data) 3 times during 2019 (in winter, summer, and autumn) via a USB stick from the central patient monitoring device in the ICU as previously described by others. The clinical audit log consists of the time, bed number, alarm type (ie, parameter, device, alarm criticality), and alarm handling (eg, threshold adjustments, use of the pause function). Each log file contains data from 31 days.

No actual patient-identifying data elements were collected. For further deidentification, dates were shifted into the future by a pseudorandom offset for all patients; the bed number was replaced by a pseudonym. Day and night rhythm, weekends, the season, and the bed characteristic (double room, single room) were not affected by this process. The deidentified raw data can be retrieved from an open data repository [20].

Data Analysis Framework

Overview

We organized our data analysis in a framework based on suggestions by Hüske-Kraus et al [12], who introduced quality dimensions along with metrics of an alarm system. Each dimension summarizes multiple metrics (Table 1).

Table 1. Data analysis framework applied in this study in line with the quality dimensions introduced by Hüske-Kraus et al [12] and including metrics suggested by Hüske-Kraus et al [12] as well as metrics suggested by other sources for each dimension, wherever possible.

Quality dimension	Definition	Metrics used in this study
Alarm load	Metrics related to the number of alarms	Alarms per bed per day, frequency of individual alarms, alarms per device, alarms per criticality (red, yellow, and blue; ie, alarm at high criticality, alarm at medium criticality, and technical alarm at low criticality, respectively), average temporal distribution of alarms and alarm flood conditions (10 or more alarms occurring within 10 minutes) [18]
Avoidable alarms	False-positive alarms, nonactionable alarms, and technical alarms	Technical alarms per bed per day, technical alarms per device
Responsiveness and alarm handling	Alarm duration, response time, muting of alarms, and corrective actions	Duration of alarms
Sensing	The quality of the technical infrastructure, such as consumable, overmonitoring, and undermonitoring	Average usage of the alarm pause function per bed per day, proper pause-to-pause ratio [12], redundant monitoring of physiological parameters
Exposure	How alarms are distributed in the unit	Average alarm frequencies per room and per bed per room type, number of beds issuing more alarms than the average

Data Analysis

We cleaned and analyzed the data with R [21] in combination with the packages *dplyr* [22], *tidyr* [23], and *stringr* [24]. We used the package *lubridate* [25] for date and time information and the package *ggplot2* [11] for the visualizations. The log entries were structured in 4 columns: Time, Bedname, Action, Devicename. New variables (eg, the time an alarm was generated and its criticality) were extracted for each log entry from the information contained in the column Action. In total, the alarm logs contain data from 93 days.

Alarm Load

Visualizing the frequency of individual alarm parameters helps to identify "bad actors" — alarms that occur much more frequently than others [8] while investigating the number of alarms each medical device issues — can help to prioritize alarm management interventions. The metric "alarms per bed per day" alone is not necessarily an indicator of the alarm load on respective ICUs and should be accompanied with information such as the criticality of the alarms (red, yellow, blue), the frequency of individual alarms, the frequency of alarms per device, the number of alarm flood conditions, and a temporal perspective. To conduct device-related analyses, we assigned each alarm parameter to 1 out of 7 devices (ventilator, ECG, IBP, intracranial pressure, temperature, NIBP, and pulse oximetry [SpO_2]). Technical alarms included alarms with a blue criticality and general monitoring device–related alarms (such as missing patient information, low batteries, or interrupted arterial blood pressure measurements). Devices, where the absolute cumulative frequency of alarms was less than 500 in the dataset were only included in the overall count of alarms (Multimedia Appendix 1).

To visualize the average distribution of alarms across 24 hours, we calculated the average number of alarms of each 1-minute bin between 12:00 am and 11:59 pm for the 3 devices issuing the most alarms and applied the scatterplot smoothing function of the R package ggplot2 [26].

Alarm flood conditions are described as situations in the ICU where multiple alarms are triggered within a short time frame. Metrics related to alarm flood conditions provide information that allow an additional perspective on the alarm load of an ICU and take an acute overload of ICU staff by alarms into account [18]. We grouped the data per bed and split each bed's data into 10-minute bins starting from the date-time stamp of the first log entry. All bins containing 10 or more alarms were counted as an alarm flood, as previously described [18].

XSL•FO
RenderX

Avoidable Alarms

Avoidable alarms are defined as nonactionable (including false positive alarms) or technical [12]. Since the alarm log data lack information on whether an alarm was true or false or if it was followed by a therapeutic intervention, we cannot provide metrics such as the positive predictive value of alarms. However, most technical alarms, whether they were responded to with an intervention or not, are avoidable nonetheless [12]. Therefore, we report the average number of technical alarms per bed per day as well as the individual frequency of technical alarms.

Responsiveness and Alarm Handling

We visualize the median alarm duration per medical device in absolute seconds and over the course of 24 hours for the 3 devices issuing the most alarms. The duration of an alarm was defined as the time difference between the timestamp of the log entry of a generated alarm and that of a terminated alarm. We opted for this method, because only the "true" time of generated alarms is documented but not the "true" time of terminated alarms, where only the time of the log entry is provided.

Sensing

Using the pause function of the monitoring devices is argued to prevent unnecessary alarms [16,27]. In the investigated ICU, the alarm pause function suspends all alarms for up to 3 minutes or until it is actively terminated by the medical team. This helps prevent alarms that would be triggered when, for example, a patient is being shifted from one position to another during a physical examination. A responsible use of the pause function demands its active termination to avoid undermonitoring of the patient due to the suspended alarms for the remainder of the pause function [12] once the health care provider leaves the patient. Hence, an alarm pause can be considered a proper pause if its duration is shorter than the monitor's default pause duration. The metric "proper pause-to-pause ratio" indicates the ratio of proper pauses to all pauses [12]. We count pauses that were re-enabled within 3 minutes after their termination as one continuous pause, since the default length might not have been sufficient for the bedside procedure.

We consider an overmonitoring of patients to be indicated when parameters that monitor the same physiological event, but stem from 2 different medical devices, are routinely issuing alarms.

Exposure

The present ICU has 2 different room types: a single bedroom and a double bedroom. We aimed to find out whether a bed in a single bedroom produces more, less, or equally as many alarms as a bed in a double bedroom and whether this differs depending on the alarm criticality. In total, there are 12 beds in double bedrooms and 9 beds in single bedrooms. The average alarm frequencies per bed per room type were calculated by dividing the number of alarms per room type by 12 or by 9, respectively.

Results

Overview

The results section is clustered into 2 parts: First, we provide the DIY instructions for self-analysis of alarm data from the patient monitoring system; second, we present the results of the illustrative alarm data analysis conducted on data from our ICU.

DIY Instructions

Step-by-Step Procedure

The DIY instructions for self-analysis of the ICU's patient monitoring alarm data consist of 6 steps: (1) define or re-evaluate metrics, (2) collect data, (3) analyze data, (4) visualize metrics, (5) present to staff and set goals together, and (6) design and implement interventions (see Figure 1).

Figure 1. Feedback loop regarding do-it-yourself (DIY) instructions for self-analysis of patient monitoring alarm data in the intensive care unit.

XSL•FO
RenderX

Define or Re-Evaluate Metrics

In an interdisciplinary team consisting of ICU physicians and nurses, alarm data metrics should be defined. We recommend to initially include all metrics presented in the aforementioned data analysis framework in order to get an accurate and complete picture of the alarm situation of the respective unit. After the first iteration of the feedback loop, new metrics may be added or existing ones modified.

Collect Data

Regular collection of patient monitoring data is crucial to conduct reliable data analyses, especially if interventions are being conducted at the respective ICU. The monitoring central station at our ICU stores data for up to 90 days; hence, every 90 days, data have to be manually extracted from the system [28].

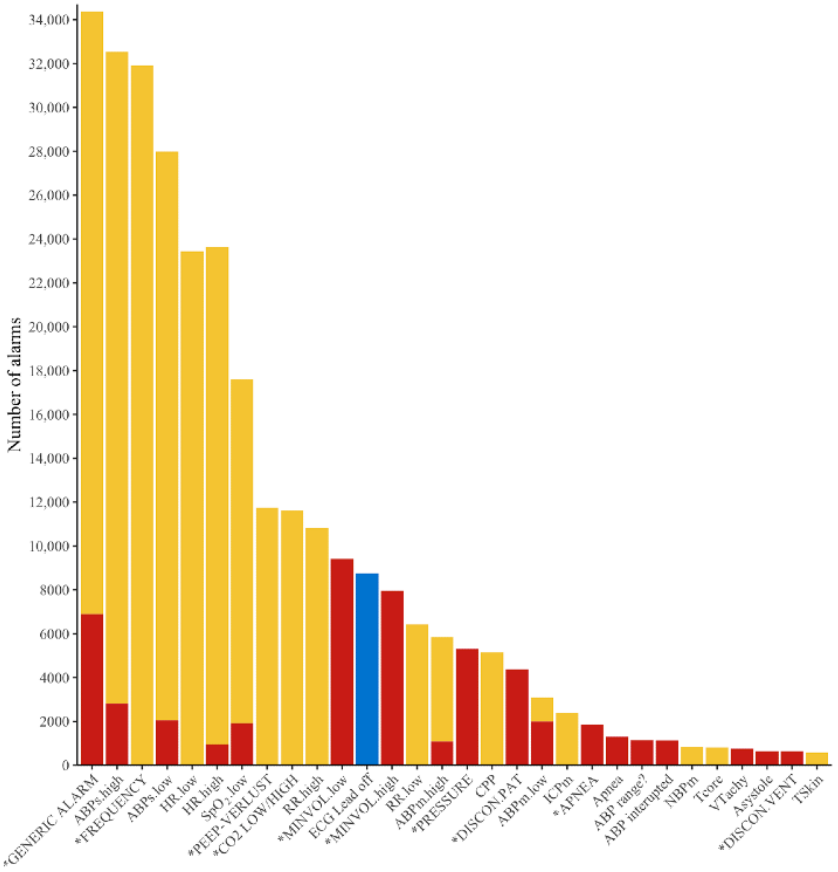
Analyze Data

We provide the fully annotated R scripts that we used to conduct the alarm data analysis to enable even beginners in R to do likewise. Further explanations can be found in the Results section and in the scripts [20].

Visualize Metrics, Present to Staff, and Set Goals

Visualizations should be summarized in a clear and intuitive format (eg, using a presentation program) and discussed with ICU staff. Together, realistic goals should be set for each parameter and possible interventions deduced. On a quarterly basis, this feedback loop should be started from the beginning. The R-Markdown file on GitHub can also be used to create comprehensive alarm reports including all metrics and visualizations reported in this paper [20].

Design and Implement Interventions



Potential interventions are deduced from the data analysis, the visualizations, and the interdisciplinary goal setting. ICU staff as the end users of the patient monitoring system should be actively involved in the intervention design and rotate regularly with new medical staff from the ICU to assess clinical relevance more reliably. Possible interventions could include adjusting the default alarm thresholds for the top 10 alarm parameters, focusing on customizing these parameters more frequently, introducing new ECG electrodes or skin preparation routines, or providing staff training (eg, on how to use the alarm pause function). Further interventions are elaborated elsewhere [29,30].

Data Analysis

Alarm Load

The analyzed alarm log data set contained, on average, 152.5 (SD 42.2) alarms per bed per day. Most alarms were type yellow (mean 120.3/152.5, SD 37.15 per day; 79%), followed by type red (mean 27.5/152.5, SD 9.37 per day; 18%). Few alarms were type blue (mean 4.6/152.5, SD 2.75 per day; 3%). The 5 most frequent alarms were a generic alarm of the ventilator, invasive systolic blood pressure (high and low), high respiratory rate issued by the ventilator, and low heart rate (see Figure 2).

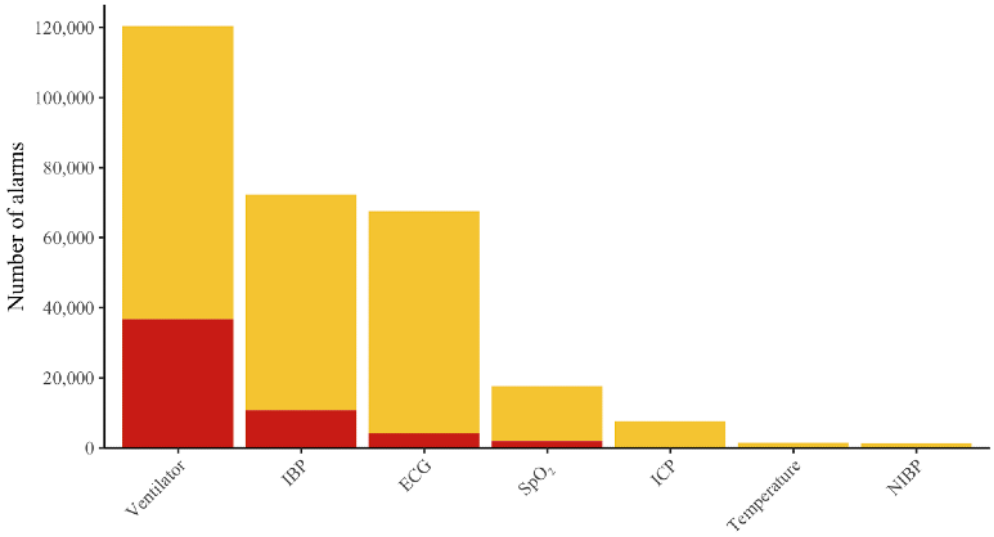
Figure 2. Frequency of individual alarm parameters within 93 days. The colors correspond to the alarm criticalities (red, yellow, and blue). *: ventilator arm; ABPs: systolic arterial blood pressure; ECG: electrocardiogram; FREQUENCY: ventilator alarm indicating that the upper respiratory rate threshold has been exceeded; HR: heart rate; RR: respiratory rate derived from the ECG (see Multimedia Appendix 2 for all abbreviations).

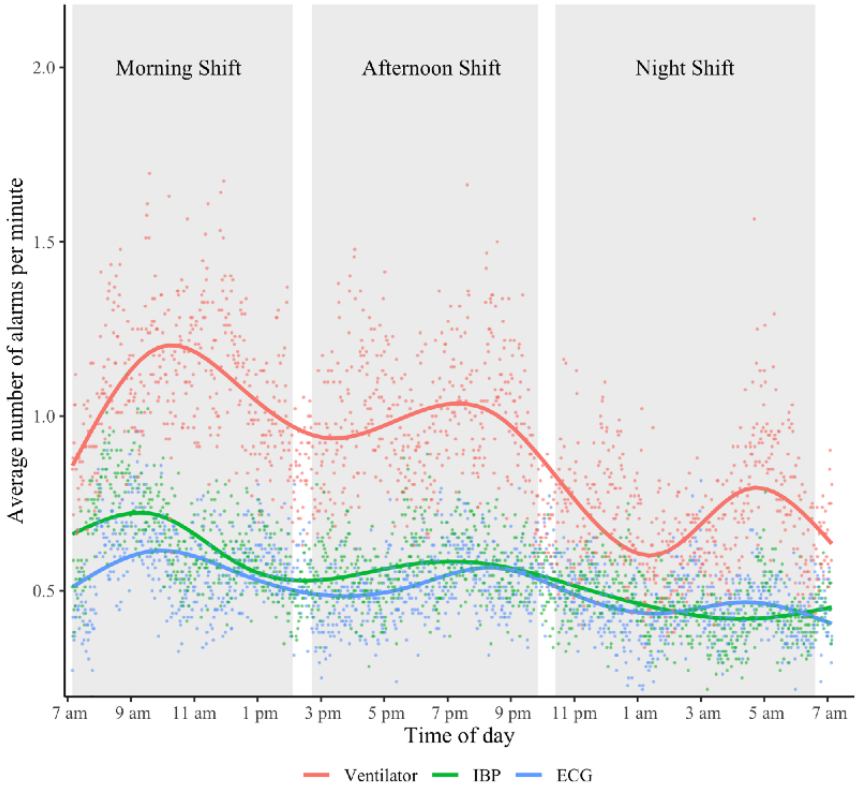
XSL•FO
RenderX

After each alarm parameter was assigned to the corresponding medical device, it was evident that the ventilator generates the most alarms, followed by IBP and ECG (see Figure 3).

When put into a temporal perspective, the average distribution of alarms across 24 hours for the 3 devices that issue the most alarms shows a downward trend, with most alarms being issued in the morning shift and fewest during the night (see Figure 4). The mean number of alarms per minute per medical device during the morning, afternoon, and night shifts were: 1.09 (SD 0.2), 1.0 (SD 0.18), and 0.71 (SD 0.17) for the ventilator; 0.65 (SD 0.13), 0.56 (SD 0.1), and 0.45 (SD 0.09) for IBP; and 0.57 (SD 0.12), 0.51 (SD 0.1), and 0.45 (SD 0.09) for ECG, respectively.

Figure 3. Alarms from medical devices within 93 days subdivided into the criticality levels (red, yellow). ECG: electrocardiogram; IBP: invasive blood pressure; ICP: intracranial pressure; NIBP: noninvasive blood pressure; SpO_2: oxygen saturation.





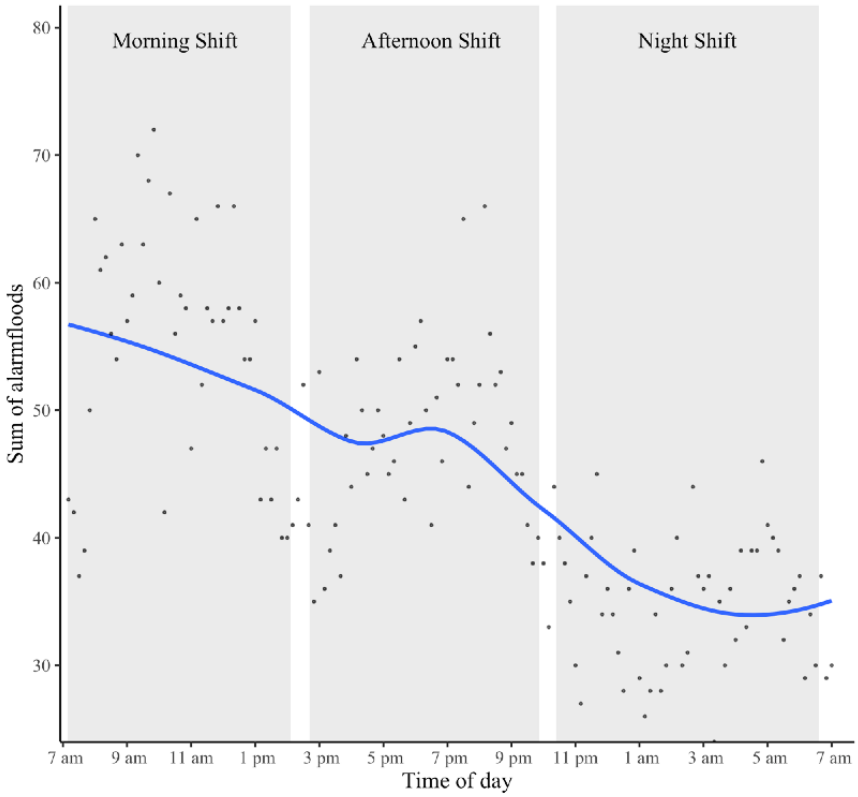


Figure 4. Average distribution of alarms across 24 hours. The white spaces between the grey bars (ie, shifts) visualize handover periods. Each dot shows the average alarm frequency of 1 minute for the specified device. The line for each device is calculated by ggplot2's smoothing function and represents a generalized additive model of the distribution (with the formula y ~ s(x, bs = "cs"). It serves to aid in detecting trends in the data. ECG: electrocardiogram; IBP: invasive blood pressure.

XSL•FO
RenderX

In total, 6468 alarm flood conditions occurred (mean 69.55, SD 31.0 per day; median 63; range 22-194), of which 5289 (82%) were comprised of between 10 and 20 alarms, 1012 (16%) between 20 and 40 alarms, and 159 (2%) between 40 and 100 alarms within 10-minute intervals. The temporal visualization over 24 hours shows a general downward trend with peaks in the morning and afternoon shifts (see Figure 5).

Figure 5. Temporal distribution of alarm flood conditions over 24 hours. Each dot indicates the sum of all alarm flood conditions that were initiated at the respective time of day in 10-minute intervals. For example, the first dot on the far left indicates that 43 alarm floods occurred between 7:10 and 7:20 AM across all days in the data. The blue line is a local regression, calculated by ggplot2's smoothing function (formula: y ~ x). The white spaces between the grey bars (ie, shifts) visualize handover periods.

Avoidable Alarms

In total, 10,846 technical alarms (red, yellow, and blue) are documented. This equals 5.6 (SD 2.8) technical alarms per bed per day, on average. With 8746 alarms (all blue), the ECG produced the most technical alarms (ECG lead fallen off), followed by IBP (1342 red alarms) and alarms related to the module cable connection (167 blue alarms).

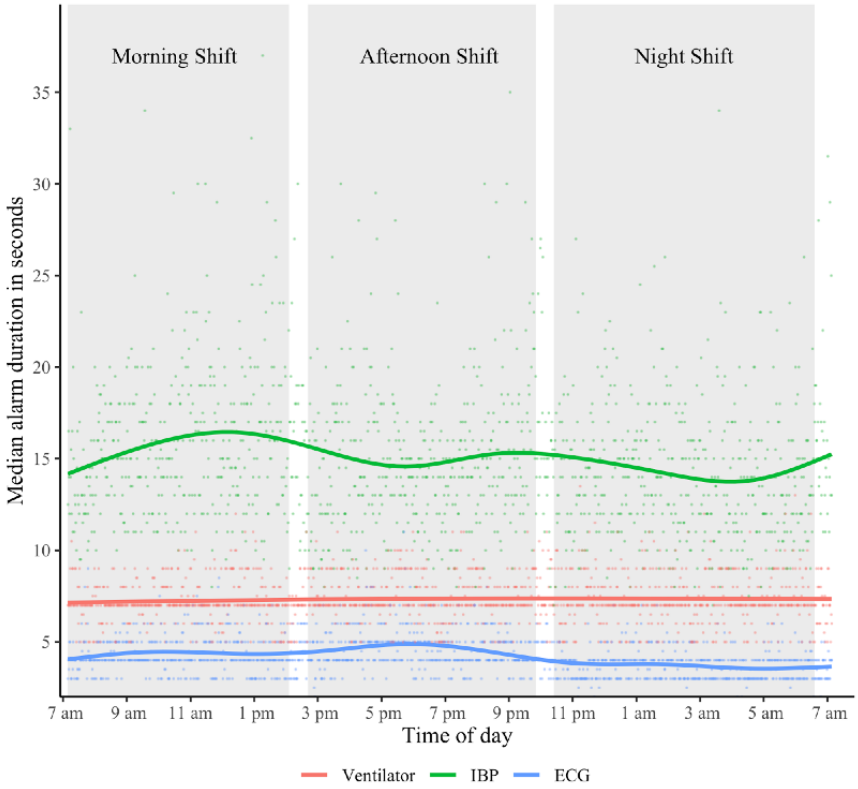
Responsiveness and Alarm Handling

The alarm duration showed a distribution that is strongly skewed to the right (for clinical alarms: mean 109.3, SD 6109.15 seconds; median 8 seconds; range 0-2,291,314 seconds; for technical alarms: mean 221.5, SD 4,898 seconds; median 7 seconds; range 0-403,440 seconds), which is why we used the median as the measure of the center for further analyses and plots. Additionally, because some durations were calculated to be unrealistically high (in some instances, multiple days), we treat all durations longer than 8 hours (approximately the length of one shift) as outliers and do not include them in the analyses.

Median alarm durations of yellow and red alarms were similar (8 seconds; range 0-22,048 seconds; range 0-28,531 seconds), while the median alarm duration of blue alarms was slightly longer (9 seconds; range 0-26,049 seconds). Regarding devices, the median duration of alarms by NIBP was the longest (64 seconds; range 0-3845 seconds), followed by temperature (26 seconds; range 0-7796 seconds), SpO_2 (16 seconds; range 0-27,580 seonds), and IBP (14 seconds; range 0-28,531 seconds). ECG and the ventilator recorded the lowest median alarm duration (4 seconds; range 0-27,579 seconds and 7 seconds; range 0-22,048 seconds, respectively). Visualizing the alarm durations over 24 hours shows that the difference across devices was relatively stable over the course of an average day (see Figure 6). However, Figure 7 shows that there were substantial differences between the median duration to red and yellow ECG alarms.

XSL•FO
RenderX

Figure 6. Median alarm duration of the 3 medical devices that issue most alarms over 24 hours. Each dot represents the median alarm duration for each minute of the day of the respective device. The line for each device is based on ggplot2's smoothing function and represents a generalized additive model of the distribution (with the formula y ~ s(x, bs = "cs"). The white spaces between the grey bars (ie, shifts) visualize handover periods. ECG: electrocardiogram; IBP: invasive blood pressure.



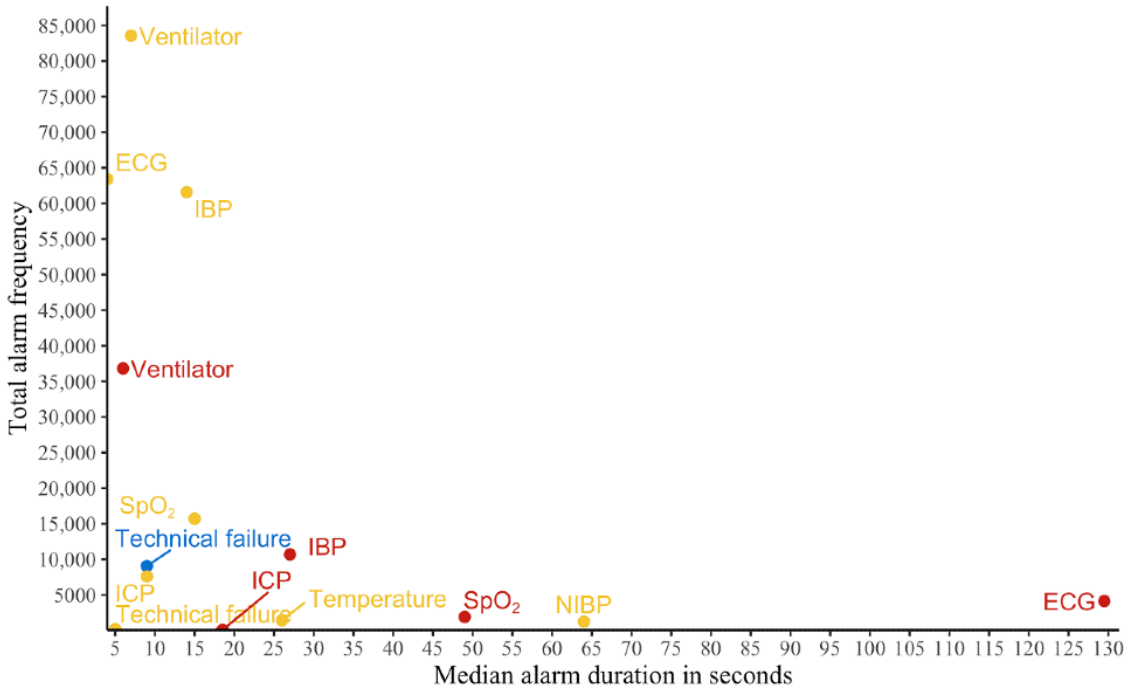


Figure 7. The median alarm duration from 8 medical devices plotted against the total number of alarms issued by the respective device. The colors correspond to the alarm criticalities (red, yellow, and blue). ECG: electrocardiogram; IBP: invasive blood pressure; ICP: intracranial pressure; NIBP: noninvasive blood pressure; SpO_2: oxygen saturation.

XSL•FO
RenderX

Sensing

On average, the alarm pause function was applied 10.86 (SD 2.6) times per bed per day. Of all pauses that were started, 92% (14,719/16,002) were not actively terminated but lasted for their default maximum length of 3 minutes and therefore do not qualify as proper pauses [10]. The ICU's proper pause-to-pause ratio is 0.09:1.

Of the ECG alarms, 16% (10,821/67,518) indicated a high respiratory rate, which amounted to 4% (10,821/297,830) of all alarms recorded in the data set, while the alarms from the ventilator related to a high respiratory rate covered another 11% (31,911/297,830) of all alarms. Additionally, both device groups had similar numbers of life-critical apnea alarms. This suggests an overmonitoring of the respiratory rate.

Exposure

A bed located in a single bedroom had, on average, 26% (172.9/137.2) more alarms per day than a bed located in a double bedroom. There were 32% more red alarms per bed in a single bedroom than in a double bedroom (2972.9/2250.3) and 25% more yellow alarms per bed in a single bedroom than in a double bedroom (12,638.8/10,105.2).

The calculated average alarms per bed per day yields 152.5 alarms (SD 42.2). On average, 36% (7.6/21, SD 1.6) of the 21 beds exceeded the units average every day, issuing on average 69% of all daily alarms (2199.9/3202.4, SD 651.2).

Discussion

Principal Findings

We aimed to provide technically versed ICU staff with a framework and the tools to conduct a self-analysis of patient monitoring alarm data in order to help them assess their unit's alarm situation, inspect potential root causes of excessive alarms, and derive alarm management interventions that might help to remedy alarm fatigue. Our framework consists of 6 steps that should be iteratively applied: (1) define or re-evaluate metrics, (2) collect data, (3) analyze data, (4) visualize metrics, (5) present to staff and set goals together, and (6) design and implement interventions. We designed the framework to be useful independent of the ICU's specialization (eg, COVID-19 units, neonatal ICUs, pediatric ICUs). In our observational study, we illustrated how the alarm log data of a large German ICU can be analyzed and how alarm metrics can be visualized using the scripts that we provide (steps 2 and 3 of the framework, respectively [20]). The data analysis was structured according to the aforementioned quality dimensions [12]: The alarm load was quantified by 152.5 (SD 42.2) alarms per bed per day on average, issued mostly by the ventilator, IBP measurement, and ECG in the morning shifts (ie, high/low blood pressure, high respiratory rate, high/low heart rate). Alarm flood conditions also mostly occurred in the morning shifts with, on average, 69.55 (SD 31.12) per day. With regard to avoidable alarms, technical alarms were mostly issued by the ECG (ie, lead fallen off). The dimension "responsiveness and alarm handling" included the metric "alarm duration." The calculation yielded a median duration of 8 (range 0-2,291,314) seconds for clinical alarms and 7 (range 0-403,440) seconds for technical alarms. Regarding "sensing," the alarm pause function is, on average, applied 10.86 (SD 2.6) times per bed per day, and in 92% (14,719/16,002) was not actively terminated, resulting in a proper pause-to-pause ratio of 0.09:1. The "exposure" to alarms per bed per day was higher in single rooms (26%, mean 172.9/137.2 alarms per day per bed). Most alarms were, on average, issued by 7.6 of 21 beds (36%).

Alarm Metrics in Perspective

Cvach et al [29] suggested that most ICU patients have less than the average number of alarms per bed per day while a few have more than that. In their data analysis of adult telemetry, 19% (n=3) exceeded the unit's average on a single day; in our data analysis, on average, 36% (n=7.6) exceeded the unit's average.

Our data analysis shows that beds located in a single bedroom have a higher alarm load compared to a bed in a double bedroom. Further analysis of alarm data at the patient level could reveal whether the alarm load depends on the severity of the patient's illness. Upon presenting our results to ICU staff, they noted that patients in delirium are often treated in single bedrooms. Since delirium is a condition that can lead to erratic movements [31], this might explain the larger number of alarms coming from single bedrooms (eg, due to disconnected ECG leads). This anecdote highlights the importance of presenting the results of the data analysis to ICU staff, as suggested in Figure 1.

Slow response times can be an indicator of alarm fatigue [32]. However, response times to alarms can be slow for other reasons than alarm fatigue alone, such as the unit's floor layout and policies [17] or the staff members' individual personality traits [33]. Similarly, response times can be fast for other reasons than a well-functioning organization: ICU staff might be so severely desensitized to alarms that they start terminating them blindly, without properly evaluating the patient's situation [12]. Although response time and alarm duration are related, they are not the same. Response time describes the time between the generation of an alarm and its manual termination. Alarm duration describes the time between the generation of an alarm and any termination of that alarm (such as the auto-termination of alarms if an alarm with a higher priority is issued). Our data did not include information on whether an alarm was manually terminated or not, which is why we focused on analyzing the alarm duration.

Although the pause function of the monitoring devices can prevent unnecessary alarms [14,26], it should be used responsibly by terminating it before leaving the patient. Our data yielded a proper pause-to-pause ratio of 0.09:1, meaning that most pauses that were started were not actively terminated but lasted for their default maximum length of 3 minutes. This ratio is far from Hu¨ske-Kraus et al's [12] ideal ratio of 1, where all pauses would be a "proper pause." If it is indeed the case that health care providers leave patients with the alarm pause still engaged, then this aspect should be included in future staff training to promote a responsible use of the alarm pause function. However, other reasons for this pattern in the data should be considered as well. For example, sometimes even the maximum duration of an alarm pause is not long enough (eg, when ICU staff are in the middle of an intervention on the other

XSL•FO
RenderX

side of the bed, unable to reach the patient monitor, watching the pause automatically disengage). Hence, this nonideal proper pause ratio does not necessarily represent carelessness of ICU staff but could hint towards the maximum default length of alarm pauses as being too short.

Limitations

Quantification of the alarms does not reflect whether alarm fatigue is an issue in the respective ICU. In order to evaluate alarm fatigue as a complex sociotechnical phenomenon, the data analysis should be accompanied by a qualitative study (eg, by staff interviews or alarm fatigue surveys) [34]. Our applied grouping of metrics into dimensions is based on available literature, not delimited, and to some extent arbitrary. For example, the “alarm pause” metric could be assigned to the dimension “alarm handling” or the “alarm flood” metric to the dimension “exposure.” The software version of our monitoring system does not log technical alarms with a low priority (soft inoperable alarms), and we did not include alarms from every medical device that issues alarms (eg, perfusion pump alarms are not included). Hence, the metrics reported underestimate the actual alarm load of the unit.

Conclusion

We demonstrated that basic data analysis skills can help generate valuable insights for designing alarm management interventions and how alarm data analyses might be embedded in an overarching framework that guides in developing such interventions. We hope the presented DIY instructions and the alarm processing and visualization scripts accompanying this publication will be helpful to other intensivists and researchers and spur the publication of many ICUs’ alarm data and lessons learned from their alarm management efforts.

Acknowledgments

We express our gratitude to Julia Liehr, medical technician of the Charité CFM Facility Management GmbH, for supporting us with her technical expertise regarding patient monitoring, as well as Dirk Hüske-Kraus at Philips Healthcare for his valuable feedback on our manuscript. We acknowledge support from the German Research Foundation (DFG) and the Open Access Publication Funds of Charité – Universitätsmedizin Berlin. AP is a participant in the Charité Digital Clinician Scientist Program funded by the Charité – Universitätsmedizin Berlin and the Berlin Institute of Health.

Authors' Contributions

MK identified the need to improve the alarm situation in the ICU and initiated the study together with AP. The study was conceived by AP, CS, FB, MF, and MW. AP conducted data acquisition, supported by ES and GV. MW and AP analyzed the data, supported by PH as a computer scientist. AP wrote the manuscript, supported by MW. FB supervised all parts of the study. All authors critically reviewed and approved the manuscript. The article was extracted from the M.S. thesis of MW.

Conflicts of Interest

CS received public funding from the Stifterverband and the Einsteinstiftung, and received funding from different companies for the Leopolidna Meeting 2020 payed to the Charité - Universitätsmedizin Berlin. All other authors declare no conflicts.

Abstract

Background: Some researchers argue that the successful implementation of patient decision aids (PDAs) into clinical workflows depends on their integration into electronic health records (EHRs). Anecdotally, we know that EHR integration is a complex and time-consuming task; yet, the process has not been examined in detail. As part of an implementation project, we examined the work involved in integrating an encounter PDA for symptomatic uterine fibroids into Epic EHR systems.

Objective: This study aims to identify the steps and time required to integrate a PDA into the Epic EHR system and examine facilitators and barriers to the integration effort.

Methods: We conducted a case study at 5 academic medical centers in the United States. A clinical champion at each institution liaised with their Epic EHR team to initiate the integration of the uterine fibroid Option Grid PDAs into clinician-facing menus. We scheduled regular meetings with the Epic software analysts and an expert Epic technologist to discuss how best to integrate the tools into Epic for use by clinicians with patients. The meetings were then recorded and transcribed. Two researchers independently coded the transcripts and field notes before categorizing the codes and conducting a thematic analysis to identify the facilitators and barriers to EHR integration. The steps were reviewed and edited by an Epic technologist to ensure their accuracy.

Results: Integrating the uterine fibroid Option Grid PDA into clinician-facing menus required an 18-month timeline and a 6-step process, as follows: task priority negotiation with Epic software teams, security risk assessment, technical review, Epic configuration; troubleshooting, and launch. The key facilitators of the process were the clinical champions who advocated for integration at the institutional level and the presence of an experienced technologist who guided Epic software analysts during the build. Another facilitator was the use of an emerging industry standard app platform (Health Level 7 Substitutable Medical Applications and Reusable Technologies on Fast Healthcare Interoperability Resources) as a means of integrating the Option Grid into existing systems. This standard platform enabled clinicians to access the tools by using single sign-on credentials and prevented protected health information from leaving the EHR. Key barriers were the lack of control over the Option Grid product developed by EBSCO (Elton B Stephens Company) Health; the periodic Epic upgrades that can result in a pause on new software configurations; and the unforeseen software problems with Option Grid (ie, inability to print the PDA), which delayed the launch of the PDA.

Conclusions: The integration of PDAs into the Epic EHR system requires a 6-step process and an 18-month timeline. The process required support and prioritization from a clinical champion, guidance from an experienced technologist, and a willing EHR software developer team.

Introduction

Background

Researchers have argued that the successful implementation of patient decision aids (PDAs) into clinical workflows depends on their integration into electronic health records (EHRs) [1,2]. The task of integrating third-party tools into EHRs is complex [3]. Security concerns dominate the challenge, as institutions have become reliant on EHRs to manage key operational workflows [3]. Third-party software that brings external connections and URL links to EHRs is subject to extensive scrutiny [4]. Updates to either the EHR or linked third-party products are perennial concerns, given the cost of downtime or system failure.

Many software vendors provide system-wide EHR software (eg, Epic, Cerner, or Allscripts) [5]. However, there are major differences between the same EHR product when installed at different health care institutions: this is because they are tailored to organizational and clinical preferences and integrated with other ancillary software [6]. Clinicians also differ in how and when EHRs are used with patients [7]. These uses can include showing images or test results and sending health information via the patient portal [8]. Although some common integration processes can be identified, solutions cannot be replicated from one institutional setting to others and tailoring is always required.

PDAs provide evidence-based information in a comparative format to facilitate shared decision-making, in which patients and clinicians are supported when making informed decisions together [9]. PDAs serve as catalysts to engage patients in decision-making processes and can be used before, during, and after clinical encounters [10,11]. Recent systematic reviews and meta-analyses have shown that PDAs increase knowledge about options and reduce decisional conflict, thereby helping patients make decisions that align with their preferences [12,13]. Despite improving a range of outcomes, their implementation in the clinical workflow remains a challenge [14,15]. Given the widespread adoption of EHRs and clinicians' reliance on them [16], many have presumed that integrating PDAs into EHRs will lead to their increased use in clinical practice [2,17]. However, this presumption has not yet been tested at scale.

Studies that have evaluated the integration of PDAs in EHRs have focused on measuring their use by clinicians [1,18-22], measuring their impact on patient outcomes [23-25], or user testing the tool to improve the navigation and design in the EHR system [26-29]. The integration of 2 PDAs, namely the Statin Choice and Diabetes Medication Choice tools, in the EHR at the Mayo Clinic led to their increased use [18,20,21]. Coylewright et al [1] also demonstrated an increased use and observed that adoption rates of an EHR-based *HealthDecision* tool steadily increased over an 8-year period, with a *high rate of sustained implementation after the fifth use*.

Nevertheless, we were only able to identify a few examples of PDAs being integrated into EHR systems [1,18-29]. Anecdotally, researchers and practitioners recognize that embedding PDAs in EHRs is a complex and time-consuming process; however, we could not identify the literature that described the required processes. Therefore, we lack an understanding of *how* best to integrate these tools into EHRs, and the steps required, especially given the recent development of new interoperability standards [30]. An opportunity arose to address this research gap as part of a project to implement the uterine fibroids Option Grid PDA at 5 health care institutions in the United States (Uterine Fibroids Options [UPFRONT] study) [31].

Objectives

The aims of this work are to (1) identify the steps and the time required to integrate an Option Grid PDA into the Epic EHR system and (2) examine facilitators and barriers to the integration effort. We hypothesize that some institutions will successfully integrate the Option Grid PDA into Epic as part of a multistep, time-intensive process.

Methods

Design

As part of a Patient-Centered Outcomes Research Institute (PCORI)–funded, stepped-wedge implementation trial, we asked each participating institution to integrate Option Grid PDAs into their Epic EHR systems. Despite the stepped-wedge design, we began the integration effort at all institutions almost immediately upon receiving funding to provide ample opportunity to complete the process ahead of the active implementation phase of the broader trial, which is when clinicians would be expected to use Option Grid with their patients. Successful integration was defined as the completion of changes to the Epic system that allowed clinicians to easily access an external website that provides access to both interactive and PDF versions of the uterine fibroid Option Grid PDAs [31]. Facilitators are key elements or factors that enable a successful integration. To examine the processes required, we adopted an exploratory case study design and collected data by recording relevant meetings and taking field notes [32]. We analyzed our conversations with the clinical champions, their research teams, and Epic software analysts from various departments (such as compliance, risk management, and information security) at each institution. Our case study was reported using the checklist by Rodgers et al (Multimedia Appendix 1) [33]. The Dartmouth College Committee for the Protection of Human Subjects (approval number: STUDY00031464) granted ethical approval for our study.

Settings

The implementation study took place in the following institutions: (1) Dartmouth-Hitchcock Medical Center in Lebanon, New Hampshire; (2) Barnes-Jewish Hospital in St. Louis, Missouri; (3) Montefiore Medical Center in Bronx, New York; (4) Brigham and Women's Hospital in Boston, Massachusetts; and (5) Mayo Clinic in Rochester, Minnesota. Each of these institutions had installed the Epic EHR product at different times. Our case study is based on our efforts to integrate the Option Grid into the Epic EHR system at these 5 institutions. Table 1 provides a brief description of each institution's Epic experience, expertise, and infrastructure.

XSL•FO

Table 1. Description of each institution's Epic experience, expertise, and infrastructure.

Institution	Date of Epic adoption	Number of Epic software analysts[a]	Any previous experience with third-party software integration?	Does the clinical champion have experience with using patient decision aids?
Dartmouth-Hitchcock Medical Center	April 2011	170	Yes	Yes
Barnes-Jewish Hospital	June 2017	150	Yes	No
Montefiore Medical Center	April 2015 to June 2016	200	Yes	No
Brigham and Women's Hospital	June 2015	Unknown	Yes	Yes
Mayo Clinic	May 2018	300	Yes	No

[a]Estimated number.

Option Grid PDA

The Option Grid PDA for symptomatic uterine fibroids is part of a suite of tools developed and updated by EBSCO (Elton B Stephens Company) Health, a commercial entity that provides clinical decision support for health care organizations [34]. Our collaboration with EBSCO Health for developing and maintaining the uterine fibroids PDA came at no cost to the research effort. The uterine fibroid tool compares 7 treatment options: (1) watch and wait, (2) medicine with hormones, (3) medicine without hormones, (4) embolization, (5) endometrial ablation, (6) myomectomy, and (7) hysterectomy. The tool is available in English and Spanish for the following 2 formats: text-only and text accompanied by pictures (Picture Option Grid). For the study duration, each participating institution was granted access to the entire suite of 30 Option Grid tools.

When clinicians click the Option Grid button, they are first presented with the entire suite of PDAs. Once clinicians select the uterine fibroids Option Grid, they have the opportunity to select as many as 7 treatment options that are relevant to a particular patient. Once the PDA is generated, the clinician can use 3 features to document the options discussed in the encounter: print a PDF version, copy and paste a script that includes the options selected, or send a *permalink* to the patient so that they can view the Option Grid at their own convenience. The script is an optional feature that enables clinicians to document the use of the PDA and the options discussed in the EHR. The clinician must either use this feature or write a note in the EHR regarding the conversation that occurred with the PDA, as Option Grid does not exchange any information with the EHR. Figure 1 shows an example of an Option Grid PDA for symptomatic uterine fibroids.

Figure 1. Snapshot of the text version of the uterine fibroid Option Grid patient decision aid.

Recruitment

The 5 institutions were selected to participate in our implementation trial because of their inherent diversity, their interest in implementing PDAs, and, in some cases, their experience of practicing shared decision-making. Institutions (from inner city Bronx to rural New Hampshire) treat an ethnically diverse patient population across both urban and rural settings. At each of the 5 institutions, an obstetrics and gynecology specialist was recruited for the role of clinical

XSL•FO
RenderX

champion (site principal investigator) for their interest in using PDAs to improve health care delivery. The clinical champions contacted the Epic software analysts and explained the importance of integrating the uterine fibroids Option Grid PDA into the EHR. The clinical champion also introduced software analysts to the UPFRONT study team, which included an experienced Epic technologist employed at EBSCO Health (FA).

Data Collection

Videoconference meetings were scheduled between the UPFRONT team and the Epic software analysts at each institution. Following the introductory meeting, the Epic software analysts dictated the frequency of the meetings based on their needs for assistance or clarification from the Epic technologist. The software analysts reached out to our study team to schedule meetings. The meetings were a time to collect the work summaries that had been collected by the software analysts, identify any barriers they were facing, and discuss solutions to overcome those barriers. Each meeting was audio-recorded. The transcribed audio recordings and field notes from the meetings provided the data for analysis.

Consent

The Dartmouth College Committee for the Protection of Human Subjects waived the requirement for the written documentation of informed consent. Standard information regarding the study was provided to the participants. The study team sought verbal consent from the audio recording at the start of videoconference meetings. If verbal consent was not granted by one or more members, then the study team took notes of meeting discussions.

Analysis

For aim 1, 2 researchers (PS and DS) reviewed meeting transcripts and field notes and documented the steps taken to integrate the Option Grid into Epic. Our description of the steps was reviewed and edited by the Epic technologist (FA) and modifications were made if required. To determine the amount of time required for the integration, we counted the number of months from the original email to the clinical champions to gauge their interest in a possible integration effort to the moment the Option Grid was launched in the site's Epic environment. For aim 2, we conducted an inductive thematic analysis of the transcripts and field notes. Two researchers (PS and DS) independently coded a sample of transcript pages and then discussed and agreed on a codebook. The finalized codebook (Multimedia Appendix 2) was applied to all the data to highlight the facilitators and barriers to the integration effort. Codes were grouped into different code categories, which were revised and discussed by PS and DS to determine the themes. Coding disagreements were resolved by a third researcher (GE).

Results

Overview

A total of 27 meetings were held. These included 25 videoconferences (Zoom, Webex [Cisco], or Skype [Microsoft Corporation]) and 2 telephone meetings. Of the 27 meetings, we were able to record 22 (81%) meetings and collated notes for the remaining 5 (19%). The bidirectional exchange of information between the Epic software analysts and the study team (including the Epic technologist) during the meetings at each institution yielded a total of 183 transcripts or field note pages (total word count: 91,336; see Table 2 for details).

Aim 1: The Steps Taken to Integrate the PDA Into Epic

We were able to describe the process of integrating the Option Grid PDAs into Epic by identifying 6 common process steps across the institutions (Textboxes 1 and 2).

The timeline for completing the 6 steps varied across institutions, but overall, up to 18 months (January 2019 to June 2020) was required to integrate the Option Grid PDAs into the Epic EHR system. The timeline began in January 2019, which was when all clinical champions received an email to gauge interest in integrating Option Grid into a clinician-facing menu in their Epic system. Although work began to place a button in an agreed location nominated by clinicians at each institution, a policy decision was made by EBSCO Health in August 2019 to use Substitutable Medical Applications and Reusable Technologies (SMART) and Fast Healthcare Interoperability Resources (FHIR) standards and list the application on Epic's App Orchard to simplify the setup and maintenance of the tool throughout the study period. Owing to the COVID-19 pandemic, integration efforts at 2 institutions were paused to redirect resources to other more pressing initiatives. One institution was able to resume the effort, whereas the other institution had competing priorities and was forced to furlough some personnel involved in the integration process. Thus, we were only able to complete the integration of Option Grid into Epic at 4 of the 5 sites. Figure 2 details the integration timeline following the policy decision, beginning with the security risk assessment (Step 2) and ending with the Option Grid launch (Step 6).

XSL•FO
RenderX

Textbox 1. Steps to integrate the Option Grid patient decision aids into the electronic health record.

Step 1: Negotiating task priority with Epic software teams

- The clinical champions at each site requested the changes into their Epic systems, establishing the clinical benefit of providing easy access to the Option Grid website in a clinician-facing menu location. Epic teams had to reprioritize their tasks, given existing work schedules. In one setting, agreement to reprioritize required negotiation and financial support

Step 2: Security risk assessment

- Each institution had different security risk assessment processes, with each requiring departmental approval. Typically, 3 levels of security checks were required, related to the changes in outpatient processes or menus, information flows and dependencies, and communication with third-party tools. Epic has different modules (ie, outpatient, inpatient, and research) and each has its own operations and approval groups. The Ambulatory Operations group is responsible for reviewing requests related to general outpatient workflows (Barnes-Jewish Hospital and Montefiore Medical Center). In the case of Barnes-Jewish Hospital, the integration had to also be approved by the Interfaces Operations group, which manages requests related to any information that gets moved in and out of Epic via interfaces, and the Infrastructure team, which manages the App Orchard. The Mayo Clinic also had 3 levels of security: (1) Security, Privacy, Architecture and Data Assurance reviews new technology that will be integrated into Epic; (2) Clinical Decision Support reviews electronic health record (EHR) change requests that have endorsement from a clinical or practice committee and includes some form of clinical decision support (ie, patient decision aids [PDAs]); and (3) the Obstetrics and Gynecology specialty group, which reviews any new process, procedure, or app that will be integrated into Epic from the clinical perspective. The 4 levels of security at Brigham and Women's Hospital include (1) the clinical vetting that reviews the study context with 2 clinicians; (2) the technical feasibility of the project evaluated by an Epic team leader, (3) technical assessment (see Step 3 for details); and (4) the security risk assessment that represents an internal process to review the application being integrated into Epic. Security review was considered unnecessary at Dartmouth-Hitchcock because the Option Grid tools were merged with an existing decision support product—HealthDecision. Analysts were particularly focused on data exchange requirements between the Option Grid app and Epic. The lack of protected health information (PHI) transfer was important. Using Substitutable Medical Applications and Reusable Technologies on Fast Healthcare Interoperability Resources to allow approval for the synchronization of the private Option Grid App Orchard app with the institution's Epic environment (Step 4 for details) standardized the process across all 5 sites

Step 3: Technical review

- The Epic software analysts determined the number of personnel and time required for the overall software changes. Once the level of effort, allocation of tasks, and timelines were established, the software analysts were ready for the build

Step 4: Epic configuration

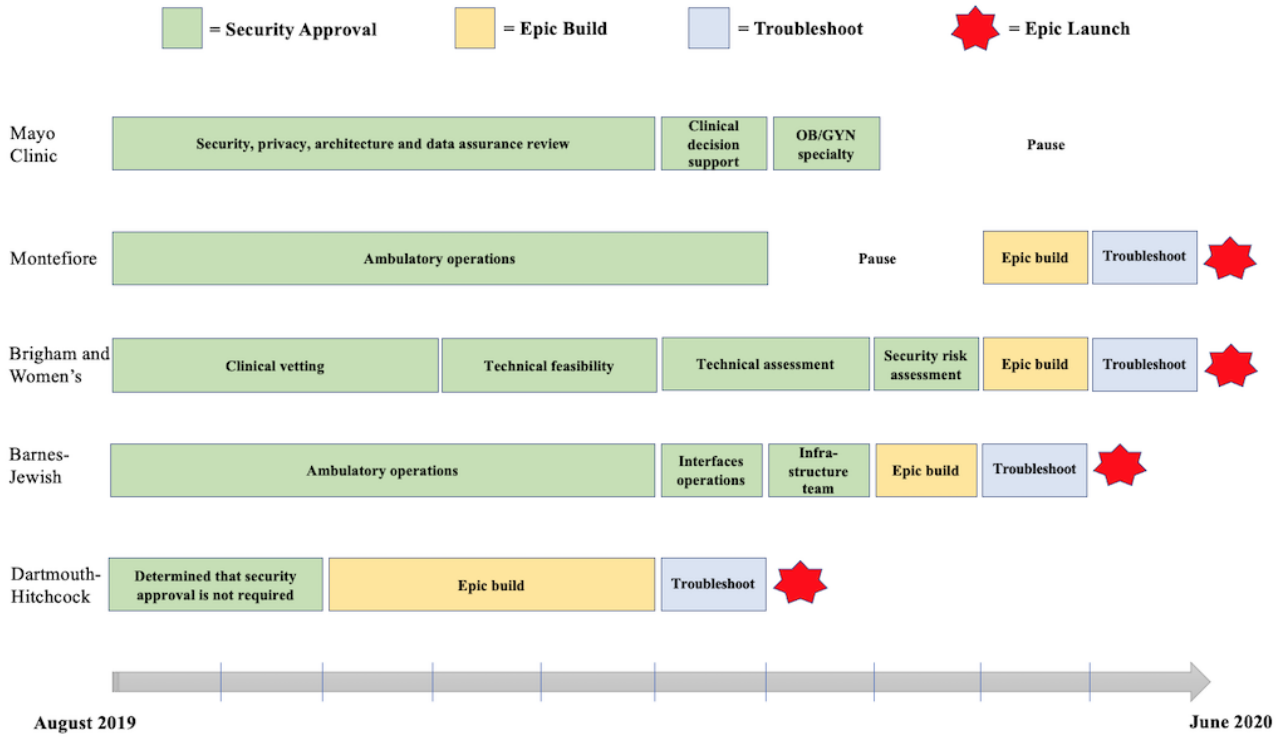
- Before commencing the build, all clinical champions indicated their preference for placing the Option Grid button in the patient's chart under the More menu in their toolbar at the top. Some clinical champions preferred that the button be accessible to the entire institution, whereas others preferred a restricted access to their obstetrics and gynecology department. Our study team's Epic technologist then developed and shared a build guide with each institution. The guide outlined the study objectives, the Epic-specific configurations required, and described how the Option Grid would not require access to PHI. The Epic software analysts configured access to the Option Grid PDA using Health Level 7 Substitutable Medical Applications and Reusable Technologies on Fast Healthcare Interoperability Resources (see Textbox 2 for further details). The guide contained 4 steps:
    - Accessing the app at the Epic App Orchard
    - Enabling synchronization of the Option Grid PDA on the App Orchard with the institution's Epic environment
    - Establishing a test environment before launch in a production environment
    - Requesting whitelisting of the Option Grid domains so that the app could be accessed within Epic's EHR menus, tasks, and options. Epic uses the term Hyperspace to describe this view of the software. Launching Option Grid within Hyperspace allows clinicians to have an easy access to the PDAs, without having to navigate to an external website

Step 5: Troubleshooting

- The software analysts ensured that menu locations, access requests, and user identification were all functioning as planned. This step represented a final check to ensure that all the Option Grid features were operational

Step 6: Launch

- After troubleshooting, the new configuration was migrated to the production environment and the Option Grid was launched. This means that clinicians could access the Option Grid button and be directed to the Option Grid website where they can generate a PDA for their patients



XSL•FO
RenderX

Textbox 2. Health Level 7 Substitutable Medical Applications and Reusable Technologies on Fast Healthcare Interoperability Resources authentication.

SMART on FHIR

- Substitutable Medical Applications and Reusable Technologies (SMART) is an "open, standards-based platform that enables innovators to create applications that seamlessly and securely run across the healthcare system" [35]. Health Level 7 (HL7) is an "industry organization that develops standards for the exchange, integration, sharing and retrieval of EHR information" [36]. HL7 adopted the OAuth2-based SMART App Launch framework as a core interoperability standard. HL7 also developed the Fast Healthcare Interoperability Resources (FHIR) standard to ensure *interoperability, extensibility, and speed* while searching for information across clinical applications [37]. SMART, along with FHIR—collectively referred to as SMART on FHIR—connects third-party apps to Epic, enabling them to reliably and securely launch in Epic's Hyperspace desktop client [38]. We used SMART on FHIR authentication for the following 3 reasons:
  - Improved analytics: allows the tracking of app use so that we can determine the number of eligible patients who received the uterine fibroid Option Grid patient decision aid (PDA)
  - Improved control for data access: SMART on FHIR allows a better control of the information shared with third-party apps
  - Uses existing authorizations: using FHIR allows clinician access to the Option Grid PDAs in their existing user interface (Epic's Hyperspace)
- To leverage SMART on FHIR, Epic requires apps to participate in its App Orchard app store. For the UPFRONT (Uterine Fibroids Options) study, EBSCO (Elton B Stephens Company) chose to list Option Grid as a private app on the Epic App Orchard and allowed access by the 5 participating institutions. This also simplified the setup and maintenance of the PDA app during the study period.

Figure 2. Timeline of the electronic health record integration of the Option Grid patient decision aid. OB/GYN: obstetrics and gynecology.

Aim 2: Thematic Analysis of Facilitators and Barriers to EHR Integration

We identified 4 integration facilitators (Textbox 3):

Textbox 3. Facilitators of electronic health record integration.

Facilitators

1. Clinical advocacy: presence of a clinical champion at each institution
2. Electronic health record expertise: presence of an Epic technologist with experience in building apps in Epic
3. Standardization of process: use of Substitutable Medical Applications and Reusable Technologies on Fast Healthcare Interoperability Resources standards
4. Avoidance of protected health information (PHI) data transfer: no exchange of PHI between Option Grid and the institution's local Epic environment

XSL•FO
RenderX

Clinical Advocacy

The clinical champions provided the required professional arguments for integration and served as a gateway to the Epic software analysts and lobbied for prioritization of the task. For instance, the principal investigator at Montefiore Medical Center advocated for the Epic software analysts to prioritize the integration effort:

> *We are getting it prioritized by the Epic work group with a goal for the summer.* [Principal investigator at the Montefiore Medical Center]

EHR Expertise

Having an EHR expert on our study team with a direct experience of Epic EHR environments and of the app's requirements at EBSCO was a major facilitator. He developed a *build guide*, which facilitated the integration of Option Grid PDAs in Epic at the 5 settings. Throughout the meetings, the EHR expert supported the software analysts by answering questions, clarifying points of confusion, and providing solutions for any technical issues that arose throughout the process. The following is an example of an exchange between the Epic expert and a software analyst at Barnes-Jewish Hospital during the troubleshooting step of the integration process:

> *The environment is listed in our App Orchard listing and has the test client ID. Can we test? [launch URL provided] The tokens in the OAuth context values are the same.* [Epic technologist]
>
> *Thank you—I updated the URL item in the record and tested it again. That seemed to work! I am able to open the Uterine Fibroids Option Grid, copy and paste information, open a PDF, and print the PDF.* [Barnes-Jewish hospital software analyst]

Standardization of Process

First, the use of SMART on FHIR standards provided a helpful and officially sanctioned way to better control the information being shared with a third party such as the Option Grid PDA. As described in Textbox 2, the process provided clinicians with single sign-on credentials and enabled us to track the number of times each clinician generated or accessed a uterine fibroid PDA. The Epic technologist also indicated that Epic recommends SMART on FHIR over alternative launch methods such as active guidelines and other URL-based methods:

> *The reason we went with SMART authentication is because Epic specifically advised us to do so for newer implementations.* [Epic technologist]

Avoidance of Protected Health Information Data Transfer

Placing the Option Grid PDA as a private app in Epic's App Orchard restricted Option Grid from retrieving protected health information (PHI). Option Grid instructed Epic to block certain features (ie, incoming application programming interface), so their organization would be unable to attain PHI. This arrangement eased the security concerns at each institution. For example, a software analyst at the Mayo Clinic informed us that it would be easier to obtain approval from the security team if PHI was not leaving their Epic environment:

> *When we bring in new technology it has to go to Security, Privacy, Architecture and Data Assurance (SPAD) review, but if there is no PHI it will get blessed faster.* [Mayo software analyst]

We identified 3 themes that represented barriers to the integration effort (Textbox 4).

Textbox 4. Barriers of electronic health record integration.

Barriers
1. Commercial third-party autonomy: lack of control over the Option Grid patient decision aid product owned by EBSCO Health
2. Electronic health record updates and maintenance: periodic Epic upgrades causing some delays and functionality issues
3. Unforeseen software problems: found while troubleshooting the app leading to minor delays to launch

Commercial Third-Party Autonomy

Although our collaboration with EBSCO was an overall facilitator, it also presented a barrier. EBSCO owns the Option Grid product, and as researchers, we have no influence on product development. Future product development may require additional integration efforts during the life of the study and remain a risk area. For instance, the policy decision in August 2019 to change the integration strategy forced software analysts to adapt and use a different configuration than originally planned. The following is a part of the study team's communication to each institution, explaining the shift in integration strategy:

> *EBSCO has been working on enhancing Option Grid and its integration with Epic. This process will utilize SMART and FHIR standards. As a result, we are requesting to delay the integration build in your Epic environment.* [UPFRONT study team]

EHR Updates and Maintenance

Some institutions have regular Epic upgrades and either refrain from integrating apps during those upgrades or impose a freeze on all new software configurations. The software analysts did their best to plan ahead and sidestep this barrier at the final step. The following are 2 quotes that highlight reluctance to launch the button during an upgrade:

> *Some customers have code freezes that could last more than a month when they have Epic upgrades.* [EHR technologist]
>
> *We generally don't push out new applications during an Epic upgrade.* [Brigham software analyst]

XSL•FO
RenderX

Unforeseen Software Problems

We experienced unforeseen software-related problems during the troubleshooting steps. In some settings, clinicians were unable to print PDF versions of the tool or copy and paste the script documenting the uterine fibroid options discussed in the patient's record. These software issues were conveyed to our EHR technologist:

> *We confirmed that the copy/paste does not work when launching the application.* [Dartmouth software analyst]
>
> *The PDF button did not work. I was still able to navigate elsewhere on the page, but the PDF button was non-responsive.* [Brigham software analyst]

These issues were quickly resolved through collaboration between the software analysts and the Epic technologist and did not significantly delay the launch of the Option Grid in the site's Epic environments.

Discussion

Principal Findings

The integration of Option Grid PDAs into an EHR such as Epic requires clinical advocacy, a standardized process that avoids using PHI, and expertise to guide the process. Without the support of a clinical champion in each setting, we would not have been able to initiate the process of PDA integration. At the core of the work are issues of security and reassuring the organization that data transfers will not breach security protocols. SMART on FHIR addresses the data security requirements by allowing for a better control of the information being shared with a third party such as Option Grid. The availability of an EHR expert on our study team provided the necessary guidance and reassurance to the existing Epic teams. With all these components and facilitators present, the integration process took up to 18 months to achieve. Barriers were the lack of control over the Option Grid product, EHR updates and maintenance, and unforeseen software problems that caused delays and functionality issues.

Strengths and Limitations

Our use of a case study method to elicit a real-world, in-depth understanding of the steps required to integrate PDAs into Epic, and the associated barriers and facilitators, is novel and provides new insights. However, this study has limitations. First, we were only able to examine the Epic EHR system, so we do not know if our description of the integration process steps applies to other systems. Second, the Option Grid PDAs do not require the use of PHI data. Some PDAs being developed require the exchange of PHI, which we suspect would prolong integration timelines at many institutions. Third, all the institutions were large academic medical centers with expertise in configuring the Epic EHR system, so we do not know if our findings are applicable to smaller clinical practices that lack such capability. Fourth, we did not conduct a thematic analysis to address our first aim. However, despite the absence of a thematic analysis, we feel like a review of meeting transcripts, with oversight from an Epic technologist, represents the appropriate method to determine the steps to integrate the Option Grid PDA into Epic. Furthermore, it is not known whether EBSCO Health would provide an Epic technologist to other customers or organizations aiming to integrate Option Grid in their Epic. Finally, because of the COVID-19 pandemic, we were only able to integrate the Option Grid PDAs at 4 of the 5 institutions. One institution had to redirect resources to other initiatives and were faced with staffing limitations, which led to a pause in the integration effort. We did not include this as a barrier, considering that under normal circumstances, the institution would be positioned to complete the integration of Option Grid in their Epic.

Results in Context

To the best of our knowledge, this is the first study to describe SMART on FHIR standards to integrate third-party PDAs, such as Option Grid, into an EHR system. Our results address an important gap outlined by a recent feasibility study that integrated a third-party prostate cancer screening PDA app into the EHR [3]. The authors of that study recognized the potential of SMART on FHIR to standardize secure data exchange and enable integration across a variety of EHRs [3]. However, research has focused on the interoperability of FHIR standards. For instance, a recent review showed how FHIR moved clinical information (medical images and quality metrics) found on different platforms in the EHR into a single platform to streamline the workflow of radiologists [37]. Similarly, another system has used FHIR standards to collect data from multiple sources in the EHR, automate analyses of laboratory test results, and generate easy-to-read reports for patients and their clinicians [39].

For aim 2, a key facilitator of Option Grid PDA integration into Epic systems was the presence of a clinical champion. This aligns with the results of an effort to integrate an EHR-based PDA in the emergency department for concussion and brain injury decisions [40]. They reported the critical need to engage clinicians and other information technology stakeholders [40]. In our case, the clinical champion served as an intermediary between the study team and the Epic software analysts, facilitated prioritization, and identified the EHR menu button location to ensure visibility. Clinicians' input in the integration process is reported to potentially cause the sustained use of the tools in practice [41,42] and is key to an integration effort, regardless of the format or mode of delivery [14,43-45].

Implications

Integrating third-party software into EHR systems requires a clinical champion to advocate for the task at the institutional level and an EHR expert who can guide software analyst teams throughout the process. From a policy perspective, implementing SMART on FHIR-compatible servers, which has been done at Duke Medical Center, can improve interoperability and the seamless integration of patient-facing apps [46]. However, the technologies for standardizing the integration of various types of apps, such as Option Grid, do not necessarily mean that they will be used in clinical practice. Integration, though difficult to achieve, seems to be the first step to ensure that clinicians have access to such tools. Providing an integration guide for other organizations to follow and identifying the barriers and facilitators of the process will enable more tools to be integrated into workflows. However, access alone might not lead to use,

XSL•FO
RenderX

as observed by others [21]. Future work should include usability, acceptability, or health technology assessments to further evaluate how to trigger clinicians to access and use embedded PDAs [22].

Conclusions

Integrating the uterine fibroid Option Grid PDA into clinician-facing menus in Epic was an approximately 18-month process, facilitated by a clinical champion who lobbied for the prioritization of the effort at the institutional level, and an EHR expert who guided the Epic software analysts throughout the study. The use of Health Level 7 SMART on FHIR standardized the integration effort, provided clinicians with single sign-on credentials, and more importantly blocked the exchange of PHI between Epic and Option Grid PDAs. Whether integration leads to patient use remains an open question.

Acknowledgments

The authors would like to thank the clinical champions at each institution for spearheading the EHR integration effort and serving as the gateway to the Epic software analysts: Dr Erika Banks, Dr Raymond M Anchan, Dr Shannon K Laughlin-Tommaso, Dr Tessa Madden, and Dr Tina C Foster. They also appreciate the time and effort of every Epic software analyst they encountered in their journey. They want to thank Dr Jon Keevil at EBSCO for working with site personnel to synchronize the private Option Grid App Orchard app with their Epic environment. Research reported in this study was funded by the PCORI award (grant SDM-2017C2-8507). The statements presented in this study are solely the responsibility of the authors and do not necessarily represent the views of the PCORI, its Board of Governors, or the Methodology Committee.

Conflicts of Interest

GE has edited and published books that provide royalties on sales by publishers, including Shared Decision Making (Oxford University Press) and Groups (Radcliffe Press). GE's academic interests focus on shared decision making and coproduction. He owns copyright in measures of shared decision making and care integration, namely collaboRATE, integRATE (measure of care integration), consideRATE (patient experience of care in serious illness), coopeRATE (measure of goal setting), toleRATE (clinician attitude to shared decision making), Observer OPTION-5, and Observer OPTION-12 (observer measures of shared decision making). In the past, he provided consultancy for organizations, including (1) Emmi Solutions LLC (limited liability company) who developed patient decision support tools; (2) the National Quality Forum on the certification of decision support tools; (3) Washington State Health Department on the certification of decision support tools; and (4) SciMentum LLC, Amsterdam (workshops for shared decision making). He is the founder and director of &think LLC, which owns the registered trademark for Option Grid PDAs, and founder and director of SHARPNETWORK LLC, a provider of training for shared decision making. He provides advice in the domain of shared decision making and PDAs to (1) Access Community Health Network, Chicago (Adviser to Federally Qualified Medical Centers); (2) EBSCO Health for Option Grids PDAs (consultant); (3) Bind On Demand Health Insurance (consultant); (4) PatientWisdom Inc (Adviser); and (5) Abridge AI (artificial intelligence) Inc (Chief Clinical Research Scientist).

MAD is a consultant to Access Community Health Network. Together with GE, she developed the Option Grid PDAs, which are licensed to EBSCO Health. She receives consulting income from EBSCO Health and may receive royalties in the future.

FA is the Vice President of Clinical Decision Support Technology at EBSCO Health with existing and future applications on the Epic App Orchard and a previous Epic employee.

No other authors have conflicts of interest to declare.

Abstract

Background: Older adults are increasingly accessing information and communicating using patient-facing portals available through their providers' electronic health record (EHR). Most theories of technology acceptance and use suggest that patients' overall satisfaction with care should be independent of their chosen level of portal engagement. However, achieving expected benefits of portal use depends on demonstrated support from providers to meet these expectations. This is especially true among older adults, who may require more guidance. However, little is known about whether misalignment of expectations around technology-facilitated care is associated with lower perceptions of care quality.

Objective: The aims of this study were to analyze whether older adults' assessment of primary care quality differs across levels of patient portal engagement and whether perceptions of how well their provider uses the EHR to support care moderates this relationship.

Methods: We conducted a cross-sectional survey analysis of 158 older adults over the age of 65 (average age 71.4 years) across Michigan using a 13-measure composite of self-assessed health care quality. Portal use was categorized as none, moderate (use of 1-3 functionalities), or extensive (use of 4-7 functionalities). EHR value perception was measured by asking respondents how they felt their doctor's EHR use improved the patient–provider relationship.

Results: Moderate portal users, compared to those who were extensive users, had lower estimated care quality (–0.214 on 4-point scale; *P*=.03). Differences between extensive portal users and nonportal users were not significant. Quality perception was only particularly low among moderate portal users with low EHR value perception; those with high EHR value perception rated quality similarly to other portal user groups.

Conclusions: Older adults who are moderate portal users are the least satisfied with their care, and the most sensitive to perceptions of how well their provider uses the EHR to support the relationship. Encouraging portal use without compromising perceptions of quality requires thinking beyond patient-focused education. Achieving value from use of patient-facing technologies with older adults is contingent upon matched organizational investments that support technology-enabled care delivery. Providers and staff need policies and practices that demonstrate technology adeptness. Older adults may need more tailored signaling and accommodation for technology to be maximally impactful.

Introduction

Patients' increased access to, and engagement with, their digitized health information has featured prominently in recent federal law and quality-based payment programs designed to accelerate value-generating use of health information technology [1,2]. The Medicare and Medicaid Electronic Health Record (HER) Incentive Programs have helped to advance use of patient portal technologies as a mechanism for information access and electronic patient–provider communication. Portals are intended to increase patient engagement in managing their own health and health care needs, and improve accessibility and efficiency of receiving certain clinical advice, reminders, and services [3-5]. However, evidence linking portal use to improved measures of quality or value is mixed [6-9]. This uncertainty regarding the value of portal use is especially true for older adults, a population for which there has been substantial attention concerning lag in adoption [10] and less understanding of variation in patterns of portal use and perceptions of information technology–enabled care [11-14]. More recent evidence suggests some narrowing of the digital divide based on age [12,15] and significant potential for enhanced communication and self-management engaging older adults through portal technologies [13,16,17]. However, the "right" level of portal use to encourage among older adults is difficult to pinpoint and context dependent.

Patients, provided that they are offered portal access in the first place [15], make usage choices based on technology expectations (eg, perceived usefulness and ease of use) and enabling factors, such as the level of support, encouragement, and education received from providers on how to engage with the portal [18-20]. Together, enabling factors and expectations shape intention and actual portal use, as articulated by the technology acceptance model and the more updated Unified Theory of Acceptance and Use of Technology [21,22] (see Figure 1). However, the linkage between level of portal use and patients' overall satisfaction with care is ill defined.

Figure 1. Integrated conceptual model of portal use and perception of care quality modified by expectation confirmation.

Empirically, there appears to be little association between how much a portal is used (ie, a dose response) and objective measures of quality (eg, hemoglobin A_{1c} control, readmissions) [23,24]. A key theoretical consideration is that portals are a shared tool between patients and providers. A patient's perception of benefit from using the portal is reevaluated with every experience the user has in using the portal to facilitate communication and needed services with a health care provider. Whether a patient is happy with care at their chosen level of portal engagement is therefore dependent on whether the experience matches their expectation [25,26]. Extending the technology acceptance model with expectation–confirmation theory (see Figure 1) reflects this more interactive understanding [27]. (Dis)confirmation of patient expectations around the use of portals, shaped by how the provider organization is engaging from their end, may modify the relationship between chosen levels of engagement and patients' self-assessment of care quality.

Among older adults, the extent to which their level of portal engagement is matched by perceived reciprocal investment by their provider is a heightened contextual factor that may influence how older adults assess their quality of care. Older adults' expectations for how their primary care providers can structure and deliver health care in a more technology-advanced way continue to evolve, and their perceptions of this alignment in investment is heightened given the additional guidance and support that older adults more often need in order to feel comfortable in engaging with patient-facing technologies [28,29]. Observations about how the provider uses the EHR in-clinic—perceived adeptness of use, continuity or disruption of attention and communication, and whether providers voice frustration with use—meaningfully shape whether patients perceive that their provider's use of technology adds value to, or detracts from, the value of their care [30-32]. To the extent that older adults' value assessments around portal engagement may be tied to perceptions of how effectively their providers use the EHR, we must consider these as possibly interdependent factors that shape overall assessment of care quality [29,31,33].

This study used a novel dataset of older adults surveyed about their health needs, provider relationships, and perceptions of health system experiences. We characterized the nature of portal engagement among a sample of older adults and then addressed the following 2 specific research questions: (1) Are older adults' assessments of primary care quality independent of the level of

XSL•FO
RenderX

personal engagement with patient portal technologies? (2) To what extent do patient perceptions of how their provider uses technology modify observed relationships between extent of patient portal use and assessment of care quality? Ultimately, this paper seeks to provide actionable insights that help providers leverage health information technology investment for improved experiences of primary care for a large and growing older adult population.

Methods

Setting and Data Source

A statewide survey regarding older adults' perceptions of health care needs and navigation of primary care services was developed and administered between March 2019 and June 2019 across Michigan, which has population demographics that closely represent nationwide aging trends [34]. The survey instrument was informed by 4 focus groups with a total of 18 older adult participants, and drew upon elements of previously validated surveys, including the clinician/group survey of the Consumer Assessment of Healthcare Providers and Systems (CAHPS) and the National Poll on Healthy Aging [35,36]. "Think aloud" cognitive testing was then conducted with an additional 10 participants for survey refinement to ensure functionality, appropriate wording, and comprehension [37,38]. We used this adaptive measure development approach because many validated measures of primary care quality are general to the adult population; this broader survey effort sought to define quality from the specific perspective of aging. [39] This survey study was reviewed and determined to be exempt from full human subjects review by the University of Michigan Institutional Review Board. The full survey instrument is available upon request.

Participants were recruited statewide using an online health research platform managed by a large academic medical center with a pool of roughly 50,000 prospective participants [40]. Respondents needed to be over 65 years of age, comfortable with written English, have a person whom they consider their "regular doctor", and have passed a brief cognitive test. All respondents must have received health care in the United States at least once in the past year but not necessarily with their regular doctor. Because we used a convenience sampling approach, we collected a number of demographic and health status indicators to help characterize our final sample and appropriately limit the generalizability of our findings [14,16]. Participants received a brief overview of the study and the URL for accessing the survey via Qualtrics where they also provided written informed consent. Respondents were asked to reflect specifically on health care experiences with the person they consider their primary care provider. Survey sections containing the questions of interest for our analyses were distanced from each other within the instrument, and question order within each section was randomized across participants [41]. Participants received US $10 for participation.

Measures

Outcomes

Our primary outcome was a composite measure of participants' overall self-rated health care quality. The survey contained 13 questions that assessed dimensions of quality. Four of these questions were adopted from the CAHPS patient survey [36]; 9 additional questions assessing care coordination, patient-centered care experience, and age-sensitive care delivery were added based on focus group findings to reflect the particular experiences of older adults (Multimedia Appendix 1). All questions were assessed on the same 1-4 scale ("not true," "somewhat true," "fairly true," or "very true") as preferred by respondents during cognitive testing and reverse coded as necessary. We averaged the values provided across all 13 questions to assign each respondent a summary value between 1 and 4. The Cronbach α reliability coefficient was .94, and exploratory factor analysis supported use of a single factor, with all questions loading on to this factor at or above 0.68 (Multimedia Appendix 2).

Technology Perception and Use

We used 2 health information technology–related survey questions. One measure captured how respondents use health information technology via available patient portal features. We asked about usage of 7 features across 3 domains: information availability (viewing laboratory/test results, reviewing physician's advice, finding medications), communication (messaging with provider, answering previsit questions), and convenience (refilling medications, paying bills online). These questions were adapted from the National Poll on Healthy Aging [35]. We then created 3 categories of portal use: no portal use, moderate portal use (1-3 features used), and extensive portal use (4-7 features used).

The second question focused on perception of provider's use of EHRs. We asked respondents, on a 1-4 scale, if they felt their doctor's EHR use improved their patient–provider relationship. We focused on improved relationship as a measure of EHR use given our interest in the value of EHR for communication and patient engagement. We created a binary indicator for EHR value perception; participants who reported a 1 or 2 ("not true" or "somewhat true") were labeled as having a low EHR value perception and those who reported a 3 or 4 ("fairly true" or "very true") were labeled as having a high EHR value perception.

Covariates

The following self-reported demographic and clinical profile characteristics were available from survey data: age, race, sex, highest education completed, and an indicator of financial status (how often respondent has money left over at the end of the month). Clinical profile measures included the patient's self-reported health status (poor or fair, good, and very good or excellent), an indicator of polypharmacy (ie, whether a participant self-reports taking 4 or more pills) [42], number of primary care and number of total health care encounters in the past 6 months, and whether the participant has a caregiver. We also asked respondents the duration of their relationship with their doctor (<5 years, 5-10 year, 10+ years).

XSL•FO
RenderX

Check for Common Method Bias

Because our main variables of interest (ie, information technology perception/use questions) and our composite quality outcome measure derived from the same survey instrument, we tested for common method bias prior to conducting any analyses [41]. Factor analysis on the combination of all included measures confirmed that there was no single latent factor accounting for most of the covariance among survey questions.

Analytic Methods

We first calculated summary statistics for all available demographic and clinical profile characteristics of our survey respondents, and, where possible, considered comparative national statistics to understand how well our sample compared to the demographic profile of older adults across the United States. We also calculated summary statistics for our outcome measure: the 13-item composite of self-reported health care quality.

For our information technology–specific questions, we calculated the percent of respondents using each of the 7 available portal features. To understand the distinguishing characteristics of respondents at each level of portal use (eg, nonportal users, moderate portal users, extensive portal users), we assessed bivariate relationships between portal use and all available demographic and health status measures (listed above as covariates). We also tested the association between our portal use categories and the EHR value perception measure (ie, how respondents perceive value in their provider's use of the EHR). Because health status and health care needs may influence the specific portal features considered useful to an individual, we also ran a supplemental analysis to look at whether the types of portal use (ie, which features) varied based on self-rated health status and/or extent of medication use.

We next examined the bivariate relationships between all available respondent characteristics and the composite quality measure to assess which characteristics are relevant to include in our full models. We estimated full multivariate ordinary least squares regression models with robust SEs. Examining the distribution of errors postestimation supported this model choice. We first estimated the independent adjusted effects of the extent of respondent portal use and the EHR value perception on the composite quality outcome measure. We then reran these models and included an interaction between these variables to assess whether EHR value perception moderates the association between respondents' personal portal use and self-reported health care quality.

Results

Summary of Data

Our survey yielded 167 responses from adults over the age of 65, with 158 surveys sufficiently complete for full analysis. The average age of respondents in our sample was 71.4 years. Respondents were 66.5% (105/158) female, highly educated (45.2% [71/157] reporting higher than a bachelor's degree), and in good health (57.6% [91/158] reporting very good or excellent health status; Table 1). These characteristics, in addition to a younger-skewed age distribution and underrepresentation of rural respondents, differentiate our sample relative to national corresponding statistics. About one-third of participants (46/153, 30.1%) had a formal or informal caregiver who supported their health and health care needs, and 17.9% (28/158) expressed concern with technology use. Individuals varied in clinical complexity (54/157 [34.3%] taking 4 or more pills daily) and financial security (53/158 [33.5%] reporting money rarely or sometimes left over at the end of the month). Over half (88/158, 55.7%) of the respondents had been seeing their doctor for at least 5 years.

Our 13-item composite outcome measure of perceived health care quality averaged 3.46 out of 4 across our sample (SD 0.46). Of the 158 respondents, 30 (19.0%) reported uniformly high quality on all 13 questions.

Portal use among this sample was relatively high. Portal use was found to be positively associated with the number of doctors a patient had seen in a 6-month time frame and negatively associated with age, technology concerns, and financial stability (Multimedia Appendix 3). Most health status characteristics (eg, self-reported health status, polypharmacy, having a caregiver) were not associated with extent of portal use. Of all respondents (N=164 with portal use data), 127 (77.4%) used at least 1 of 7 available functionalities (Figure 2). The most commonly used features were viewing test/laboratory results (72.6%, 119/164) and communicating with the doctor (56.1%, 92/164). The average respondent used 3 different functions; 22.6% (37/164) of the sample reported no portal use, 30.4% (50/164) used 1-3 features (moderate), and 47.0% (77/164) of the sample used 4 or more features (extensive). We found that individuals taking more medications were more likely to use the portal to find their medication list but less likely to use the portal for answering previsit questions. We observed no significant differences by self-reported health status (Multimedia Appendix 4).

Overall, 67 respondents (41.5%) reported that the EHR improved their relationship with their physician (high EHR value perception; Figure 3). This percentage was greatest among extensive portal users (42/76, 55%). Respondents who were nonusers and moderate portal users were significantly less likely to have high EHR value perception (nonusers: 9/34, 26%; moderate users: 16/49, 33%; chi-square *P* value=.01).

Regression Results

Bivariate analyses that tested association of each patient-level covariate and the composite quality outcome measure revealed only 3 significant associations: respondents' length of relationship with their provider, self-reported health, and whether the respondent had money leftover at the end of the month. The multivariate models presented include only these controls. Models with all available covariates included had consistent findings; because of our sample size, we present the more parsimonious model.

Column 1 of Table 2 presents our noninteracted multivariate model. Relative to extensive portal users, moderate portal use was significantly associated with lower self-rated quality (–0.214 on 4-point composite scale; *P*=.03). Adjusted differences between extensive portal users and nonportal users were not significant. Estimates of self-reported quality were also significantly higher for individuals with high EHR value perception relative to low perception (0.288; *P*<.001). Among control variables, higher quality was associated with individuals having a longer (10+ years) relationship duration with their provider and with being in very good or excellent health. Effects of financial stability were not significant.

When we interacted EHR value perception with respondent portal use (column 2 of Table 2), we still observed high EHR value perception to be positively and significantly associated with self-rated quality, and that there were significant differences in quality only between extensive and moderate portal users (not between extensive and nonportal users). The interaction terms were not statistically significant, suggesting that these significant differences in self-rated quality by portal use category are more salient among those with low EHR value perception. Figure 4 visually demonstrates the effect of EHR value perception on the relationship between portal use and self-rated quality. In the noninteracted model (ie "independent effects"), the effect of EHR value perception remained consistent across all levels of portal use. The interacted model demonstrates differential effects where moderate portal users appear particularly sensitive to EHR value perception. Among this group, those with low EHR value perception had especially low predicted estimates of perceived quality, while those with high EHR value perception reported a more similar self-rated quality to those who were extensive portal users.

Figure 4. Adjusted estimates of self-rated quality by EHR value perception and portal use. EHR: electronic health record.

Discussion

Principal Findings

Using novel statewide survey data of older adults' health care needs and preferences, we found that moderate portal users, those who use just a few available features, had the lowest self-rated quality, lower than both extensive portal users and nonportal users. Among this group, it was particularly those individuals also with low EHR value perception who had the lowest estimates of self-rated quality. Those with high EHR value perception had estimated quality levels similar to those of extensive portal users. These analyses preliminarily support an expectancy confirmation theory extension to patient technology acceptance. Our findings are a first step toward understanding how a mismatch between older adults' chosen level of engagement in technology-enabled care and perceptions of how well their provider uses technology to deliver services may drive variation in how older adults assess overall quality of their primary care.

Our results reveal an important emerging dual consideration with older adults. The number of older adults who are interested in and capable of participating in technology-supported health care is growing especially as it enables them to age in place [49,50]. Even those with some trepidation are starting to engage with these tools, and thoughtful support of this experience is increasingly a key component of how they perceive their care experience. These considerations now exist alongside longstanding concerns for a significant number of older adults who still have very salient individual and structural barriers to engagement (to the point that they are not even meaningfully captured via a primarily online survey like what has been presented in this study). Both issues merit attention and investments in improvement.

Fostering higher and more equitable rates of portal engagement with older adults requires offering portal access more equitably [15] and coaching patients (and their family members) through the features while being more explicit about shared expectations and the "rules of engagement" regarding portal use [13,20]. Encouraging patient portal use without compromising perceptions of quality, however, also requires that clinics demonstrate that they are competent, proactive users of technology. This means, first, that providers and staff must convey their own commitment to using the portal as a communication tool, including more robust provider or staff training and explicit policies around responsiveness and follow-up [20,29]. Enabling and sustaining this commitment requires health care organizations to support providers in these efforts, for example, by building time for portal encounters into scheduling and productivity considerations, and using EHR features such as shared task queues to facilitate delegation of communications that do not require physician response [51].

Our results also underscore the importance of opinions that patients form regarding providers' adeptness at using the EHR during in-person care. These opinions—in particular for those

XSL•FO
RenderX

patients who are engaging with the portal but are not quite super users—are strongly associated with perceptions of care quality. Significant EHR usability challenges and documentation burden have persisted as being reasons for why providers are frustrated with using their systems [52,53]. However, patients' unmet expectations may increasingly become a consequence to providers' obvious frustration and disengagement with the EHR. Primary care settings need implementable strategies to convey to patients the ways that technology is being leveraged to support their care, for example, by training and evaluating providers and staff on participative communication strategies that use screen sharing or integration of EHR task completion with patient engagement [31,54]. This may be especially necessary for providers caring for those with mistrust of the health care system and/or those with limited English proficiency or other communication or health literacy barriers, who may benefit from engaging with technology but may be wary of providers' capacity to deliver high value care through the EHR. Policy efforts are also needed to encourage vendors to improve usability and development of features that meaningfully support the most cognitively challenging and time-intensive tasks in primary care [55]. Ongoing federal initiatives that focus on enabling use of third-party applications for self-management and patient-generated health data (ie, tools untethered to the EHR) need to also be accompanied by guidelines and support for integrating these tools in to practice.

Future Work

As older adults' options for technology-assisted health and health care continue to grow, shared expectations are increasingly important for how use of these tools will be supported and matched by adept technology use among providers. Future research should emphasize the salient contextual factors that influence technology use and technology perceptions particularly relevant to older adults' health care utilization. For example, older adults are likely to receive support from family or informal caregivers, and caregivers' perception of provider quality may influence their older relatives' perception of quality. Future research should consider how the informal caregivers' role could be best accommodated and facilitated in the presence of EHR-supported care delivery [56,57]. Simultaneously, providers and organizations should be considerate of the potential for additional burdens on caregivers to foster their older relative's engagement with technology. Organizational changes required to meet these identified needs are not insignificant, but can build the essential capacity for patient-centered, value-based care.

Limitations

This study has two key limitations. First, this survey is a cross-sectional analysis and we cannot make any causal claims about the impact of patient or provider use of technology on older adults' assessment of care quality. Our research approach is descriptive and not designed to address the endogeneity of portal use with respect to health needs and the nature of recent health encounters. Second, the study uses a convenience sample and diverges on some key characteristics (ie, age distribution, educational achievement, rurality) relative to nationwide statistics. The sample also comprised mostly community-dwelling older adults and was primarily accessed online, excluding those older adults living in nursing home facilities, those with severe illnesses, and those with significant technology barriers. Our findings are thus not broadly generalizable, particularly for more clinically and socially complex older adult populations, but do provide important insights for the growing number of older adults who are interested and capable of participating in technology-supported health care.

Conclusions

Despite significant barriers for many (ie, connectivity and individual comfort with technology), certain populations of older adults are using patient portals and updating their expectations about technology-enabled health care delivery at growing rates. This 2019 statewide survey is evidence for widespread but highly variable portal use. Older adults who are moderate portal users are the least satisfied with their care and the most sensitive to perceptions of how well their provider uses the EHR to support care. This offers preliminary evidence to inform an understanding of the link between patient technology use and perceptions of care quality, moderated by expectancy confirmation. Patients' satisfaction with care at different chosen levels of portal use depends on whether providers offer an experience that aligns with their expectations. Encouraging older adults in more nascent use of patient portals may negatively affect perceptions of care quality if providers are not demonstrating adeptness with their own technology use during in-person visits and for asynchronous interaction. Organizationally, clinics need to consider changes to technology-enabled care—such as better access for, and integration of, caregivers—that are sensitive to, and accommodating of, the evolving needs and expectations of older adults. Ultimately, regulatory and payer policy changes are necessary to address the root causes of provider's frustration and disengagement with technology-supported care practices, especially poor EHR usability and lack of support for integration and efficient use of portals or other remote technologies.

Acknowledgments

The authors thank the study respondents for taking the time to participate, and thank Katie Larin for her contributions to this manuscript. Abstract

Background: Interventions to define medical jargon have been shown to improve electronic health record (EHR) note comprehension among crowdsourced participants on Amazon Mechanical Turk (AMT). However, AMT participants may not be representative of the general population or patients who are most at-risk for low health literacy.

Objective: In this work, we assessed the efficacy of an intervention (NoteAid) for EHR note comprehension among participants in a community hospital setting.

Methods: Participants were recruited from Lowell General Hospital (LGH), a community hospital in Massachusetts, to take the ComprehENotes test, a web-based test of EHR note comprehension. Participants were randomly assigned to control (n=85) or intervention (n=89) groups to take the test without or with NoteAid, respectively. For comparison, we used a sample of 200 participants recruited from AMT to take the ComprehENotes test (100 in the control group and 100 in the intervention group).

Results: A total of 174 participants were recruited from LGH, and 200 participants were recruited from AMT. Participants in both intervention groups (community hospital and AMT) scored significantly higher than participants in the control groups (P<.001). The average score for the community hospital participants was significantly lower than the average score for the AMT participants (P<.001), consistent with the lower education levels in the community hospital sample. Education level had a significant effect on scores for the community hospital participants (P<.001).

Conclusions: Use of NoteAid was associated with significantly improved EHR note comprehension in both community hospital and AMT samples. Our results demonstrate the generalizability of ComprehENotes as a test of EHR note comprehension and the effectiveness of NoteAid for improving EHR note comprehension.

Introduction

Access to and demand for heath information has led to a greater focus on patient-centered care [1,2]. Patient-centered care "makes the patient and their loved ones an integral part of the care team who collaborate with health care professionals in making clinical decisions" [2]. While prior work has shown that more active involvement by patients can lead to better outcomes [3,4] and that patients are more proactive than ever in seeking out health information [5,6], challenges remain for patients with low health literacy. The National Assessment of Adult Literacy estimates that approximately 36% of Americans have health literacy levels rated as "basic" or "below basic" [7]. This estimate, combined with the finding that physicians often overestimate the health literacy of their patients [8,9], shows that there is a gap between patient desire for health information and their ability to understand it. This gap can lead to adverse effects for patients as well as higher costs for health care centers [10-16]. Identifying low health literacy individuals and providing resources to improve their understanding are two key areas in population health research [17-20].

One aspect of health literacy that has become more critical in recent years is eHealth literacy [21,22]. As increasing numbers of patients are able to view their medical records online via patient portals (eg, the OpenNotes project) [23], there is a growing need for eHealth literacy tests and interventions to assess and improve eHealth literacy. One tool for assessing eHealth literacy is the ComprehENotes test [24], which tests the ability of individuals to understand free-text notes in a sample of electronic health records (EHRs). The ComprehENotes test consists of multiple-choice questions generated by groups of physicians and medical researchers, and validated using item response theory (IRT). Research has shown that providing access to NoteAid, an educational intervention tool that automatically defines medical terms in lay terms [18,25], improves scores on ComprehENotes items [26]. However, participants in these studies were recruited from the Amazon Mechanical Turk (AMT) platform, and thus may not represent the typical patient population [27,28]. For example, the AMT participants' self-reported demographic characteristics revealed that these participants tended to be younger and better educated than patients at risk of low health literacy [7].

This study examined the impact of NoteAid on participants recruited from Lowell General Hospital (LGH), a community hospital in Massachusetts, including diabetes patients and their friends and family members. We sought to answer the following research question: "Does NoteAid improve EHR note comprehension for participants recruited from a community hospital?" (RQ1).

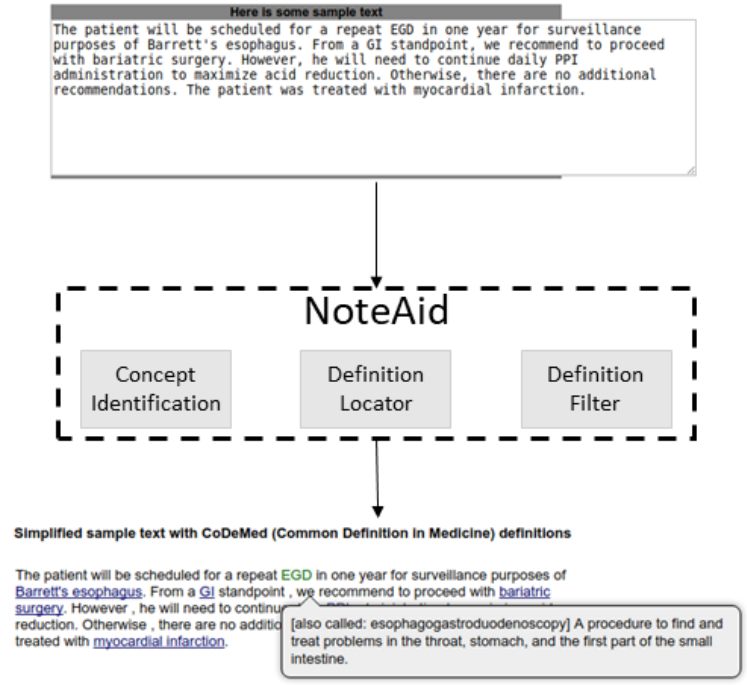
As a secondary goal, we sought to analyze the differences in performance between participants at the community hospital and participants on the AMT platform. Prior work has shown that NoteAid leads to improved scores on the ComprehENotes test for AMT participants [26]. However, overall scores for all participants on AMT were relatively high, and the population of AMT participants did not include groups typically at higher risk for low health literacy. Therefore, we compared performance on ComprehENotes between participants recruited from a community hospital and participants recruited from AMT to identify differences. The second research question was as follows: "Are participants at a community hospital different from AMT participants in terms of their EHR note comprehension levels as measured by the ComprehENotes test?" (RQ2).

As a third goal, we sought to determine whether NoteAid is equally effective for improving EHR note comprehension between participants at a community hospital and participants on the AMT platform. The third research question was as follows: "Is NoteAid equally effective or differentially effective for community hospital participants as for AMT participants in improving EHR note comprehension?" (RQ3).

Finally, we investigated the performance of different demographic groups on the ComprehENotes test, both with and without NoteAid, to see if ComprehENotes scores vary across subgroups, and whether NoteAid is equally effective across these subgroups. The fourth and fifth research questions were as follows: "Is EHR note comprehension consistent across different demographic groups?" (RQ4) and "Is NoteAid equally effective or differentially effective across different demographic groups?" (RQ5).

Methods

Overview



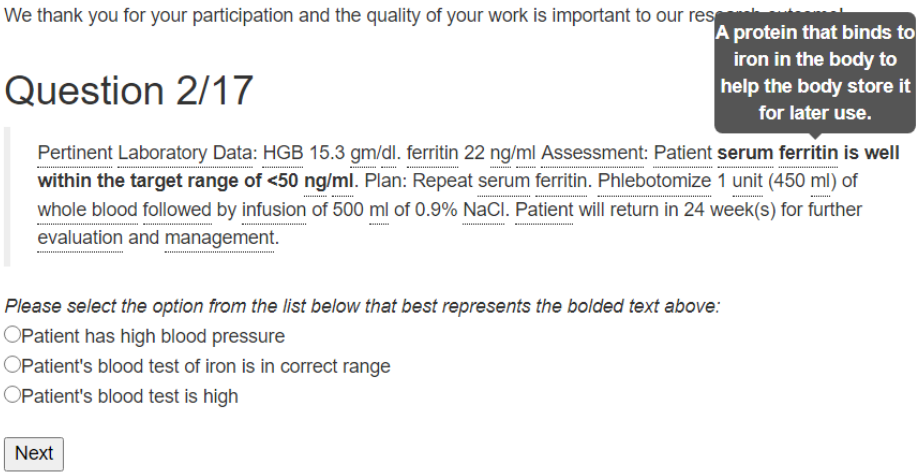
The work in this study was approved by the Institutional Review Boards (IRBs) at the University of Massachusetts Medical School and LGH. All participants from LGH were shown an information sheet describing the study, had the ability to ask questions before participating, and provided verbal informed consent before participating. AMT participants provided electronic informed consent before participating.

NoteAid

NoteAid is a web-based natural language processing (NLP) system for linking medical jargon to lay-language definitions [18,25]. The following two components are central to NoteAid: a repository of lay definitions for medical terms (CoDeMed) and the NLP system for linking medical concepts to these definitions (MedLink). NoteAid is implemented as a web application, where users can navigate to the NoteAid website and enter a snippet of text from their own EHR note. NoteAid will then process the note text and display the note with terms defined via tooltip text. Defined terms are underlined, and users can display a term definition by moving the mouse cursor over the term (Figure 1).

XSL•FO
RenderX

Figure 1. An example of medical terminology definition using NoteAid (image source: [26]).



ComprehENotes

Overview

The ComprehENotes test is the first test to directly assess the ability of individuals to comprehend EHR notes. The ComprehENotes test consists of 14 passages taken from deidentified EHR notes. A section of the passage is presented in boldface, and the test takers are asked to select which of three options is the closest in meaning to the bold text (Figure 2). As detailed by Lalor et al [24], the ComprehENotes test was built by a group of physicians and nonclinical medical researchers using the sentence verification technique [29]. Questions were administered to a sample of 660 English-speaking adults on AMT. The psychometric properties of the questions were subsequently analyzed using the IRT method to confirm the performance of the test questions [24,30].

Prior work [24] has shown that ComprehENotes test scores are consistent with demographic expectations with regard to health literacy (ie, less educated respondents score lower than more educated respondents). In addition, providing access to lay definitions for medical terms via NoteAid is associated with higher scores on ComprehENotes [26].

Figure 2. An example of a ComprehENotes test question with embedded NoteAid definitions as implemented on the web application. In this example, the definition of "ferritin" (gray box) is useful in understanding that the bold text describes a blood iron test.

XSL•FO
RenderX

ComprehENotes Administration at a Community Hospital

For the community hospital participants, we implemented the ComprehENotes test as a web application on a tablet, which allowed for flexibility in terms of delivery and intervention modifications. The hardware used was one Microsoft Surface Pro and one Apple iPad Pro 11. When a participant loaded the application, he or she was randomly assigned to either the control or intervention group. Participants provided demographic information on the app, and then proceeded to take the test. The test was administered one question at a time. The order of the questions was randomized. Responses were directly collected and stored on our server. Other than self-reported demographic information, no user information was stored on the server.

ComprehENotes Administration on AMT

For AMT participants, the ComprehENotes test was implemented as a web application where quality control questions were additionally included to ensure that participants completed the task to the best of their ability. Specifically, the AMT participants were given three quality control "check questions" interspersed throughout the ComprehENotes test. These questions were included to ensure that the AMT participants were paying attention as they were completing the task [31]. If participants answered a check question incorrectly, they were presented with a message indicating that they have answered a check question incorrectly, and were given the option to start the task over or exit the window without completing the task.

Integrating NoteAid With ComprehENotes

For the intervention groups (community hospital and AMT), each ComprehENotes question was preprocessed by NoteAid and the results were embedded into the test web application directly. Definitions for terms were added to the web application as tooltip text. Terms were underlined to indicate that a definition was available, and when a participant hovered over a defined term, the definition would automatically display (Figure 2). This behavior was also described in the introductory text paragraph of the web application so that the participants were aware of the definitions and knew how to access them.

Data Collection

Community Participant Recruitment

With IRB approval, participant recruitment was conducted at LGH. Staff members of the research team (WH and MT) approached diabetes patients in the waiting room before or after their appointments. Patients and persons accompanying patients in the waiting room were eligible to participate if they were over 18 years old, able to speak and read English, and comfortable using a tablet. In some cases, patients who started the survey could not finish it before their appointments and therefore were not included in the study. Partial responses were not included in our analyses.

The staff approached a potential participant and asked whether he/she would be interested in a short online English survey to see how he/she understands medical jargon terms in doctors' notes. Then, the staff explained the fact sheet, including information regarding time to complete, IRB approval, and contact information. The staff also noted that the EHR notes in the questionnaire were not from their own personal EHR notes. We informed participants that once the survey started, they could discontinue participation at any time. Each participant was given a US $10 gift certificate. Participants were randomly assigned to the control or treatment group when they accessed the web page to complete the test via a random number generator implemented in Python.

AMT Participant Recruitment

A total of 200 participants were recruited on AMT (100 in the control group and 100 in the intervention group). Task visibility on the AMT platform was restricted to AMT workers located in the United States with prior task approval rates above 95%. The prior task approval rate percentage was used as an indicator of high-quality prior work, and selecting the United States as the location was used as a proxy for English proficiency. We did not collect any medical history information from participants. While the test administered to the AMT and community hospital participants was the same, there were several differences in test administration. First, AMT participants completed the task remotely, while the community hospital participants completed the task locally and under the supervision of research staff. Second, community hospital participants were randomly assigned to either the control or intervention group upon enrollment. On AMT, the task was implemented as a parallel randomized study. We first collected responses from 100 AMT participants for the control task (ie, no access to NoteAid). We then created and released a second AMT task with the intervention task. This intervention task was not available to AMT participants who participated in the control task. AMT participants were paid US $3 to complete the task. In pilot studies, we observed that AMT participants typically took between 15 and 20 minutes to complete the task; therefore, a US $3 payment approximated a US $9 to $12 hourly wage.

Data Analysis

For our specific hypotheses regarding the effects of NoteAid in the two participant recruitment sources (hereafter referred to as "*source*") (RQ1-3), we ran a two-way analysis of variance (ANOVA) to compare the four groups in our data set, using the proportion of the passage-item pairs answered correctly as the dependent variable and *source* (community hospital vs AMT) and *condition* (control vs intervention) as two crossed factors. Specifically, for our third research question, we tested the interaction effect between *source* and *condition*. An interaction would indicate that NoteAid's effect on the test score differs between AMT participants and community hospital participants. In this case, for our primary research question, we would compare community hospital participants in the control and intervention groups to determine the effectiveness of NoteAid among community hospital participants, and for our secondary research question, we would compare the community hospital participants and AMT participants separately under the intervention and control conditions. If the interaction is not significant, the two main effects would be tested to address the primary and secondary research questions.

XSL•FO
RenderX

To examine the effects of participant demographic characteristics and possible variations in the effect of NoteAid on the test score among different demographic categories (RQ4-5), we further considered a model with three-way interactions among *condition*, *source*, and each of the demographic variables (age, race, education, and gender) along with relevant lower order effects. The four effects concerning the same demographic variables were treated as one family, and each of them was tested at level α'=.0125. If an interaction was detected and simple effects were examined, their tests were further adjusted with Bonferroni correction. Pairwise comparisons among demographic categories were also adjusted with the Bonferroni method.

Given the discrete nature of the dependent variable and the likely ceiling effect due to the overall good performance, we supplemented the ANOVA with generalized linear models (GLMs), treating the dependent variable as a binomial outcome with possible overdispersion to account for individual differences.

Results

Demographics

We recruited a total of 188 participants at the community hospital location from the end of December 2019 to the beginning of March 2020. Results from 174 participants were included in the final analysis. Of the 174 participants, 141 were patients and 33 were persons accompanying patients. Fourteen participants were recruited and began the task, but did not complete it as they were called to their appointments and therefore were not included in our final analyses.

Characteristics of the AMT participants and the community hospital participants are presented in Table 1. The distribution of age was very different between the groups. The AMT participants were primarily younger, with the majority of AMT participants under 34 years old, while the majority of community hospital participants were over 55 years old. There were also differences in education. A majority of AMT participants had a bachelor's or master's degree, while fewer community hospital participants had either degree. The majority of community hospital participants had at the most an associate's degree.

Within the community hospital sample, the age, education, race, and gender profiles in the control group were similar to those in the intervention group, as expected for a randomized experiment. Chi-square independence tests for contingency tables were not significant after multiplicity adjustment. The same was true for the AMT sample.

[a]AMT: Amazon Mechanical Turk.

Effect of the Intervention and Participant Recruitment Source

Table 2 shows the descriptive statistics (proportion correct) of the four groups. Results of the two-way ANOVA are presented in Table 3. Note the CIs in Table 3 are not simultaneous CIs, but one-at-a-time CIs.

The interaction effect in the ANOVA was not significant (P=.89), suggesting no evidence that the effect of NoteAid was different across the two participant recruitment sources. Further analyses show that both the main effects of *source* (AMT or community hospital) and of *condition* (baseline or intervention) were significant. Participants who took the ComprehENotes test on AMT on average scored higher than the community hospital participants, and the difference was significant. In addition, participants who had access to NoteAid scored higher than those who did not have access to NoteAid. The difference was again significant.

Our analysis with GLMs yielded similar results. The main effect of *condition* was significant (odds ratio [OR] 1.23, 95% CI 1.10-1.38; P<.001), the main effect of *source* was significant (OR 1.33, 95% CI 1.18-1.49; P<.001), and the interaction effect between *source* and *condition* was not significant (P=.72).

Table 2. Summary statistics for the source by condition contingency table in our analysis of variance.

Source	Condition	
	Control[a]	Intervention[a]
AMT[b]	0.756 (0.246), n=100	0.830 (0.201), n=100
Community hospital	0.646 (0.179), n=85	0.727 (0.191), n=89

[a]Data are presented as mean proportion correct (SD), sample size.

[b]AMT: Amazon Mechanical Turk.

Table 3. Analysis of variance table.

Variable	df	Sum squares	Mean squares	*F*	Cohen *d* (95% CI)
Source	1	1.06	1.06	24.70[a]	0.52 (0.31 to 0.72)
Condition	1	0.56	0.56	13.06[a]	0.37 (0.17 to 0.58)
Source × condition	1	0.001	0.001	0.02	0.03 (−0.38 to 0.44)
Residuals	370	15.88	0.04	N/A[b]	N/A

[a]*P*<.001.

[b]N/A: not applicable.

Effects of Demographic Variables

To study the effects of demographic variables, the single case of an American Indian, the two cases where individuals refrained from reporting gender, and the seven cases with missing demographic information were removed from the data set before analyses. To mitigate data sparsity in the contingency table, the category “less than high school” was combined with “high school” in *education*, and the highest and lowest age groups were combined with their adjacent groups. Results from ANOVA and GLMs gave qualitatively the same results. However, ANOVA yielded predicted scores exceeding one and demonstrated clear violation of homoscedasticity. We chose to report results from the GLMs. An outlying residual was identified in the analyses, but its removal yielded similar results.

The only significant effect involving a demographic variable was the interaction between *source* and *education* (χ^2_3=16.9, *P*<.001). This shows that the effect of *education* differed across the AMT and community hospital participants. Separate analyses of data from the two groups found that *education* did not have a significant main effect (χ^2_3=2.05, *P*=.56) in the AMT group, but had a significant main effect (χ^2_3=37.30, *P*<.001) in the community hospital group. Pairwise comparisons revealed that community hospital participants with “high school or lower” education had significantly lower performance than those with a bachelor’s degree and those with a master’s degree. The interaction between *condition* and every demographic variable was not significant, suggesting no evidence of any variations in the effect of NoteAid for people in different demographic categories.

Discussion

Principal Results

In this work, we have demonstrated the effectiveness of NoteAid for improving EHR note comprehension in participants recruited from two different sources (a community hospital setting and AMT). For both samples, access to NoteAid significantly improved ComprehENotes scores (RQ1). To the best of our knowledge, NoteAid is the only tool available that has been shown to improve patient health literacy, both in this work and in prior work [25,26]. Samples recruited from these two sources varied, in particular with regard to age and education. AMT participants were younger and more educated than participants recruited from the community hospital. Consistent with prior findings on health literacy and education levels [7], the community hospital participants scored significantly lower than the AMT participants on the ComprehENotes test (RQ2).

Although there were demographic differences between the participant recruitment sources (LGH and AMT), we did not find evidence that the effect of NoteAid was different across the recruitment sources (RQ3). We found that age, race, and gender did not have a significant effect on scores. We did find that the effect of education differed between the two sources (RQ4). For the LGH sample, participants with a high school education or less had significantly lower scores than individuals with a bachelor’s or master’s degree. This result is consistent with existing literature that those with less education are at greater risk for low health literacy [7]. In contrast, no education effect was detected for the online platform AMT participants (RQ5). It is important to include participants recruited from an actual hospital setting to confirm the effectiveness of health literacy tests (eg, ComprehENotes) and tools (eg, NoteAid) across samples.

Results from both LGH and AMT confirmed prior research on the effectiveness of NoteAid for improving participant EHR

XSL•FO
RenderX

note comprehension [18,26]. We showed that participants with access to NoteAid achieved higher scores on average than those without access to NoteAid, consistent with both patient self-reporting and empirical analyses in prior work [18,26]. However, this is the first study to test NoteAid empirically in participants recruited from a community hospital setting. While the effectiveness of NoteAid was consistent across our participant recruitment sources, participants from the two sources varied in terms of key characteristics (eg, age and education).

Electronic patient portals are becoming more common, with as many as 44 million patients estimated to have access to their notes [32]. Notes are being made available as part of the OpenNotes initiative [33] and in a variety of other health care settings, from the US Department of Veterans Administration [34,35] to private organizations [36]. As a result, more information about personal health is available to patients. In a recent study, surveyed patients reported that they understood "most or all" of the content in their EHR notes [37]. However, all patients surveyed had previously read at least one of their notes, and most would be considered highly activated patients. Patients who can and do currently view and understand their notes typically have high patient activation [3,38]. They are active in managing their health care, have lower likelihood of outcomes, such as emergency department visits, and are more likely to engage in preventive care [3]. Individuals with low patient activation typically do not understand their role in the health care process and are less likely to participate in tasks associated with health care management (eg, viewing their patient portal) [38]. For those surveyed patients with a high school diploma or lower, self-reported note understanding was significantly lower, consistent with our results [37]. In addition, a common comment from survey respondents was that they had difficulty understanding medical jargon in the note, with respondents requesting access to jargon definitions. Self-reported levels of understanding may not reflect actual understanding, as measured by validated instruments such as ComprehENotes [39,40]. Our results showed significant improvement in comprehension regardless of education level, indicating that NoteAid is an effective intervention.

There are two key challenges for ensuring that patients can realize the benefits associated with accessing their own notes as follows: (1) defining medical jargon so that patients understand the content of their notes, and (2) motivating low activation patients to view their notes and take an active role in managing their health care. The NoteAid tool directly addresses the first challenge, as demonstrated by this work and prior work. As more patients have access to their notes, providing access to definitions at the same time can reduce issues with patients not understanding the content in their newly available notes. It may also indirectly address motivation. If low activation patients struggle with medical jargon, having the jargon automatically defined can reduce the barrier to entry for their participation in care. Implementation of NoteAid directly into EHR software, for example, via an application programming interface (API), would allow for patients to have jargon terms defined within the patient portal itself, without needing to search for definitions outside of the platform. This aligns with a recent call for "easy-to-understand information" as part of a proposal for improving patient portals [41]. Further, NoteAid can be used by anyone who assists in the management of a patient's care. If a patient chooses to share an EHR note with a family member, the family member can use NoteAid to define medical jargon terms, so that he or she can better understand the note and better assist with the patient's care. In this case, even patients who themselves might struggle to use NoteAid or read their notes can benefit from the tool.

Limitations

There are several limitations in this study. First, local recruitment of individuals for our trial had to be halted due to COVID-19. While we were able to gather 174 responses from local participants and identify a significant effect of using NoteAid, a larger sample size would allow for more fine-grained analysis of the results, for example, examination of scores according to various demographic characteristics. While this might be seen as an argument in favor of moving such data collection efforts to crowdsourcing platforms, our results indicate that local population scores are significantly lower than the scores of users on crowdsourcing platforms (RQ2). In addition, the demographic differences between individuals in the local population and individuals on AMT indicate that simply relying on AMT is not sufficient. We confirm prior work demonstrating the effect of NoteAid on EHR note comprehension in AMT workers [26], but go one step further to show that the tool is useful for local patients (a considerably different cohort).

A second limitation is with regard to the NoteAid tool. Certain terms or acronyms in EHR notes can have more than one meaning. The task of correctly identifying the appropriate meaning of an ambiguous term is a well-studied problem in natural language processing called *word sense disambiguation*. While a number of methods have been proposed to handle this problem [42-44], there is active research to improve these models. A NoteAid system in a production environment would need to be able to disambiguate between possible definitions so that a patient would receive the definition for the correct term in his or her own note [25]. In the case of our study, NoteAid definitions were manually inspected and added to the ComprehENotes test as part of our web application implementation. Therefore, we were able to confirm the correct definitions for the terms in our EHR note snippets before running our tasks.

Finally, our local subject group was restricted to diabetes patients and those accompanying them to their appointments. There is a risk that this local setting is too narrow in terms of scope for the results to be more generally applicable. However, the ComprehENotes test is not a test of diabetes EHR note comprehension. The test includes questions from EHR notes related to a number of diseases, such as diabetes, cancer, heart failure, and hypertension, in order to include a wide range of subjects in the assessment [24]. Coupled with the fact that we saw similar results in the AMT participants, we believe that the results could be generalized beyond diabetes patients to a wider patient cohort.

Conclusion and Future Work

The findings reported here provide evidence of the effectiveness of NoteAid for improving EHR note comprehension across two different participant samples: patients from a community hospital and participants from a popular online crowdsourcing platform. Despite the demographic and education differences between the two samples, NoteAid improved scores on the ComprehENotes test for both, indicating that it is an effective intervention for improving EHR note comprehension. These results support broader use of ComprehENotes as an EHR note comprehension test and NoteAid as an effective tool for improving EHR note understanding.

Future work should explore patient personalization in NoteAid. Providing lay definitions for all medical jargon in a note may lead to information overload for patients with low education and may be unnecessary for patients with high education. To improve comprehension for low health literacy patients, other mediums (eg, short animations and text definitions) may be more effective. Operationally, making NoteAid jargon definitions available for a patient's own notes via an API would increase the ways in which researchers and EHR vendors can implement jargon definitions so that patients have access to them.

Future work applying the NoteAid tool to other contexts is another interesting direction. While NoteAid has been shown to improve patient EHR note comprehension [25], the methodology of the tool is generalizable. The concept identification-definition linking process can be applied to other texts where complex jargon is common to improve readability and understanding. If a lay-language dictionary is built for a particular domain (eg, legal text), it would be possible to use NoteAid to identify and define those complex terms so that individuals can more easily understand the text.

Acknowledgments

The authors thank the anonymous Amazon Mechanical Turk participants who participated in the Amazon Mechanical Turk tasks and the subjects who participated in the community hospital tasks. The authors would like to thank Harmon Jordan for his helpful conversations with regard to this work. This work was supported in part by grant I01HX001457 from the Health Services Research & Development, US Department of Veterans Affairs and by grant R01LM012817 from the National Institutes of Health (NIH). Abstract

Background: Patient-accessible electronic health records (PAEHRs) enable patients to access their health records through a secure connection over the internet. Although previous studies of patient experiences with this kind of service have shown that a majority of users are positive toward PAEHRs, little is known about why some patients occasionally or regularly choose not to use them. A better understanding of why patients may choose not to make use of digital health services such as PAEHRs is important for further development and implementation of services aimed at having patients participate in digital health services.

Objective: The objective of the study was to explore patients' rationales for not embracing online access to health records.

Methods: Qualitative interviews were conducted with 40 patients in a department of internal medicine in a Norwegian hospital in 2018-2019. Interview transcripts were subjected to thematic content analysis. In this paper, we focus on the subject of nonuse of PAEHRs.

Results: We identified 8 different rationales that study participants had for not embracing PAEHRs. When patients reflected on why they might not use PAEHRs, they variously explained that they found PAEHRs unnecessary (they did not feel they were useful), impersonal (they preferred oral dialogue with their doctor or nurse over written information), incomprehensible (the records contained medical terminology and explanations that were hard to understand), misery oriented (the records solely focused on disease), fear provoking (reading the records could cause unwanted emotional reactions), energy demanding (making sense of the records added to the work of being a patient), cumbersome (especially among patients who felt they did not have the necessary digital competence), and impoverishing (they were skeptical about the digital transformation of individual and social life).

Conclusions: It is often assumed that the barriers to PAEHR use are mostly practical (such as lack of hardware and access to the internet). In this study, we showed that patients may have many other valid reasons for not wanting to adopt this kind of service. The results can help guide how PAEHRs and other digital health services are promoted and presented to patients, and they may suggest that the goal of a given new digital health service should not necessarily be full uptake by all patients. Rather, one should recognize that different patients might prefer and benefit from different kinds of "analog" and digital health services.

Introduction

Background

Over the past decade, patient-accessible electronic health records (PAEHRs) have been requested, developed, introduced, and advocated for in health care systems in several nations [1,2]. The existing literature conveys the impression that a majority of patients are satisfied with PAEHRs and argue that they can increase patient involvement, improve patient-provider communication, support self-management, and promote patient empowerment [3-6]. In a survey of patient experiences in Norway, the majority of users were satisfied overall with PAEHRs [7] and perceived online access to their medical records as useful for tasks such as looking up health information, keeping track of ongoing treatments, preparing for medical appointments, and sharing medical documentation with others. Similar findings have been reported from other countries [8-10].

Notwithstanding this, there are always significant minorities of patients in PAEHR surveys who are less enthusiastic about PAEHRs. For example, 6% of respondents in a Swedish survey indicated that they did not think PAEHRs led to better understanding [8], 12% of respondents in a US survey were concerned about their privacy in connection with PAEHR use [9], and 19% of respondents in the Norwegian study mentioned above had become worried because of information they found in their health records [7].

Little is known about the perspectives of patients who do not access their records. A qualitative study from Sweden included 15 patients with cancer without experience using PAEHRs [11]. The main argument of these patients for not accessing records was reported to be "that they have a good relationship with their physician and that they receive the information they need," but their rationales for not using the service were not explored further. A better understanding of why patients may resist using new digital health services like PAEHRs is important for further successful development and implementation of digital services.

Digitalization in Norway

Compared with many other countries, Norway has high coverage of internet access and use, with 98% of the population aged between 16 and 79 years having used the internet for different purposes during the last 3 months [12]. A range of different public and commercial services have been extensively digitalized (eg, banking—to the degree that it is now highly inconvenient to handle personal banking outside the web), and most citizens employ digital tools in their everyday lives [13]. Therefore, we saw Norway as a good setting for studying patients' views on electronic health services that go beyond issues concerning the digital divide.

Providing all patients with electronic access to their health records has been a goal for the Norwegian government since 2012 [14]. A white paper entitled "En innbygger, en journal" ("One citizen, one health record") argued that such access "gives citizens overview of their own information and knowledge about their health and illness. This provides a basis for co-decision making and active cooperation between health care professionals and patients and clients. Patients and clients will, through access and participation, be able to point out errors in the health records and improve the quality of the documentation" [14].

"Pasientjournal": The PAEHR Used in Norwegian Specialized Health Care

In December 2015, PAEHRs were introduced under the name Pasientjournal by the publicly owned Northern Norway Regional Health Authority, the owner of the hospital in which fieldwork for this study was carried out. The stated goal was to "increase patient empowerment and patients' involvement in their own health, and improve the quality of services" [15]. In a video promoting the service, the Pasientjournal is described as a tool for becoming an "enlightened patient" [16].

The Pasientjournal service is now available to anyone seeking public specialist health care in 3 of Norway's 4 health regions, which cover roughly 80% of the Norwegian population. It gives patients access to almost all documents in their medical records. They can retrieve and read doctors' notes, discharge notes, outpatient clinic notes, nurses' documentation, physiotherapy notes, referral notes, radiology reports, and some pathology test results. Laboratory results are not yet available but will be in the near future. All documents are accessible by the patient as soon as they have been digitally signed by the responsible health care professional. The list of documents is ordered chronologically and can comprise a few entries to hundreds of entries depending on how much contact the patient has had with health care services. Patients can click on any given document to read its full contents. Apart from reading, the patient cannot take any other action online. If one has a question or discovers something incorrect, one is encouraged to contact the hospital for further guidance. Patients log onto the service using the same identification procedure as for several other public digital services.

Based on qualitative research in a Norwegian hospital, the aim of this paper was to explore what patients conceive of as the main weaknesses and disadvantages of PAEHRs as well as their rationales for not actively embracing online access to their health records. We based our analysis on interviews with PAEHR users (both regular and occasional) as well as with patients who had never accessed their records online.

Methods

The fieldwork for this study was carried out in 2018-2019 in a hospital owned by the Northern Norway Regional Health Authority. We have decided to conceal the name of the hospital as part of our efforts to protect study participants' personal information.

Study Design

This paper draws on a study that was inspired by the ethnographic research tradition. The first author (HSV) did fieldwork for a period of 12 weeks in the hospital's department of internal medicine, which consists of several wards and outpatient clinics and covers a range of medical specialties (nephrology, endocrinology, cardiology, pulmonology, gastroenterology, hematology, and oncology). Fieldwork entailed participant observation as well as semistructured

XSL•FO
RenderX

interviewing of patients and health care professionals, with the overarching goal of exploring how PAEHRs are incorporated into everyday practices in a hospital. This paper is based on an analysis of the patient interviews conducted in the study.

Qualitative Interviews and Recruitment of Study Participants

A total of 40 patients were interviewed. They were recruited in the course of participant observation, during which the first author (HSV) accompanied doctors and nurses while they were doing their daily work in the department. Patients who gave their consent were invited to take part in an interview. The researcher had no knowledge of the invited patients' experience with PAEHRs prior to inviting them to participate in the study, unless this had become evident in the observed interaction with their doctor or nurse. To help ensure that patients were competent to give consent and in a condition that allowed them to sit through an interview, potential study participants were discussed with their care providers before they were invited to participate in the study. All but one of the patients who were asked to participate accepted the invitation. They received information about the study both orally and in writing before they were asked to provide written consent to participate.

Patients were recruited as the first author moved around the clinic and aimed to include patients with a variety of ages, genders, and diagnoses. The variety was obtained by recruiting patients from both the inpatient and the outpatient clinic and by following health care professionals from different medical specialties. Of the 40 interviewees, 22 were women and 18 were men. Their ages varied between 21 and 84 years. The study participants had a range of different medical conditions in the domains of nephrology, cardiology, cancer, hematology, lung diseases, and infections. Among the 40 interviewees, 32 knew about Pasientjournal prior to the interview and 8 did not. Among the latter, 6 indicated that they felt positive about the idea of logging into and reading their medical records while 2 did not. A little less than half (ie, 16 individuals) had used PAEHRs either occasionally or regularly prior to the interview.

The interviews, which lasted between 15 and 60 minutes, took place by the hospital bed in the case of admitted patients and in offices and examination rooms in the case of outpatients. An interview guide listing topics to be covered (eg, the patient's history of illness, prior knowledge and use of the PAEHR, health information–seeking habits, and other digital habits) was used as a memory aid during the conversations, but participants were encouraged to speak freely and the interviewer sought to let the participants take the lead in the dialogue. The interviewer's aim was to be a conversation partner who traveled along with the patient into their stories rather than someone trying to "dig out" information from them (this style of interviewing was inspired by Brinkmann and Kvale's metaphor of the interviewer as a "traveler" [17]).

In this paper, we draw on the data generated through qualitative interviewing, focusing specifically on patients' rationales for not using PAEHRs. We plan to return to other study findings in future works.

Data Analysis

All interviews were transcribed verbatim, and transcripts were read carefully several times. Following a stepwise deductive-inductive approach [18], we then coded the interviews empirically close with in vivo coding, meaning that many of the codes contained words and expressions used by the study participants themselves. The initial coding was done by the first author and then discussed thoroughly with the coauthors. In a subsequent step, codes were grouped into themes. Identified themes were discussed and reordered during several analysis meetings involving all authors until a common understanding had been reached. For the purpose of this paper, themes relating to why patients do or do not use PAEHRs were chosen and further analyzed. The themes identified in this article were generated on the basis of interviews with patients who did not want to use the PAEHR (in spite of knowledge of the service) as well as with patients who had personal experience with Pasientjournal.

Researcher Positions

Fieldwork was conducted by the first author (HSV). She is a woman in her 30s who is a trained physician and has clinical experience from work in hospitals (but she had not worked in a clinical setting for several years when fieldwork started and had not worked in a clinical setting after PAEHRs were introduced). She also has personal experience as a close relative of severely ill patients. Her medical background made it easy to move around in the clinic, as many hospital "codes" and routines were well known to her. She made efforts to explain to study participants that she was there as a researcher and not as a representative of the hospital management. At the hospital's request, she dressed in white scrubs during fieldwork. She thereby blended in with the staff and at times had to underline for the study participants that she was not present by virtue of her medical skills.

The second and third authors (AKL and KM, respectively) are also trained physicians, but both currently work full time as associate professors (in the fields of medical anthropology and medical history, respectively).

All authors engage with many digital tools in their personal and work lives and view themselves as highly computer literate and often appreciate digital solutions. None of the authors had clear opinions on PAEHRs prior to the study. They entered the study with curiosity and a wish to better understand patient experiences with PAEHR.

Ethical Considerations

The study was approved by the Norwegian Data Protection Authority (case no. 56987). Exemption from health care workers' duty to maintain confidentiality was obtained from the Regional Committee for Medical and Health Research. In the hospital, fieldwork was approved by the head of the clinic, the chief of research, and the data protection officer. All study participants gave informed written consent to participate and were told that they could withdraw from the study at any time without giving a reason. Directly person-identifying information were omitted in transcripts, and audio recordings were deleted after transcription. A key that linked the data to participants'

XSL•FO
RenderX

names and contact information was kept in a separate and securely locked location. All data were stored and processed in "Service for Sensitive Data" (Tjeneste for Sensitive Data), University of Oslo's platform for collecting, storing, analyzing, and sharing sensitive data in compliance with the Norwegian privacy regulations.

Results

The study participants had a range of different rationales both for and against the use of Pasientjournal. In this paper, our focus was on the latter, and in this section, we present the 8 different rationales against the use of Pasientjournal that we identified in the course of the study.

Unnecessary: No Need to Access the Health Records

One rationale against the use of PAEHRs was that the digital health records seemed unnecessary. For some of the study participants who had never accessed their PAEHR, the question was clearly not why they did not use the service but rather why they would ever do such a thing. They struggled to see how they could benefit from accessing Pasientjournal. Many felt they got the information they needed from their doctors and trusted them to provide necessary guidance and information. Some questioned how reading the records would make a difference for their health. For example, a woman in her 70s stated the following when the first author tried to dig into the reason behind her lack of interest in the PAEHR: "No, I do not believe that it would make me healthier" [Patient 12, a woman in her 70s; no PAEHR experience].

On the ward, paper copies of discharge notes were routinely given to all patients at departure. Many study participants felt that this was all the written information they needed:

> *"I don't know, really. The times I've been admitted, I've usually gotten the discharge note handed out, so I have not, like, had any reason to ... or felt a need for it. I have been given good information from the doctors I have been seeing as well"* [Patient 22, a woman in her 50s; no PAEHR experience]

In summary, some study participants had not felt motivated to spend time accessing the PAEHR, and they often argued that they had felt satisfied with the information they had been provided orally and in written discharge notes.

Impersonal: Prefer Dialogue to Information

Some study participants not only thought that information received in dialogue with health care workers was "good enough" but reasoned that it was superior to the information accessible through PAEHRs. Patient 14, for example, pointed out that medical records do not allow you to ask anyone the questions that pop up while you are reading and for that reason saw PAEHRs as inferior to face-to-face communication:

> *"Though I probably would get the same information, but you do not get to ask the questions you might have there and then, or get it explained if there is something you find hard to understand. I do think it is better to speak to someone about it than just reading it!"* [Patient 14, a woman in her 40s; PAEHR user]

A bit worried, she went on to ask if there was an intention to replace physical meetings with this form of written information, and added, "If so, I would see that as a loss."

For some, the thought of logging onto a computer to access information about one's own health seemed rather soulless. For Patient 11, for example, the human contact in face-to-face communication had considerable value:

> *"I'm a very verbal kind of person. If there is something that really annoys me, at work for example; the times where you are expected to find all the information for yourself, instead of just meeting up in the hallway and I can say: Let's meet up after lunch and discuss this. So I really like that human contact, and sometimes it's kind of a principle for me to pursue that line."* [Patient 11, a man in his 40s; PAEHR user]

A common finding throughout the fieldwork was that patients' use of superlatives in conversations about health care was typically related to individuals who had made a positive impression. Many praised individual physicians and nurses who had made a difference for them (although some, of course, also told of negative experiences). The same type of superlatives was hardly ever used about PAEHR.

Incomprehensible: Patients Are Not the Intended Reader of the Medical Records

Another reason why PAEHRs were not always perceived as attractive was that the language used in medical records could be hard to understand. Patient 7, for example, a retired cleaner, had never logged into Pasientjournal for the very reason that she did not think she would understand much of the contents:

> *"It has to be understandable, so they must not use a lot of foreign words that I don't know or Latin words for different things, this and that and that"* [Patient 7, a woman in her 60s; no PAEHR experience]

Patient 32 expressed a similar sentiment, even though she worked as an auxiliary nurse. When asked if she knew she could access her records, she answered:

> *"Yes, I do know that, but I am thinking: What's the point? The doctors' language ... I certainly do not understand much of that."* [Patient 32, a woman in her 50s; no PAEHR experience]

Many of the participants who had accessed their records also described how the medical records could be difficult to comprehend. Patient 10, for example, had accessed Pasientjournal to see what her doctor had written about the results of a sleep monitoring procedure she had undergone. She found the note, but she felt she could not really make much sense of it:

> *"You know, many of the documents in there, they are more like letters to doctors, or therapists, so there is a lot of inexplicable words, and I do not understand everything, I really don't."* [Patient 10, a woman in her 20s; PAEHR user]

XSL•FO
RenderX

Misery Oriented: Too Much Focus on Disease

Several study participants had reservations about PAEHRs because they wanted to avoid unnecessary focus on ill health. Patient 3, for example, a man in his 60s who had a chronic condition that demanded regular blood transfusions, explained it this way:

> *"I wouldn't say that I am totally uninterested in my disease; of course I'm not. But I'm not all that interested in it either, as long as everything is working as well as it does. So, I have chosen not to think about this disease too much. ... I think it is important for the total well-being, or the feeling of not digging oneself down in the disease and give it your main focus. I focus on all the things I can do, and that's a whole lot of things. ... I believe that it is important to be able to live with this kind of serious, chronic disease; that you do not go around thinking about it all the time. I believe that will make you feel like you are locked in inside yourself."* [Patient 3, a man in his 60s; no PAEHR experience]

Similarly, Patient 32, a woman in her 50s, also questioned what good might come from worrying about things she could not do anything about:

> *"You see, what good will it do to anyone around me if I were to dig down in my own misery? If this is something I will die from, then I want to live while I'm alive"* [Patient 32, a woman in her 50s; no PAEHR experience]

What these participants seemed to argue was that immersing oneself in disease and medical knowledge may not be a favorable way of dealing with illness and might even stand in the way of "good health."

Fear Provoking: Promoting Unnecessary Worry

Some study participants were concerned that reading the medical records would make them upset or worried. In their assessment, accessing their records had the potential to harm.

> *"No, if one starts to follow up on that stuff, one will start to speculate about all sorts of things, and then it certainly becomes worse. ... that is also why I never Google survival outcomes on stenting of heart vessels, that's for sure!"* [Patient 13, a man in his 50s; no PAEHR experience]

As Patient 15 pointed out,

> *"In some ways it feels good to be kind of ignorant, too. I do not want to read any reports before I know that this [the disease] has turned out good, in a way."* [Patient 15, a man in his 40s; no PAEHR experience]

Some participants who had used Pasientjournal explained how reading the health records had led to negative feelings. For example, a man suffering from incurable cancer explained how reading about his prognosis felt harder and more brutal than talking to his doctor about it:

> *"Even if it is information that I already know, it's sort of hard at times to sit down and read, when it's there, black on white, that they [the doctors] are not that optimistic anymore, you know. ... so it's kind of brutal."* [Patient 4, a man in his 50s; PAEHR user]

Avoiding the worries and negative feelings that they believed could result from being exposed to the illness focus in the health records constituted an important rationale for some of the participants for not engaging with the PAEHR.

Energy Demanding: Unsuitable When Ill Health Drains You of Your Vigor

When experiencing serious disease, patients may be indisposed of their normal capacities. Under such circumstances, some of the study participants had simply not had the energy to log onto Pasientjournal. In the case of Patient 5, this phase had lasted for several months after she was diagnosed with and went through surgery for breast cancer. Although she knew about the PAEHR and thought of it as an interesting service, she had not yet had the energy to use it 3 months after her surgery:

> *"I have read about that thing, that it is a possibility, but it has been so much information to digest and absorb that I did not reckon I had the time to log on there. ... have just been so overwhelmed with thoughts, with this disease, so I have just not had the energy"* [Patient 5, a woman in her 40s; no PAEHR experience]

Participants who had experienced serious disease talked about the overwhelming situation they suddenly had found themselves in when going from being healthy and resourceful to becoming a patient. Some also described how being a patient involved a lot of work. Patient 1, for instance, had just retired when she was diagnosed with cancer. She described how dealing with her new situation felt like a job with lots of tasks to take on:

> *"Everything was just so unfamiliar, and I did not know how to handle things when I became ill, and all the stuff that came along with the disease. ...This [being sick], it is actually a full-time job. With added extra hours!"* [Patient 1, a woman in her 60s; no PAEHR experience]

The "energy demanding" rationale against PAEHR use draws from the experience of illness as something that demands effort from the patient in many different ways. In such situations, the task of reading health records may be too much to deal with on top of everything else.

Cumbersome: Screen May Not Be Better Than Paper

PAEHR solutions make health records available to patients through the internet. While this is often touted as making information "easily available," some study participants felt that electronic access was a cumbersome thing. Some, especially in the older age groups, explained how navigating and engaging with new digital services could be an onerous task. Although many used personal computers and smartphones for other undertakings, they could find themselves struggling when they had to handle a new service on their own. Most patients had relatives who they turned to with "data troubles," but some felt uneasy bothering them too much. Patient 37, who regularly turned to her son for help with "technical stuff," explained:

XSL•FO
RenderX

> *"You know, my son, he is an expert on data, so he tries to explain it to me: 'Mother, you have to click here, and then this and that,' but then he has to run to catch the bus, and I'm like: 'What did he say???' Even before he's out the door, it's all gone for me."* [Patient 37, a woman in her 70s; no PAEHR experience]

Among the participants who questioned the "easiness" of digital solutions was Patient 12, a woman in her 70s. She had become upset when her pharmacy stopped giving out lists of prescriptions on paper and instead encouraged its customers to go online. She had logged on several times to check her prescriptions, but when the pharmacy did away with the new policy, she was relieved. Although she mastered the digital tool and could access her prescriptions, she found it much less complicated to be given a paper copy when she picked up her medicines. Patient 37 and Patient 12 are examples of patients who do not find that digital access represents progress and is "easier" than analog solutions.

A consequence of needing assistance to use a patient portal is that one must be willing to let the helper see the contents of one's medical records. Some study participants were not comfortable with this, and one explained that this was the main reason why she had never used the Pasientjournal.

Impoverishing: Resisting the Digital Transformation of Individual and Social Life

A final rationale against the use of PAEHRs was a general skepticism toward the ongoing digitalization of life worlds. Patient 7, for example—a woman in her 70s who was admitted to the hospital with newly discovered cancer—explained that she felt frustrated by how everyone was hooked on their screens and how this affected the social life in her family.

> *"I don't want to get into that stuff. I see everyone sitting there with their tablets all the time; they are completely absorbed. You lose the social part, I've said that from the beginning. And it's all...and it includes the kids as well, and the grandkids. They are all staring into a tablet, they all have a phone they are constantly playing on, or something. And I really resent much of that! Because you don't have the social engagement anymore."* [Patient 7, a woman in her 70s; no PAEHR experience]

Patient 7 had chosen not to engage in any digital affairs. She left that to her husband. They had a computer at home, but she never used it. "I'm not at all interested in that!" she stated, and she did not see the PAEHR as a service worth embracing. Patient 7 was the most prominent representative of an antidigital attitude in our study.

Other study participants were less vigorous in their rejection of digitalization but still expressed that they wanted to reduce the time spent in front of screens and computers, limiting such activities to strictly necessary chores. Patient 38, a man in his 70s, had heard of PAEHRs but had not yet used Pasientjournal. When asked if he would consider accessing his hospital health records, he was a bit hesitant, and said, "I guess I could do that." When pushed a bit further, he explained how he had experienced that computers interfered with his former work life as a shop owner:

> *"It took me away from the clients. Instead of being out in the shop and talking to customers, I was stuck at the back dealing with computer issues and troubles."* [Patient 38, a man in his 70s; no PAEHR experience]

Based on his experiences, Patient 38 felt a reluctance to engage too much with computers.

Discussion

Principal Findings

In this study into patients' rationales for not embracing online access to health records, we identified 8 main motivations for nonuse. These results expand the current knowledge of patients' perspectives on PAEHRs.

A fundamental reason why some study participants did not embrace PAEHRs in our study was that they did not think that reading their own medical record was particularly useful. It was unclear to them exactly what, if anything, reading medical notes would add to their understanding of their ailment, medical care, and/or condition. These views are in contrast to the more positive perspectives on the utility of PAEHRs reported in several previous studies [7,11] as well as by many of the participants with user experience in this study (to be published in another article). Participants who fronted the "unnecessary" rationale against PAEHRs felt that they got the necessary information from their doctors and did not seem to desire more medical information.

Several patients also preferred dialogic information given face to face rather than written information, which brings us to the second rationale identified: medical records are impersonal. Reading PAEHRs is an activity that does not typically involve human contact or interaction, and PAEHRs provide no 2-way interaction. As you read, there is no one to ask, no one to laugh or cry with, and no one to seek comfort and reassurance from. If considerations related to efficiency and costs should lead to human interaction being substituted by digital access to records that are not written primarily with the patient in mind, health care would surely risk becoming impoverished.

Many of our study participants (albeit not all) felt that their health care services were well-functioning and that their need for information and explanation was met in direct communication with their health care providers. One could hypothesize that PAEHRs might be perceived of as relatively more useful in a setting where patients were not as content with the services and the information they received. There may be some evidence to support this hypothesis. Surveys of PAEHR users in the United States have found that patients from underserved groups (less educated, non-White, older, and Hispanic patients, and individuals for whom English is a second language) are the ones most likely to report "major benefits" from reading medical notes [9].

An issue raised by study participants who had never used PAEHRs, as well as those who had used it either frequently or

XSL•FO
RenderX

infrequently, was that laypeople are not the intended audience for the documents accessible through PAEHRs. A survey of Norwegian PAEHR users previously found that understanding the content of the medical records is a challenge for many: 36% indicated that it was hard to understand what the documents were about, and 59% reported that they had difficulties understanding the medical terminology [7]. A Danish study that examined the language in 10 medical records with the aim of identifying "potential lay-friendliness, patient-centeredness, and patient empowerment" found that the records were written in highly specialized expert language dominated by expert terminology, expert syntax, expert presuppositions, and difficult abbreviations [19]. The authors concluded that "the majority of Danes will not fully understand their own e-records and will have a high potential for misunderstandings" [19]. In sum, few medical record entries are written with patients as the intended reader. Notes are typically prepared with other functions in mind and tend to be worded with the understanding that the medical file is a communication platform for professionals engaged in the care of the patient. The logic behind assessments, choices, and treatments is seldom explained explicitly; the text rests on the expectation that the reader is a health care professional with certain crucial preunderstandings. In short, the health record is not a resource dedicated to providing enlightenment, sympathy, or education to patients. Of course, this is not to say that the information in the records are never useful for patients, and many patients see PAEHRs as a good place to find information. Other studies have found that some patients use the PAEHR to remember what they talked about with their doctor or to prepare for an upcoming doctor's appointment [20]. However, as described in this study, the unfamiliar and professional atmosphere in the health record served as a barrier to PAEHR use for some patients, and they preferred using other sources for information about their health and illness. In the future, this barrier may be lowered by tools providing easy translation and explanations of medical terminology used in the PAEHR [21]. It must also be pointed out that Pasientjournal is currently only available within specialized health care services, and therefore the contents in the health records are often of a specialized and rather complex nature. One could hypothesize that the content of the records kept in general practice might be of a more accessible and understandable nature, and that the "incomprehensible" rationale might be less prominent in general practice settings than in hospitals.

Medical records may shift one's focus from healthy and wholesome parts of life to sickness and worries about ill health. Avoiding unnecessary focus on sickness and pathology seemed to be an important strategy for some of our study participants. Similar findings were described in a qualitative study of self-management practices among patients with chronic conditions. Van de Bovenkamp and Dwarswaard [22] explained how "self-management is very much shaped by patients' ideas of the good life." A study by Henwood et al [23] of health information–seeking practices among women in midlife similarly identified resistance against the idea that patients should seek out medical information by themselves rather than trusting their doctors to equip them with it. The quotation used by the authors in the article's title—"ignorance is bliss sometimes"—resonates with some of the patients' views in this study: more knowledge is not necessarily for the better. Moreover, some of our study participants clearly also actively resisted the biomedical version of their conditions as presented in the medical records [24]. To them, illness was more than the biomedically relevant information written down in the PAEHR. Illness included feelings, everyday challenges, and encouragements—in short, components of a life that the biomedically dominated health records were lacking.

In addition, some participants stayed away from PAEHRs because they felt that medical records might have the capacity to induce fear and anxiety, and some described situations in which reading the medical records had led to unwanted emotional reactions. This is reflected in a Norwegian survey of PAEHR users as well: 20% of respondents indicated that they had become worried by reading health records [7]. Clearly, how much and what kind of information one seeks at what time will depend on individual factors and previous experience and may also change over time. Some PAEHR nonusers preferred to stay somewhat "ignorant" and rely on the doctor to curate the necessary information for them.

The "new patient role" has been critiqued for not recognizing that patients oftentimes are unable and weakened—temporarily or permanently—when they are sick, and that this affects their ability to act as they otherwise would and make "rational" choices [25,26]. Reading and making sense of the health records is a complicated task (at times even for health professionals). It requires concentration over time and cognitive capacity to absorb information. Lack of concentration can be a temporary or enduring result of a patient's condition or a side effect of medication—all described by participants in this study. For some of the interviewees, this was exactly why they had not accessed their health records. Moreover, as also described by participants in this study, becoming a patient may resemble taking on a new full-time job. As Mol argued in *The Logic of Care* [26], the notion of the neoliberal "patient citizen" (or "active patient" in the PAEHR context) presupposes a nonsuffering person who can make well-argued individual choices, whereas in reality the patient is often weakened by disease and emotional distress that delimits his or her ordinary capacities. The experiences of our participants related to Mol's argument that good care implies engagement in ongoing attempts to adapt knowledge and technologies in a collaboration involving patients and their health care providers as well as their diseased bodies and complex lives.

Certainly, technological obstacles also played a role in our study. To make use of PAEHRs, some of our participants felt they would have to ask for help from relatives or friends, thereby revealing the dependency situation digital health records may impose on patients. Wyatt et al [27] have described how using the internet for health information seeking may require access to competent helpers that can guide less-experienced users in finding and making sense of the information. This was also a concern for some of the participants in this study, and perhaps not surprisingly, especially among some of those who were older. Several participants used the internet for other purposes but were not confident they could handle a new service or task without assistance. Many were hesitant to ask for help from relatives or friends who were more digitally competent ("warm

XSL•FO
RenderX

experts," to use Bakardjieva's term [28]). Depending on the nature of a person's current and former health-related issues, the record can contain information that patients feel is sensitive and too private to share with others, even (and sometimes especially) with close relatives. The threshold to ask for help from "warm experts" might therefore be higher in the case of PAEHRs than for many other digital tasks.

Finally, some of the study participants were generally critical toward the digitalization of individual and social life. In a world characterized by optimism on behalf of digital innovations, this kind of general resistance is at times dismissed as reactionary, and its representatives may at times seem to be rendered invisible in public discourse. However, our study revealed sound and rational arguments for staying outside of digital life. In health care services, this group must also be taken into account to ensure that all patients are equally taken care of within the health care system.

Limitations and Further Research

This article builds on qualitative research and we are therefore in no position to know how common the rationales against PAEHR use identified by our study participants may be. Moreover, our study was limited in time, geography, and size, and further work in the same location or elsewhere could bring out additional rationales of relevance and importance. Furthermore, there is a potential for researcher bias here as we know that many health personnel are skeptical toward PEAHRs and the 3 authors are all physicians. However, all 3 of us have chosen other careers than the clinical as our main jobs and do not primarily identify as clinicians. None of us had preconceived ideas of a potential negative impact before embarking on this study.

There is a need for more research on rationales for not using PAEHRs. Surveys quantifying different rationales for and against PAEHR use, as well as studies of the demography of users and nonusers, are important. There is also a need for more qualitative studies exploring potential differences between specialist health care settings and primary health care settings, as well as possible factors contributing to positive outcomes from and experiences with PAEHRs.

Practical Implications

This study demonstrates that patients may have good reasons for not using PAEHRs and could help guide how PAEHRs are promoted among patients. While PAEHRs are a beneficial service for many patients, it may not be the case for all patients. Health care providers should take this into consideration and should avoid assuming that information is received or understood because it is available via PAEHRs. Moreover, when PAEHRs are promoted, one should avoid making the assumption that online access to health records will be useful for all or should be used by all.

Conclusions

It is often assumed that barriers against PAEHR use are mostly practical (such as lack of access to hardware, slow internet connections, etc) and that once such hurdles are removed, PAEHRs will be widely embraced. In this paper, however, we have demonstrated that patients may have many good reasons not to celebrate or adopt this kind of service. Assessed as a potential source of insight and understanding, some find that PAEHRs are less than perfect because they are devoid of human interaction and contact, use language that they do not understand, promote a 1-sided focus on misery, may lead to unnecessary fear, demand more energy than one may have when sick, threaten to expose one's secrets, and can be cumbersome to make work. Perhaps more than anything else, what the study participants highlighted was that the information in health records is not in a format that is genuinely written for patients. To the contrary, health records are primarily a peephole into biomedical perspectives on the patient's misfortune and ill health. What one gets access to through PAEHRs is often biomedical explanatory models written in biomedical language for biomedically trained professionals. This study demonstrates that not all patients view this as either helpful or favorable, and promoting the view that PAEHRs are something all patients ought to engage with might lead some patients to feel pushed into a domain they are not comfortable in.

Acknowledgments

Fieldwork, transcription, and coding were conducted by the first author (HSV). All authors contributed to the design of the study, analysis of the data, and writing and editing of the manuscript. The study was funded by the University of Oslo. We would like to thank the hospital that kindly invited us to conduct the research and to express our deep gratitude to all of the study participants who contributed to this study with their time, thoughts, experiences, and perspectives.

Abstract

Background: In recent years, there has been increased interest in the development of remote psychological assessments. These platforms increase accessibility and allow clinicians to monitor important health metrics, thereby informing patient-centered treatment.

Objective: In this study, we report the properties and usability of a new web-based neurocognitive assessment battery and present a normative data set for future use.

Methods: A total of 781 participants completed a portion of 8 tasks that captured performance in auditory processing, visual-spatial working memory, visual-spatial learning, cognitive flexibility, and emotional processing. A subset of individuals (n=195) completed a 5-question survey measuring the acceptability of the tasks.

Results: Between 252 and 426 participants completed each task. Younger individuals outperformed their older counterparts in 6 of the 8 tasks. Therefore, central tendency data metrics were presented using 7 different age bins. The broad majority of participants found the tasks interesting and enjoyable and endorsed some interest in playing them at home. Only 1 of 195 individuals endorsed *not at all* for the statement, "I understood the instructions." Older individuals were less likely to understand the instructions; however, 72% (49/68) of individuals over the age of 60 years still felt that they *mostly* or *very much* understood the instructions.

Conclusions: Overall, the tasks were found to be widely acceptable to the participants. The use of web-based neurocognitive tasks such as these may increase the ability to deploy precise data-informed interventions to a wider population.

Introduction

Background

For decades, neuropsychological methods have been leveraged to understand and characterize the relative strengths and weaknesses of individuals experiencing an array of neuropsychiatric syndromes [1-5]. These profiles have also been shown to predict future deterioration in Alzheimer disease and other cognitive and functional outcomes in schizophrenia, bipolar disorder, depression, and traumatic brain injury [6-8]. However, traditional paper and pencil assessments are lengthy and expensive and require considerable training on the part of the assessor. Given these concerns and the rising availability of personal mobile technologies, a movement to capture reliable cognitive functioning digitally has begun [9-12]. Although

XSL•FO
RenderX

remote cognitive technologies are still budding, they promise several benefits in clinical and research settings.

Remote platforms greatly increase the accessibility of psychological testing. The National Institute of Mental Health has established a priority to reach typically underserved populations, such as individuals living with limited physical mobility or in rural areas [13]. Digital measures allow testing to be conducted within the comfort of one's own home, thereby increasing the ability to serve historically difficult-to-reach patients. Remote testing would also likely reduce the time providers spend scheduling and carrying out in-person assessments. These benefits may also help to reduce assessment costs. Accessibility concerns have taken center stage during the current global pandemic, highlighting the need for reliable, easy-to-use, and remote measures.

In addition to opportunities for accessibility, digital remote methods for cognitive testing encourage the use of longitudinal assessments. Repeated measurements provide a wealth of information above and beyond individual snapshots of performance [14]. A study of individuals at clinical high risk for conversion into a psychotic disorder found that although baseline measures of cognition helped differentiate at-risk individuals from healthy participants, cognitive trajectories followed for 2 years differentiated converters from nonconverters [15]. Another study of healthy older adults found that repeated memory assessments pushed to a handheld device were widely accepted and showed associations with the hippocampal brain structure, whereas typical baseline measures of cognition did not [16].

Although in-person neuropsychological methods unquestionably have their benefits and function optimally in distraction-free testing environments, the generalizability of data collected in these unique settings has been questioned [17]. There is a growing body of literature evaluating assessments that can be administered in people's daily lives, thus potentially capturing more meaningful data on how they function within their own environments [18,19]. For example, a clinician may be more interested in how their patient performs cognitively while completing their night shift at work rather than in a highly controlled testing center at midday.

Digital methods also provide a means to measure important metrics such as reaction time (RT) and trial-by-trial performance, which have also shown associations with clinical outcomes [20-22]. These potential benefits, alongside the added ability of electronic health record integration, may further facilitate person-centered practice and move us closer toward the goal of precision medicine [23]. However, little to no normative data currently exists for these task batteries, limiting the interpretability of new findings [24].

A particular novel mobile assessment platform implemented by the Posit Science Corporation has shown recent utility capturing cognitive performance differences common to psychiatric disorders, such as schizophrenia and depression, using a neuroscience-informed approach to task development [25,26]. These tasks were designed to capture the variability associated with aberrant neural mechanisms underlying an individual's ability to flexibly acquire new information and adapt to changing cognitive and emotional demands, integral processes for normative cognitive functioning and general learning ability [26-29]. Sound sweeps, a task of auditory processing speed, showed improvements during a cognitive training intervention in individuals with recent-onset and chronic schizophrenia [30]. The greatest improvement was observed during the first 20 hours of training, followed by a plateau at subsequent assessment points. Intraindividual variability in the time taken to reach this plateau was also associated with the likelihood that the intervention would generalize to other untrained cognitive domains, suggesting a potential target-mediated treatment response. Another study found that improvements in sound sweeps performance after cognitive training were correlated with gains in working memory and global cognition [31]. Despite the apparent utility of these tasks, they have yet to be adequately evaluated in normative data samples.

Objectives

Therefore, we set out to test a battery of 8 web-based cognitive tasks developed by Posit Science in samples drawn from the general community. Sensory perception, social cognition, and executive functions were digitally assessed in-person with state fair attendees and remotely through testing of college students. In addition, the usability and feasibility of this new battery were investigated in a subset of participants.

Methods

Participants

All study procedures were approved by the institutional review board of the University of Minnesota (UMN). Recruitment and study participation took place either in-person at the Minnesota State Fair (MSF) or remotely for course credit at UMN. The MSF is the second-most highly attended state fair in the United States, with approximately 2 million Midwesterners visiting every year [32]. State fairgoers represent a wide array of demographic backgrounds [33]. MSF participants were asked to participate if they were aged between 18 years and 80 years (inclusive), and UMN students were asked to participate if they were aged between 18 years and 40 years (inclusive). Inclusion criteria for all participants were (1) no visual, auditory, or motor impairments that would prevent completion of the assessments; (2) fluent and literate in English; and (3) no use of illicit substances or alcohol over the prior 8 hours. We received cognitive data from 816 participants and usability survey responses from 219 participants who participated in a substudy. However, cognitive data from 35 participants who took the battery multiple times were omitted from the primary cognitive analyses below, and survey data were omitted for another 24 participants who completed usability questionnaires multiple times. Therefore, 781 participants were included in the primary analyses, and survey data from 195 participants were inspected (Table 1).

Table 1. Participant demographics by sample.

Demographics	Sample		Total (N=781)
	College (n=202)	State fair (n=579)	
Gender[a]			
Female, n (%)	144 (71.6)	338 (58.6)	482 (62.0)
Male, n (%)	57 (28.4)	237 (41.1)	294 (37.8)
Intersex, n (%)	0 (0.0)	2 (0.3)	2 (0.3)
Age, mean (SD)	20.12 (2.28)	44.82 (17.72)	38.4 (18.7)
Years of education, mean (SD)	14.59 (1.5)	16.57 (2.77)	16.1 (2.65)
Grade point average, mean (SD)[b]	3.45 (0.35)	N/A[c]	3.45 (0.35)
Occupation level, mean (SD)[d]	5.16 (1.68)	3.06 (1.84)	3.81 (2.05)

[a]Three participants preferred not to respond.

[b]Grade point average only collected in the undergraduate samples.

[c]N/A: not applicable.

[d]Hollingshead two-factor index: occupational scale.

Procedures

After receiving informed consent, the study participants provided demographic information and completed a battery of cognitive tasks. College students participated remotely via their own personal devices (eg, tablets or personal computers) and were asked to find a stable internet connection to complete the tasks in a quiet, private environment using headphones, preferably over-the-ear headphones. MSF participants completed the study procedures in an enclosed fair structure using lab iPads (Apple Inc) and over-the-ear headphones. Participants were randomly assigned to complete 3 to 4 of the 8 cognitive assessments. State fair participants completed a subset of the measures because of the time limit set by the Driven to Discover State Fair program. A maximum of 30 minutes was allowed for giving consent and the completion of demographic information, cognitive measures, and questionnaires. Participants were randomly assigned to complete 1 of 2 cognitive batteries that were equivalent in length and comparable in terms of the number of auditory, visual, and social cognition tests.

Online Neurocognitive Assessments

Our work aims to translate measures from basic cognitive neuroscience into short, computerized assessments of discrete cognitive processes that individuals can easily complete with minimal assistance in various settings [25]. These assessments are designed to enable the interpretation of specific deficits that could signal that an individual is experiencing cognitive difficulties and impaired learning ability.

The first step in the development of the assessment suite was to decide on the cognitive domains and processes that are known to play a critical role in an individual's ability to learn new information, to interact adaptively with cognitive and emotional challenges in the environment, and to adapt to new learning demands. In line with the principles of team science, we integrated theoretical perspectives, technical expertise, and empirical knowledge drawn from a team of cognitive neuroscientists working in human and animal model systems, clinical researchers, and preclinical translational behavioral neuroscientists. Through a consensus-building process, we identified 3 critical neural domains: (1) perceptual processing (sound sweeps and beep seeker), (2) executive functioning (bubble pop, pathfinder, and mind bender), and (3) social-emotional processing (face to face, tap the emotion, and emotional face). Within each domain, we identified constructs, that is, a definable cognitive process that could be measured at the behavioral level and for which there existed clearly hypothesized and measurable neural-circuit mechanisms (eg, for executive functioning, set-shifting). We identified a cognitive neuroscience paradigm that could selectively and parametrically measure each of these constructs at the behavioral level. Guided by item response theory, these assessments use adaptive testing models to adjust the difficulty level according to the user, thereby reducing the duration of the test [34]. Online neurocognitive assessments (ONAs) take an average of 184 (SD 201) seconds to complete. Instructions on sampling the ONAs are presented in Multimedia Appendix 1.

Beep Seeker: Auditory Discrimination and Sensory Memory

Beep seeker is an auditory discrimination task in which participants are presented with a target tone and are asked to identify it in later trials amidst 2 other distractor tones. Accurate identification of the target tone prompts subsequent trials with more similar distractor tones. A linear staircase method was used to identify the participant's discrimination threshold on a scale of 1 to 15, with higher scores indicating better performance.

Sound Sweeps: Auditory Perception and Processing Speed

Sound sweeps is an auditory perception task in which participants are presented with 2 consecutive tones that may either sweep from a low to high pitch or high to low pitch. The participants were asked to identify the direction of each sweep. The sweep sounds' speed varied according to trial performance,

XSL•FO
RenderX

and participant performance was measured as $\log_{10}$(average RT in seconds).

Bubble Pop: Visual-Spatial Working Memory

Bubble pop is a working memory task in which participants are asked to follow a set of target bubbles that independently move around the screen alongside other distractor bubbles. The number of target bubbles varied with the performance. Accuracy was measured as the number of bubbles correctly tracked using a 2-up, 1-down staircase method.

Pathfinder: Visual-Spatial Learning

Pathfinder is a learning test. A path with 15 nodes is presented. The participant then attempted to recreate the path from memory. If a node is missed, the trial ends, and the path is shown again (5 trials in total). Accuracy was measured as the percentage of nodes correctly recalled out of the total number of nodes.

Mind Bender: Cognitive Flexibility

Mind bender is a task that instructs participants to identify images that follow an established rule around other pictures that violate the rule. Performance was measured as $\log_{10}$(correct trial RT in milliseconds).

Tap the Emotion: Emotion Detection and Inhibitory Control

Tap the emotion requires the participant to tap the screen when a happy or sad face appears and inhibits the prepotent response to tap when presented with a neutral face. Performance was measured as the mean accuracy of neutral trials.

Face to Face: Emotion Identification

A face is shown with a specific emotion, followed by a series of faces with various emotions. Participants were asked to identify the target emotion first shown among the series of faces. The task varies in difficulty by changing the number of emotions presented and the number of faces to choose from. Performance was measured as $\log_{10}$(duration of target stimulus presentation).

Emotional Face: Inhibitory Control of Emotion

Emotional face provides a measure of executive attention, in which an expressive face is shown and overlaid with a congruent or incongruent word (Stroop effect). The increased RT to incongruent stimulus combinations captures the capacity for conflict resolution. Performance was measured by subtracting the mean RT of the correct congruent trials from the mean RT of the correct incongruent trials.

Usability Questionnaire

This lab-designed measure asked participants to indicate how much they agreed with a series of 5 statements using a 5-point Likert scale ranging from *not at all* to *very much*. The specific questions are shown in Multimedia Appendix 2.

Statistical Analysis

All main outcomes were screened for normality. Although some measures showed skewness and kurtosis (eg, beep seeker, tap the emotion, and face to face), all had adequate variance. The task distributions are shown in Multimedia Appendix 1. Nonparametric statistics were subsequently used for beep seeker, tap the emotion, and face to face. Outliers greater than 2.5 SD from the mean were winsorized and represented less than 1% of the data. For ease of comparison, outputs from sound sweeps, mind bender, and face to face were transformed so that higher scores indicated better performance.

General tendencies, dispersion metrics, and associations with demographic variables were calculated for each ONA. A total of 2 individuals identified as intersex were excluded from the gender comparison of ONA performance because of insufficient power. Given that 6 of 8 ONAs showed significant associations with age, task performance was also summarized across 7 different age ranges. To investigate concurrent and discriminant validity across ONAs, a Spearman rank-order correlation matrix was summarized; however, a factor analysis was not conducted because of inefficient overlap of measures completed across samples and a subsequent lack of power.

Results

In total, 781 individuals completed at least one ONA (college, n=202; MSF, n=579). Table 2 presents the means, SD, and ranges for each task.

XSL•FO

Table 2. Normative statistics by online neurocognitive assessment.

Assessments	Participant, n (%)	Task metric, mean (SD)	Minimum[a]	Maximum[b]
Beep seeker	269 (34.4)	5.01 (4.63)	1.00	15.00
Sound sweeps[c]	269 (34.4)	0.98 (0.33)	0.00	1.70
Bubble pop	293 (37.5)	5.07 (1.20)	1.00	7.80
Path finder	323 (41.4)	52.32 (24.97)	1.00	100.00
Mind bender[c]	256 (32.8)	−9.09 (1.03)	−11.60	−6.80
Tap the emotion	426 (54.5)	78.48 (17.88)	20.00	100.00
Face to face[c]	339 (43.4)	−2.03 (0.42)	−3.45	−1.50
Emotional face	252 (32.3)	53.19 (80.11)	−169.00	342.90

[a]Minimum value refers to the lowest task metric across participants on a given task.

[b]Maximum value refers to the highest task metric across participants on a given task.

[c]Raw task output was inverted so that higher scores indicated better performance.

Over 96.4% (188/195) of participants found the ONAs to be at least *a little bit* interesting enjoyable. Almost 91.8% (179/195) of individuals found the tasks at least *a little bit* easy. Only 1 participant endorsed *not at all* to the statement, "I understood the instructions." The vast majority of participants found the ONA instructions easy to understand at the level *of a little bit* or more. Age was found to be negatively associated with the extent to which people agreed that they understood the instructions (ρ=−0.21; *P*=.004). Still, over 72% (49/68) of participants over the age of 60 years reported that they *mostly* or *very much* aligned with the statement, "I understood the instructions." In addition, when asked how much people agreed with the statement, "I would play these games at home," 69.2% (135/195) endorsed *a little bit* or more.

Task relationships with demographic variables such as gender, age, and education are presented in Table 3 and those with occupation level and grade point average (GPA) are presented in Table 4. Male participants outperformed female participants on beep seeker (Wilcoxon rank-sum [W]=6927; *P*=.01), sound sweeps (two-tailed *t* test: $t_{163.65}$=−2.12; *P*=.04), and path finder (two-tailed *t* test: $t_{264.93}$=−4.11; *P*<.001). Age was negatively correlated with task performance on sound sweeps (Pearson correlation [*r*]=−0.33; *P*<.001), bubble pop (*r*=−0.50; *P*<.001), path finder (*r*=−0.38; *P*<.001), mind bender (*r*=−0.41; *P*<.001), tap emotion (ρ=−0.24; *P*<.001), and face to face (*r*=−0.19; *P*<.001). Given the consistent association with age, task performance is displayed across 7 age bins, as shown in Tables 5 and 6. Counterintuitively, fewer years of education were associated with better performance on bubble pop (*r*=−0.13; *P*=.03), mind bender (*r*=−0.13; *P*=.04), and tap the emotion (ρ=−0.16; *P*=.001); however, when controlling for age, these relationships were not significant. Higher levels of occupation were significantly associated with an elevation in beep seeker (ρ=0.15; *P*=.02). Lower levels were associated with better performance on sound sweeps (*r*=−0.16; *P*=.03), bubble pop (*r*=−0.17; *P*=.01), path finder (*r*=−0.24; *P*<.001), mind bender (*r*=−0.21; *P*=.001), and tap the emotion (ρ=−0.20; *P*<.001), but when age was accounted for, only bubble pop remained associated ($F_{1,227}$=4.12; *P*=.04). GPA was not significantly correlated with any of the ONAs.

Emotional face	35	55.09 (73.18)	30	52.26 (107.65)	6	38.07 (110.4)

Most visual tasks were significantly associated with one another, with Spearman rho coefficients ranging from 0.19 to 0.42, indicating some expected shared variance and evidence for the measurement of unique constructs (Table 7). Beep seeker and bubble pop, which measure similar memory processes across auditory and visual domains, were also correlated with one another; however, the Spearman rho was only 0.28, suggesting that they largely capture distinct constructs. In addition, although significant, sound sweeps was found to be only minimally associated (ρ=0.16-0.36) with other theoretically distinct constructs (eg, visual-spatial learning and emotion detection).

Discussion

Principal Findings and Significance

In this study, we tested a new web-based neurocognitive assessment battery for individuals from the general community. Normative metrics were collected across 8 tasks measuring auditory discrimination, auditory perception, visual-spatial working memory, visual-spatial learning, cognitive flexibility, emotion detection, emotion identification, and inhibitory control of emotion.

Participants found the assessments to be widely acceptable across a range of ages. Age was negatively associated with the extent to which participants were able to understand task instructions; however, the broad majority of individuals in older age groups found the tasks understandable. Still, future iterations of these tasks should consider adaptations to better reach these individuals, such as improving task instructions, increasing practice trials, embedding video tutorials, or lowering the starting level of difficulty to reduce initial frustration. Despite finding the tasks widely interesting and enjoyable, fewer individuals indicated an interest in playing games at home. This difference may suggest that fewer participants would choose to engage with these tasks as a leisure activity but may be open to completing them if recommended by a member of their health care team. It is important to note that contrary to the survey wording, these tasks are not considered to be games and should not be interpreted as such. In contrast to traditional neuropsychological assessments, these measures are brief, allowing clinicians to collect a wealth of cognitive information in a relatively short period. These findings highlight the acceptability and efficiency of the battery.

Participant age was associated with 6 of the 8 tasks, with younger participants performing better than older participants. This trend has been widely observed in the cognitive literature [35-37]. Therefore, normative task data were stratified by age. Hearing sensitivity and sensitivity to mistuned, oddball, or discontinuous tones have been shown to deteriorate with age [38-40]. The slowing of processing speed with age has also been well documented [41,42]. Visuospatial working memory performance also decreases with age, potentially because of differences in chunking strategies and proactive interference [43-45]. Better performance observed with path finder, a task of visuospatial learning, may be due in part to more efficient within-task adaptability by younger individuals, a result identified previously with visuospatial tasks [43]. Other similar age-related associations have been documented in learning

XSL•FO
RenderX

paradigms [46]. The findings of this study of decreased cognitive flexibility with age are also largely supported by other studies, such as those examining task-switching capacity [47,48]. Finally, in the literature, older age has been found to be related to poorer emotion recognition, processing facial emotion, and inhibitory control [49-51]. These results likely explain why performance on tap the emotion and face to face, tasks of emotion processing and inhibitory control, was negatively associated with age; however, it is unclear why emotional face did not show an association. Given these findings, which are supported by the greater cognitive literature, normative task data were stratified by age. Therefore, normative task data were stratified by age.

Better performance on a visual learning task was observed in men, corroborating previous gender findings with learning tasks that involve spatial navigation and manipulation [52,53]. These results appear to follow previous findings, suggesting male advantage in detecting interaural time and intensity differences, complex masking tasks, and lateralization of auditory discrimination processing, although these differences are small [54,55]. With samples larger than those in this study, age- and gender-specific norms could be constructed to better characterize the individual performance.

Although previous research has demonstrated associations between performance on cognition and education tests, our task battery did not show relationships with GPA or years of education after controlling for age [56,57]. These findings may indicate that the ONAs successfully captured neural system functioning as opposed to more notion-based intelligence. In addition, only bubble pop performance was related to the occupation level after controlling for age, suggesting a potential benefit of work status.

The majority of predominantly visual ONAs were only minimally associated with one another, as expected, suggesting that they are likely to tap into unique domains of performance. Beep seeker and bubble pop, which measure sensory memory and working memory across auditory and visuospatial domains, respectively, were related. Previous research has supported this association and provided evidence for similar neural mechanisms underlying both memory systems [58,59]. In addition, 2 of the 3 tasks of emotion processing were only minimally correlated with one another. This finding is expected given the varying demands on processes of inhibition between the tasks and differences in the facial targets (eg, responding to faces with any emotion vs identifying faces with matching emotions). It is surprising that tap the emotion and emotional face were not associated, given that both tasks involved processing of facial emotions while inhibiting a prepotent response, although it is unclear whether this relationship would exist with a larger sample who performed both tasks.

Despite the recent development of various digital cognitive assessment tools, few studies have released normative data sets, thus limiting the information that can be gained from these tasks. Collecting normative data from the general community is an important and necessary first step before interpreting cognitive performance in clinical populations. The current global health crisis has arrested the ability to administer traditional in-person cognitive assessments in clinical and research settings. The development of valid and reliable assessment platforms, which can be delivered remotely, has become crucial.

Limitations and Future Work

Despite the strengths of our results, a few limitations exist that should be considered. Although 74.1% (579/781) of the sample came from the general community, a subset of participants was recruited through their attendance at a large public college institution. Therefore, young adults' performance in this sample may differ somewhat from that of the general population. Due to the limited overlap of measures that each participant completed, we were unable to evaluate whether subsets of the tasks were explained by common underlying factors to investigate construct validity. Similarly, the correlations between tasks should be interpreted with caution, given the variability in the number of individuals who were administered each task. Data on participant race and ethnicity were also not collected as part of this study. In addition, 2 individuals identified as intersex prevented our ability to reliably predict how a greater population of intersex individuals may perform on the presented tasks. Future work should aim to evaluate race and gender minorities more specifically to better understand the performance and feasibility of these populations.

Experiential cognitive assessment in patients' homes may help gain a better understanding of their true cognitive states, but it also raises the possibility that individuals will lack the attention or motivation to properly engage in testing [9]. Failure to prevent some patients from using substances or eliciting outside help during testing may also be a necessary aspect of remote testing [24,60]. In these situations, performance on a given task may not truly represent the intended cognitive domain, as it is likely to be in a distraction-limited environment. More information is also needed to understand how cognition in the general community fluctuates from shorter to more extended periods when assessed remotely.

The accessibility of these and other digital assessments provides an opportunity to integrate objective behavioral assessments directly into medical records to guide care. Given that the field of health informatics is still budding, future work should evaluate the extent to which these tasks capture unique variance and predict outcomes amidst other data.

Conclusions

This study presented the performance of individuals from the general community using a novel cognitive assessment tool that can be employed remotely. Participants found the tasks to be interactive and easy to use. The development and validation of web-based tasks such as these widely expand the accessibility of cognitive assessment to new populations such as rural groups and others with limited physical mobility and may also increase the ability of health practitioners to conduct repeated testing. Quick, easy-to-use digital assessment platforms with remote capabilities such as this may help bring the field closer to achieving more impactful patient-centered care.

Abstract

Background: Viscoelastic test–guided coagulation management has become increasingly important in assessing hemostasis. We developed Visual Clot, an animated, 3D blood clot that illustrates raw rotational thromboelastometry (ROTEM) parameters in a user-centered and situation awareness–oriented method.

Objective: This study aimed to evaluate the applicability of Visual Clot by examining its effects on users that are novices in viscoelastic-guided resuscitation.

Methods: We conducted an investigator-initiated, international, multicenter study between September 16, 2020, and October 6, 2020, in 5 tertiary care hospitals in central Europe. We randomly recruited medical students and inexperienced resident physicians without significant prior exposure to viscoelastic testing. The 7 participants per center managed 9 different ROTEM outputs twice, once as standard ROTEM tracings and once as the corresponding Visual Clot. We randomly presented the 18 viscoelastic cases and asked the participants for their therapeutic decisions. We assessed the performance, diagnostic confidence, and perceived workload in managing the tasks using mixed statistical models and adjusted for possible confounding factors.

Results: Analyzing a total of 630 results, we found that the participants solved more cases correctly (odds ratio [OR] 33.66, 95% CI 21.13-53.64; *P*<.001), exhibited more diagnostic confidence (OR 206.2, 95% CI 93.5-454.75; *P*<.001), and perceived less workload (coefficient –41.63; 95% CI –43.91 to –39.36; *P*<.001) using Visual Clot compared to using standard ROTEM tracings.

Conclusions: This study emphasizes the practical benefit of presenting viscoelastic test results in a user-centered way. Visual Clot may allow inexperienced users to be involved in the decision-making process to treat bleeding-associated coagulopathy. The increased diagnostic confidence, diagnostic certainty, reduced workload, and positive user feedback associated with this visualization may promote the further adoption of viscoelastic methods in diverse health care settings.

avatar technology; coagulation management; hemostasis; intuitive design; rotational thromboelastometry; user-centered design; Visual Clot; testing

Introduction

Since Hartert invented viscoelastic testing in 1948 [1] and its later clinical introduction in the 1980s [2,3], viscoelastic coagulation monitoring has become increasingly important in assessing acute bleeding in patients. To this end, several leading guidelines have proposed the use of viscoelastic-guided transfusion algorithms [4,5]. Compared to standard laboratory coagulation assays, rotational thromboelastometry (ROTEM) is faster [6,7], reduces inappropriate blood transfusions [8], and is more cost-efficient overall [9]. Further, previous studies showed that goal-directed viscoelastic hemostatic resuscitation improved patient outcomes in various different surgical specialties [9-13]. However, despite its evident importance, widespread acceptance, and increasing use, correctly interpreting ROTEM outputs remains a significant challenge for inexperienced physicians.

Hence, our research department aimed to simplify viscoelastic test outputs by developing Visual Clot technology. This animated, 3D blood clot illustrates the raw ROTEM parameters in a user-centered and situation awareness–oriented method. Visual Clot displays different coagulation components as either present or absent based on empirical ROTEM cutoff values, without making the final decision for the user. Figure 1 shows the functionality of the Visual Clot technology. In a previous, prospective, dual-center study, Visual Clot helped anesthesia and intensive care physicians in Germany and Switzerland to improve their therapeutic decisions in coagulation management [14]. In a computer-based environment, the physicians were faster, exhibited more confidence, and experienced less workload in managing the hypothetical ROTEM outputs [14]. After their initial experiences, the same physicians considered Visual Clot as intuitive, easy to learn, and useful for the decision-making process [15].

Figure 1. Example of the animated blood clot, Visual Clot. Blood drops are shown in cases of deficient hemostatic components.

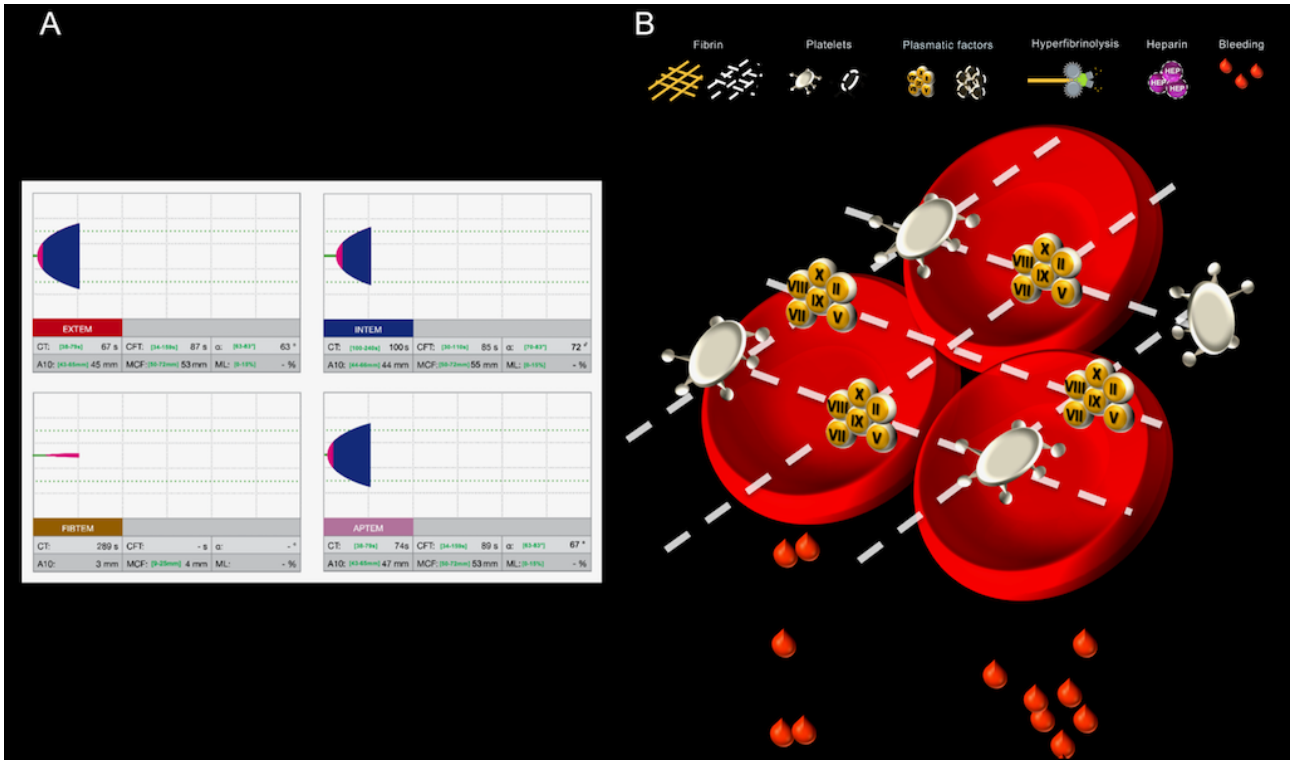
In contrast to the previous research [14,15], this study aimed to evaluate the applicability of Visual Clot by examining its effects on users that are novices in viscoelastic-guided resuscitation. Without giving any instructions on analyzing or interpreting

XSL•FO
RenderX

viscoelastic results, we tested the performance of using Visual Clot compared to that of using standard ROTEM readings. We hypothesized that these inexperienced users would solve more simulated bleeding scenarios correctly, with more diagnostic confidence and less perceived workload using this avatar technology. The results of this study may support the concept of Visual Clot technology and demonstrate its potential for involving inexperienced physicians in coagulation diagnostics and management. Moreover, this study promotes the further development of user-centered, situation awareness–oriented visualization technologies.

Methods

This was an investigator-initiated, computer-based, within-subject, international multicenter study comparing standard ROTEM results with a corresponding animated viscoelastic visualization in simulated bleeding situations. We conducted this study between September 2020 and October 2020 in 5, large, tertiary care hospitals. The Cantonal Hospital Winterthur and University Hospital Zurich in Switzerland, the University Hospital Frankfurt and University Hospital Wuerzburg in Germany, and Hospital Clinic de Barcelona in Spain participated as different centers. The leading ethics committee in Zurich waived this study as it was not within the scope of the human research act (no. BASEC-Nr. Req-2020-00906). The other centers in Germany and Spain also waived ethical approval. All participants agreed in writing to the further use of obtained data for research purposes.



Study Procedure

For participants, we included medical students in their last or penultimate year of study and inexperienced resident physicians without significant prior exposure to viscoelastic coagulation testing. Further inclusion criteria were that they had never seen Visual Clot before and had no or minimal self-declared ROTEM skills. All participants worked in the respective hospitals. Participant selection was according to availability in clinical practice and inexperience in viscoelastic resuscitation. This subject population was completely different from that of the previous Visual Clot study [14], in which we investigated the technology's effect on experienced anesthesia and intensive care physicians.

We prepared 9 different bleeding scenarios that indicated specific coagulation disorders or a normal hemostatic state. In Multimedia Appendix 1, we provide a detailed list of all scenarios including their recommended therapeutic options. We showed each scenario twice, either as standard ROTEM readings or as the corresponding Visual Clot. Figure 2 shows an example of a standard ROTEM presentation with a corresponding Visual Clot, while Multimedia Appendix 2 shows the Visual Clot instructional video. We programmed Visual Clot according to the Zurich coagulation algorithm (Multimedia Appendix 3), which was validated in clinical practice [11]. When showing the bleeding scenarios as standard ROTEM readings, we provided the participants with the same coagulation algorithm's normal values [11]. At the beginning of the study, we first asked the participants to fill out a demographic survey on personal data, such as age, gender, and educational level. We then randomly presented the 9 different coagulation scenarios twice without any instructions on how to interpret them. We used online software [16] to randomize the sequence of these 18 scenarios, providing each participant with a unique set. We showed all ROTEM readings or the respective Visual Clot on an Apple MacBook (Apple Inc). Using exclusively the respective viscoelastic results presentation, we asked the participants to choose their targeted therapeutic recommendations from a total of 6 given answer options. It was possible that multiple therapeutic interventions were necessary for sufficient treatment. We provided the answers as checkboxes in multiple choice form using the app iSurvey (Harvest Your Data) displayed on an iPad (Apple Inc) [17]. We encouraged all participants to submit their therapeutic recommendations as quickly and accurately as possible. After each scenario, the participants rated their diagnostic confidence and perceived workload in fulfilling the given task. At the end of the study session, we asked the participants to rate 4 statements on a 5-point Likert scale (from strongly disagree to strongly agree). These statements aimed to obtain a deeper understanding of the participants' opinions about Visual Clot technology.

RenderX

Figure 2. Example of a standard rotational thromboelastometry (ROTEM) presentation with a corresponding Visual Clot. Adhering to the coagulation algorithm used at the University Hospital Zurich, this hemostatic state represents fibrin deficiency.

Outcomes

The primary outcome of this study was performance, a binary outcome defined as correctly or incorrectly solved scenarios. In scenarios with multiple required therapeutic elements, we considered them to be correctly managed if the participant selected all the correct therapeutic options and no incorrect ones. As secondary outcomes of this study, we assessed the diagnostic confidence binary as unconfident or confident, and the perceived workload using the raw NASA (National Aeronautics and Space Administration) Task Load Index questionnaire. This subjective workload assessment tool has been validated in many different areas, including health care [18-23]. The raw questionnaire defines the total perceived workload as the arithmetic mean of 6 different, workload-associated subscores [23-25]. This study did not investigate the physical demand subscore, as our tasks were not physically challenging.

Statistical Analysis

As a first unadjusted analysis, we applied the McNemar test to compare the numbers of correctly and incorrectly solved cases with ROTEM and Visual Clot. We calculated mixed logistic regression models with a random intercept for each participant for the binary outcome variables, performance as correct or incorrect, and confidence as unconfident or confident. Further, we calculated a linear mixed model with a random intercept per participant for the continuous outcome regarding perceived workload as measured by the overall NASA Task Load Index scores. Apart from the variable denoting the respective viscoelastic modality (ROTEM vs Visual Clot), we adjusted all models for the center, gender, and job experience as confounders. We did not include the respective scenario as a confounding factor because the order was completely randomized for each participant and would not have consequently influenced the overall results.

As we expected similar or greater performance differences as in the previously published Visual Clot study with experienced ROTEM users, we conducted an a priori sample size calculation based on these previous results [14]. We had reported a median of 44% (317/720) correct decisions for ROTEM and 100% (720/720) correct decisions using the Visual Clot. Based on the McNemar test and assuming the proportions of correct solutions were found in the pilot study, we calculated a sample size of 15 participants to achieve a significance level of 5% and a power of 90%. As the data collection was very cost- and time efficient, we decided to include 7 participants in each center to adjust the analyses for the different centers.

We examined all data using R Version 3.6.2 (R Foundation for Statistical Computing) and created graphs using GraphPad Prism Version 9.0.0 (GraphPad Software Inc). Statistical significance was considered at a P value <.05.

Results

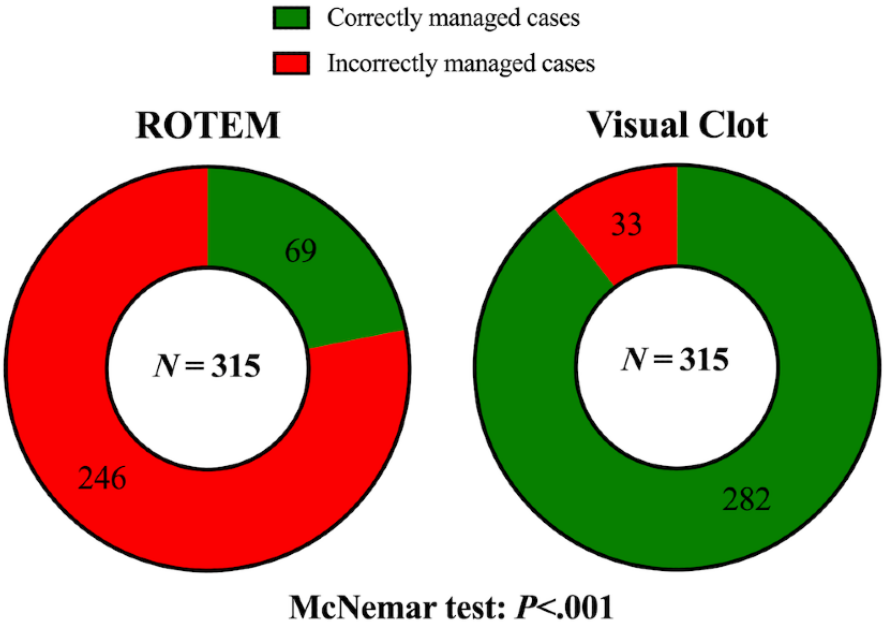
Between September 16, 2020, and October 6, 2020, each of the 5 study centers included 7 participants, amounting to 35 participants in total. We exposed each participant to 18 coagulation management scenarios, providing ROTEM results in 9 cases and Visual Clot in the remaining corresponding cases. No data were excluded in the final analysis. We investigated a total of 630 results, 315 per viscoelastic output modality. Regarding the participants, 49% (17 of 35) were female and none had previous contact with Visual Clot technology. Table 1 displays further study and participant characteristics. In

XSL•FO
RenderX

Multimedia Appendix 4, we provide the full statistical analysis of this study.

Table 1. Study and participant characteristics (N=35).

Characteristic	Value
Study centers, n	5
Age (years), median (IQR, range)	28 (25-32, 24-36)
Self-rated theoretical ROTEM[a] knowledge[b], median (IQR, range)	0 (0-10, 0-20)
Number of ROTEMs interpreted per year[c], median (IQR, range)	0 (0-0, 0-6])
Experience, n (%)	
Penultimate year of medical studies	3 (9%)
Last year of medical studies	10 (29%)
First year resident physician	19 (54%)
Second year resident physician	2 (6%)
Third year resident physician	1 (3%)



[a]ROTEM: rotational thromboelastometry.

[b]The self-rated ROTEM knowledge scale ranges from 0 (very low) to 100 (very high).

[c]The number of ROTEM interpreted per year ranges from 0 (very low) to 100 (very high).

Regarding our primary outcome, binary performance, the mixed logistic regression provided very strong evidence for a difference between the 2 viscoelastic modalities. The odds of correctly solving the case were about 33 times as high when using Visual Clot compared to when using conventional ROTEM tracings (odds ratio [OR] 33.66, 95% CI 21.13-53.64; *P*<.001). In Figure 3, we illustrate the unadjusted comparison between the viscoelastic modalities using the McNemar test. There was no significant difference in performance between the genders (OR 0.63, 95% CI 0.38-1.03; *P*=.06) or the different study centers (all *P* values >.05; Cantonal Hospital Winterthur *P*=.41; University Hospital Frankfurt *P*=.65; University Hospital Würzburg *P*=.60; Hospital Clinic de Barcelona *P*=.69). The job experience, represented by the educational level, did not differ significantly in terms of performance either (all *P*>.05; last year of studies *P*=.59; first year of residency *P*=.64; second year of residency *P*=.96; third year of residency *P*=.75).

Figure 3. Donut charts displaying the binary performance defined as the number of correctly and incorrectly solved cases using standard ROTEM results (left donut) or Visual Clot (right donut). The unadjusted analysis using the McNemar test showed very strong evidence for a difference between the 2 viscoelastic modalities (*P*<.001). N=315 per viscoelastic modality. ROTEM: rotational thromboelastometry.

For the analysis of the participants' diagnostic confidence ratings, our results showed very strong evidence in favor of Visual Clot. The odds of being diagnostically confident were about 200 times higher than when using ROTEM printouts (OR 206.2, 95% CI 93.5-454.75; *P*<.001). Regarding this outcome, no significant differences were not found for the ratings of genders (*P*=.96), centers (Cantonal Hospital Winterthur *P*=.10; University Hospital Frankfurt *P*=.42; University Hospital

XSL•FO
RenderX

Würzburg *P*=.12; Hospital Clinic de Barcelona *P*=.08), or job experiences (last year of studies *P*=.73; first year of residency *P*=.97; second year of residency *P*=.32; third year of residency *P*=.18).

Finally, mixed linear regression yielded very strong evidence for a difference between the 2 viscoelastic modalities regarding perceived workload ratings. The overall raw NASA Task Load Index scores were on average about 40 points lower if Visual Clot was used, with a coefficient of –41.63 (95% CI –43.91 to –39.36l; *P*<.001). In Figure 4, we provide the analysis of the overall perceived workload and its subscores as boxplots.

Figure 4. Boxplots representing the analysis of the participants' perceived workload after using the respective viscoelastic modality. The overall workload and its subscores were evaluated using the modified, raw NASA Task Load Index questionnaire. Low workload scores correspond to low perceived workload. The box represents the first and third quartiles, with the line indicating the median. N=315 per viscoelastic modality. The whiskers represent the 5th and 95th percentile. NASA: National Aeronautics and Space Administration; ROTEM: rotational thromboelastometry; TLX: Task Load Index.

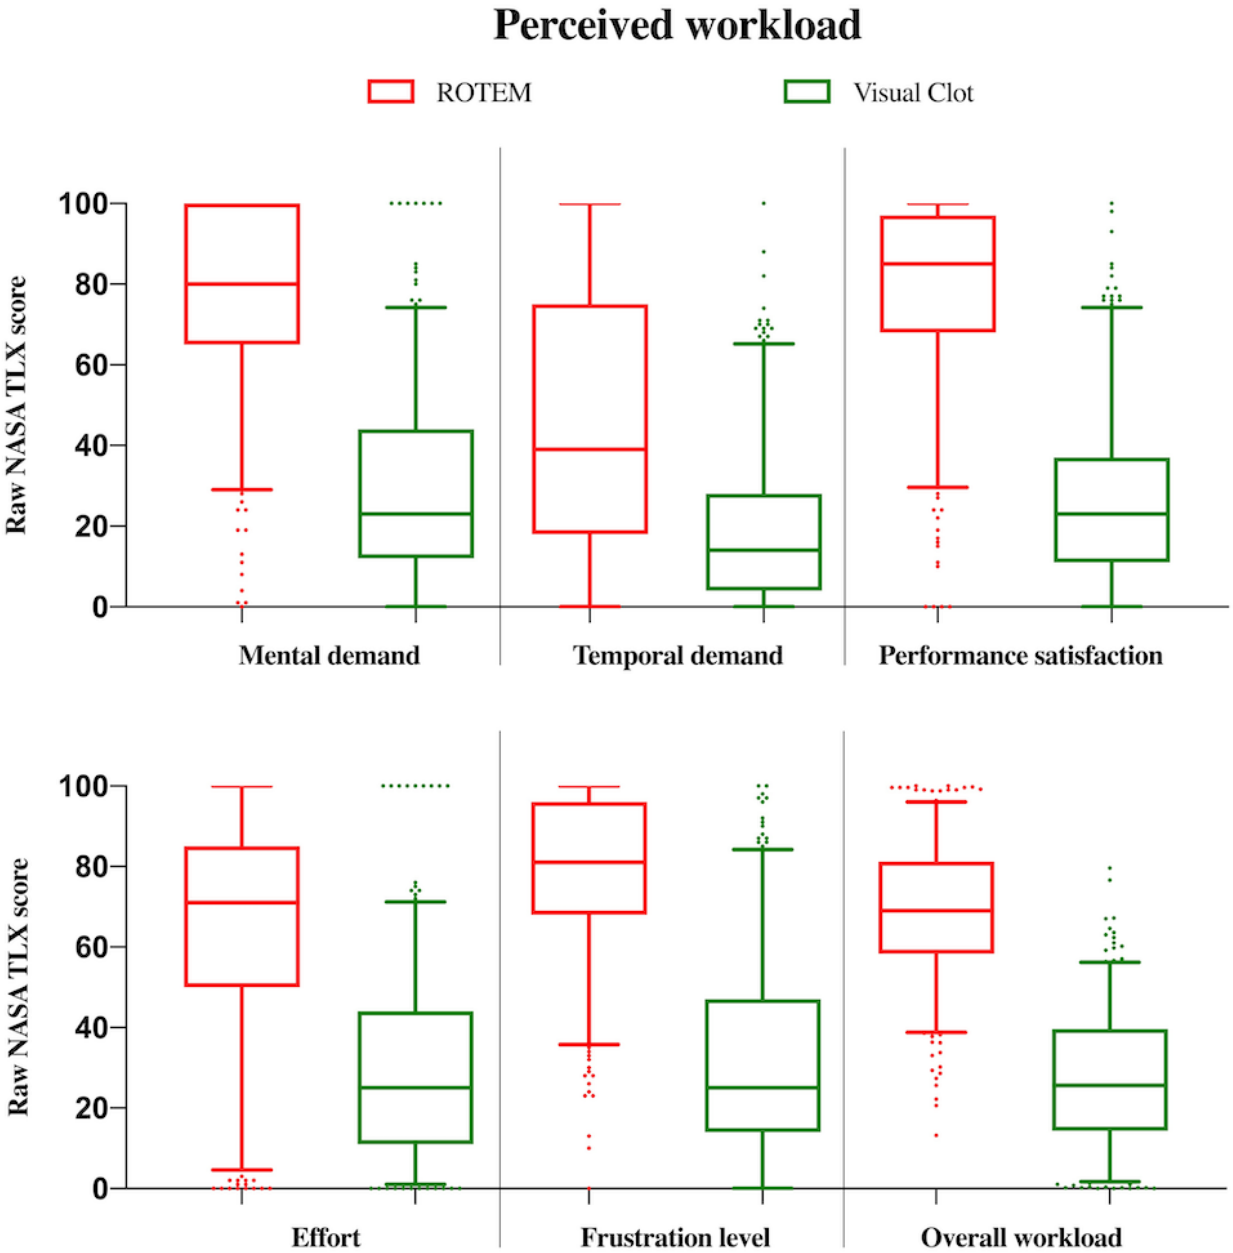


Figure 5 illustrates the 4 statements regarding the participants' opinions about Visual Clot and the results of their assessment. All following results are presented as agree (strongly agree or agree), neutral, or disagree (strongly disagree or disagree). Out of 35 participants, 34 (97%) agreed that the interpretation of Visual Clot was simple and 33 (94%) agreed that Visual Clot helped them feel better prepared to interpret viscoelastic test results. Moreover, all participants (35/34, 100%) agreed that they would use Visual Clot technology in a real bleeding situation, and 28 of 35 (80%) would want their treating physician to use Visual Clot if they were experiencing acute bleeding.

Figure 5. Graphical presentation of the participants' rated survey statements as 10 x 10 parts of whole dot plots. Results are presented as median and IQR. N=35 in each rated statement.

Discussion

This study compared 315 within-subject therapeutic decisions of 35 participants who were inexperienced in viscoelastic-guided hemostatic resuscitation and who did not receive any instructions in interpreting the result printouts. Using the animated blood clot, Visual Clot, the participants interpreted more viscoelastic test results correctly than when using the standard ROTEM tracings. Moreover, they felt more confident in their therapeutic decision and perceived less workload using Visual Clot technology. None of the participants had any previous contact with the avatar-based presentation before attending the study. We examined the results using mixed models and adjusted for different confounders.

Analysis of the participants' performance revealed that the participants selected the correct therapeutic options in over 90% (282 of 315) of the Visual Clot cases, while they made the same choices in only about 22% (69 of 315) using the corresponding ROTEM. This resulted in a relative risk ratio of about 4 and 33-times higher odds of correctly interpreting the test results when using Visual Clot technology. This positive effect persisted both across the different study centers and across the participants' educational levels. These results are even more pronounced than those in the primary Visual Clot study, where we investigated viscoelastic-experienced physicians [14]. There, the odds of a correct therapeutic decision using the avatar technology were around 22 times increased. Visual Clot appears to have significant positive effects even without any instructions for interpretation and even for users with minimal viscoelastic-guided resuscitation knowledge.

Indeed, perceived usability is a prerequisite for user acceptance of innovative technologies [26]. Both users' intuition (ie, unconscious reasoning) and the technology's characteristics, such as shape, color, and presentation of its features, directly influence how people interact with unfamiliar devices [27]. Out of 35 participants, 33 agreed that interpreting Visual Clot was simple. In a previous study investigating physicians' opinions on Visual Clot, the participants found the avatar useful, easy to learn, and intuitive [15]. Likewise, they mentioned that it allowed a faster overview of complex coagulation situations [15]. Visual Clot dichotomizes a disease state or the presence of substrates necessary for optimal clotting based on pathological, self-determinable ROTEM thresholds of an integrated, adequate coagulation algorithm. Indicating essential factors as present or absent and demonstrating them in a playful, user-centered manner reduces information complexity, leading to increased cognitive reception [28]. This binary illustration facilitates decision-making, may help to enforce local coagulation guidelines, and can reduce uncertainty in ambiguous

XSL•FO
RenderX

situations through its clear presentation. On the other hand, the standard ROTEM printouts require that the physician understands the numerical results and the data-driven tracings in the context of the coagulation algorithm's normal values to form a mental model of the current bleeding situation. This seems to cause more insecurity and incorrect therapeutic decisions that may affect the treatment of patients.

Our analysis showed a significant reduction of participants' perceived workload scores when using Visual Clot than when using traditional ROTEM results. Furthermore, our analyses showed 200 times higher odds of being confident when using Visual Clot. Again, these results are more pronounced in these novice users than in the experienced anesthesiologists and intensive care specialists of the previous Visual Clot study [14]. In large hospitals, inexperienced resident physicians may be confronted with acute bleeding situations and coagulopathy even before they possess sufficient medical training in this field. This may cause a high-pressure working environment, which is known to degrade performance [29] and lead to fatigue from perceived work overload [30]. Staff well-being directly influences the prevalence of medical errors [31], and confidence positively affects performance [32]. We should strive to minimize workload and promote the staff's diagnostic confidence to ensure better patient outcomes.

In this study, all of the participants agreed that they would use Visual Clot in a real bleeding situation. Further, 80% (28 of 35) agreed that they would want their treating physician to use this technology if they were experiencing acute bleeding themselves. It seems that the participants trust the technology and accept its application. However, we designed Visual Clot to complement the quantitative ROTEM data as a graphical representation, rather than to replace them.

This study had several limitations. Using a computer-based simulation design, we generated ROTEM printouts and corresponding Visual Clot animations that were clearly attributable to a coagulation disorder or normal hemostatic state. Viscoelastic results in real clinical bleeding may be less distinctive. Future studies are needed to confirm the results of this study in real bleeding-associated coagulopathic situations. However, simulation studies are considered an optimal environment to train and assess new methods [33]. Further, we performed this study in tertiary care hospitals in central Europe, and the results may differ elsewhere in the world. However, we consider this unlikely as all participants were novices to viscoelastic-guided management and therefore did not yet benefit from those large facilities' medical training.

This study also possesses several strengths. The analyses were adequately powered due to the a priori sample size calculation. Furthermore, the within-subject comparisons may largely rule out alternative explanations for our findings. The multicenter design and balanced participant selection across the 5 study centers minimized selection bias.

This study emphasizes the relevance of designing viscoelastic test results in a user-centered, situation awareness–oriented method. The avatar-based blood clot presentation enabled users with no or minimal knowledge in viscoelastic-guided coagulation management and without any prior training to solve almost all coagulation scenarios correctly. It further improved the participants' diagnostic confidence and reduced their perceived workload. Straightforward and confident interpretation may benefit new and experienced users in a wide range of treatment settings and promote the adoption of viscoelastic methods. The most significant benefits will likely be gained by inexperienced users and users who need to make quick decisions in stressful situations, such as on the battlefield, in spaceflight, or in the emergency room. The potential benefits of this technology and the emerging use of viscoelastic testing with its evidence-based importance justifies further investigation of Visual Clot in real clinical bleeding, with the ultimate aim of improving patient outcomes.

Acknowledgments

The authors are sincerely grateful to the staff of all participating study centers for their support in conducting this study. Further, the authors thank all study participants for their time and effort. Instrumentation Laboratory Company/Werfen Corporation had no role in the design of the study, the data collection, analysis and interpretation of data, or the decision to submit this article for publication.

This study was funded by the Institute of Anesthesiology at the University Hospital Zurich, Zurich, Switzerland.

Authors' Contributions

SS, TRR, JB, DRS, CBN, and DWT designed the study.
SS, TRR, MTG, PM, JH, KZ, ER, MLB, FJR, FP, DRS, CBN, and DWT contributed to the acquisition or interpretation of data.
SS, TRR, JB, DRS, and DWT performed data analysis.
SS, TRR, JB, MTG, PM, JH, KZ, ER, MLB, FJR, FP, DRS, CBN, and DWT drafted the manuscript or provided critical revision.
All authors gave approval of the final version of the manuscript for publication.
All authors agree to be accountable for all aspects of the work, including the accuracy and integrity of the work.

Abstract

Background: Hematological medicine is a practical discipline that is difficult to study. Problem-based learning (PBL) is an innovative student-centered teaching method wherein students define their own learning objectives from clinically based problems. Considering that WeChat is the most popular communication app in China, we selected it as a new platform for online PBL to reduce the limitations of traditional PBL in hematology teaching.

Objective: This study aims to explore a new pedagogical method called WeChat-PBL, which is based on real micro clinical cases for postgraduates majoring in hematology and to demonstrate its feasibility and acceptability.

Methods: A total of 48 hematological postgraduates and 7 tutors participated in this study. We divided the participants into 7 groups where students can learn theoretical knowledge. After each course, the members of each group were required to complete in-class quizzes. Moreover, the students and tutors were required to fill out periodic (after each class) and overall (after each semester) evaluations.

Results: A total of 8 micro clinical cases were presented in WeChat-PBL. The average quiz score for acute myelogenous leukemia, chronic myeloid leukemia, multiple myeloma, acute promyelocytic leukemia, and lymphoma were 89.0%, 86.0%, 83.4%, 88.8%, and 77.5%, respectively. Periodic evaluations showed that both students and tutors were satisfied with the process of WeChat-PBL. The overall evaluation results showed that WeChat-PBL was able to positively impact the learning experiences of hematological postgraduates.

Conclusions: Our results indicate the feasibility and acceptability of the WeChat-PBL teaching method for postgraduates majoring in hematology.

problem-based learning; PBL; WeChat; hematology; postgraduate; education

Introduction

Postgraduate education is an important way to expand the knowledge and skills of students [1]. Today, with the continuous advancement of teaching reforms in China, the number of medical students enrolled in postgraduate degrees is increasing, especially in hematology. Hematology is a branch of medicine that explores the diagnosis, treatment, and prevention of diseases related to blood. The clinical manifestations of patients with hematological diseases are often serious and progress rapidly [2]. Both the diagnosis and treatment of hematological diseases are complex. For example, the diagnosis of leukemia, a serious disease in the hematological system, requires a number of laboratory examinations, including blood, bone marrow, immunity, molecular, and genetic analyses, which makes it difficult for students to master knowledge on blood diseases.

XSL•FO
RenderX

All of these characteristics make hematology a difficult subject to learn, and students need to change their role from passive to active. The choice of appropriate teaching methods is also important. Problem-based learning (PBL) may be one of the best methods for teaching hematology postgraduates.

The traditional pedagogy, which is teacher centered, class oriented, and examination driven, places students in a passive state of "reception" [3]. PBL is a student-centered instructional method wherein students define their own learning objectives from clinically based problems [4,5]. As an established approach, PBL has been reported to be suitable for use in graduate entry medical schools [6]. Recently, PBL has become the subject of considerable interest in postgraduate education [7]. PBL can not only cultivate postgraduates' leadership, teamwork, communication, and problem-solving abilities, which are useful for lifelong learning, but also facilitate postgraduates to become responsible for their own learning. Mindaugas and colleagues [8] found that PBL may be an effective approach for postgraduates because the PBL learning process is more demanding and self-directed, which facilitates independent and creative thinking. However, we must also admit that traditional PBL has its limitations. Generally, PBL students must get together in the classroom to discuss and share opinions. Considering the geographic and time dispersion of students, traditional PBL among hematological postgraduates is difficult to conduct. Therefore, the traditional PBL should be modified to address the physical and temporal restrictions in this cohort.

With the development of the internet in China, traditional PBL can be feasibly transferred to an online PBL setting in a virtual environment. The new mode of PBL would be constructed using modern digital technology. Thus, the time and physical restrictions of traditional PBL education would be eliminated. A previous study validated digital PBL, stating that it is as effective as traditional PBL and more effective than traditional learning in improving knowledge [9]. WeChat is one of the fastest growing mobile apps developed by Tencent, with over 697 million currently active user accounts [10], and it is the most popular platform among university students in China [11]. It has connected more than half a billion Chinese people at present. Similar to WhatsApp, WeChat permits users to send messages to an individual or a specific group in various formats, including texts, videos, voice recordings, and images [12]. WhatsApp has been introduced into medical education in colleges and universities in Western countries with great success [13,14]. In China, WeChat has also become increasingly popular as an interactive communication tool in medical education [15]. Thus , WeChat may be an appropriate tool for online PBL, which can eliminate the physical limitations of traditional PBL.

This study aims to explore a new pedagogical method called WeChat-PBL, which is based on real micro clinical cases for postgraduates majoring in hematology, and to demonstrate its feasibility and acceptability.

Methods

Participants

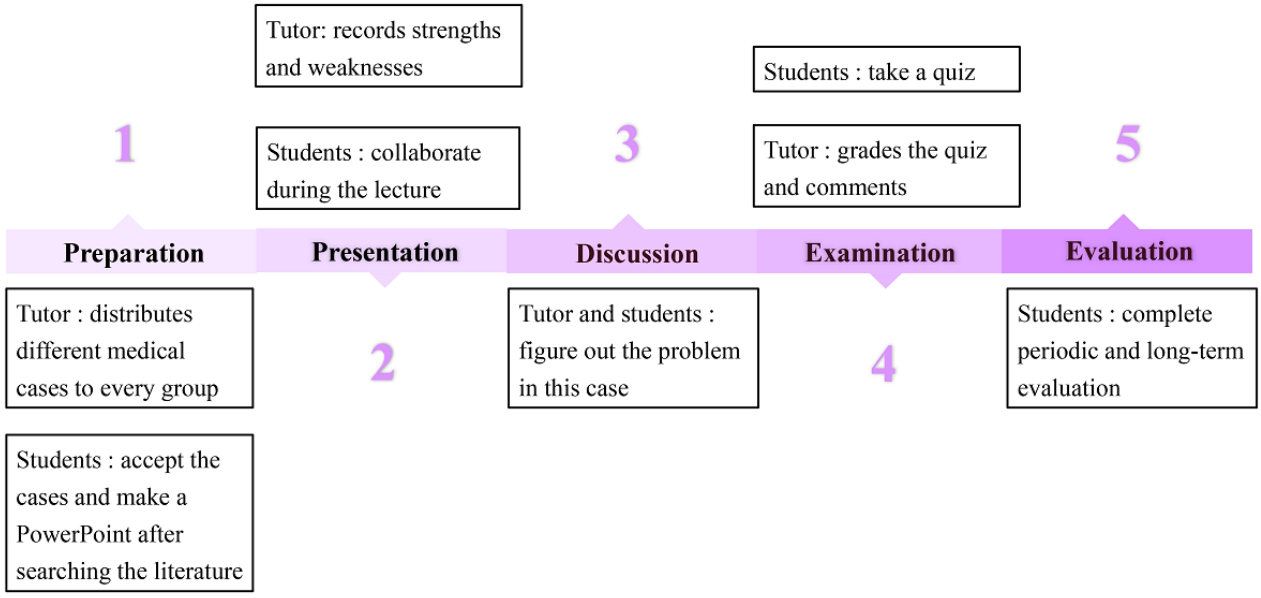
A total of 48 hematological postgraduates studying in Zhongnan Hospital, Wuhan University, were enrolled in our study. Clinical doctors (n=7) with 1 or more years of experience in traditional PBL teaching were assigned as tutors in the WeChat-PBL groups. Our new mode of PBL was constructed on the basis of the WeChat app. WeChat is a popular app that is available on Android, iPhone, and Windows. It is supported by Wi-Fi, 4G, and 5G data networks. Using WeChat, students can communicate with each other anywhere and at any time [16]. All students who participated in this project had their own mobile phones with the WeChat app installed. All were familiar with the practical aspects of WeChat in the PBL context. We randomly divided the participants into 7 groups. Each group comprised 6 or 7 students and 1 tutor. WeChat-PBL was used from August to October 2020. Informed consent was provided to the participants and signed prior to beginning the study. The study was approved by the Medical Council of Wuhan University.

The WeChat-PBL Pedagogy Method

Micro clinical cases including clinical characteristics and relevant questions were uploaded to the WeChat-PBL group 3 days before class. The WeChat group included a tutor and 6 or 7 postgraduate students. Then, the 7 members were divided into 2 groups to create their own Microsoft PowerPoint (Microsoft Corp) according to the micro medical cases the teacher presented by reading books, reviewing the literature, or asking others. In the PBL class, the representative of each group uploaded their PowerPoint and showed it to the others using the video conferencing function in WeChat. Members in the WeChat-PBL group could then pose questions about the selected case and discuss various issues by sending text, images, voice recordings, videos, or documents. As a person who facilitates and motivates learning in the group, the tutor summarized and explained the questions. Owing to the functions of WeChat, all the messages could be easily and instantly read, making WeChat-PBL highly efficient.

The WeChat-PBL Student Examination System

PBL is a learner-centered instructional method by which students learn content and thinking strategies [17]. Self-regulated learning skills play an important role in learning efficiency [18]. Some students are highly self-disciplined, whereas others are not. To help students with poor self-discipline, examination is necessary. All participants were required to complete a quiz after each class, graded by the tutor, and the average score was calculated based on the quiz result. The tutor visually displayed the students' progress through the WeChat-PBL group and monitored students who performed poorly. This assessment was conducted immediately after each class.



Evaluating WeChat-PBL

Curriculum evaluation is important to ensure the quality of education [19], and this also applies to WeChat-PBL. The key to evaluating WeChat-PBL is to assess whether postgraduates are effectively gaining knowledge, improving skills, and

XSL•FO
RenderX

developing scientific research abilities. The evaluations were divided into 2 sections: periodic evaluation of the WeChat-PBL process and an overall evaluation of the whole WeChat-PBL project. The students and tutors were required to complete the periodic evaluation after each PBL class (eg, evaluation of students' participation in creating PowerPoints and performance in the WeChat-PBL group). The overall evaluation of WeChat-PBL was conducted in the form of a group discussion after each semester. The questions were designed in accordance with previous studies [20,21] and with the specific features of this study. The questions displayed in the *Results* section were discussed by all tutors who participated in this research to ensure its quality. The basic flowchart of the WeChat-PBL mode is shown in Figure 1.

Figure 1. Basic flowchart of the WeChat-PBL teaching mode.

Analysis

Microsoft Excel 2013 (Microsoft Corp) was used to perform the data analysis. The average score for each micro clinical case (ie, disease) was calculated by adding up all the quiz scores and divided by the total number of participants involved in the case. Percentages were used to describe the overall evaluation results and was calculated by the number of participants who agreed with each item divided by the total number of participants (N=48). The content of the periodic evaluations within the WeChat-PBL groups was analyzed qualitatively.

Results

PBL Cases

In our study, 8 real clinical cases were presented in WeChat-PBL. A total of 5 different kinds of hematological diseases—acute myelogenous leukemia, chronic myeloid leukemia, multiple myeloma, acute promyelocytic leukemia, and lymphoma—were studied. Every WeChat-PBL group comprised 3 classes. It took 6-10 days to finish 1 PBL case.

Student Examination

The average quiz score for the 5 kinds of hematological diseases were as follows: acute myelogenous leukemia, 89.0%; chronic myeloid leukemia, 86.0%; multiple myeloma, 83.4%; acute promyelocytic leukemia, 88.8%; and lymphoma, 77.5%. The majority of students (41/48, 85.4%) communicated actively within the groups, whereas 7 communicated less actively in the beginning. The tutor spoke with them privately, inquired about the reason behind the reduced participation, and encouraged them to actively take part in the discussions. Finally, all students became active in the group discussions.

Evaluation of WeChat-PBL

Periodic evaluation results showed that every students played an active part in making their PowerPoint. The tutors were satisfied with the performance of the students and reported that students exhibited obvious improvement in both theoretical study and scientific research abilities.

The overall evaluation was conducted in the form of a group discussion. The results of this discussion are presented in Table 1. Most students had a better understanding of PBL (41/48, 85.4%). Almost all students were satisfied with their performance in WeChat-PBL, including completing the tasks assigned to them on time (44/48, 91.7%), applying prior knowledge to solve problems (48/48, 100.0%), and communicating ideas with group members effectively (42/48, 87.5%) The majority (44/48, 91.7%) believed that their clinical skills and scientific research abilities were improved through the use of WeChat-PBL. In addition, most of the students reported that group members and the tutor offered timely feedback (45/48, 93.8%) and held the view that the WeChat-PBL teaching mode was reasonable (42/48, 87.5%) and better than traditional PBL (39/48, 81.2%). The majority of students thought that WeChat was an effective app for online PBL for postgraduates majoring in hematology (39/48, 81.2%). In terms of the quality of the micro clinical cases presented in WeChat-PBL, the majority of students thought that it was valuable and interesting (43/48, 89.6%). Not surprisingly, almost all students felt that the role of the tutor was very important in

XSL•FO
RenderX

the PBL group setting (46/48, 95.8%). However, only 30 out of 48 participants (62.5%) felt free to pose questions in the WeChat-PBL group.

Table 1. Results of the overall evaluation of the WeChat-PBL teaching mode.

Number	Question	Respondents, n (%)	
		Agree	Disagree
1	Did you have a better understanding of PBL[a]?	41 (85.4)	7 (14.6)
2	Did you enjoy the discussions in WeChat-PBL?	41 (85.4)	7 (14.6)
3	Did you complete the tasks assigned to you on time?	44 (91.7)	4 (8.3)
4	Did you apply prior knowledge to solve problems?	48 (100.0)	0 (0.0)
5	Did you feel free to pose questions?	30 (62.5)	18 (37.5)
6	Did you actively take part in the discussions?	34 (70.8)	14 (29.2)
7	Were you able to communicate ideas with your group members effectively?	42 (87.5)	6 (12.5)
8	Do you think that the micro clinical cases presented in WeChat-PBL are valuable and interesting?	43 (89.6)	5 (10.4)
9	Did your clinical skills and scientific research abilities improve through WeChat-PBL?	44 (91.7)	4 (8.3)
10	Did your group members and tutor offer timely feedback?	45 (93.8)	3 (6.2)
11	Do you think the teaching mode of WeChat-PBL is reasonable?	42 (87.5)	6 (12.5)
12	Do you think the teaching mode of WeChat-PBL is better than that of traditional PBL?	39 (81.2)	9 (18.8)
13	Did your tutor consistently show enthusiasm with PBL?	48 (100.0)	0 (0.0)
14	Do you think that the tutor played an important role in student learning in the PBL group?	46 (95.8)	2 (4.2)
15	Do you think that WeChat is an effective app for online PBL for postgraduates majoring in hematology?	39 (81.2)	9 (18.8)

[a]PBL: problem-based learning.

Discussion

Principal Findings

The new PBL mode based on WeChat was designed to promote the abilities of hematological postgraduates, including clinical reasoning, team skills, and metacognition. This mode of online PBL successfully eliminated the physical and temporal limitations of traditional PBL in postgraduate teaching. In our study, the average quiz score for acute myelogenous leukemia, chronic myeloid leukemia, multiple myeloma, and acute promyelocytic leukemia was very high. The majority of students reported that their clinical skills and scientific research abilities improved through WeChat-PBL and thought that WeChat was an effective app for online PBL for postgraduates majoring in hematology, indicating the acceptance and effectiveness of the WeChat-PBL teaching mode.

In this study, almost all students felt that the role of the tutor was very important in the PBL group. A previous study has also validated that the tutor plays an important role in student learning in the PBL group [22]. Dissatisfaction with PBL has arisen owing to the teaching capabilities and enthusiasm of the facilitators [23,24]. Barrows and colleagues [25] expressed the view that the tutor should facilitate and motivate learning rather than serve as a source of knowledge. However, other studies support the idea that the best tutors are those with both the ability to promote learning and present clinical content [26]. Dolmans et al [27] have reported that the tutor's acts not only have an impact on the productiveness but also the effectiveness of the PBL group's work. To help tutors become more effective in PBL tutorials, continuous training that can facilitate tutors' reflections of their own development as teachers [28,29] and assist them in shifting from a traditional lecturing role to a multifaceted role as a mentor, coach, model, and guide [30] is needed.

The majority of data on tutor training has mainly focused on general moderation techniques for tutors [31]. In 2005, Azer [32] presented a group of challenges faced by PBL tutors and 12 tips for successful group facilitation. Tutors can read books, educational reviews, and research articles and regularly record teaching experiences by using reflective journals to achieve the essence of these tips in teaching. Moreover, PBL has 7 sequential steps, including case presentation, problem definition, brainstorming, generating hypotheses, defining learning goals, self-study, and synthesis [21]. Tutors should cultivate themselves according to these steps.

Eight micro clinical cases were presented in WeChat-PBL, and 89.6% of students found these cases to be valuable and interesting. Because the cases are brief and interesting,

XSL•FO
RenderX

WeChat-PBL is time-efficient, effective, and interesting to the learner and teacher. Our study involved real-life cases and the actual experiences of health professionals, which is helpful to enhance the relevance of the subject matter. Professional knowledge is integrated with clinical presentations. Student learning, therefore, is associated with real-life situations.

PBL is a learner-centered instructional pedagogy, in which students play a central role in their learning [17]. Thus, several competencies including knowledge acquisition, practical skills, and professional attitudes are important for them to become active, cooperative, and self-directed [33]. Assessment of competence is vital for students to identify and respond to their own learning needs, providing insights into their actual performance. Examination drives learning, and it affects not only what students learn but also how they learn [34]. In our study, we assessed the students by evaluating their performance in the WeChat-PBL group, completion of the work, and a quiz after each class. We observed an obvious correlation between the examination scores of students who participated more actively than others.These data highlight the importance of effective assessment systems for monitoring student progress in the PBL curricula.

Of note, our WeChat-PBL teaching mode has several obvious advantages compared with the traditional PBL. First, WeChat is the most popular app in China [35]. It is a very convenient way for students to communicate. By uniting traditional classroom education with the WeChat app, students can learn actively at any time, both before and after class. Second, the frequent notifications in the WeChat group establish periodic contact between students, which encouraged student feedback on the course and facilitated student-student and student-teacher interactions. Third, more teamwork can be encouraged through WeChat-PBL than traditional PBL given that students can communicate easily with the help of the WeChat app. Fourth, the micro clinical cases were uploaded to the WeChat-PBL group before class. Students were able to prepare for the session in advance, thus cultivating the learner in an efficient, goal-directed manner.

Conclusion

A great number of changes have taken place in the instructional methods used to teach medical students. Hematological medicine is a practical discipline that is difficult to master. In our study, we demonstrated the feasibility and acceptability of the WeChat-PBL teaching mode for postgraduates majoring in hematology. The new PBL mode is time-saving and convenient. Additionally, it provides a suitable platform for sharing the latest information and educational resources. It emphasizes interoperable, interactive, effective, and participatory teaching styles. Despite the limited sample size in our study, our results indicate that WeChat-PBL is applicable to postgraduates majoring in hematology. In the future, further comprehensive, large-scale, and high-quality studies should be conducted to confirm our findings and thus promote the applications of this new teaching mode for hematological postgraduates.

Abstract

Ongoing training in the area of basic life support aims to encourage and sustain the willingness to act in out-of-hospital cardiac arrest situations among first aiders. The contribution of witnesses and first aiders has diminished rapidly, as suspicion associated with the COVID-19 pandemic has risen. In this paper, we present teaching methods from the medical education field to create a new teaching-learning process for sustaining the prehospital involvement of first aiders and encourage new first aiders. The most important benefit—improving outcomes—can be achieved by introducing a variety of teaching-learning methods and formative assessments that provide participants with immediate feedback to help them move forward in the basic life support course. The new reality of web-based learning that has been introduced by the pandemic requires an innovative approach to traditional training that involves techniques and methods that have been proven to be useful in other fields.

Introduction

Due to public health concerns in the wake of 2020, which were caused by the novel COVID-19, face-to-face contact in medical training was promptly substituted with remote teaching. The teaching-learning process was moved to the houses of participants through a variety of learning management systems and videoconferencing services [1]. Similarly, all hands-on resuscitation training in the form of in-person, hands-on sessions was stopped [2]. Nevertheless, the European Resuscitation Council (ERC) as well as the International Liaison Committee on Resuscitation (ILCOR), in their educational update in April 2020 on teaching during a pandemic, highlighted the importance of sustaining sudden cardiac arrest training in some form, despite the modified conditions for knowledge transfer. The ILCOR and national societies underlined the significance of continuing education to improve resuscitation knowledge, certain skills, and, most importantly, patient-centered care to sustain and encourage the willingness to act during out-of-hospital cardiac arrest (OHCA) situations [3,4]. Complementary basic life support (BLS) teaching methods involving computer-based and video-based e-learning or the gamification approach have been proven to be useful in the area of BLS [5,6]. However, the cost-effectiveness and standardization of the training delivered via these educational methods should also be considered [7,8].

The long-term retention of BLS competencies is essential and outweighs skills performance during teaching sessions, according to published evidence [9,10]. Such pieces of evidence have opened a new door in the era of BLS training. Additionally, as BLS training is conducted in each health care professional undergraduate medical curriculum, there have been additional demands for finalizing modules that were planned for educational months, which changed due to the COVID-19 pandemic. The Polish Ministry of Health, together with the Ministry of Education, suspended face-to-face education from March 12, 2020, onward [11]. Therefore, the opportunity for

XSL•FO
RenderX

launching a web-based BLS course arose (e-BLS) in response to new conditions.

To expand people's knowledge about distant and web-based possibilities for learning in the area of BLS, we present a proposal for a newly designed e-learning course about BLS competencies. This course was developed to (1) enable participants to understand and cultivate the necessary competencies in each of the OHCA domains and (2) promote the implementation of the steps required for helping people in need of BLS. The course design entails a novel teaching methodology that has been extensively researched in the medical education field.

Methods

The Goal Of Training and Its Objectives

A multimodal, participant-centered, interactive, web-based course for addressing the unique challenges of sudden cardiac arrest that a layperson may face daily was developed. The overarching goals of the course are to (1) enable participants to understand and cultivate the necessary competencies in each of the OHCA domains and (2) promote the implementation of the steps required for helping people in need of BLS. Specific objectives were determined by analyzing the ERC guidelines update for the COVID-19 pandemic. This was done to set up BLS course learning objectives and the needs assessment of the participants (Table 1).

XSL•FO
RenderX

Table 1. Objectives, instructional methods, and implementation strategies for each basic life support (BLS) competency session.

Session topic (number of sessions; time of each session)	Objectives	Instructional design and implementation
Safety (2; 45 minutes)	• Personal safety and the safety of people in need of BLS in cardiac arrest situations during the COVID-19 pandemic (hand hygiene, the donning and doffing of gloves and masks, types of masks, methods for approaching a person in need of BLS, and scene safety)	• Video-based training [12]: Students review the instructional videos on the e-learning platform, produce instructional videos to present their skills, and receive feedback from the faculty on their performance.
BLS (3; 45 minutes)	• Standard algorithms and modifications resulting from pandemic (methods that do not involve the look, listen, and feel technique and continuous, chest compression–only CPR[a] without mouth-to-mouth ventilation)	• Video-based training and decision trees [13]: After familiarizing themselves with the assigned materials and conducting video discussions, students are presented with selected sudden cardiac arrest recognition and management scenarios related to BLS. Students have 5 attempts to solve each of the two decision trees and receive immediate feedback.
AED[b] (3; 45 minutes)	• Description of the equipment, equipment use, and where and how to find equipment during an out-of-hospital cardiac arrest • Using an AED as a nonaerosol-producing step	• Video-based training and decision trees: After familiarizing themselves with the assigned materials and conducting video discussions, students are presented with selected sudden cardiac arrest recognition and management scenarios related to BLS. Students have 5 attempts to solve decision trees and receive immediate feedback. • Simple game scenario [6]: Participants implement the BLS/AED algorithm in a simple virtual environment, and the player or student has to save a person by applying CPR actions. • Find your AED: Participants find the closest device to their place of residence by using the Staying Alive app [14].
pBLS[c] and FBAO[d] (3; 45 minutes)	• Standard algorithms and modifications resulting from the pandemic	• Video-based learning and decision trees: After familiarizing themselves with the assigned materials and conducting video discussion, students are presented with selected pediatric sudden cardiac arrest recognition and management scenarios related to pBLS. Students have 5 attempts to solve 1 decision tree and receive immediate feedback. • Instructor-led, live practice session on Zoom about FBAO algorithms for infants and chest compressions for infants: Participants use available toys resembling a newborn.
Special circumstances leading to sudden cardiac arrest, such as anaphylaxis, heart attacks, strokes, diabetes, drowning, hypothermia, burns, and seizures (3; 45 minutes)	• Definitions, standard algorithms, and modifications resulting from the pandemic	• Peer assessments [15] and teacher assessments of the presentations of assigned topics are prepared in a group of 3 people and recorded by participants.
Review (4; 45 minutes)	• Review of all of the topics	• The Script Concordance Test [16,17]: This includes 8 BLS scenarios accompanied by questions concerning possible next steps (Multimedia Appendix 1). Each of the questions is supplemented by a new piece of information concerning the sudden cardiac arrest health issue being considered. Students use a 3-point Likert scale to determine whether and to what extent the new piece of information influences further evaluations.

[a]CPR: cardiopulmonary resuscitation.

[b]AED: automated external defibrillator.

[c]pBLS: pediatric basic life support.

[d]FBAO: foreign body airway obstruction.

Participants: Target Group

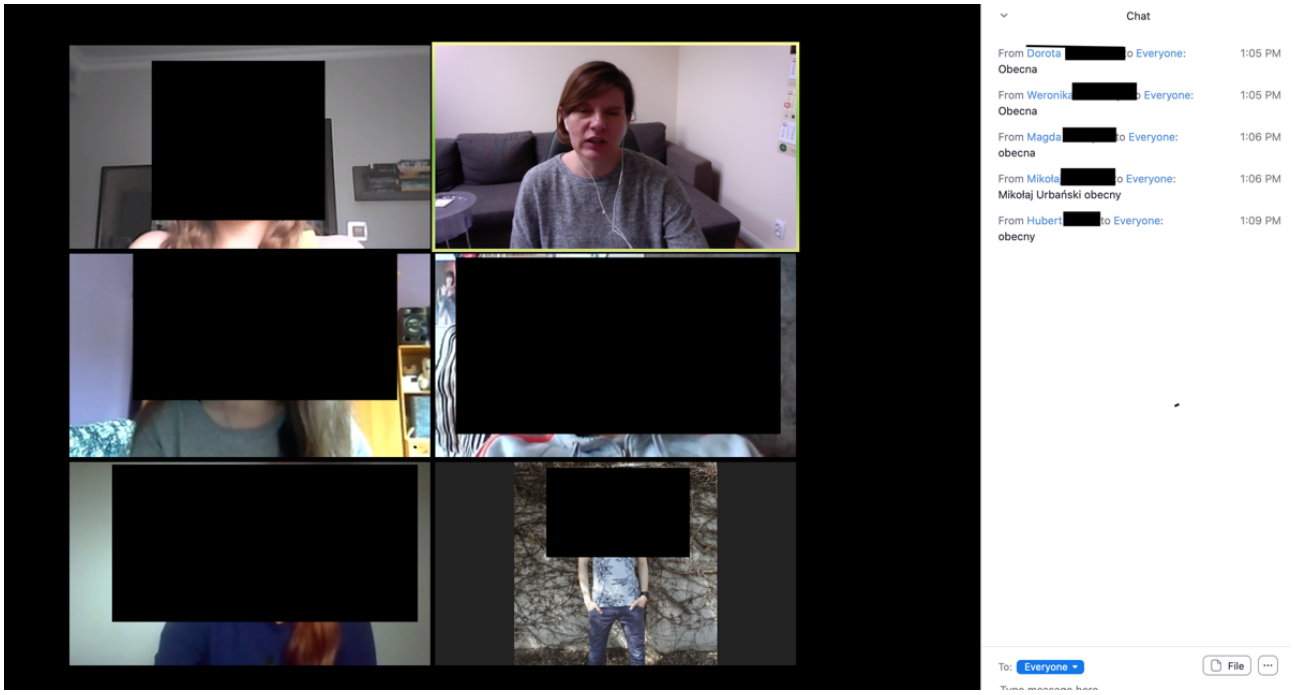
The course aims to provide an introduction to BLS and strengthen the elements of the chain of survival. No professional BLS experience is required. However, the course can also be treated as a refresher course for maintaining participants' motivation to assist in OHCA situations and providing an update on BLS training to health professionals. Therefore, the target

XSL•FO
RenderX

population includes students of medical faculties (medicine, dentistry, nursing, midwifery, biomedicine, paramedics, public health, and dieticians), first aiders with initial first aid knowledge, lay rescuers who are enrolled in a first aid course, and health care providers who want to refresh their knowledge.

The e-learning modules have been embedded in the curriculum of students in all medical faculties of the local medical university, as first aid is obligatory in all curricula. The decision trees and the Script Concordance Test (SCT) have been prepared in Polish and English language for Polish and foreign students. The course is planned for 20 teaching hours and takes place in an academic environment.

To target other professional groups and voluntary first aiders, a massive, open, web-based course will be established to enable their participation and access to the proposed activities.



Evaluation

The course will be assessed on the basis of participants' achievements on the final, summative, multiple-choice question test; the SCT; and decision trees as well as data from an anonymous survey based on the Utrecht Seminar Evaluation questionnaire by Spruijt et el [18]. The authors made the tool available upon our request.

Learning Management Systems and Videoconferencing Services

Based on the advice of experienced researchers, two platforms that are well known to participants were chosen to host the course—Zoom (Zoom Video Communications Inc; Figure 1) and Moodle (Figures 2 and 3)—to alleviate uncertainty and distrust among the students [19]. Zoom enabled live meetings with participants for discussing a given topic, whereas Moodle, a web-based guiding platform, was used to store all of the information on the course meetings and requirements and the organization, all of the materials and resources assigned to topics, and the links to the formative tasks described in this paper. To adjust to web-based classes, participants received detailed instructions on the use of both platforms. The decision trees' software constituted another university software; however, links to each task appeared on Moodle and were assigned to a given subject (BLS, BLS/automated external defibrillator [AED], or pediatric BLS), and detailed instructions on how to access the task as well as the rules of engagement were provided.

Figure 1. An anonymized screen shot from an individual Zoom meeting.

XSL•FO

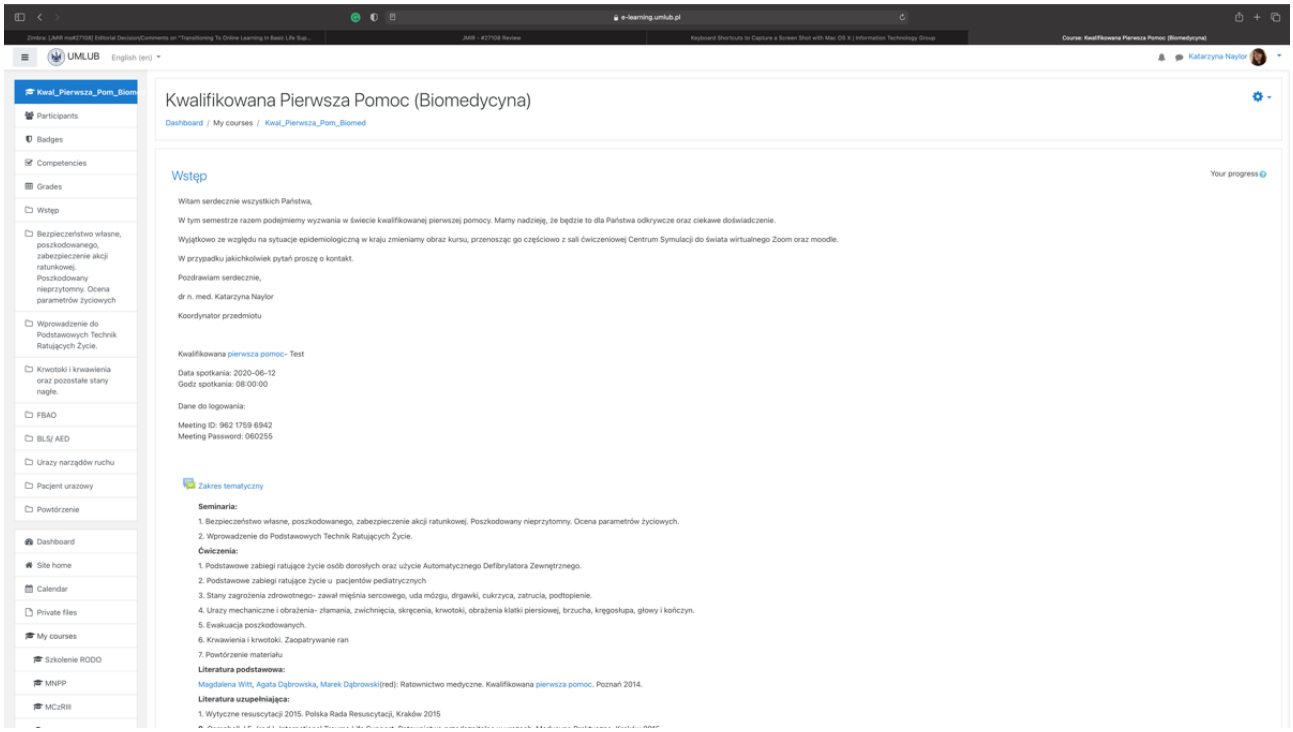
Figure 2. A general overview of an introductory Moodle course website.



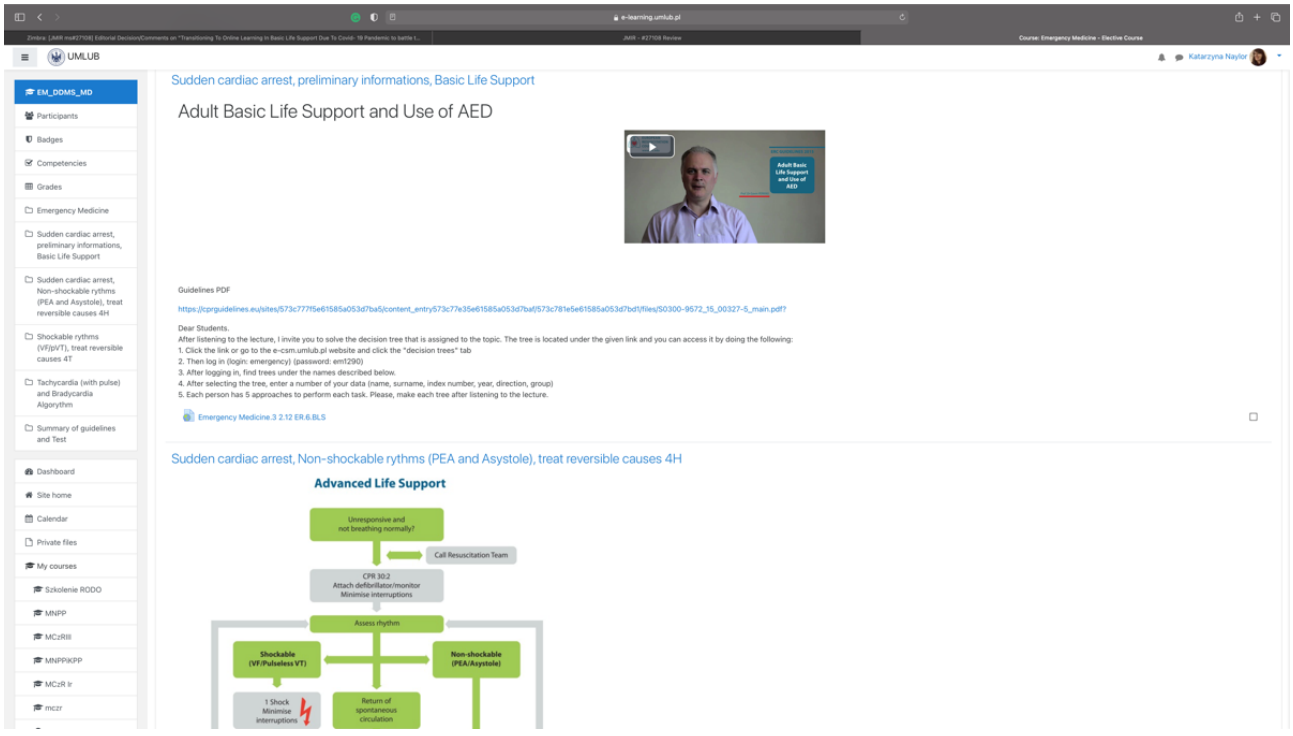


Figure 3. A screenshot of another course on Moodle and a decision tree for instruction. AED: automated external defibrillator; PEA: pulseless electrical activity; VF: ventricular fibrillation; VT: ventricular tachycardia.

The educational game for engaging with BLS/AED drills was also located on a different server. A freely available resource was used [20]. Elements of the game were scored, and participants posted their obtained results on the Moodle forum.

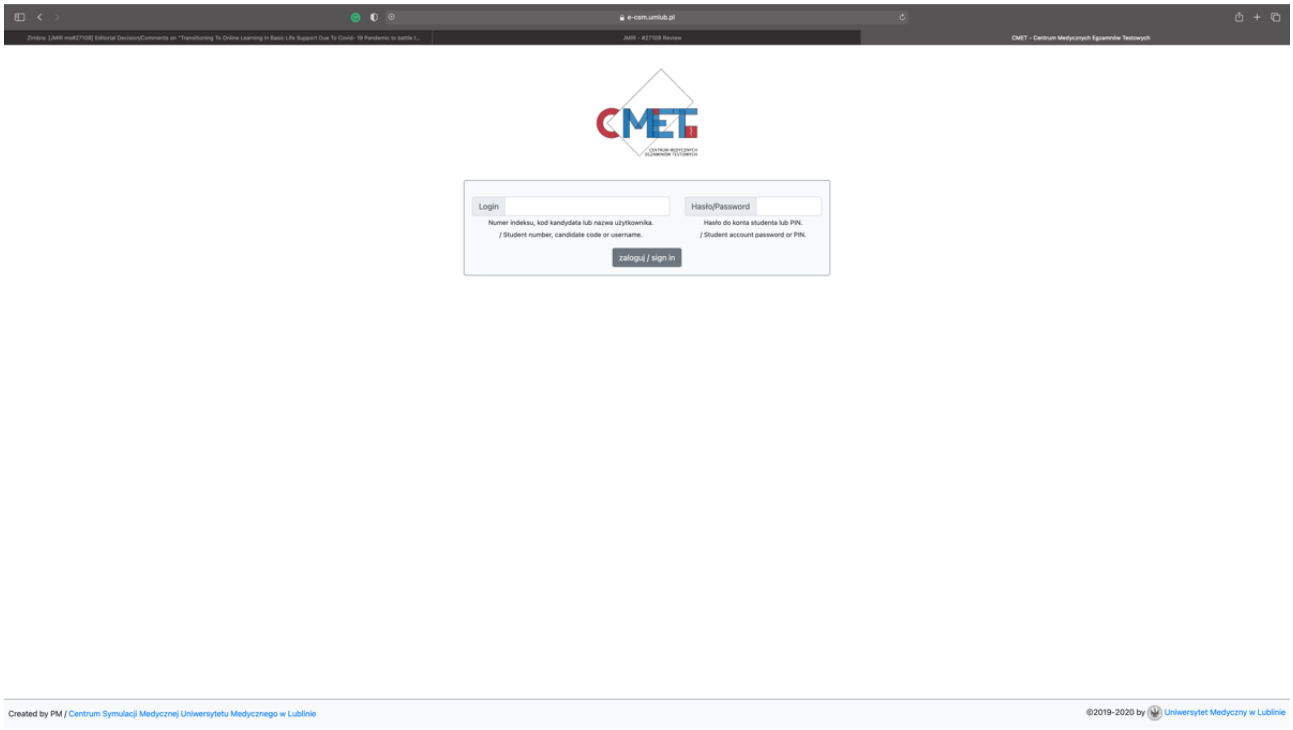
Another type of software that was used during the course was a newly developed testing system—the Testing Centre for Medical Exams (Centrum Medycznych Egzaminów Testowych [CMET]) [21]. The final summative assignment was held on CMET. The CMET used the following 3-level system for constructing the summative assessment (multiple-choice questions): (1) teachers input the questions into the system; (2) specialists in the area reviewed the questions; and (3) the course coordinator accepted, edited, or sent back the questions (with comments) to their primary creator. This was done to ensure the quality of the provided tasks and generate a more complex task (Figures 4 and 5).

Before the final assignment, the participants receive access to a practice test to confirm their login details and familiarize

XSL•FO
RenderX

themselves with the system's construction. During the test, each student is individually timed during their attempt and receives immediate feedback on the questions alongside their results after they finalize their attempt.

Figure 4. A screenshot of a login page to the CMET website. CMET: Centrum Medycznych Egzaminów Testowych.



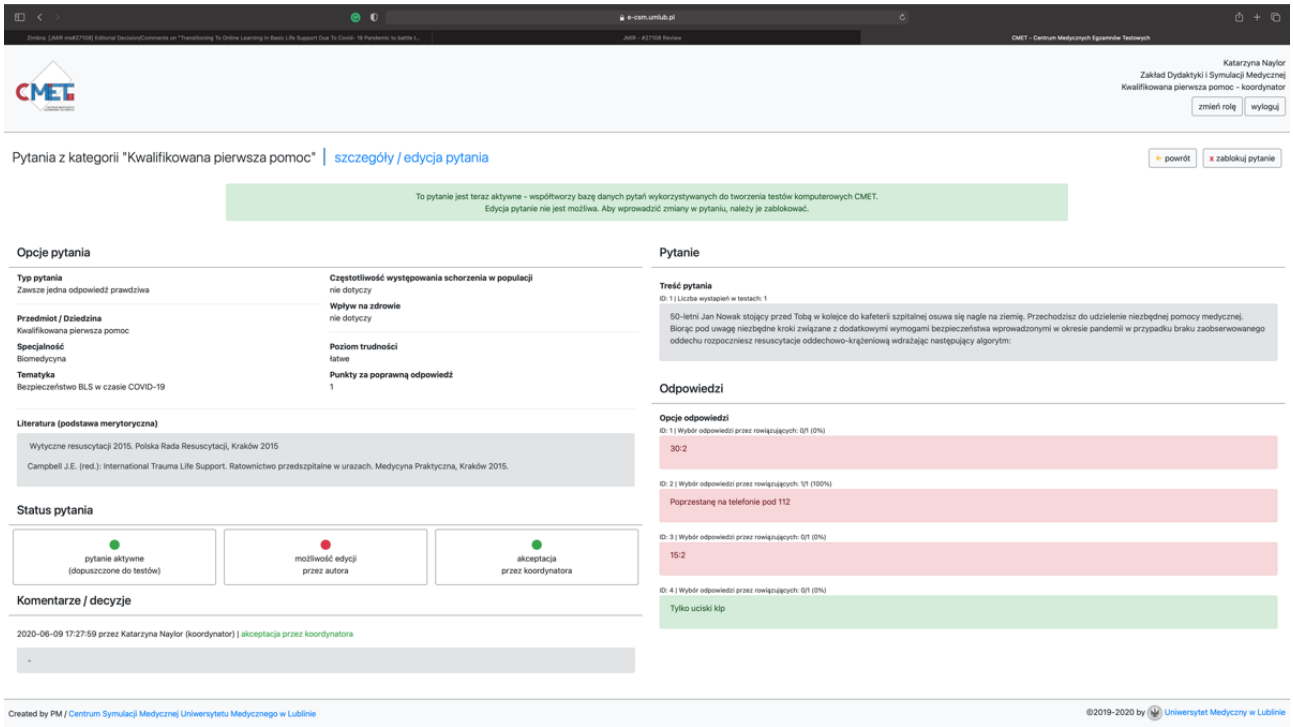


Figure 5. A screenshot of a coordinator account page for a single question on the CMET website. CMET: Centrum Medycznych Egzaminów Testowych.

Discussion

Content and Facilitation

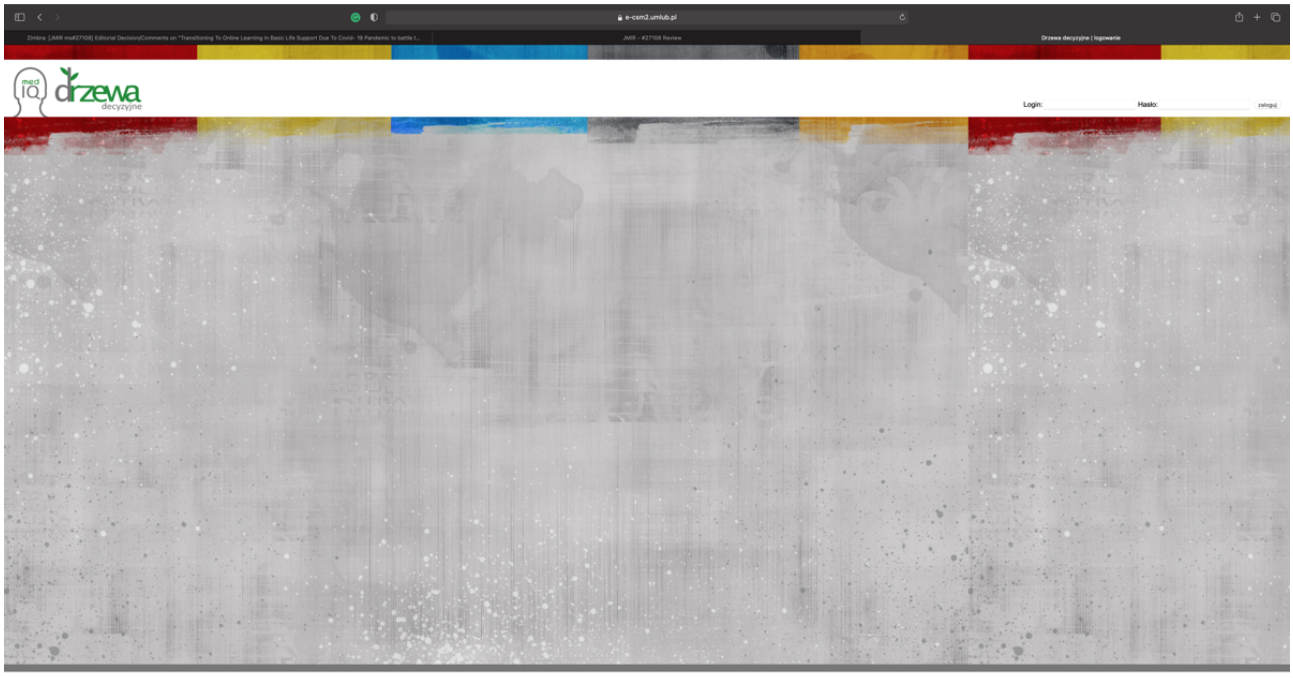
The implemented assessment points support learning and correspond with the implemented content. Our assessments points focus on formative assessment; they are not used as a tool for passing judgment and making pass-fail decisions but as a tool for assisting with and supporting learning [22]. Formative assessments are also known as assessments for learning or learning-oriented assessments. Such assessments aim to provide feedback on understanding and help participants move forward in the course (Table 1).

XSL•FO
RenderX

Novel Assessment Formats That Promote Knowledge Acquisition

Learning is promoted through the formative tasks in the outlined BLS web-based course. Participants need to be consciously analyzing and applying gathered "intel" on a given subject in order to benefit from the experience. All of the proposed types of formative assessments in our course aim to produce feedback on performance to advance the learning of participants [23].

The American Heart Association (AHA) has implemented a video-based approach (a teaching approach centered on using videos) that allows AHA course participants to practice BLS techniques while watching videos (ie, practice-while-watching method) during AHA courses. The AHA also provides the option of an e-learning module, in which participants familiarize themselves with the content of videos and textual content before participating in hands-on sessions [24]. Additionally, the ERC has focused on implementing the Peyton approach (ie, a 4-step method) during their hands-on sessions [25]. Therefore, the focus of BLS courses was placed on face-to-face training, and web-based materials were only used to prepare for face-to-face meetings.



The SCT

The SCT as an assessment method for evaluating clinical reasoning that has several advantages in BLS training. Students tackle a genuine case to demonstrate their ability to incorporate new data into the information on the provided scenario [16,17]. They can compare their reasoning and conduct related discussions, thereby allowing them to learn from each other. This is especially important in emergency situations and OHCA situations, in which quick and timely decisions are required. Additionally, the SCT goes beyond pure fact checking; it requires logical thinking and knowledge application based on procedural knowledge (Multimedia Appendix 1).

Decision Trees

Decision trees are based on the assumption that machine learning algorithms are helpful in the medicine field, as errors can have a dire consequence. Decision trees have been used in the decision-making process in clinical settings [13,26]. Nevertheless, the existing system allows first aiders to tackle the complexities and uncertainties of OHCA. Existing decision tress allow for the implementation of knowledge at the more critical level of the Millers pyramid in BLS competency training (Multimedia Appendix 2; Figure 6).

Figure 6. A screenshot of a login website for accessing the decision trees.

Gamification

The BLS/AED game was designed to complement BLS teaching and refresh skills in a unique, enjoyable way [6]. The game presents an OHCA scenario by using simple graphics and takes players to a virtual environment where they make choices based on the steps of the BLS/AED algorithm (Multimedia Appendix 2). The game is educational and is a unique medium for knowledge transmission; such games have been proven to promote active learning, help with solving clinical problems, and help learners gain experience in a risk-free environment [6]. At the end of the game, the participants of our course will receive feedback on their performance, and they will have an opportunity to undergo another attempt (Multimedia Appendix 3).

Conclusions

There is a large variety of web-based first responder and BLS courses. Although the new reality resulting from a pandemic and teaching and learning during a pandemic can have difficulties, they also create new possibilities. Enabling continuous BLS training with appropriate tools, including a

XSL•FO
RenderX

variety of didactic methods and assessment formats, can facilitate an uninterrupted process of learning for battling the fear of out-of-hospital resuscitation during the COVID-19 pandemic. However, the modifications in distant BLS learning are at an early stage, and there is a need for robust research that determines (1) their association with participant outcomes; (2) their impact on OHCA; and (3) whether such methodologically diverse learning is cost-effective. Addressing these issues will provide further insight into the role and effectiveness of new technologies and their potential impact on acquiring and sustaining BLS competencies.

Possible Implications for Practice

First, during the pandemic, the OHCA and BLS curricula require more care for nurturing and supporting competencies in the area of public health. Second, an integrated web-based program requires the combination of modern technology and formative assessments that are dedicated to developing critical thinking and decision-making skills that encourage people to take action in OHCA situations. Third, appropriate modern resources are an integral part of creating modern curricula for BLS that encourage people to take action in OHCA situations.

Limitations

One of the limitations of our research may be that a lot of time is required to complete all of the formative activities. An increase in the amount of time devoted to a given training course puts an additional burden on course participants. However, well-thought-out activities that mirror real-life situations should encourage participants to spend more time in tackling such activities.

Abstract

Background: As a type of donation-based crowdfunding, medical crowdfunding has gradually become an important way for patients who have difficulty paying medical bills to seek help from the public. However, many people still have limited confidence in donating money to medical crowdfunding projects.

Objective: Given that the features of a medical crowdfunding website may be important to gain users' trust, this study draws upon two-factor and trust theories to explore how different design features of medical crowdfunding websites affect potential donors' cognition-based trust and affect-based trust, and how these types of trust affect the intention to donate.

Methods: A 2 (informativeness: high vs low) × 2 (visual cues: cool color vs warm color) × 2 (social cues: with vs without) between-subject laboratory experiment was performed to validate our research model. A total of 320 undergraduate students recruited from a university in China participated in the controlled laboratory experiment.

Results: Cognition-based trust (β=.528, P<.001) and affect-based trust (β=.344, P<.001) exerted significant effects on the intention to donate of potential donors of medical crowdfunding. Informativeness as a hygiene factor positively influenced potential donors' cognition-based trust ($F_{1,311}$=49.764, P<.001) and affect-based trust ($F_{1,311}$=16.093, P<.001), whereas social cues as a motivating factor significantly influenced potential donors' cognition-based trust ($F_{1,311}$=38.160, P<.001) and affect-based trust ($F_{1,311}$=23.265, P<.001). However, the color of the webpages affected the two dimensions of trust differently. Specifically, medical crowdfunding webpages with warm colors were more likely to induce affect-based trust than those with cool colors ($F_{1,311}$=17.120, P<.001), whereas no significant difference was found between the effects of cool and warm colors on cognition-based trust ($F_{1,311}$=1.707, P=.19).

Conclusions: This study deepens our understanding of the relationships among the design features of medical crowdfunding websites, trust, and intention to donate, and provides guidelines for managers of medical crowdfunding platforms to enhance potential donors' trust-building by improving the website design features.

Introduction

Background

Medical expenses are forcing a staggering number of people into poverty worldwide [1]. According to data from the US Census Bureau, 11.2 million Americans are living below the poverty line because of health care costs [2]. Although public health insurance provides coverage for almost all of China's 1.4 billion people, many patients and their families still have difficulty paying medical bills that outpace government insurance provision [3]. Some of them have had to take out loans to pay for their medical expenses, adding to their financial woes and imposing a growing burden of consumer debt on China [4]. As a result, medical crowdfunding, a convenient and effective way to raise funds to alleviate the burden of medical expenses, has skyrocketed in the last few years [5]. For example, GoFundMe, a world-leading crowdfunding platform, reports that more than one-third of the fundraising campaigns it hosts are for health care expenses and that these campaigns raise more than US $650 million annually [6].

In the context of charitable giving, the information asymmetry that exists between charitable project promoters and potential donors is a barrier to successfully soliciting individual donations. Potential donors are often deprived of complete (and updated) information about how their donations will be used [7]. They need charitable project promoters to disclose information about their past performance and governance, as well as information about beneficiaries [8]. To adequately address the information asymmetry problem, and thus increase donations, promoters need to share customized information with targeted donors through appropriate information channels. Medical crowdfunding platforms help patients to make personalized charitable appeals, and to show their illnesses and financial difficulties on their own webpages, which can partially reduce the level of information asymmetry between the crowdfunders and the donors. As such, medical crowdfunding is becoming increasingly popular as it harnesses the power of the crowd to raise funds and reduce the risk of "medical bankruptcy" [5].

Despite the popularity of medical crowdfunding, the failure rate of crowdfunded projects is reported to be high. Many promising projects have failed to meet their fundraising goals for different reasons. The lack of experience in the use of information technology (eg, computers and the internet), insufficient health care literacy, and poor writing skills can all contribute to the failure of a medical crowdfunding project [9]. Fraudulent campaigns, loss of privacy, and small personal social networks may be additional barriers to receive donations from others [9,10]. Hence, many studies have focused on identifying the factors that influence the success of charitable crowdfunding, such as donors' intrinsic and extrinsic motivation [11,12], project content [13], project goal [14], fundraisers' characteristics [13-15], and social influence [16].

Recently, several studies have recognized trust as a critical determinant of funding intention in different crowdfunding contexts [17-20]. In the context of medical crowdfunding, many people have limited confidence in contributing to crowdfunding projects because they are afraid of fraud or do not know whose needs are more urgent. These trust issues result in many medical crowdfunding projects being not fully funded. Therefore, focusing on how to increase people's trust in medical crowdfunding platforms and projects is important. Medical crowdfunding is similar to crowdfunding based on rewards or equity; however, it also has unique characteristics. Medical crowdfunding can essentially be considered as an act of philanthropy, and its success requires not only rationally convincing potential donors but also emotionally motivating them. However, the existing literature on other types of crowdfunding have primarily focused on the effect of a single rational dimension of trust, cognition-based trust [20,21], while largely neglecting the effect of the emotional dimension of trust, affect-based trust. Previous research has noted that emotional appeals are strongly associated with prosocial behavior [22]. Therefore, the first aim of this study was to investigate the role of affect-based trust in a medical crowdfunding context and to examine how such trust affects the intention to donate simultaneously with cognition-based trust.

Despite the increasing number of studies on the relationship between trust and crowdfunding investments, less attention has been paid to the factors that build trust in the context of medical crowdfunding. Therefore, the second focus of this study was on the antecedents of cognition-based and affect-based trust in medical crowdfunding, which can help us to better understand the development of trust. Among the limited research on the antecedents of trust in the field of crowdfunding and charitable giving, most studies have focused on the project type, project content, and fundraisers' expertise and reputation [18-20], whereas few studies have considered how website design features affect potential donors' trust in crowdfunding platforms and projects. Medical crowdfunding websites play an especially important role in publicizing projects and persuading people to donate. On medical crowdfunding websites, fundraisers can write their own charitable appeals to describe their personal experiences of illness and financial difficulties to attract potential donors. As such, medical crowdfunding platforms need to devote considerable efforts to their website design to increase trust and facilitate online donations. Thus, research on design features of medical crowdfunding websites is needed to understand the role of the medical crowdfunding website in influencing people's trust and intention to donate.

To bridge the aforementioned research gaps, in this study, we adopted two-factor and trust theories to identify hygiene and motivation factors in the website design of a medical crowdfunding website, and examined how they affect people's cognition-based trust and affect-based trust, and their ultimate intention to donate.

Trust

Trust in Medical Crowdfunding

The rapid growth of crowdfunding platforms has attracted the attention of scholars, and numerous studies have been performed on the factors that influence crowdfunding success. In these studies, trust has emerged as a key determinant of funding intention in different crowdfunding contexts [17-20]. Trust can be defined as a willingness to accept vulnerability based on beliefs about the trustee's ability and character, and the

XSL•FO
RenderX

emotional bond between the trustor and the trustee [23]. This definition indicates that trust includes not only the intellectual/cognitive dimension (ie, cognition-based trust) but also the emotional/affective dimension (ie, affect-based trust [24]). Table 1 presents a sampling of quantitative research on the role of trust in crowdfunding, revealing the relatively minimal research that has focused on the context of donation-based crowdfunding. Moreover, these studies have provided only partial insight into the two dimensions of trust in crowdfunding. Most of them have conceptualized trust as a one-dimensional construct and revealed that trust in the crowdfunding platform or project creators has a positive effect on individuals' investment decisions [25]. Some other scholars have primarily addressed donors' cognition-based trust, arguing that the credibility and the trustworthiness of the fundraiser and platform are vital factors that influence investors to fund the project [26]. However, little attention has been devoted to the cognitive and affective dimensions of trust simultaneously in the context of crowdfunding.

Similar to other types of crowdfunding, potential donors of medical crowdfunding need to scrutinize the quality of the projects and judge their credibility before deciding to donate. In addition, medical crowdfunding can be regarded as an act of philanthropy where potential donors are incentivized to donate out of sympathy for specific patients seeking help. Therefore, the emotional dimension of trust is also noteworthy because it can evoke an emotional response and inspire people to donate. Hence, this study attempts to contribute to trust theory and the crowdfunding literature by examining whether cognition-based trust and affect-based trust exert positive effects on intention to donate in the context of medical crowdfunding.

Cognition-Based Trust, Affect-Based Trust, and Intention to Donate

Generally, cognition-based trust is grounded in careful and rational reasoning [36]; it focuses on the "good reasons" why individuals are trustworthy and calls for rational choices based on credible information about the intentions or capabilities of others [37]. Previous research has found that potential sponsors often depend on their evaluation of a crowdfunding project's credibility when they decide whether or not to donate their money to the cause [15,38]. In the field of medical crowdfunding, if potential donors believe that the crowdfunding platform is reliable and the charitable appeal of the fundraiser is logical and reasonable, then their cognition-based trust will be promoted, thereby increasing their intention to donate. Thus, we propose the following hypothesis:

> *H1: Potential donors' cognition-based trust is positively correlated with intention to donate.*

By contrast, affect-based trust focuses on the "emotional bond" between parties. This type of trust is derived not from one's understanding and reasoning but rather from their instincts and feelings [23,37]. Kang et al [18] provided evidence that investors' trust related to emotions has a positive effect on their willingness to invest in crowdfunding platforms. Liu et al [15] also revealed that individuals will increase their willingness to donate because of their affective state derived from the concerns of the charitable crowdfunding fundraiser's situation. Patients

XSL•FO
RenderX

can use crowdfunding platforms to connect emotionally with potential donors to raise funds for health care [39]. Thus, we propose the following hypothesis:

> *H2: Potential donors' affect-based trust is positively correlated with intention to donate.*

Previous studies have argued that individuals will invest further in a relationship only when their basic expectations about the reliability of the relationship are met [24]. Cognition-based trust influences affect-based trust, particularly in the beginning of relationship formation [23]. In many online contexts, cognition-based trust has been empirically demonstrated to be an antecedent of affect-based trust [23,40]. Kang et al [18] investigated the crowdfunding field and found that a rational assessment of the crowdfunding project allows the investor to decide whether to trust the fundraiser, which can enhance their communication and help establish a strong emotional connection. Xu and Wang [41] also argued that logically coherent and complete stories are a prerequisite for eliciting potential donors' empathy and to inspire their charitable behavior. In the context of medical crowdfunding, the cognition-based trust that potential donors develop from carefully reviewing the information provided by the patients can reduce their feelings of insecurity, which in turn arouse emotional responses and facilitate a higher level of affect-based trust. Hence, we propose the following hypothesis:

> *H3: Potential donors' cognition-based trust is positively correlated with their affect-based trust.*

Website Design Features and Trust

Antecedents of Trust in Crowdfunding

Considering that trust can be easily broken in virtual environments, some studies have been performed on how to establish and maintain trust in various contexts [42]. The building of trust in online communities has been wildly studied. For example, Mpinganjira [43] revealed that information usefulness, community responsiveness, and shared vision have a significant influence on consumers' overall trust in health-related virtual communities. Nadeem et al [44] found that social presence of online brand communities, social presence of others, and social presence of interaction have positive effects on social commerce trust. Given that online communities are groups of people with common interests and shared goals, community members gradually develop trust in the community through long-term social interaction. Unlike online communities, people do not need long-term interactions to build trust in a crowdfunding context, but rather rely on a direct and rapid appraisal of the crowdfunding website and the project. Thus, understanding the antecedents of trust in the context of crowdfunding is critical in improving the success rate of crowdfunding projects [45].

Existing research in the field of crowdfunding has mainly examined three categories of antecedent variables of trust: project-, fundraiser-, and platform-related characteristics [15,18,20]. Table 2 provides examples of representative studies focusing on the antecedents of trust. Only a few studies investigated the platform-related characteristics that affect trust. Among these limited investigations, attention was mainly focused on the overall quality or functional features of the platform. For example, Liu et al [15] revealed that website quality and transaction convenience have positive effects on the perceived credibility of a charitable crowdfunding project. Kang et al [18] found that perceived accreditation, structural assurance, and a third-party seal of a crowdfunding platform exert different effects on investors' trust beliefs. However, little attention has been paid to the question of how website design features affect individuals' trust and intention to donate. Website design factors have been demonstrated to be critical in affecting user response and experience [46]. As people learn the details of funding projects by viewing medical crowdfunding websites, exploring the design features of medical crowdfunding websites may contribute to an improved appreciation of trust and intention to donate.

[a]N/A: not applicable.

Website Design Features and Two-Factor Theory

A substantial body of literature in the field of information systems has investigated the relationship between website design features and trust. Several website design features have been identified as antecedent variables of trust in various contexts such as navigation design [47,48], privacy and security [47,49], website quality [50], and ease of use [46,48]. However, these antecedents have been examined in a disjointed manner and lack a holistic view of how website design features influence trust. Moreover, existing research has mainly identified the usability and functional features of websites from a cognitive perspective, with less consideration given to the emotional aspects of website design features [46]. Some researchers have demonstrated that a website that meets most usability guidelines does not necessarily lead to higher user favorability [51]. Other scholars have also argued that users' evaluations of a website are often determined by their overall impression of the website, thereby requiring an examination of the holistic aspects of website design features [46,52]. Medical crowdfunding platforms not only need to cognitively enhance the design of their websites to persuade potential donors but should also harness the affective features of their website to evoke potential donors' emotional response and facilitate their willingness to donate. Therefore, in this study, we adopted the Herzberg two-factor theory as a theoretical framework for integrating the cognitive and affective aspects of website design features that influence users' trust in the context of medical crowdfunding.

The two-factor theory was proposed by Herzberg in 1959 [53], which is also known as the hygiene motivation theory. This theory was initially used to explain factors that lead to satisfaction or dissatisfaction in employees' work environment and has gradually been used in a wide range of different domains [54]. Recently, an increasing number of studies have been performed using two-factor theory to examine website design features, and their effects on user attitudes and behaviors in different types of websites [55-57]. In these studies, website design features are systematically distinguished into two categories: hygiene and motivation factors.

Informativeness

Hygiene factors are a collection of attributes closely related to the basic functionality of a website [58]. As the primary purpose of a medical crowdfunding website is to provide the visitors with information about the crowdfunding project, informativeness was selected as the hygiene factor of a medical crowdfunding website in this study. Informativeness can be defined as the extent to which a website offers rich and useful information to users [59,60]; thus, it reflects a website's ability to provide information to its visitors [61]. Previous research has demonstrated that website informativeness is an important prerequisite for users' attitudes toward the website [62], and that it also plays a crucial role in reducing risk and building trust [63]. In the field of crowdfunding, few studies have explored the relationship between informativeness and trust. For example, Kang et al [18] found that funders' cognition-based trust in crowdfunding projects is enhanced if the crowdfunding website provides funders with complete and timely information about the project through a bulletin board. In medical crowdfunding websites, greater informativeness (eg, charitable appeals with several texts and images) helps donors make rational judgments, which in turn makes it easier for them to develop cognition-based trust in the project and the platform. Therefore, we propose the following hypothesis:

XSL•FO
RenderX

H4a: Informativeness is positively correlated with potential donors' cognition-based trust.

Previous research on shopping websites has revealed that the informativeness of a website positively influences consumers' emotional responses [64]. Majumdar and Bose [13] also demonstrated that charitable crowdfunding fundraisers use detailed information to emphasize their needs and suffering to attract others' attention. On the basis of emotional contagion theory, fundraisers' suffering and sadness presented in their stories may increase potential donors' affective reactions. Similarly, detailed information about a medical crowdfunding project not only gives the potential donor insight into the fundraiser's situation but also serves as a means for the fundraiser to get others to listen and alleviate their own suffering. Adding words and images that describe the patient's suffering can result in easily evoking potential donors' affect response and enhancing their emotional bonding with the fundraiser. At the same time, rich project information allows potential donors to know more about the fundraiser and shorten the perceived psychological distance between them, thereby inspiring a higher level of affect-based trust. Hence, we propose the following hypothesis:

H4b: Informativeness is positively correlated with potential donors' affect-based trust.

Visual Cues

Motivation factors are a collection of attributes that are closely related to the additional value-added services offered by a website [58]. Previous studies have found that in contrast to hygiene factors, motivation factors are crucial for website users' satisfaction [55,57]. In the medical crowdfunding context, motivation factors are the website design features of a medical crowdfunding website that stimulate potential donors to make donation decisions beyond meeting their basic information needs. In this study, the website's visual cues (ie, warm or cool colors) and social cues were selected as motivation factors.

The visual design of a website has proven to be an impactful determinant of trust [48]. Among the many visual design elements, color serves as a specific visual stimulus that shapes a visitor's perception of the ambient temperature [65]. Such perceived cool or warmth on temperature elicits varying degrees of social proximity, language concreteness, and relational focus, and exerts an effect on individual behavior through the mechanism of insula [66]. Williams and Bargh [67] showed that the warmth sensed by the body can influence interpersonal judgments and prosocial behavior. Literature from several fields has noted that red and orange tend to evoke warmth, whereas blue and green are reminiscent of cold [68]; this comparison seems to convey a more positive role of warm colors. However, an ever-increasing number of studies in recent years have challenged this view by emphasizing the effects of cool colors. Rizomyliotis et al [69] found that cool backgrounds are more likely to inspire stronger positive attitudes and behavioral intentions than warm colors, and cool colors usually create a sense of relaxation and calm [70]. On the one hand, cool colors are often linked to competence, trust, safety, and sincerity, such that many companies incorporate blue into their brand logos to create a professional and trustworthy image, and consumers regard blue logos to be more reliable than other colors [71]. On the other hand, in terms of the information processing of individuals, Ettis [72] suggested that cool colors (eg, blue) facilitate individuals' information seeking, processing, and consideration. Therefore, medical crowdfunding sites with more cool-colored elements may be more conducive to donor attention, and could promote rational and logical reasoning about the help-seeking information on the platform, which in turn will enhance the donors' cognition-based trust in the platform and the project. Thus, we propose the following hypothesis:

H5a: Potential donors' cognition-based trust in a medical crowdfunding website with a cool-toned (blue) interface is higher than that in a warm-toned (orange) interface.

Previous studies have documented that perceived warmth is associated with interpersonal intimacy; that is, perceived warmth creates feelings of interpersonal closeness [73], and promotes interpersonal trust, cooperation, and friendship [74]. Specifically, warm colors are more evocative of warmth than cool colors [66] and provide consumers with a sense that their surroundings are more socially dense [75]. In this manner, a warm-toned interface of a medical crowdfunding website will bring warm psychological perceptions and positive attitudes to donors, making them feel less distant from the medical crowdfunding platform and other help-seekers, and thus more likely to evoke their emotional trust toward the platform and project. Hence, we posit the following hypothesis:

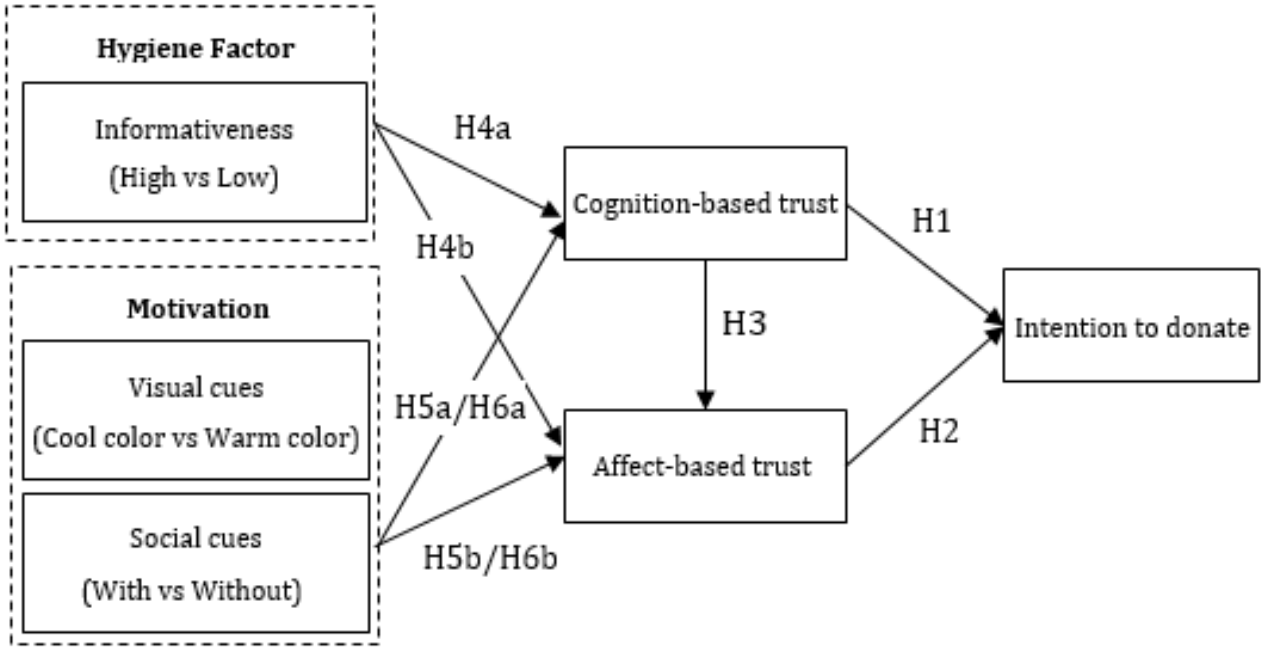
H5b: Potential donors' affect-based trust in a medical crowdfunding website with a warm-toned (orange) interface is higher than that in a cool-toned (blue) interface.

Social Cues

Social cues in web design refer to social presence and social interaction embedded in the web interface through various communication tools [76]. These cues have been shown to have important influences on individuals' cognition-based trust in various contexts such as online shopping and e-commerce. For example, early consumer endorsement in the form of online reviews in e-commerce can help other consumers determine the usefulness of a product, build cognition-based trust, and thus facilitate rational shopping decisions [77]. Social cues can serve as a collective endorsement, allowing the crowdfunding fundraisers to signal credibility [78]. In medical crowdfunding, fundraisers need to reach out to others through social networks to attract more donations. Therefore, the presence of social cues (eg, proofs and reviews from other donors) helps to exhibit the authenticity and credibility of a project, thereby inspiring a higher level of cognition-based trust from potential donors. On this basis, we posit the following hypothesis:

H6a: Potential donors' cognition-based trust in a medical crowdfunding website with social cues is higher than that without social cues.

The presentation of social cues on a website leads to a perception of warmth and friendliness, which triggers a sense of social presence [79]. Given that social presence is strongly associated



XSL•FO
RenderX

with emotional responses and interpersonal warmth [80,81], the use of social cues will help users build affect-based trust [79]. Furthermore, affect-based trust also indicates that the trustor builds trust in the trustee according to their benevolence and moral norms [82]. In medical crowdfunding websites, social cues such as other donors' feedback and the fundraiser's replies can be used as third-party opinions to evaluate the fundraiser's benevolence and moral norms, which enhance affect-based trust-building. Thus, we posit the following hypothesis:

> *H6b: Potential donors' affect-based trust in a medical crowdfunding website with social cues is higher than that without social cues.*

On the basis of these hypotheses, we propose the research model shown in Figure 1.

Figure 1. Research model.

Methods

Experimental Design

To test how the design features of medical crowdfunding websites influence potential donors' intention to donate, we performed a laboratory experiment with a 2 (informativeness: high vs low) × 2 (visual cues: cool color vs warm color) × 2 (social cues: with vs without) between-subject factorial design to test the hypotheses. We designed eight medical crowdfunding webpages for the experiment.

The webpages were developed to mimic the layout of the mobile versions of Qingsongchou, a major medical crowdfunding platform in China, to enhance the external validity. A fictional medical crowdfunding project was shown in these webpages. The project began with a charity appeal about a patient with cancer who cannot pay his medical bills. We chose cancer for two reasons. First, cancer is one of the most common disease types with a high mortality rate. Second, we crawled the information of medical crowdfunding projects on the Qingsongchou website, and found that cancer is the most common cause in medical crowdfunding projects. To protect patient privacy, we made changes to basic patient information (eg, profile picture, nickname, name, and home address). Eight screenshots of the experimental webpages are presented in Multimedia Appendix 1.

Variable Manipulations

Approach

We used a laboratory experimental approach because it allowed us to examine the effects of website design features on users' intention to donate. Three website design features needed to be manipulated in our study: informativeness, visual cues, and social cues.

Manipulations of Informativeness

This study manipulated the informativeness of the medical crowdfunding webpages into two groups: high informativeness and low informativeness. The high informativeness group presented more categories of information (ie, patient's charity appeal, goals and progress of crowdfunding, medical certificate, proof of the patient's financial hardship, and information about the disease) in the webpage, along with more pictures and longer text. The low informativeness group contained fewer categories of information (ie, only the patient's charity appeal, goals and progress of crowdfunding, and medical certificate), along with fewer pictures and shorter text.

Manipulations of Visual Cues

The visual cues in this study focused on the overall color of the webpages, including the background color of the pages and the font colors. The main color of the pages in the cool color groups was blue (hue: 170, saturation: 239, luminance: 128, transparency: 90%), whereas the main color of the warm color

XSL•FO
RenderX

groups was orange (hue: 15, saturation: 239, luminance: 128, transparency: 90%) [83].

Manipulations of Social Cues

Webpages in the "with social cues" group showed the buttons for retweeting the project to social media, social endorsement from others, and information about other people's donations. Those in the "without social cues" groups did not contain such information.

Measurement

This research model includes three latent constructs: cognition-based trust, affect-based trust, and intention to donate. We selected the scales of these constructs from previous research with adaptive modifications to fit the context of medical crowdfunding. All of the measurements were scored on a 7-point scale (1: absolutely disagree, 7: absolutely agree). To eliminate the influence of the participants' mood on the results of the experiment, we introduced participants' mood as a covariate in the research model. Mood was measured by the item "How would you rate your current emotional state?", which was scored from 1 (negative) to 7 (positive). The scale showed good reliability and validity.

We used the backtranslation method to translate the original English scale into the Chinese version and compared the two versions of the scales to check for translation accuracy. Four experts in the field of information systems were invited to evaluate the content validity of the scales. Following the opinions of the survey experts, we made some revisions to the items, such as revising the wording to improve clarity and accuracy, shortening the length of items to reduce survey fatigue, modifying ambiguous items, and revising items to make them more tailored to the medical crowdfunding context. Table 3 shows the three latent constructs and their measurement items.

Table 3. Research constructs and measurements.

Construct	Measurement items	References
Cognition-based trust	(1) I can rely on this medical crowdfunding platform and project; (2) the medical crowdfunding platform and project have my confidence; (3) the medical crowdfunding platform and project have high integrity	Kang et al [18], Ranganathan et al [84]
Affect-based trust	(1) If I share my problems with this medical crowdfunding platform, it would respond caringly; (2) the medical crowdfunding platform displays a warm and caring attitude toward me; (3) I can talk freely with the medical crowdfunding platform about my problems	Ranganathan et al [84], Johnson and Grayson [85]
Intention to donate	(1) The probability that I would donate money to the medical crowdfunding project is high; (2) my donation intention to the medical crowdfunding project is high; (3) the likelihood of my donating money to the medical crowdfunding project is high	Liu et al [15]

Data Collection

A total of 320 undergraduate students recruited from a university in China participated in the controlled laboratory experiment. Each participant was assigned to one of eight webpages varying in informativeness, color, and social cues. The participants were then asked to complete the questionnaire after viewing the webpage. The age of the participants ranged from 18 to 26 years (mean 21.719 years). Analysis of variance showed no significant differences in gender ($F_{7,312}$=1.097, P=.37) or age ($F_{7,312}$=1.690, P=.11) across the eight experimental conditions. All subjects were randomly assigned to one of these eight treatment groups and completed the questionnaire after viewing their assigned webpages.

Results

Manipulation Checks

We performed manipulation checks using the measurement items adapted from previous studies. The item "The medical crowdfunding platform offers relevant, timely, and accurate information about the project" was adopted from the works of Kang et al [18] and Kim et al [86] to measure informativeness. This item was scored on a 7-point Likert scale (1: absolutely disagree, 7: absolutely agree). The item "To what extent do you feel warm when you see the colors of the website's interface?" was adopted from the work of Motoki et al [87] to measure the warmth of the webpage's color, which was also rated on a 7-point Likert scale (1: not warm at all to 7: very warm). We also checked the presence of social cues by adapting the scale of Friedrich et al [88], "Have you noticed the social cues on the medical crowdfunding site?", with the item rated on a 3-point scale (1=no, 2=not sure, 3=yes).

The results from a t test revealed that subjects assigned to the high informativeness conditions agreed more that the webpage has richer information than those in low informativeness conditions (mean 4.925 vs 3.031, t_{318}=17.618; P<.001). Similarly, the t test results showed that the participants who viewed webpages with orange color felt warmer than those who viewed pages with blue as the dominant color (mean 4.875 vs 2.663, t_{318}=18.829; P<.001). The t test results also suggested that the score for the webpages with social cues was higher than that of pages without social cues (mean 2.838 vs 1.250, t_{318}=29.088; P<.001). All of the results of the manipulation check were significant.

Measurement Validation

Cronbach α for checking the internal consistency was initially computed using SPSS 24.0. Table 4 shows that the Cronbach α of each construct exceeded .90, which is higher than the recommended value of .70. A confirmatory factor analysis was then performed using AMOS 22.0 to examine the convergent validity of the constructs. Table 4 shows that the values of factor loadings and composite reliability of all constructs were greater than 0.70, and the average variance extracted (AVE) exceeded 0.5. These results showed good convergent validity [89].

XSL•FO
RenderX

Table 4. Convergent validity and internal reliability.

Construct	Factor loading	Cronbach α	AVE[a]	CR[b]
Cognition-based trust (CT)		.909	0.773	0.911
CT1	0.814			
CT2	0.907			
CT3	0.913			
Affect-based trust (AT)		.865	0.686	0.867
AT1	0.780			
AT2	0.848			
AT3	0.854			
Intention to donate (ID)		.915	0.784	0.916
ID1	0.881			
ID2	0.903			
ID3	0.872			

[a]AVE: average variance extracted.

[b]CR: construct reliability.

Finally, we computed the square root of the AVE values of all constructs and the correlation coefficients between these constructs to test the discriminant validity. The square roots of the AVE values were greater than other correlation coefficients, which indicated adequate discriminant validity [90].

Hypothesis Testing

We utilized AMOS22.0 to test the hypotheses regarding the effects of cognition-based trust and affect-based trust on intention to donate. As predicted, cognition-based trust had a significant and positive influence on intention to donate (β=.528, *P*<.001), supporting H1. The effect of affect-based trust on intention to donate was significant and positive (β=.344, *P*<.001), supporting H2. In addition, cognition-based trust significantly influenced affect-based trust (β=.641, *P*<.001), supporting H3. Thus, H1-H3 were supported.

Given that we have two dependent variables (ie, cognition-based trust and affect-based trust), we performed multivariate analysis of variance to check whether the experimental treatments had a general effect on both variables. Three website design features (ie, informativeness, visual cues, and social cues) were modeled as the fixed factors, and participants' mood was included as a covariate. The main effects of informativeness (Wilks λ=0.862, F_{310}=24.870; *P*<.001), visual cues (Wilks λ=0.902, F_{310}=16.846; *P*<.001), and social cues (Wilks λ=0.882, F_{310}=20.741; *P*<.001) were significant. We then performed two analyses of covariance (ANCOVAs) on cognition-based trust and affect-based trust separately.

A three-way ANCOVA was initially performed on cognition-based trust. The main effect of informativeness on cognition-based trust was significant ($F_{1,311}$=49.764, *P*<.001), indicating that higher informativeness is associated with higher donor cognition-based trust in the platform and the project. Thus, H4a was supported. Similarly, social cues had a significant effect on cognition-based trust ($F_{1,311}$=38.160, *P*<.001). In other words, donors' cognition-based trust is higher when social cues are present in medical crowdfunding webpages. Thus, H6a was supported. However, visual cues had no significant effect on cognition-based trust ($F_{1,311}$=1.707, *P*=.19). Thus, H5a was not supported. Moreover, no significant interaction effect was observed among informativeness, visual cues, and social cues.

A three-way ANCOVA was then performed on affect-based trust. The results indicated a significant main effect of informativeness ($F_{1,311}$=16.093, *P*<.001), visual cues ($F_{1,311}$=17.120, *P*<.001), and social cues ($F_{1,311}$=23.265, *P*<.001). Thus, H4b, H5b, and H6b were supported. Moreover, no interaction effect was found.

Mediation Analysis

To further verify whether the two different types of trust mediate the effects of website design features on intention to donate, we performed a mediation analysis in SPSS 24.0 with the PROCESS plugin developed by Hayes [91]. First, we used cognition-based trust as the independent variable, affect-based trust as the mediator, and intention to donate as the dependent variable. A mediation bootstrapping analysis with 5000 bootstrap samples revealed that the bootstrap 95% CI did not include 0 (β=.185, 95% CI 0.120-0.261), showing that affect-based trust mediates the effect of cognition-based trust on intention to donate.

Next, we used intention to donate as the dependent variable, three website design features (ie, informativeness, social cues, and visual cues) as independent variables, and cognition-based trust as the mediator to test the mediating mechanisms involved. The effects of informativeness (β=.545, 95% CI 0.380-0.721) and social cues (β=.454, 95% CI 0.297-0.629) on intention to donate were mediated by cognition-based trust. However, cognition-based trust did not mediate the relationship between visual cues and intention to donate (β=−.102, 95% CI –0.271 to 0.692).

XSL•FO
RenderX

Finally, we examined the mediation role of affect-based trust. Affect-based trust mediated the relationship between informativeness (β=.159, 95% CI 0.105-0.214), visual cues (β=.325, 95% CI 0.178-0.482), social cues (β=.299, 95% CI 0.141-0.464), and intention to donate.

Discussion

Principal Findings

This study reveals that cognition- and affect-based trust significantly influence medical crowdfunding users' intention to donate. This finding is in line with previous studies that demonstrate the salient impact relationship between trust and intention to donate [17,19]. However, the difference is that this study did not distinguish among the different dimensions of trust [19,20,92] and instead only examined cognition-based trust [17]. This study validates the effects of different dimensions of trust on intention to donate in the context of medical crowdfunding. The results show that not only does cognition-based trust have a significant effect on intention to donate for medical crowdfunding projects but so does affect-based trust. We further found that affect-based trust plays a mediating role in the relationship between cognition-based trust and intention to donate.

Furthermore, this study introduced Hertzberg two-factor theory into the research model and identified two types of medical crowdfunding website design features (ie, hygiene and motivator factors). The results indicate that informativeness as a hygiene factor positively influences potential donors' cognition-based trust and affect-based trust. Among the motivation factors, social cues significantly influence potential donors' cognition-based trust and affect-based trust. However, webpage color as a visual cue affects the two dimensions of trust differently. Specifically, medical crowdfunding webpages with a warm color were more likely to induce affect-based trust than those with a cool color, whereas no significant difference was found between the effects of cool and warm colors on cognition-based trust. One possible explanation for this finding is that cognitive processes are not instantaneous, and cognition-based trust is formed only after individuals can cognitively process and evaluate available evidence [93,94]. The evidence presented on medical crowdfunding websites has a bearing on whether a patient can be cured of a serious illness and escape bankruptcy due to the illness, which requires the potential donors to devote energy to evaluate and extrapolate. Although different hues of color can cause potential donors to perceive temperature and interpersonal warmth differently, these perceptions are not directly responsible for the differences in their cognition-based trust.

Our results also indicate that cognition- and affect-based trust have mediating effects on the relationship between website design features and intention to donate. Different website design features have different influences on cognition- and affect-based trust, which in turn exert different effects on intention to donate. Particularly, informativeness and social cues indirectly affect intention to donate through cognition- and affect-based trust. Webpage colors significantly affected intention to donate through affect-based trust, whereas cognition-based trust had no mediating effect on the relationship between webpage colors and intention to donate.

Implications

Theoretical Implications

The theoretical contributions of this study are as follows. First, this study contributes to the theory of trust and enriches the literature on crowdfunding. Despite the existence of impressive studies that have examined trust and willingness to fund in different crowdfunding contexts, few of them have discussed trust issues in the context of medical crowdfunding. This study identifies the importance of affect-based trust in medical crowdfunding, which is often ignored in other crowdfunding contexts. Specifically, affect-based trust not only influences intention to donate for medical crowdfunding projects simultaneously with cognition-based trust but it also mediates the influence of cognition-based trust on intention to donate.

Second, identifying the antecedents that influence cognition- and affect-based trust is important for trust development. This study explored the holistic aspects of the design features of medical crowdfunding websites to understand how users develop trust to medical crowdfunding platforms and projects. We applied Hertzberg two-factor theory to identify hygiene and motivation factors in website design features as antecedent variables that influence the two types of trust. We validated the positive influence of informativeness as a hygiene factor of website design on cognition- and affect-based trust, and demonstrated the motivating effects of visual and social cues on trust. These findings enrich the literature on website design by broadening the application of two-factor theory to the design of medical crowdfunding websites.

Third, previous studies have briefly introduced the relationships between website design features and users' behavioral intention; however, few studies have attempted to reveal the mechanisms underlying the effects of website design features on the intention to donate in medical crowdfunding. By integrating the design features of medical crowdfunding websites, trust, and intention to donate, we contribute to filling this gap, while demonstrating the mediating role of cognition-based trust and affect-based trust on such impacts.

Practical Implications

This study has important implications for medical crowdfunding platform operators and users. First, our empirical results reveal the significant effects of cognition- and affect-based trust on intention to donate. Therefore, platform operators and project initiators of medical crowdfunding should not only enhance the authenticity and credibility of their platforms and projects but also emphasize their affective elements.

Second, the informativeness of the projects presented on medical crowdfunding platforms is a hygiene factor that can elicit users' trust. Medical crowdfunding platform operators should develop more functions that contribute to the information richness of the website, such as providing a wider range of information categories and the functions of uploading pictures and videos. Moreover, project initiators need to elaborate more on their

XSL•FO
RenderX

situations and charitable appeals to inspire potential donors logically and emotionally.

Third, visual and social cues on medical crowdfunding platforms also have significant effects on potential donors' trust. This finding provides medical crowdfunding website designers with some guidelines. They can enhance the usage of warm colors to create a warm and caring atmosphere to boost users' affect-based trust. They can also provide more social cues such as other peoples' comments to increase potential donors' cognition- and affect-based trust.

Limitations and Future Research Directions

Despite the contributions of this study, we have identified several limitations. First, the subjects in this experiment were undergraduate students. Our primary reason for choosing students as subjects was that students are easier to recruit than other social groups and are more obedient, which is beneficial to the success of laboratory experiments. In addition, as Chinese medical crowdfunding projects are mainly diffused through internet apps such as Weibo and WeChat, social media users have become the main source of donations. Weibo users under the age of 25 account for 57.4% of the total number of users [95]. In terms of age distribution, students are an important user group for social media and are thus the main potential donors for medical crowdfunding. However, despite the representativeness of students, they still do not accurately represent the overall population of medical crowdfunding users. Therefore, future research will need to recruit a larger population to improve the representativeness of the subjects.

Second, this study focused on three website design features based on the previous literature and the context of medical crowdfunding. However, there may be other website design features that can influence users' trust and donations. For example, we only focused on color in visual cues, whereas font styles or page layout may also affect users' trust in the platform and the project. Future research can identify more website design features of relevance.

Third, this study manipulated informativeness as a one-dimensional variable incorporating text length, number of pictures, and categories of information without considering the interactions among these features. Future research can introduce new content-related features and further explore the interactions among these factors.

Finally, individuals may perceive colors in varied and nuanced ways. In our study, we only focused on one color feature that is most likely to be noticed by the user (ie, hue) and ignored the other features of color. Future research can explore the effects of other color features (eg, saturation and luminance) on potential donors' trust.

Conclusions

The purpose of this study was to explore the role of cognition- and affect-based trust in the medical crowdfunding context and to test the effects of medical crowdfunding website design features on these two dimensions of trust. By applying trust theory and Hertzberg two-factor theory, we identified several hygiene and motivation website design factors, and confirmed their influencing mechanisms on trust in our empirical study. This study not only enriches the literature on crowdfunding but also provides implications for medical crowdfunding platform operators and users on how to promote trust.

Abstract

Background: COVID-19 has spread around the world and has increased the public's need for health information in the process. Meanwhile, in the context of lockdowns and other measures for preventing SARS-CoV-2 spread, the internet has surged as a web-based resource for health information. Under these conditions, social question-and-answer communities (SQACs) are playing an increasingly important role in improving public health literacy. There is great theoretical and practical significance in exploring the influencing factors of SQAC users' willingness to adopt health information.

Objective: The aim of this study was to establish an extended unified theory of acceptance and use of technology model that could analyze the influence factors of SQAC users' willingness to adopt health information. Particularly, we tried to test the moderating effects that different demographic characteristics had on the variables' influences.

Methods: This study was conducted by administering a web-based questionnaire survey and analyzing the responses from a final total of 598 valid questionnaires after invalid data were cleaned. By using structural equation modelling, the influencing factors of SQAC users' willingness to adopt health information were analyzed. The moderating effects of variables were verified via hierarchical regression.

Results: Performance expectation (β=.282; *P*<.001), social influence (β=.238; *P*=.02), and facilitating conditions (β=.279; *P*=.002) positively affected users' willingness to adopt health information, whereas effort expectancy (*P*=.79) and perceived risk (*P*=.41) had no significant effects. Gender had a significant moderating effect in the structural equation model (*P*<.001).

Conclusions: SQAC users' willingness to adopt health information was evidently affected by multiple factors, such as performance expectation, social influence, and facilitating conditions. The structural equation model proposed in this study has a good fitting degree and good explanatory power for users' willingness to adopt health information. Suggestions were provided for SQAC operators and health management agencies based on our research results.

Introduction

After the outbreak of COVID-19, the Chinese government implemented community isolation measures to control the spread of the epidemic, and because of these measures, the internet became the public's primary tool for searching for health information. Web-based knowledge-sharing platforms such as Zhihu (Zhihu Inc) and other social question-and-answer communities (SQACs) have been playing an increasingly important role in disseminating health information to the public. By 2019, Zhihu had more than 220 million registered users and had produced more than 28 million questions and 130 million answers. In recent months, the topic of COVID-19 has attracted more than 10,000 followers who had more than 13,000 related questions. Zhihu also has more than 20 million followers in their *Health* section and more than 750,000 health-related posts. We believe that exploring the willingness to adopt health information (WAHI) among users of SQACs could characterize community users' health information needs and behaviors. We believe that the findings of this study can promote public health literacy by improving the quality and efficiency of SQAC users' health information searches, adoption, and use.

Health information has flourished as a topic in recent information behavior literature. Many scholars have conducted in-depth research on health information resources [1-3], requesters [3-5], dissemination environments [6,7], and technology [8,9]. Specifically, after the epidemic of COVID-19 began, the research area of health information behavior attracted more attention [10-12]. Health information adoption is the final step in the health information diffusion path; it directly determines the effects of any information dissemination, and because of its significance, many researchers have investigated health information adoption among SQAC users. For instance, Diviani et al [13] found that low health literacy and related skills were negatively related to the ability to evaluate web-based health information and trust such information. Lee et al [14] investigated the level of seeking health-related information on the internet and how health literacy, access to technology, and sociodemographic characteristics impact behaviors related to seeking health-related information. Additionally, Ridout and Campbell [15] reviewed relevant research on young people's acquisition of health information from social networking sites and found that social networking site–based interventions were highly usable, engaging, and supportive for young people. More and more research findings have determined that further research on the influence factors of health information adoption intentions among SQAC users is necessary and meaningful.

SQACs are public social media platforms in which normal users both search for and share experiences and knowledge on any given topics [16]. These web-based communities have the characteristics of professionalism, interactivity, and open editing [17], and they have high potential influence on health information dissemination. Multimedia Appendix 1 shows a screenshot of the Zhihu website, and each part of the website is annotated in detail. In the existing research on SQACs, the two primary areas of focus have been platform design [18,19] and user behavior [16,17,20]. Jin et al [20] explored patient behaviors related to seeking health care information on SQACs based on dual-process theory and the knowledge adoption model, and Shi et al [21] compared the health information needs of Chinese and American patients with diabetes. The latter authors found that communities from different countries had different attributes. One commonality in extant health information adoption research is that it is grounded in the text information that already exists on social media platforms. There is far less research on SQAC users' health information behaviors based on users' own subjective self-reports.

Venkatesh et al [22] proposed the unified theory of acceptance and use of technology (UTAUT) by summarizing the advantages and disadvantages of other theoretical models in the field of technology acceptance. The core factors of the UTAUT include performance expectation (PE), effort expectancy (EE), social influence (SI), and facilitating conditions (FCs); gender, age, experience, and the voluntariness of use were used as moderators in the model. Due to the native characteristics of the UTAUT model, it has a stronger affinity and adaptability for most acceptance behavior research. Many scholars have embraced the UTAUT as a new theoretical blueprint in technology acceptance behavior research and have incorporated it into a vigorous acceptance behavior research stream. Bawack and Kamdjoug [23] conducted an empirical study on the acceptance of hospital information systems in limited-income countries based on the UTAUT. In a similar study based on the adjusted UTAUT, Nunes et al [24] found that gender, age, and other individual characteristics were moderating factors of users' willingness to adopt health applications. Abdelhamid [25] extended the UTAUT model and found that higher autonomy positively affected patients' willingness to exchange health information. Zhou et al [26] studied the mobile health (mHealth) information retrieval behavior of South African college students based on the UTAUT and found that perceived usefulness was the main influencing factor of their willingness to accept health information exchange. Liu et al [27,28] established a taxonomy of clinical decision support interventions based on the UTAUT model and tried to explore how patient care can be improved through clinical decision support. The UTAUT model has been used widely in the research area of users' acceptance behaviors. However, few scholars have used the UTAUT model to study SQAC users' WAHI. The goal of this study was to establish an effective model for analyzing SQAC users' WAHI based on the UTAUT model and to identify the influencing factors of users' WAHI.

Hypotheses and Modeling

PE Factor

PE is defined as the degree to which an individual believes that using a system will help them attain gains in job performance [22]. In the environment of SQACs, PE refers to users' perceptions of the benefits of adopting health information. Researchers measure PE with the following five structural variables: perceived usefulness, extrinsic motivation, job fit, relative advantage, and outcome expectations [29]. Based on the environment of SQACs, we proposed four additional PE items [29-31] on our questionnaire scale, as follows: (1) "the health information on Zhihu can play an important role in understanding and solving health-related problems," (2) "making

XSL•FO
RenderX

full use of the health information on Zhihu can help me better solve some problems," (3) "the health information on Zhihu has helped me or others around me improve our health," and (4) "the health information on Zhihu has a high reference value for my health decision-making." In general, researchers have shown that PE has positive effects on acceptance [32,33]. On the basis of these findings, we proposed the following research hypothesis: PE positively affects SQAC users' WAHI (H1).

EE Factor

In the UTAUT model, EE is defined as the degree of ease associated with the use of a system [22]. In this study, it refers to a user's perception of the difficulty of adopting relevant health information in SQACs and applying such information to practice. The following three constructs capture the concept of EE: the perceived ease of use, complexity, and ease of use [22]. Cimperman et al [34] and Adenuga et al [35] found that EE was a positive variable in models, and we proposed the following two scale items based on the previously mentioned studies [22,36] for our questionnaire: (1) "the health information on Zhihu is easy to understand" and (2) "the health recommendations on Zhihu are usually easier to implement." Users are more likely to adopt health information that is easy to understand and implement, and on the basis of these findings, we proposed the following hypothesis: EE positively affects SQAC users' WAHI (H2).

SI Factor

Venkatesh et al [22] defined SI as the degree to which an individual perceives that it is important for others to believe that they should use a new system, and SI can be represented by a subjective norm, social factors, and an image. The differences in health levels between other people before and after adopting health information will affect individuals' willingness to accept of health information. On the basis of previous research findings [36,37] and the three dimensions of SI measurement proposed by Venkatesh et al [22], we proposed the following three scale items: (1) "there are other people available to look up or solve health-related problems on Zhihu," (2) "other people around me have pushed health information from Zhihu to me," and (3) "Zhihu's image makes me feel that it will help me understand or solve health-related problems." On the basis of the research finding that SI has a positive effect on acceptance [38-40], we proposed the following hypothesis: SI positively affects SQAC users' WAHI (H3).

FCs Factor

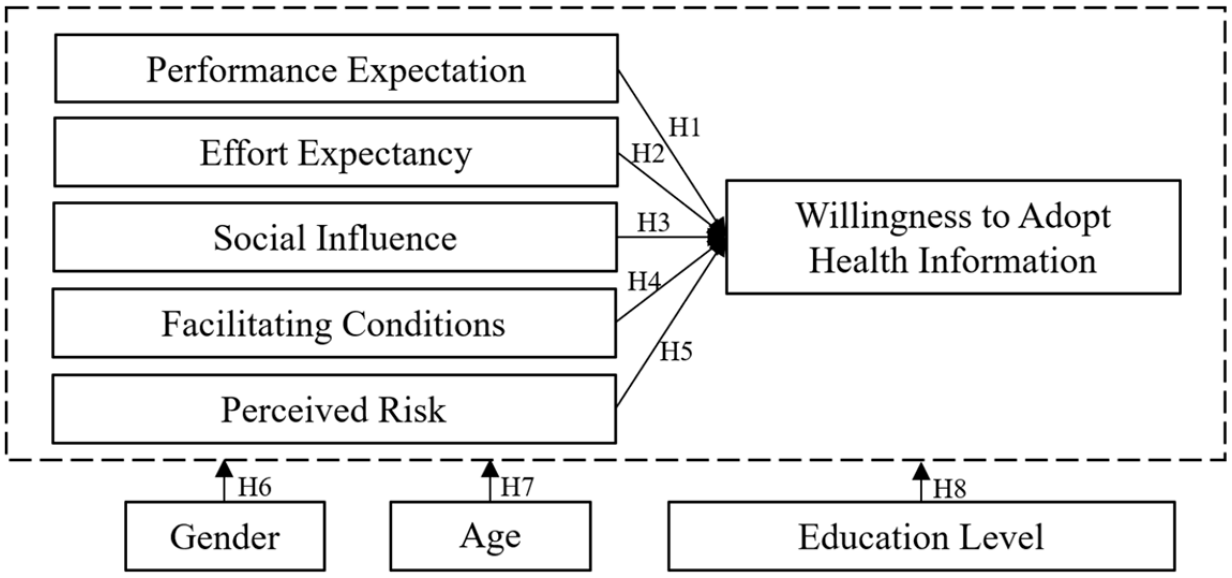
FCs refer to the perceived (organizational, societal, etc) convenience of or support for adopting something new, such as a new technology [22]. In this study, we investigated the FCs of perceived health information convenience and support among SQAC users. Health information support in an SQAC environment mainly comprises the following three aspects: (1) community users' assistance with understanding relevant health information, (2) the convenience and ease of obtaining relevant health information from users, and (3) individual users' own knowledge and experiences. On the basis of these features [36], we proposed three questionnaire items, as follows: (1) "I have the resources, hardware and knowledge reserve to effectively use the health information on Zhihu," (2) "I can get help from others when I encounter problems while browsing and consulting health information on Zhihu," and (3) "seeking health information on Zhihu is one of the common ways for me to understand and solve health-related problems." Garavand et al [41] found that FCs had a positive effect on major students' adoption of mHealth apps. On the basis of these research findings, we proposed the following hypothesis: FCs positively affect SQAC users' WAHI (H4).

Perceived Risk

Perceived risk (PR) is one of the most important and widely used concepts in psychology, economics, and other fields. At present, the widely used measurement dimensions of PR include economic risk, time risk, information security risk, and health risk. PR is also one of the important determinants of health information adoption; the higher the perceived risk, the lower the willingness to adopt such information. A study [42] of Chinese patients' intention to adopt mHealth services showed that PR negatively affects respondents' trust and willingness to accept mHealth services. Although the UTAUT model integrates many variables from different classical models, it does not include the impact of PR on users' willingness to accept technology. Therefore, we decided to extend the PR variable in the model. Physiological risk, psychological risk, and time risk are the main risks for SQAC users' WAHI available on Zhihu. On the basis of the above findings, we proposed the following three items for our questionnaire scale: (1) "taking advice from relevant health information on Zhihu could cause physiological harm," (2) "taking advice from the health information on Zhihu could cause some psychological pressure," and (3) "the health information on Zhihu could be a useless waste of my time." Furthermore, we proposed the following hypothesis: PR negatively affects SQAC users' WAHI (H5).

Moderating Variables

Moderating variables such as gender, age, and the voluntariness of use play a very important role in the original UTAUT model [22]. The original UTAUT model is a widely used measurement model. However, when measuring and explaining a phenomenon with the aid of the UTAUT model, the variables in the model must be adjusted based on objective facts. When users decide whether to adopt certain health information, they are faced with high health costs, which are directly related to their own or other people's health. Compared to the intention to adopt information technology, the influence of the voluntariness of use variable on SQAC users' WAHI is less important. Therefore, the voluntariness of use variable was removed from the model. Demographic characteristics may have different levels of significance in terms of their effects on the WAHI. Haluza et al [43] found that sociodemographic attributes, including gender influence, not only affect private the web-based habits of users but might also affect the acceptance of health technologies and their professional use in a clinical setting. Tarver et al [44] found that age is one of the significant social-economic influencing factors of web-based health information communication. Irizarry et al [45] proposed that age and education level strongly influence patient users' interests and their ability to use patient portals. Based on existing relevant theories, we selected gender,



XSL•FO
RenderX

age, and education level as the three moderating variables in the model and proposed the following hypotheses: gender has a significant moderating effect on the influence of independent variables for adoption intention (H6), age has a significant moderating effect on the influence of independent variables for adoption intention (H7), and educational level has a significant moderating effect on the influence of independent variables for adoption intention (H8).

Model

Based on the structural characteristics of SQACs and SQAC users' adoption of health information, we reset the moderating variables of the UTAUT model and incorporated PR variables into the UTAUT model to construct the final model of SQAC users' WAHI. We present the model in Figure 1.

Figure 1. The model of social question-and-answer community users' willingness to adopt health information.

Methods

Participant Selection and Data Collection

We selected users who exhibited health information behaviors (health information browsing, commenting, searching, and other relevant behaviors) on Zhihu as the respondent sample for this study. On the basis of our literature review findings, we designed a web-based questionnaire survey scale. The scale was comprised of the items we previously outlined, and it was used to measure 19 indicators of 6 variables related to the WAHI among users of SQACs. All scale items were rated on 5-point Likert scales. We selected 22 postgraduates as presurvey participants to test the availability and quality of the questionnaire. Based on the presurvey results of the questionnaire, we deleted one of the index items for the variable EE (ie, "it often takes more time to retrieve health information in Zhihu"). After adjusting the questionnaire content and structure, the final scale was chosen via expert discussion. We included screening items in the final demographic indicators section of the questionnaire to ensure that all of the data we used came specifically from the Zhihu user group. We administered the web-based survey over 14 days between June 5 and 19, 2020, on the web-based questionnaire platform Wenjuanxing (Liepin Holdings Limited). The questionnaire was distributed by Zhihu users' forwarding the questionnaire link via WeChat (Tencent Holdings Limited). Before the survey process could advance, we presented the content of this study and required respondents to confirm their informed consent for participating further in this study. In total, data from 921 participants' were collected in this study. After filtering out the data of the nonusers of Zhihu and data with missing values and obvious errors, valid data from 598 participants were obtained, with an effective rate of 64.93%. A detailed list of questions can be found in Multimedia Appendix 2.

Statistical Analysis

We used Microsoft Excel for data cleaning and preprocessing before the data analysis. The statistical analysis tools we used in this study mainly included SPSS version 24.0 (IBM Corporation), Analysis of Moment Structures (AMOS) version 24.0 (IBM Corporation), and Process macro version 3.3 for SPSS [46]. Considering that the age distribution of Zhihu users was relatively concentrated, to avoid having a sample size of 0 for certain age groups and to increase the rate of unnecessary systematic errors, we grouped samples by age (20-year increments). With the structural equation model, we calculated the path coefficients between variables to verify the hypotheses. With Process, we conducted hierarchical regression to verify whether the moderating effects of each moderating variable in the model were significant. We set a *P* value of less than .05 as statistically significant.

Quality Control

Composite reliability and the Cronbach α are the most commonly used indicators of questionnaire reliability. As shown in Table 1, the Cronbach α and composite reliability values for each variable, except those for EE, were greater than .7, and the overall Cronbach α value for the questionnaire was .917. These results indicated the good reliability of the questionnaire that we developed for this study [47]. The validity testing of questionnaires entails testing two components—content and

XSL•FO
RenderX

structure validity. As our model and the index expression were verified by others many times, the questionnaire had high content validity. Structural validity consists of convergent and discriminant validities. Convergent validity requires the factor loading and average variance extraction (AVE) values for each index item to exceed .5. As shown in Table 1, all of the variables in this study exceeded this threshold, except for EE. Discriminant validity requires the correlation coefficient of each variable to be less than the square root of the AVE value of the variable itself, and Table 2 reflects that the questionnaire passed the discriminant validity test.

Table 1. The factor load, Cronbach α, average variance extraction (AVE), and composite reliability (CR) values of each variable.

Variables and indices	Factor load	Cronbach α	AVE	CR
PE[a]		.881	.636	.883

Results

Demographic Characteristics

The demographic characteristics of the participants in this study are shown in Table 3. Of the 598 respondents, 69.90% (n=419) were female and 94.15% (n=563) were aged 19 to 38 years. Just over three-quarters of the survey respondents (477/598, 79.77%) had an undergraduate or higher education.

Table 3. Statistical description of the sample.

Variables and categories	Value, n (%)
Gender	
Male	179 (29.93)
Female	419 (69.90)
Age (years)	
≤18	21 (3.51)
19-38	563 (94.15)
39-58	14 (2.34)
Education	
Senior high school and below	7 (1.17)
Junior college	10 (1.67)
Undergraduate	477 (79.77)
Master and above	104 (17.39)

Model Test

We completed the path verification of the model with AMOS 24.0 and SPSS 24.0, and Table 4 presents the model fitting findings. The model fit indices that we calculated were chi-square to df ratios, the root mean square error of approximation (RMSEA), the normed fit index, the relative fit index, the incremental fit index, the Tucker-Lewis index, and the cumulative fit index. Conventionally, model fit is considered good when the chi-square to df ratio is <3, the RMSEA is <0.08, and the normed fit index , relative fit index , incremental fit index, Tucker-Lewis index, and cumulative fit index are >0.9 [48,49].

The structural equation model and the path coefficients are shown in Table 5. Paths "EE to WAHI" (*P*=.79) and "PR to WAHI" (*P*=.41) were not significant, whereas paths "PE to WAHI" (β=.282; *P*<.001), "SI to WAHI" (β=.238; *P*=.02), and "FC to WAHI" (β=.279; *P*=.002) were significant. Our findings supported H1, H3, and H4 but failed to support H2 and H5.

Table 5. Path test of the structural equation.

Hypotheses	Path	Unstandardized estimates	Standardized estimates (SE[a])	Critical ratio	*P* value	Results
H1	PE[b] to WAHI[c]	.280	.282 (.084)	3.314	<.001	Accept
H2	EE[d] to WAHI	.036	.027 (.141)	0.256	.79	Reject
H3	SI[e] to WAHI	.224	.238 (.098)	2.296	.02	Accept
H4	FC[f] to WAHI	.262	.279 (.085)	3.080	.002	Accept
H5	PR[g] to WAHI	.030	.032 (.036)	0.825	.41	Reject

[a]SE: standard error.

[c]WAHI: willingness to adopt health information.

[d]EE: effort expectancy.

[e]SI: social influence.

[f]FC: facilitating condition.

[g]PR: perceived risk.

Moderating Effect Test

With Process macro version 3.3 for SPSS, we completed the testing of the moderating effects of the moderating variables in the model, and we present the specific significance of moderating effects in Table 6. The results in Table 6 indicate that gender significantly moderated the effect that PE had on SQAC users' WAHI. This supported H6. However, H7 and H8 were not supported. Table 7 shows the model parameters from before and after we incorporated gender as a moderating variable. With regard to model 1, Table 7 presents the standardized coefficients of each variable and the corresponding R^2 and *F* test values for when the moderating variables were not included. With regard to model 2, Table 7 reflects the parameter changes that occurred after we introduced gender as a moderating variable. Compared to model 1, model 2's explanatory power for SQAC users' WAHI improved after we incorporated the different moderating variables. Figure 2 shows a visual representation of the moderating effects in this study.

XSL•FO
RenderX

The slope of Figure 2 indicates the effect that PE has on SQAC users' WAHI. A larger slope means that the model is more sensitive to the WAHI. We found that the slope of the male sample was considerably larger than that of the female sample (Figure 2). Therefore, we believe that the male group had more obvious fluctuations than the female group.

Table 6. The significance of moderating effects.

Path	Gender	Age	Education level
PE[a] to WAHI[b]	√[c]		
SI[d] to WAHI			
FC[e] to WAHI			

[a]PE: performance expectation.

[b]WAHI: willingness to adopt health information.

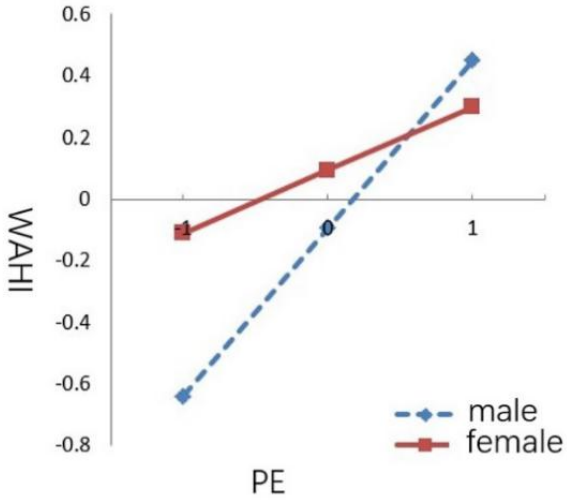
[c]The moderating effect was significant at the .05 level.

[d]SI: social influence.

[e]FC: facilitating condition.

Table 7. Hierarchical regression test of moderating effects.

Index	Model 1[a]			Model 2[b]		
	B	*t* test (*df*)	*P* value	B	*t* test (*df*)	*P* value
Performance expectation	0.331	8.126 (597)	<.001	0.375	8.123 (597)	<.001
Social influence	0.210	5.250 (597)	<.001	0.190	5.029 (597)	<.001
Facilitating conditions	0.251	6.171 (597)	<.001	0.249	6.179 (597)	<.001
Gender	N/A[c]	N/A	N/A	0.094	1.913 (597)	<.001
Interaction item[d]	N/A	N/A	N/A	−0.170	−2.390 (597)	.02



[a]Model 1 had an R^2 value of 0.461 (P<.001) and an F test value ($F_{3,594}$) of 169.643.

[b]Model 2 had an R^2 value of 0.470 (P<.001) and an F test value ($F_{5,592}$) of 104.804.

[c]N/A: not applicable.

[d]The interaction item for the gender and performance expectation.

Figure 2. The moderating effect of gender on the "PE to WAHI" path. PE: performance expectation; WAHI: willingness to adopt health information.

Discussion

Principal Findings

Since the outbreak of COVID-19, the role of SQACs in the public's access to health information has grown in prominence. This study was an analysis of the influencing factors of SQAC users' WAHI during the COVID-19 pandemic. We conducted measurements by using a questionnaire that comprised items grounded in the UTAUT and its individual components. Based on our results, PE (P<.001) and SI (P=.02) had significant positive effects on the WAHI. PE reflects users' expectations

XSL•FO
RenderX

for improved health if they adopt health information, and the WAHI increases in a community if the community users believe that the information is helpful to them. However, in contrast with PE, SI affected WAHI through the people around the users. Improved health among individuals who adopt health information will encourage SQAC users to adopt the health information that is recommended by these individuals. Abdelhamid [25] found that perceived usefulness and SI were the most important factors affecting health information exchange between patients, and our findings were consistent with that conclusion.

Under the premises of compliance and legality, SQAC operators can make full use of the traces of users in SQACs (eg, browsing content, page stay times, likes, collections, content, and the theme of private messages). With the help of this kind of information, SQAC operators could enhance the strength of relationships among different users who pay attention to the same health topics. With the epidemic of COVID-19, people's health concerns have become more focused. This provides a rare opportunity for SQAC operators to improve users' relationship strength. Furthermore, actively guiding users to share their understanding of and experience with health information is another effective method for improving users' PEs and SI. By using these methods, we can further enhance users' WAHI and users' health levels.

FCs positively affected SQAC users' WAHI. FCs are an integration of users' peripheral auxiliary functions in the process of adopting health information. They are formed based on individuals' levels of comprehension, the convenience of retrieving information from platforms, and other users' help in understanding health information. When the effectiveness of this auxiliary role improves, the process of SQAC users' adoption of health information becomes smoother, and users' confidence in adopting health information increases. Through this virtuous cyclical process, health information is continuously shared, exchanged, and adopted, and improving the health information retrieval mechanism can increase the quality of the health information retrieved.

EE (P=.79) and PR (P=.41) had no significant effects on SQAC users' WAHI. We believe that it was the interaction of many factors that led to this result. The native environment and characteristics of the original UTAUT could explain why EE had no significant effects on WAHI. Compared to the cost of users' adoption of information technology or information systems in the study conducted by Venkatesh et al [22], during the establishment of the original UTAUT model, the cost of SQAC users' adoption of health information was lower. To some extent, if the cost of health information adoption is low, the significance level of EE will also be low. However, risk comes from the unknown. Sudhakar et al [50] found that lower education levels were significantly related to lower health literacy. For most SQAC users, higher education means higher information literacy. In this study, irrespective of the total number of SQAC users or the sample size, users' demographic characteristics reflected a higher educational level, which is important for understanding and using health information. Coughlin et al [51] found that persons with limited health literacy are less likely to use patient web portals. We believe that SQAC users who adopt health information and have lower educational levels face more difficulties and risks than those with higher educational levels. However, there could also be deeper reasons for why EE and PR did not significantly affect SQAC users' WAHI. Our inconclusive results require us to conduct more in-depth and detailed research.

As shown in Tables 6 and 7, the moderating effect of gender on path "PE to WAHI" (P=.02) was significant, and Figure 2 shows that the WAHI among men was more sensitive to PE than the WAHI among women. Baumann et al [52] found that gender had different moderating effects on the influencing factors of web users' health information search behaviors. Through empirical research, Ek [53] found that men received far less informal health information from family members, friends, and colleagues than women. Therefore, the PEs of men are more effective in increasing their WAHI than the PEs of women. SQAC operators should pay more attention to the moderating role of gender in the "PE to WAHI" path when attempting to identify optimal health information dissemination schemes. Different coping strategies should be implemented for users of different genders. However, we can effectively improve the WAHI among SQAC users by differentiating the information that they receive based on user gender.

Contributions and Limitations

In this study, we proposed a model of the WAHI among users of the Zhihu SQAC that was based on the modification of the native UTAUT, and we found good explanatory power for our model. We also analyzed the different influencing factors of the WAHI among Zhihu users. PE, SI, and FCs were the primary influencing factors, and the effect of PE differed according to gender. We proposed several suggestions and measures that can be implemented based on our research findings in this study.

Although we strove to be rigorous, there were still several limitations in this study. First, this was a questionnaire survey based on the subjective cognition of SQAC users; thus, we could not avoid the interference of various subjective factors associated with self-reporting. Second, this was a cross-sectional study, and as such, it was impossible to observe changes in SQAC users' WAHI over time. Third, although we ensured that the sample was as representative as possible, there were still some inevitable systematic errors. Fourth, although SQACs are gradually becoming an indispensable platform that users can use to obtain health information, most users are still using search engines and other methods to obtain such information, and we did not adequately explain the interactions among these different sources of health information and users' willingness to adopt such information. Fifth, the model established in this study is a limited extension of the UTAUT model, which cannot cover all of the influencing factors of the dependent variables. Other variables such as information quality, trust, and medical experience will be modeled and studied as the focus in follow-up research. In addition, there were still several limitations in our choices for variable indices. After considering the efficiency of this study, we excluded some indicators that we subjectively considered unimportant, but whether the inclusion of these indicators would enhance the explanatory power of the model remains to be further studied. Finally, we only attempted to

XSL•FO
RenderX

identify the moderating effects of demographic characteristics. Therefore, only gender, age, and education level were selected for verification. Whether other demographic indicators have a significant impact needs to be further verified. In spite of the above limitations, the conclusions and suggestions of this study can be used as references by relevant health management agencies.

Conclusions

We constructed a UTAUT-based model to explain the WAHI among users of the Zhihu SQAC during the COVID-19 pandemic. We tested our hypotheses by using data from a survey (which we administered on the internet) that we analyzed via structural equation modelling. The results showed that PE, SI, and FCs had positive effects on SQAC users' WAHI; EE and PR did not affect users' WAHI. We also found that gender (P=.02) had a significant moderating effect in the model. We hold the opinion that enhancing the strength of user relationships and improving users' experiences with SQAC platforms are the most useful methods for improving the WAHI among users of SQACs. In addition, we need to encourage all users to improve their health information literacy. Although there are limitations in this study, SQAC operators, researchers, and policy makers can refer to our results to guide policy decisions.

Acknowledgments

This study was supported by the Western China Social Sciences Program "Research on Health Information Transmission Path and Diffusion Model Based on Mobile Internet" (item number: 16XTQ012). We appreciate the help of all of the participants who participated in the questionnaire survey. In addition, we are also very grateful to all reviewers for their careful examination of this paper.

Abstract

Background: Unfractionated heparin is widely used in the intensive care unit as an anticoagulant. However, weight-based heparin dosing has been shown to be suboptimal and may place patients at unnecessary risk during their intensive care unit stay.

Objective: In this study, we intended to develop and validate a machine learning–based model to predict heparin treatment outcomes and to provide dosage recommendations to clinicians.

Methods: A shallow neural network model was adopted in a retrospective cohort of patients from the Multiparameter Intelligent Monitoring in Intensive Care III (MIMIC III) database and patients admitted to the Peking Union Medical College Hospital (PUMCH). We modeled the subtherapeutic, normal, and supratherapeutic activated partial thromboplastin time (aPTT) as the outcomes of heparin treatment and used a group of clinical features for modeling. Our model classifies patients into 3 different therapeutic states. We tested the prediction ability of our model and evaluated its performance by using accuracy, the kappa coefficient, precision, recall, and the F1 score. Furthermore, a dosage recommendation module was designed and evaluated for clinical decision support.

Results: A total of 3607 patients selected from MIMIC III and 1549 patients admitted to the PUMCH who met our criteria were included in this study. The shallow neural network model showed results of F1 scores 0.887 (MIMIC III) and 0.925 (PUMCH). When compared with the actual dosage prescribed, our model recommended increasing the dosage for 72.2% (MIMIC III, 1240/1718) and 64.7% (PUMCH, 281/434) of the subtherapeutic patients and decreasing the dosage for 80.9% (MIMIC III, 504/623) and 76.7% (PUMCH, 277/361) of the supratherapeutic patients, suggesting that the recommendations can contribute to clinical improvements and that they may effectively reduce the time to optimal dosage in the clinical setting.

Conclusions: The evaluation of our model for predicting heparin treatment outcomes demonstrated that the developed model is potentially applicable for reducing the misdosage of heparin and for providing appropriate decision recommendations to clinicians.

outcome prediction; clinical decision support; dosage recommendation; machine learning; intensive care unit

Introduction

Existing rule-based protocols guide clinicians to initiate, modulate, or terminate a certain treatment procedure according to evidence-based clinical guidelines or best practices [1]. However, in real clinical scenarios, dynamic changes occur continuously in individual patients with complex diseases and physiological situations, which frequently exceed the scope of the typical model described in the guidelines [2]. In particular, in critical care settings, there is a decision-making dilemma between evidence-based medicine and individualized medicine due to the lack of high-quality evidence and the urgency for the accuracy and effectiveness of the treatment [3]. Fortunately, in the era of big data and artificial intelligence and based on progress in data acquisition, integration, and application in critical care medicine, machine learning techniques sometimes can help with diagnosis, treatment, and prediction in intensive care units (ICUs) [4-6].

Heparin (or unfractionated heparin, UFH) infusion is one example of a medication for which retrospective data have been proven to provide valuable support in clinical settings, especially in critical settings in which patients are vulnerable to thromboembolism or hemorrhage or to severe complications caused by these conditions [7]. For decades, UFH dosing has been based solely on a patient's weight: a weight-based heparin dosing nomogram is the standard practice for the application of UFH. The heparin nomogram mainly consists of an empirical initial loading dose followed by a step-by-step modulation according to a series of blood clotting parameters that are monitored every 4-6 hours [8,9]. The actual optimal UFH dosage varies widely among patients with different physiological situations, and for these patients, the time to optimal dosage may be prolonged. Besides, adverse events associated with supratherapeutic or subtherapeutic anticoagulation, such as hemorrhagic tendency or thrombophilia, may occur due to the intravenous heparin's narrow therapeutic window [7]. Therefore, retrospective analysis starts by extracting sequential dose response data as well as the concurrent laboratory and other clinical data, which may greatly contribute to the improvement on the feedback delay of UFH dosage optimization [10]. In our recent study [11], based on the public Multiparameter Intelligent Monitoring in Intensive Care III (MIMIC III) and electronic ICU databases [12,13], we compared several common models for predicting the effects of heparin treatment and showed that machine learning–based models, which outperformed the standard practices, can be used to optimize and personalize heparin dosing to improve patient safety.

Although our UFH model has been evaluated and validated using public databases [10,14], it has not been validated in our local clinical setting, especially for step-by-step modulation. In this study, we extend the validation and application of the previously optimized UFH model to a local clinical database in the Department of Critical Care Medicine of Peking Union Medical College Hospital (PUMCH), which is a complementary ICU in a tertiary hospital in China. Furthermore, UFH dosage recommendation based on the machine learning model was also performed for both the MIMIC and PUMCH databases, with the goal of effectively reducing the time to optimal dosage in the clinical setting. Finally, to further promote understanding of the data model and algorithm, we performed a featured importance analysis in both databases.

Methods

Data Sets

To evaluate the adaptability of the predictive model and to implement external validation, we employed patient data, including heparin treatments from 2 databases: the MIMIC III database and the PUMCH ICU database. The MIMIC III database is a free and open intensive care medical data set published by the Computational Physiology Laboratory of the Massachusetts Institute of Technology, the Beth Israel Deaconess Medical Center, and Philips Healthcare. It contains real medical data from more than 50,000 adult patients in the ICU at the Beth Israel Deaconess Medical Center between 2001 and 2012 [8]. The PUMCH ICU database comprises the complete clinical data of patients admitted to the PUMCH ICU with a retrospective cohort of more than 20,000 ICU patients between 2013 and 2019.

Definition of Heparin Treatment Outcomes

We classified patients as subtherapeutic, normal therapeutic, and supratherapeutic according to their therapeutic activated partial thromboplastin time (aPTT) values after heparin treatment. We used the average aPTT value from 8 h to 24 h after the initial heparin infusion as the therapeutic aPTT value. Figure 1 shows the distributions of the aPTT values in the 2 data sets. Due to differences in the regions, patient characteristics, and treatment plans such as the step-by-step treatment pattern of PUMCH, the observed therapeutic aPTT distributions are quite different. Based on a previous study [14] and suggestions from clinicians, we adopted different definition ranges for the 2 data sets (Table 1). We then labelled each patient record with 1 of the 3 labels (subtherapeutic, normal therapeutic, and supratherapeutic), thereby converting the clinical outcome prediction task into a ternary classification task.

XSL•FO

Figure 1. The therapeutic activated partial thromboplastin time distributions in the 2 data sets. aPTT: activated partial thromboplastin time; MIMIC III: Multiparameter Intelligent Monitoring in Intensive Care III; PUMCH: Peking Union Medical College Hospital.

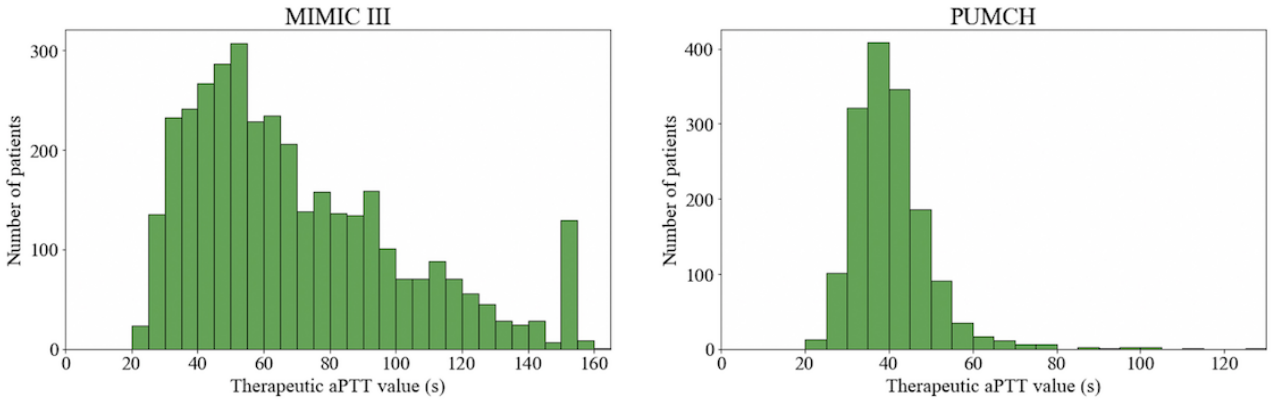

Table 1. Ranges of the therapeutic activated partial thromboplastin time classification of the 2 data sets.

Activated partial thromboplastin time (time in seconds)	Multiparameter Intelligent Monitoring in Intensive Care III data set	Peking Union Medical College Hospital data set
Subtherapeutic activated partial thromboplastin time (s)	0-60	0-35
Normal therapeutic activated partial thromboplastin time (s)	60-100	35-45
Supratherapeutic activated partial thromboplastin time (s)	>100	>45

Feature Selection

According to evidence from related studies and experience from clinical practice, various clinical features affect heparin treatment outcomes [14], that is, the therapeutic aPTT. For example, creatinine in the blood is almost entirely filtered into the urine via glomerular filtration and its concentration is stable under normal circumstances. Therefore, creatinine concentration in the blood can be used as an indicator of renal function because it reflects the filtration function of glomeruli. Measurements of renal, hepatic, cardiac, and coagulation functions were included as features of interest. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) concentrations in the blood are sensitive to hepatocellular damage, and their ratio is an important indicator of liver function. Sequential organ failure assessment (SOFA) scores were included. Furthermore, the total heparin dosage, defined as the sum of the heparin doses administered within 8 h of the initial heparin infusion, is also considered as the affected factor of heparin treatment outcomes. Therefore, to optimize the model predictions, we selected clinical features of interest from the 2 data sets, including sex, ethnicity, admission type, age, weight, initial aPTT, creatinine, AST/ALT ratio (we used the ALT value instead for PUMCH since AST values were not routinely tested every time in PUMCH), several SOFA scores, and total heparin dosage, as shown in Table 2. We used the last aPTT measurement before heparin treatment as the initial aPTT value, and the laboratory tests and SOFA scores were those closest to the initial heparin injection time.

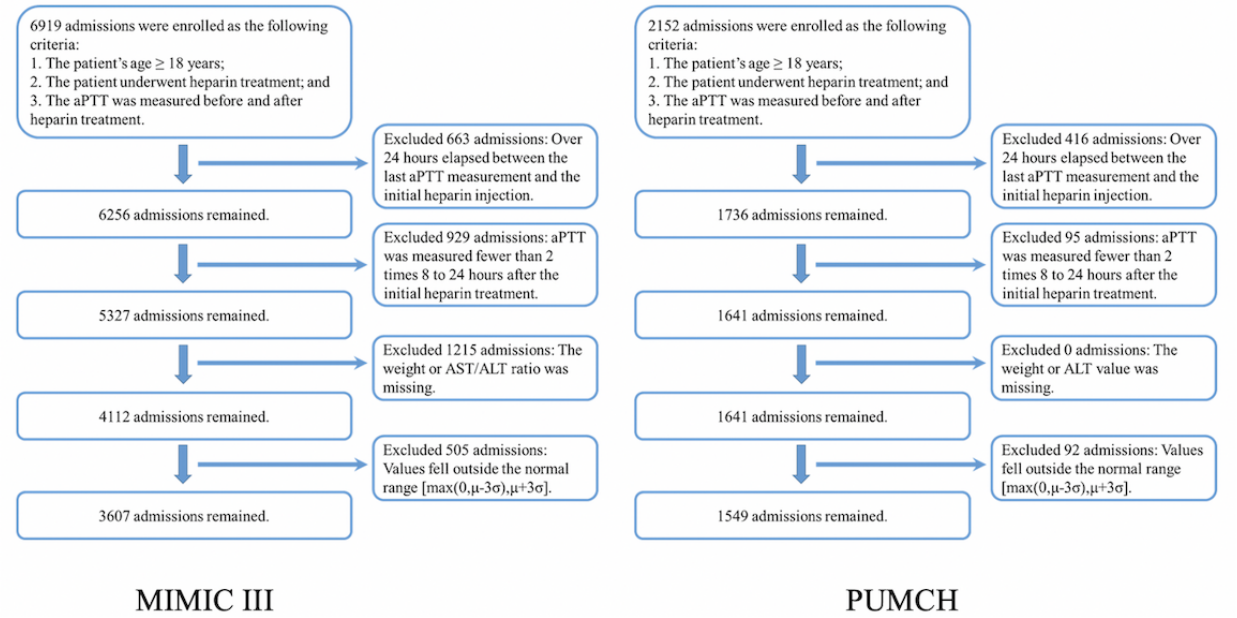
	Ethnicity	—[a]
	Admission type	—
	Age	Age
	Weight	Weight
Laboratory tests		
	Initial aPTT[b] value	Initial aPTT value
	Creatinine value	Creatinine value
	AST/ALT[c] ratio	Alanine aminotransferase value
SOFA[d] scores		
	Coagulation SOFA score	Coagulation SOFA score
	Liver SOFA score	Liver SOFA score
	Cardiovascular SOFA score	Cardiovascular SOFA score
	Renal SOFA score	Renal SOFA score
Medication	Total heparin dosage	Total heparin dosage

[a]Not available.

[b]aPTT: activated partial thromboplastin time.

[c]AST/ALT: aspartate aminotransferase/alanine aminotransferase.



[d]SOFA: sequential organ failure assessment.

Patient Inclusion Criteria

The enrollment criteria were as follows: (1) patient's age ≥18 years, (2) patient underwent heparin treatment, and (3) the aPTT value was measured before and after heparin treatment. Based on the above criteria, we initially collected 6919 patient records from the MIMIC III database and 2152 patient records from the PUMCH database. For the MIMIC III database, we first removed some patient records whose aPTT data were unavailable. We then removed records with missing values for weight or the ratio of AST/ALT. Next, we removed patient records with values of continuous features outside the normal ranges, including weight, initial aPTT value, creatinine value, AST/ALT ratio, and total heparin dosage. According to the statistical definition of outliers [15], we calculated the mean value μ and standard deviation σ of these features; the normal range includes values from $\max(0, \mu-3\sigma)$ to $\mu+3\sigma$. We therefore removed the individual records outside of this range. The normal ranges and number of outliers for each feature are listed in Multimedia Appendix 1. After this process, 3607 patient records remained. For the PUMCH database, after a similar data selection process (according to different recording methods such as the replacement of the AST/ALT ratio by the ALT value in the PUMCH database), we collected 1549 patient records as the study population of PUMCH. The details of the selection process are shown in Figure 2.

Figure 2. Study cohort selection workflow based on the inclusion and exclusion criteria. ALT: alanine aminotransferase; aPTT: activated partial thromboplastin time; AST: aspartate aminotransferase; MIMIC III: Multiparameter Intelligent Monitoring in Intensive Care III; PUMCH: Peking Union Medical College Hospital.

Data Preprocessing

SOFA scores were missing in both data sets, and the 3 nearest neighbors algorithms were used to substitute the missing value with the mean of the 3 neighbors that was closest in terms of the Euclidean distance. The missing data imputation results are listed in Multimedia Appendix 2. We applied a one-hot encoder for the gender, ethnicity, and admission type features since these are categorical features. To avoid the occurrence of feature values that are too large for model training, we applied min-max normalization to all the continuous numerical features using the following formula:

where x denotes the values of all records for a fixed feature.

Model Training

As validated in a previous study [11], a shallow neural network model works best from among several machine learning models for the heparin outcome prediction task. In this study, we used a fully connected shallow neural network model [16,17] to predict the therapeutic effect (subtherapeutic, normal therapeutic, or supratherapeutic) of patients after 8 hours of heparin treatment. This is a ternary classification task. Our artificial neural network consists of an input layer, an output layer, and 3 hidden layers. It is fully connected, which means that each neuron receives input from all the neurons in the previous layer and passes on the results to all the neurons in the next layer. The rectified linear unit function [18] was used as the activation function in order to increase the nonlinearity and improve the model efficiency. The number of neurons in the hidden layers was set at 32/64/24. The models for MIMIC III and PUMCH data sets are basically the same, except for slight differences in the input. We trained the model for 5000 epochs with a learning rate of 0.015. The fully connected neural network was built using TensorFlow (version 1.12.0). Each data set was divided into training (80%) and test (20%) sets, with the proportion of subtherapeutic records, normal therapeutic records, and supratherapeutic records being maintained. To validate the predictive performance of our model, 5-fold cross-validation was used on each data set.

Heparin Dosage Recommendation

By using the neural network model described above, we can calculate the probability that a record belongs to each of the 3 categories (subtherapeutic, normal therapeutic, and supratherapeutic) with the softmax function [19]. For a subtherapeutic or supratherapeutic patient record x and a possible dosage α, we change the actual total heparin dosage of x to α and defined $M(x,\alpha)$ to be the normal therapeutic probability after this changing. Then, we calculated $M(x,\alpha)$ by the softmax function shown below:

where r, s, and t are the outputs (a larger number means a higher probability of belonging to this category) of the neural network model for supratherapeutic, normal therapeutic, and supratherapeutic, respectively, after this changing.

For this subtherapeutic or supratherapeutic patient record x, we provided a recommended total heparin dosage $\sigma(x)$ for x, which maximized the normal therapeutic probability. More specifically, we computed the recommended dosage using the following formula:

where O denotes the set of all possible dosages. We believe that our recommended dosage is reasonable and that our model may improve the clinician's judgement.

Model Evaluation

Model Performance Evaluation

The following measures, that is, precision, recall, F1 score, accuracy, and the kappa coefficient, were used to evaluate the capability of our ternary classification model [20,21]. Because the microaveraged precision, recall, and F1 score are all equal to accuracy, we only computed the accuracy, kappa coefficient, macroaveraged precision, recall, and F1 score to gauge the classification performance. For details, see the confusion matrix in Table 3 and the formulas below.

Table 3. The confusion matrix of our prediction.[a]

Actual label	Prediction label		
	Subtherapeutic	Normal therapeutic	Supratherapeutic
Subtherapeutic	A	B	C
Normal therapeutic	D	E	F
Supratherapeutic	G	H	I

[a]This table was used to gauge the classification performance, as shown in the formulas.

Feature Importance Evaluation

To evaluate the importance of each feature in our shallow neural network model, we removed 1 feature at a time and then calculated the decline in the model accuracy. More specifically, the importance E_i of the i-th feature F_i can be calculated by the formula $E_i = A - A_i$, where is the model accuracy when all features are used and A_i is the model accuracy after removing feature F_i. The features with higher E_i values are more important to the model. We also used 5-fold cross-validation on each data set to improve the stability of the calculation.

Recommendation Result Evaluation

The recommendation dosage result was compared with the actual decision made by the clinicians in the retrospective database, and the corresponding dosage response in the clinical scenario was also evaluated to validate whether the actual dosage setting was optimal. When the actual dosage setting was subtherapeutic and our recommended dosage was higher or it was supratherapeutic and our recommended dosage was lower, then we believe our recommended dosage was reasonable. For example, for a patient with predicted subtherapeutic aPTT outcomes after 10,000 IUs of heparin treatment, if a model recommended that dosage is greater than 10,000 IUs, we considered the recommended dosage to be reasonable; if the model recommended dosage is less than 10,000 IUs, we considered the recommended dosage to be unreasonable.

Results

Patient Characteristics

Patient characteristics according to the therapeutic outcome after heparin injection in MIMIC III and PUMCH are shown in Table 4. Among the 3607 MIMIC III patients, 1718 (47.6%) showed aPPT values within the subtherapeutic range, 1266 (35.1%) had values within the normal therapeutic range, and 623 (17.3%) patients had values within the supratherapeutic range. Among the 1549 PUMCH patients, 434 (28.1%) had measured aPPT values within the subtherapeutic range, 754 (48.7%) had values within the normal therapeutic range, and 361 (23.3%) had values within the supratherapeutic range. For numeric features, the feature density distribution was generated to clarify whether the values were scattered or centered (Multimedia Appendix 3).

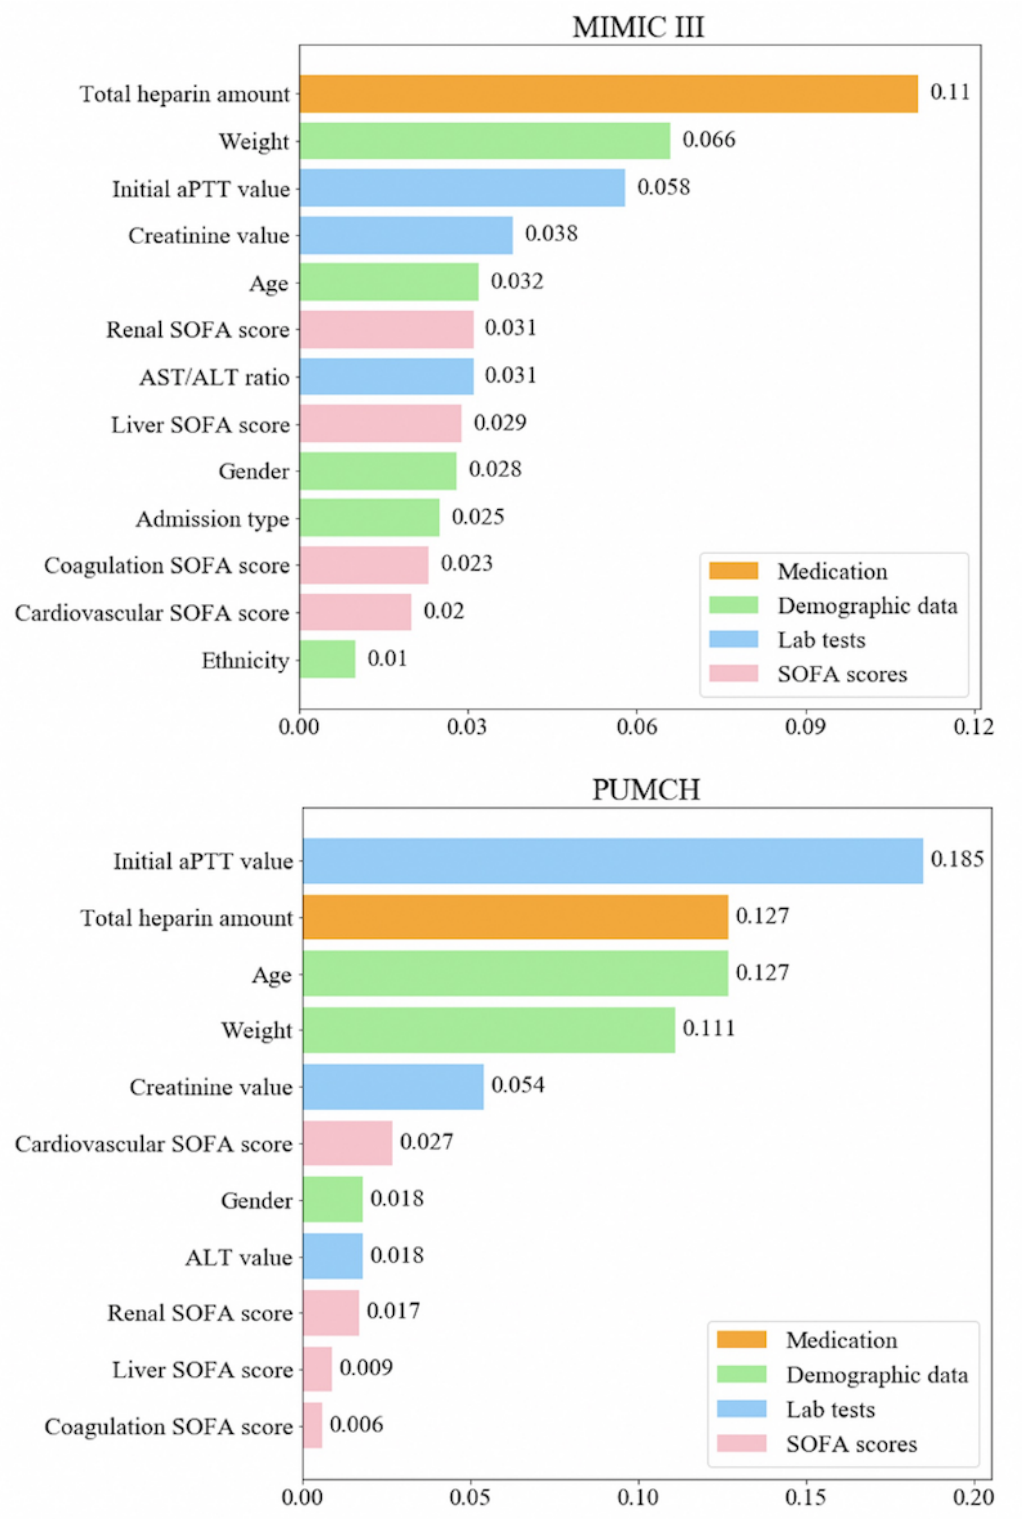
Model Performance

We divided each data set into a training (80%) set and test (20%) set. The proportions of each therapeutic level after dividing the data sets are listed in Multimedia Appendix 4. The shallow neural network model was trained and tested on a retrospective cohort of MIMIC III and PUMCH. The model performance results are listed in Table 5. For both data sets, our model achieved an accuracy of over 0.89, a kappa coefficient of over 0.82, and a macroaveraged F1 score of over 0.88. The results reflect the stable performance of the fully connected shallow neural network model and suggest that our model has generalizability for different databases.

Table 5. Model performance on the 2 data sets.



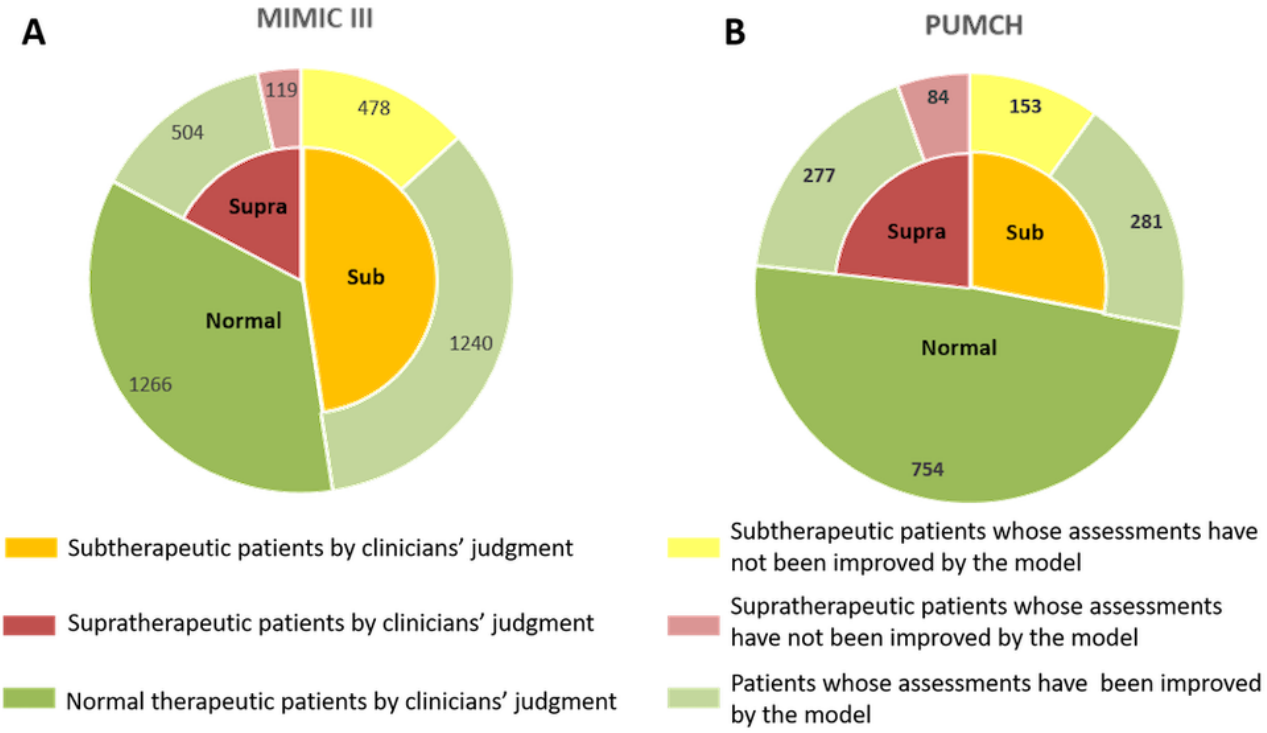
Parameters	Multiparameter Intelligent Monitoring in Intensive Care III data set	Peking Union Medical College Hospital data set
Accuracy	0.891	0.926
Kappa coefficient	0.823	0.882
Macroaveraged precision	0.890	0.931
Macroaveraged recall	0.884	0.920
Macroaveraged F1 score	0.887	0.925

Feature Importance

Figure 3 illustrates the importance of each feature in the development of our predictive model. The features are colored group-wise according to the categories listed in Table 2. A higher value indicates greater significance of the feature in the model. From the feature importance evaluation results, we conclude that the key features are basically the same in the 2 data sets but that their rankings differ slightly. For the MIMIC III data set, the total heparin dosage is the most influential model factor; weight, initial aPTT value, creatinine value, and age are key features and contributed substantially to the model. For the PUMCH data set, the highest impact feature is the initial aPTT value; total heparin dosage, age, weight, and creatinine are also important features for construction of the model. Ethnicity, SOFA scores, and gender have relatively small effects on the model in both data sets. Overall, the feature contribution analysis results are relatively consistent with clinical experience.

XSL•FO
RenderX

Figure 3. Feature importance. ALT: alanine aminotransferase; aPTT: activated partial thromboplastin time; AST: aspartate aminotransferase; MIMIC III: Multiparameter Intelligent Monitoring in Intensive Care III; PUMCH: Peking Union Medical College Hospital; SOFA: sequential organ failure assessment.



Evaluation Results of Recommended Heparin Dosage

We compared our recommended dosage with the actual dosage for subtherapeutic samples (MIMIC III: n=1718; PUMCH: n=434) and supratherapeutic samples (MIMIC III: n=623; PUMCH: n=361). For 72.2 % (1240/1718) of the subtherapeutic samples in MIMIC III and 64.7% (281/434) of the subtherapeutic samples in PUMCH, our model recommended a higher heparin dosage than the clinicians did. Moreover, for 80.9% (504/623) of the supratherapeutic samples in MIMIC III and 76.7% (277/361) of the supratherapeutic samples in PUMCH, our model recommended a lower heparin dosage than the clinicians did. In Figure 4, the solid yellow, green, and red in the inner circles represent the subtherapeutic, normal, and supratherapeutic samples, respectively. The same shaded colors

XSL•FO
RenderX

in the outer ring indicate that the recommended therapeutic state matches the inner circle, whereas fine green bars in the outer ring indicate the recommendation to increase the heparin dosage in subtherapeutic samples and to decrease the heparin dosage in supratherapeutic samples. The model recommendations may improve heparin treatment outcomes and may effectively reduce the time to optimal dosage in the clinical setting.

Figure 4. Recommend heparin dosage results in the MIMIC III (A) and PUMCH (B) data sets. MIMIC III: Multiparameter Intelligent Monitoring in Intensive Care III; PUMCH: Peking Union Medical College Hospital.

Discussion

Principal Results

In this study, we used a validated shallow neural network model for the clinical scenario of UFH infusion, which is commonly applied in the treatment and prevention of venous thromboembolism. To our knowledge, our study is the first practical validation of a machine learning–based model in the area of medication dosing optimization. We demonstrated the feasibility and efficiency of the proposed model in MIMIC III and in a local critical care database in a Chinese tertiary teaching hospital. Based on the calculated probabilities of individual circumstances, we proposed a UFH dosage recommendation for each record, and the comparison results show that the predicted recommended dosage can satisfactorily match the clinical practice.

Comparison With Prior Work

As described in a previous study by Ghassemi using the MIMIC II database [14], a large variation appears in the initial dosing and the corresponding aPTT response, which suggests an underlying discrepancy in both the interprovider practice and patient factors. In the clinical scenario, to avoid this deviation and subsequent fluctuations and treatment-related risks, in our local practice, instead of empirically setting an initial dosage, a step-by-step pattern was adopted. The applicable dosing level was determined according to a series of continuously monitored aPTT results. Therefore, in this study, we used the steady state aPTT value after 8 h of heparin treatment instead of a single value. The results show that the machine learning–based model can effectively predict the aPTT response after the initial dosing and in a step-by-step pattern, which can contribute to decreasing the duration of the therapeutic regime and avoiding treatment-related risks. In our previous work, we demonstrated that the shallow neural network algorithm performed best compared to algorithms such as extreme gradient boosting, adaptive boosting, and support vector machine [11]. Based on our local clinical database and modified treatment pattern, we validated our previously developed model and demonstrated the applicability of this machine learning–based algorithm for UFH treatment. Despite having trained the machine learning models in our previous study on 2 public data sets, which mainly come from the well-known MIMIC and electronic ICU databases, they may not be generalizable to other institutions and populations. Nevertheless, our experience has shown that in a specific clinical scenario, the models can be smoothly migrated to a new data set after retraining, which reflects the flexibility and simplicity of machine learning algorithms. It is worth noting that validation on different data sets demonstrates the generalizability of the model, but the model will not necessarily have the same set of coefficients for each data set.

The interpretability problem remains an issue in the application of machine learning algorithms to the clinical setting. Interpretability can contribute to a physician making decisions based on numerous clinical variables rather than simply providing a prediction or description [22]. In this study, we

XSL•FO
RenderX

calculated the importance of each feature in the shallow neural network model. As shown in Figure 3, the total heparin dosage, weight, initial aPTT value, creatinine value, and age are the 5 most important features for both data sets, although their specific ordering differs between data sets. In addition, as shown in Table 4, the average total heparin dosage increased successively from the subtherapeutic patients to the normal therapeutic patients and then to the supratherapeutic patients. It is reasonable that older age, lesser weight, and higher creatinine level tend to lead to supratherapeutic dosing. Conversely, younger age, higher weight, and lower creatinine level tend to lead to subtherapeutic dosing. This is consistent with clinical experience and can provide some practical support for clinicians. The feature importance analysis not only describes how the model works to a certain extent but can also prompt clinicians to pay more attention to important clinical variables. Although artificial neural network models are often regarded as black box models, we believe that the analysis and interpretation of these models will help understanding the model.

For each subtherapeutic or supratherapeutic patient, we recommended a total heparin dosage through the model. It is unreasonable to evaluate the recommended dosage with the model itself; therefore, we evaluated the rationality of the recommended dosage by comparing with the actual dosage given by the clinicians. It is noteworthy that in the MIMIC III data set, since the total heparin dosage is the most important feature, it contributed most to reasonable heparin dosage recommendation. In contrast, for the PUMCH data set, since the initial aPTT value is the most important feature and the total heparin dosage is relatively less important, the evaluation results of reasonable recommended heparin dosage are slightly low, as shown in Figure 4. Furthermore, the recommendation dosage results were initially evaluated in this study. For example, recommending increased dosage to subtherapeutic patients is evaluated as improved outcome; however, the recommended dosage may not definitely lead to a normal heparin treatment outcome—it may also lead to a supratherapeutic condition. We will further improve the evaluation method in our future studies.

Limitations

This study has several limitations. First, our study was limited by its retrospective nature and the sources of the data. The performance of this machine learning–based model should be validated in clinical practice in order to provide valuable suggestions for treatment. Therefore, in addition to model optimization and cross-validation using more clinical databases, a well-designed, prospective, crossover clinical study should be performed. Second, our results were limited by the size of the populations in the clinical databases; a larger cohort might contribute to more accurate predictions and more precise recommendations for the steady dosing level. Considering the similarity of the data and logical structure, other clinical scenarios such as therapeutic drug monitoring, homeostasis balancing, and blood transfusion control could be appropriate applications of this model. Third, as described above, considering the different time span, treatment pattern, and patient characteristics of the MIMIC III and PUMCH clinical databases, such as 2 feature sets are not completely consistent, the optimal dosing level and the corresponding aPTT results differ in the 2 data sets. Nevertheless, these disparities did not cause the dose-effect relationship to differ in either the clinical practice or the machine learning algorithm, as demonstrated by the model performance and feature importance results. Although input features need to be adjusted or preprocessed when applied to the other data set, we still regarded that the prediction model and recommendation method provide a machine learning solution when applied to heparin outcome prediction and decision-making clinical scenarios. Furthermore, from the perspective of model development, our fully connected shallow neural network model is currently a static model that does not make use of dynamic time series data. In addition, we have not incorporated other available relevant features into the model, such as medical history, comorbidities, surgery history, and intake of medications other than heparin. In the future, with the goal of achieving better predictions of the outcome of heparin treatment and recommending more reasonable heparin dosages, we will build a dynamic model such as a recurrent neural network or a long short-term memory model and incorporate more features.

Conclusions

Based on the machine learning model trained and validated in our previous work, this study aimed to further validate the model and its shallow neural network in a local clinical setting. We found that the data-driven machine learning method could be used effectively in the clinical scenario of UFH treatment with a step-by-step dosage pattern. The results provide support for predicting UFH treatment outcomes and recommending optimal UFH dosing to clinicians. We also evaluated the importance of each model feature to aid in the interpretation and understanding of the machine learning model.

Abstract

Background: The study of doctor-patient-computer interactions is a key research area for examining doctor-patient relationships; however, studying these interactions is costly and obtrusive as researchers usually set up complex mechanisms or intrude on consultations to collect, then manually analyze the data.

Objective: We aimed to facilitate human-computer and human-human interaction research in clinics by providing a computational ethnography tool: an unobtrusive automatic classifier of screen gaze and dialogue combinations in doctor-patient-computer interactions.

Methods: The classifier's input is video taken by doctors using their computers' internal camera and microphone. By estimating the key points of the doctor's face and the presence of voice activity, we estimate the type of interaction that is taking place. The classification output of each video segment is 1 of 4 interaction classes: (1) screen gaze and dialogue, wherein the doctor is gazing at the computer screen while conversing with the patient; (2) dialogue, wherein the doctor is gazing away from the computer screen while conversing with the patient; (3) screen gaze, wherein the doctor is gazing at the computer screen without conversing with the patient; and (4) other, wherein no screen gaze or dialogue are detected. We evaluated the classifier using 30 minutes of video provided by 5 doctors simulating consultations in their clinics both in semi- and fully inclusive layouts.

Results: The classifier achieved an overall accuracy of 0.83, a performance similar to that of a human coder. Similar to the human coder, the classifier was more accurate in fully inclusive layouts than in semi-inclusive layouts.

Conclusions: The proposed classifier can be used by researchers, care providers, designers, medical educators, and others who are interested in exploring and answering questions related to screen gaze and dialogue in doctor-patient-computer interactions.

Introduction

Background

Doctor-patient communication is a combination of verbal and nonverbal expressions and can affect patient satisfaction, adherence, disclosure, and outcomes [1-8]. Health communication researchers have examined various aspects of clinician-patient verbal interactions, such as the content of the clinician's speech and their voice tone [5,9] and the intent that an utterance has in communication [10]. Various nonverbal aspects have also been examined, such as facial expressions, eye contact, body posture, fluency [5,11], and the physical distance between clinicians and patients [12]. With the widespread adoption of electronic medical record systems, computers have become an integral part of clinics. As a result, the traditional 2-way doctor-patient relationship has been replaced by a triadic relationship among doctor, patient, and computer [13]. The use of electronic medical record systems during consultations has been shown to affect doctor-patient verbal [14] and nonverbal [2] communication, and consequently, doctor-patient relationships both positively and negatively [15,16]. Accordingly, the study of doctor-patient-computer interactions has become a key research area for examining doctor-patient relationships [17].

Doctor-Patient-Computer Interactions

Multiple studies, mainly in primary care settings, noted that doctor-patient communication is affected [18-25] and even shaped [26] by the use of computers during clinical encounters. The use of computers was shown to modify or amplify doctors' verbal and nonverbal behaviors [16,21,27-29] that are essential to avoid communication failures and to have effective doctor-patient communication [20]. Examples of negative verbal and nonverbal behaviors that could be amplified by the use of a computer include lack of eye contact, deficient active listening, avoidance, and interruption [30-32].

In addition to studying the effect of computer use on doctor-patient interactions, multiple studies [25,33] examined factors that affect the way these computers are used. Pearce et al [34] described the overarching styles and behaviors of doctors, patients, and computers by studying the orientation of the general practitioners' and patients' bodies as well as their conversations. Chan et al [35] found that doctors spent 50% less time using computers in examinations with psychological components than in examinations with no psychological components. Lanier et al [36] found that consultation content, physicians' gender and level of experience, and whether the consultation was new or a follow-up were modestly related to the way physicians used the computer in primary care settings.

Computational Ethnography Inside Clinics

Researchers studying doctor-patient-computer interactions need to identify which interactions are taking place during the consultations. To do so, researchers have used qualitative methods such as taking notes during live observations [31,37], conducting interviews [37,38], administering questionnaires [39], and sending unannounced standardized patients to collect information [40] and quantitative methods such as videotaping consultations and manually coding the videos [36,41,42] or setting up complex mechanisms for automatic data collection and analysis inside the clinics [43]. Methods that include direct observations are likely to generate more accurate data than clinician or patient reports; however, direct observations are costly in terms of time and human resources, may be obtrusive in a clinical environment, and may cause the participants to knowingly or unknowingly alter their behavior (because of the presence of an observer) [44]. Moreover, they present privacy and ethical concerns for patients and doctors such as concerns about data security and anonymization; changes to the research question that make it different from the one described in initial consent forms, and researchers' inability to take into account all nonpublic information or situations that will be accessed [45].

Given recent technological advancements, computational ethnography has been proposed as an alternative method for studying doctor-patient-computer interaction in depth. Computational ethnography was defined as a new family of methods for conducting human-computer interaction studies in health care settings by using "automated and less obtrusive (or unobtrusive) means for collecting in situ data reflective of real end users' actual, unaltered behaviors using a software system or a device in real-world settings [46]."

Recently, a number of tools that automate the measurement and analysis of specific behaviors in clinical settings were proposed and evaluated: Hart et al. [47] proposed and validated an automated video analysis tool to measure the synchrony and dominance in doctor-patient interactions by analyzing the cross-correlation of the kinetic energy and the frequency spectrum of their motion [47]. Gutstein et al reported developing a system that automatically learns the physician's gaze using their hand positioning [48] or body positioning and optical flow [49]. Weibel et al [43] introduced a solution that enables the capture of multimodal activity in clinical settings [43] to support computational ethnography studies in clinics. Their solution combined computer logging functionality, body motion tracking, audio detection, and eye tracking. By synchronizing data from these sensors, Weibel et al [43] were able to detect the person talking, whether the doctor is looking at the screen, the amount of gesturing, the cognitive load, information searching behavior, workflow interruptions, and the amount of computer activity; however, their solution had some limitations. First, the accuracy of the automatic classification was not reported. Second, they noted that the use of Kinect presents some limitations such as the need to set up the machine, Kinect's inability to reidentify a body once it re-enters the scene, and the occasional transfer of skeletal tracking from human to nonhuman objects. Third, to detect the person who was talking, a Dev-Audio Microcone [50] was used. This means that such a tool may not fit the needs of people looking for a cheap and portable solution with a known robustness level. In this case, recent advancements in pose and voice activity detection algorithms could address some of these limitations. For video consultations, Faucett et al [51] created ReflectLive, a tool that provides real-time feedback to clinicians about speaking contributions, interruptions, eye gaze, and face position. ReflectLive [51] uses an open-source library for audio analysis and a commercial Javascript-based computer-vision

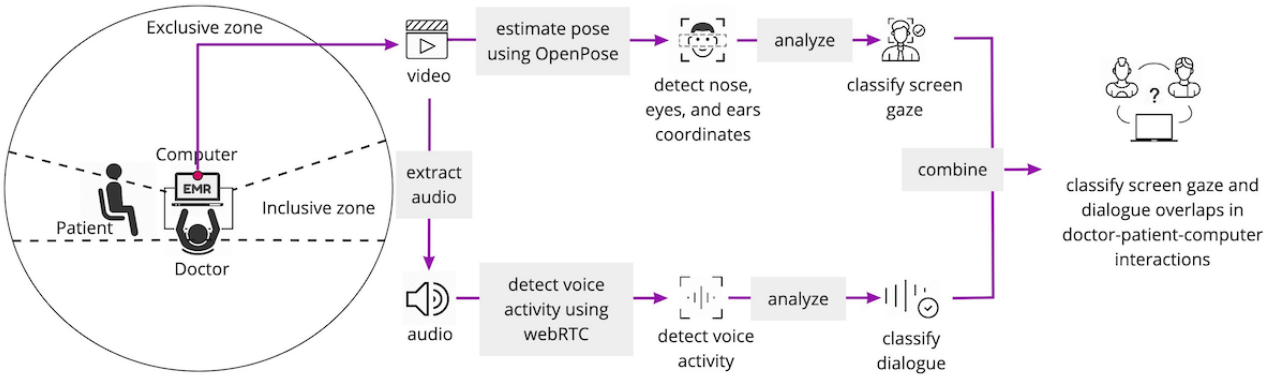
XSL•FO
RenderX

face-tracking software for visual analysis. The real-time feedback provided by ReflectLive was evaluated in terms of its usefulness to the clinicians, but the feedback's accuracy was not reported.

Currently, there are few truly robust and unobtrusive computational ethnography tools for clinical settings, as most tools require researchers to add external artifacts into the clinical environment. Moreover, to our knowledge, none of the existing tools is freely available to the public. To enable human-computer and human-human interaction studies in clinical settings, there is a need for publicly available, robust, unobtrusive, and automated tools for detecting and classifying doctor-patient-computer interactions.

Aims

We aimed to provide a public, robust, unobtrusive, privacy-ensuring, and automated tool for detecting and classifying screen gaze and dialogue in doctor-patient-computer interactions. We chose to focus on screen gaze and dialogue due to recent advancements in machine learning that render the automatic and accurate estimation of pose and voice activity possible.



Methods

Overview

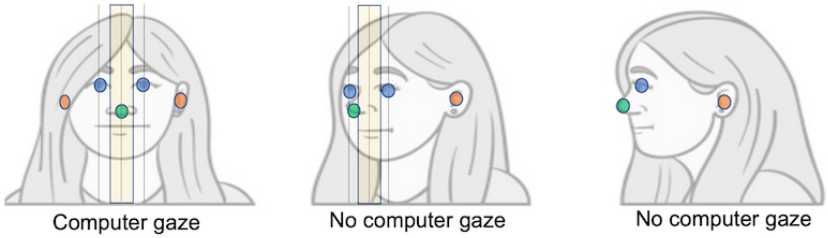
The purpose of the classifier (Figure 1) was to detect the following interactions: (1) screen gaze and dialogue: doctor gazing at the computer screen while having a conversation with the patient; (2) dialogue: doctor conversing with the patient while looking away from the computer screen, or (3) screen gaze: doctor gazing at the computer screen without conversing with the patient. Any other type of interaction in which the doctor and the patient were not having a conversation and the doctor is not gazing at their computer screen were considered out of scope.

The code of the proposed classifier is publicly available [52] and can be used by researchers, care providers, designers, medical educators, and others who are interested in exploring and answering questions related to screen gaze and dialogue combinations in doctor-patient-computer interactions.

Figure 1. Overview of the classification process. EMR: electronic medical record.

Screen Gaze Classifier

The purpose of the screen gaze classifier was to detect when the doctor's gaze was aimed at the computer screen. The input of the classifier was the video captured by the doctor's computer camera and the output was a binary classification: *no screen gaze* or *screen gaze*.



We used the pose estimation library OpenPose [53] as a tool to detect the coordinates of key points of the doctor's face. OpenPose is an open-source library that allows real-time multiperson key point detection for body, face, hands, and feet. We extracted the coordinates of the doctor's eyes ($x_{LeftEye}$, $y_{LeftEye}$), ($x_{RightEye}$, $y_{RightEye}$), ears ($x_{LeftEar}$, $y_{LeftEar}$), ($x_{RightEar}$, $y_{RightEar}$), and nose (x_{Nose}, y_{Nose}), and using the coordinates, we assumed that the doctor's gaze was targeting the computer screen if (1) the location of both the doctor's ears could be estimated, and (2) the doctor's nose was centered between the eyes. For the second condition, we allowed a tolerance equal to half the distance between the 2 eyes. We assessed these criteria (Figure 2) using the following equations for each frame in the video:

Then we assigned to each 0.5-second interval of video the most frequent classification of its corresponding frames. This results in a binary classification (no screen gaze, screen gaze) for each 0.5 seconds of video.

XSL•FO
RenderX

Figure 2. Classifying the doctor's computer screen gaze using face key point estimation.

Dialogue Classifier

The purpose of the dialogue classifier was to detect when the doctor and patient were engaging in conversation. The input of the classifier was the audio captured by the doctor's computer's microphone, and the output was a binary classification of the doctor-patient conversation: *no dialogue* or *dialogue*.

We used a library based on the webRTC voice activity detection engine (an open source project maintained by the Google WebRTC team [54]). The voice activity detection library allows the detection of voice activity in an audio file by processing audio segments and estimating the probability in each segment.

We set the length of each audio segment to 5 milliseconds, which we found to offer the best results through trial and error. We set the voice activity detection to its highest aggressiveness mode in order to increase the probability of filtering out nonspeech. We assigned to each 0.5-second interval of audio the most frequent classification of its corresponding segments. This results in a binary classification (no dialogue, dialogue) for each 0.5 seconds of audio.

Classifier of Screen Gaze and Dialogue Combinations

By combining the results of the screen gaze classifier and the dialogue classifier described above, we classify doctor-patient-computer interactions into 4 different classes (Table 1). The Screen Gaze and Dialogue (SG+D) class defines interactions wherein the doctor is gazing at the computer screen while conversing with the patient. The Dialogue (D) class defines interactions wherein the doctor is looking away from the computer screen and conversing with the patient, and the Screen Gaze (SG) class defines interactions where the doctor is gazing at the computer screen and not conversing with the patient. An interaction wherein the doctor is neither looking at the computer screen nor conversing with the patient is classified as Other. For each 0.5 seconds of video, the interactions classifier assigns 1 of the 4 classes.

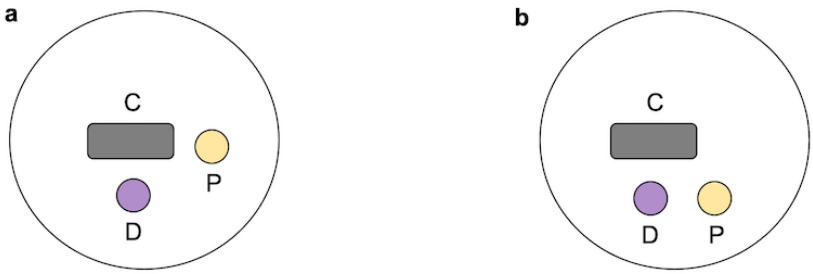


Table 1. Four classes of doctor-patient-computer interactions.

Components		Class	
Screen gaze	Dialogue	Doctor-Patient-Computer interaction	Label
Screen gaze	Dialogue	Screen Gaze + Dialogue	SG+D
No screen gaze	Dialogue	Dialogue	D
Screen gaze	No dialogue	Screen Gaze	SG
No screen gaze	No dialogue	Other	Other

Evaluation of the Classifier

We considered 2 clinical layouts in our evaluation: a semi-inclusive layout, where the patient is seated next to the computer desk, and a fully inclusive layout, where the patient is seated next to the doctor and facing the computer desk (Figure 3). The data that we used to evaluate our classifier consisted of 10 videos provided by 5 physicians. Each physician provided 2 videos—1 video simulating a consultation in a fully inclusive layout and 1 video simulating a consultation in a semi-inclusive layout. Each video was approximately 3 minutes long.

Figure 3. (a) Semi-inclusive and (b) fully inclusive layouts were considered in the evaluation. C: computer; D: doctor; P: patient.

XSL•FO
RenderX

For ground truth data, each video was initially annotated by a human coder. The coder assigned 1 of the 4 interaction classes to each 0.5 seconds of video. The coder reviewed the videos several times and refined the initial annotations until they were satisfied.

To evaluate the classifier, we compared the classifier's performance to that of a different human coder. This second coder was allowed to go through the video only once. This was to simulate a real-world scenario of video coding assigned to an external coder. The performance of the classifier and that of the second human coder were assessed in relation to the ground truth data (generated by the first coder).

The overall performance reflects the performance over the 10 videos including 5 videos in a semi-inclusive layout and 5 videos in a fully inclusive layout. The performances were assessed using an overall accuracy measure in addition to measures of precision, recall, F1 scores for each class. For each class, the support number (ie, the number of its occurrences in the ground truth data set) is reported. Weighted scores of precision, recall, and F1 scores, where the weight of a class is proportional to its support, were also measured. Difference in performance between the classifier and the human coder were assessed using 2-tailed independent *t* tests with *P* values <.05 considered statistically significant. We first report the overall performance, which reflects the performance over the 10 videos. Then, we separately report the performances over the 5 videos in a semi-inclusive layout and the 5 videos in a fully inclusive layout.

Results

Overall Performance

Table 2 shows the overall performances of the classifier and the human coder. The classifier showed a slightly lower overall accuracy than the coder (classifier: 0.83; human coder: 0.85); however, there was no significant difference between the accuracy of the classifier and that of the human coder (t_{18}=0.6, *P*=.55).

The F1 scores of both the classifier and the coder were better when classifying SG+D (classifier: 0.81; human coder: 0.81) and D (classifier: 0.89; human coder: 0.90) than that when classifying SG (classifier: 0.63; human coder: 0.55) and Other (classifier: 0.35; human coder: 0.36) interactions. Since the D class and the SG+D class were the most frequent interactions (D: 2415/3921, 62%; SG+D: 1189/3921, 30%), the overall accuracies mainly reflect performances for these 2 classes.

Confusion matrices for overall performance (Figure 4) show that the classifier and the coder had similar patterns. Both mistook SG+D for D and vice versa, SG for SG+D, and Other for D interactions. The main difference between the classifier and the coder is that the classifier tended to mistake D for Other interactions, whereas the coder tended not to.

Table 2. Overall performance of the classifier.

Classes	Classifier				Human coder				Support, n
	Precision	Recall	F1 score	Accuracy	Precision	Recall	F1 score	Accuracy	
All	—[a]	—	—	0.83	—	—	—	0.85	—
SG+D[b]	0.79	0.82	0.81	—	0.78	0.84	0.81	—	1189
D[c]	0.92	0.86	0.89	—	0.91	0.90	0.90	—	2425
SG[d]	0.64	0.63	0.63	—	0.71	0.45	0.55	—	228
Other	0.24	0.67	0.35	—	0.35	0.38	0.36	—	79

Performance in a Semi-inclusive Layout

Table 3 shows the performances of the classifier and human coder for a semi-inclusive layout. The classifier had a slightly lower accuracy than the coder (classifier: 0.80; human coder: 0.83); however, there was no significant difference between the accuracy of the classifier and that of the human coder in the semi-inclusive layout (t_8=1.04, P=0.32).

Both the classifier and the coder performed well when classifying D (classifier: F1 score 0.86; human coder: F1 score 0.88) and SG+D (classifier: 0.79; human coder: 0.82) interactions. The classifier had a slightly better F1 score than the coder when detecting SG (classifier: 0.47; human coder: 0.45), but both the classifier and the coder had low F1 scores when classifying Other interactions (classifier: 0.24; human coder: 0.21). The D and the SG+D classes had the most support (D: 1157/1958, 59%; SG+D: 702/1958, 36%) thus the overall accuracies mainly reflect performances for these 2 classes.

Confusion matrices of the classifier and the human coder (Figure 5) for a semi-inclusive layout show somewhat similar patterns for the classifier and the coder. Both mostly mistook D for SG+D and vice versa. The classifier tended to mainly mistake SG for SG+D, whereas the coder mistook SG for Other interactions as well. Finally, the coder exceedingly mistook Other for D.

Table 3. Performance of the classifier in a semi-inclusive layout.

Classes	Classifier				Human coder				Support, n
	Precision	Recall	F1 score	Accuracy	Precision	Recall	F1 score	Accuracy	
All	—[a]	—	—	0.80	—	—	—	0.83	—
SG+D[b]	0.76	0.83	0.79	—	0.81	0.82	0.82	—	702
D[c]	0.92	0.80	0.86	—	0.88	0.88	0.88	—	1157
SG[d]	0.40	0.57	0.47	—	0.61	0.36	0.45	—	69
Other	0.16	0.50	0.24	—	0.17	0.30	0.21	—	30
Weighted score	0.83	0.80	0.81	—	0.84	0.83	0.83	—	—

[c]D: Dialogue.

[d]SG: Screen Gaze.

Figure 5. (a) Classifier and (b) human coder confusion matrices for semi-inclusive layout. D: Dialogue; SG: Screen Gaze; SG+D: Screen Gaze + Dialogue.

Performance in a Fully Inclusive Layout

Table 4 shows the performances of the classifier and the human coder in a fully inclusive layout. The classifier and the coder showed similar accuracy (both equal to 0.86), and there was no significant difference between the accuracy of the classifier and that of the human coder for a fully inclusive layout (t_8=0.43, P=0.67).

The classifier and the coder had good F1 scores when classifying D (classifier: 0.92; human coder: 0.93) and SG+D (classifier: 0.83; human coder: 0.80). The classifier performed better than the coder for the SG class (classifier: 0.73; human coder: 0.59), but worse for Other interactions (classifier: 0.42; human coder: 0.52). The D and SG+D classes had the most support(D: 1268/1963, 65%; SG+D: 487/1963, 25%), thus the overall accuracy mainly reflects the performance for these 2 classes.

Confusion matrices of the classifier and the human coder for a fully inclusive layout (Figure 6) show similar patterns for the classifier and the coder. Both mistook SG+D for D, SG for SG+D, and Other interactions for D; however, the classifier tended to mostly mistake D for Other interactions, whereas the coder mostly mistook D for SG+D.

Transitions Between Doctor-Patient-Computer Interactions

We found that many errors in the classifications (for both the human coder and our classifier) were due to slight time inconsistencies during transitions. To confirm this hypothesis, we conducted an analysis of the transitions between the interactions. Table 5 reports the frequency of each transition in the ground truth data and shows that most transitions happen from D to SG+D and vice versa. We define a transition timing error as a temporal shift of 0.5 to 1 seconds between the ground truth and the classification. We only included transitions that were preceded and followed by a continuous type of interaction for at least 1.5 seconds. Table 6 reports the absolute and relative number of errors that can be attributed to early or late coding of transitions. We think these errors can be overlooked for any practical purpose.

Discussion

Principal Results

We developed an unobtrusive, inexpensive, and automatic classifier of screen gaze and dialogue combinations in doctor-patient-computer interactions. The classifier was evaluated in 2 clinical layouts, semi-inclusive and fully inclusive, and had a performance similar to that of a human coder with an overall accuracy of 0.83. The proposed classifier is unobtrusive since it does not require additional setup in the clinic and only requires that doctors record video using their computer's internal microphone and camera. The proposed classifier is an inexpensive solution since it is built using open-source tools and takes advantage of the internal camera and microphone built into most available computing devices. Finally, the video can be locally processed, thus reducing the risks of handling private and sensitive data off the clinic's premises, and ensuring that no collateral data are collected and used for purposes other than those initially consented to by the participants.

Both the classifier and the coder had better accuracies in a fully inclusive layout (both equal to 0.86) than in the semi-inclusive layout (classifier: 0.80; human coder: 0.83). The difference in performance can be attributed to the different postures that the doctor maintains when interacting in the 2 clinic layouts. In the fully inclusive layout, the doctor has to rotate their head a full 90 degrees away from the screen in order to gaze at the patient, whereas in semi-inclusive scenarios, the head rotation angle is smaller; therefore, it is easier to make distinctions between the interactions in a fully inclusive layout.

Both the classifier and the coder confused SG+D interactions and D interactions. Some instances occurred when classifying near transitions between interactions. Indeed, our analysis showed that 16.4% of the classifier's errors (110/672) and 22.2% of the human coder's errors (134/603) were early or delayed markings of transitions, which can be overlooked in practical use-cases. Unlike the human coder, the classifier tended to mistake D for Other interactions (ie, the doctor is neither looking at the screen nor conversing with the patient). This may be attributed to the fact that human coders overlook small moments of silence and regard them as response offsets that are due to turn-taking in the conversation [55] or lapses that are expected

XSL•FO
RenderX

in multiactivity settings [56,57], whereas our classifier classifies them as an absence of dialogue. Here, the classifier presents an advantage since it easily detects moments of silence that are usually overlooked by human coders. This kind of information may be useful to detect conversational dimensions such as hesitant speech [42]. However, for our purposes, this leads the classifier to overestimate the lack of verbal interaction. To counteract this, further rules are needed to identify which moments of silence are part of a conversation and which are not. These rules need to take into consideration the language and the content of the conversation [55,58], other activities that individuals are engaging in while conversing [56,57], and accompanying nonverbal behavior such as nodding and gaze [55].

As a collateral result, our experiment also confirmed the findings of previous work that highlighted the effect of the clinic layout on doctor-patient-computer interactions [59,60]. Fully inclusive videos contained more D (64% versus 59%) and SG interactions (8% versus 3.5%) and fewer SG+D interactions (25% versus 36%) than those in semi-inclusive videos. In a fully inclusive layout, the doctor has to choose whether to face the computer or their patient, whereas a semi-inclusive layout allows the doctors to maintain a conversation with their patients while looking at the computer screen.

Use Cases

Functionality

Because health communication researchers study various complex behaviors, the coding process is far more complex than a binary classification of screen gaze and dialogue over time. However, the proposed classifier could contribute to reducing the cost of future studies since gaze and dialogue are part of the behaviors that health communication researchers and medical informaticians are often interested in quantifying to examine the relationship between computer use, clinic and tool design, and physician-patient interactions [3,5,19,28,61-65]. Moreover, by detecting these behaviors over short intervals of time, more complex behaviors and patterns could be inferred as shown in our results on transitions between interactions. Therefore, the classifier can be directly used to monitor screen gaze and dialogue or extended and combined with other tools or processes to examine complex interactions in clinical settings.

For Researchers

The proposed tool can be used to study the effects of screen gaze and dialogue combinations in doctor-patient-computer interactions on quality of care and health outcomes. Currently, conducting this type of study would require (1) recording a video of the consultation, (2) transferring the video outside of the clinic, (3) manual coding of screen gaze and presence of dialogue in the video, and (4) assessing the specific outcome. This process can be facilitated by our classifier, which eliminates the need for the second and third steps.

The classifier can also be used in clinics to examine the effect of external factors on screen gaze and dialogue combinations in patient-doctor-computer interactions such as sociodemographic characteristics, clinic layout, and modifications of electronic medical record system's design. Non–self-reported large-scale studies of this kind would be nearly impossible to conduct using current methods and tools.

In addition, the gaze classifier can be used in conjunction with commonly used interaction analysis coding systems, such as the Roter interaction analysis system [42], that do not systematically account for nonverbal behaviors [66]. This would provide useful data for studies examining provider-patient communication in the presence of a computer.

For Practicing Physicians

Since the processing of the video can happen in real time, tools that allow physicians to *reflect in action* [67] can be created. The classifier can be used to create tools that allow physicians to conduct autoethnographies and reflect on their interactions with the patient, or on the role of technology in their care practice [68]. This would allow them to adapt their behavior and level of attention based on feedback. Similar concepts were proposed by Liu et al [69] and Faucett et al [51], who described tools that provide feedback to clinicians about their verbal and nonverbal communication behaviors during online consultations. Their studies highlighted the usefulness of summative [70] and real-time self-reflection tools and the need to design real-time feedback in a way that minimizes intrusiveness and ensure that it does not create extra distractions [51].

For Medical Educators and Students

Medical educators and students can use the classifier to teach and learn the best practices of doctor-patient interactions. The tool could be expanded to detect different interaction categories (eg, listening/ignoring; confronting/avoiding [71,72]) and used during practical learning sessions to provide students with formative feedback [69].

Limitations and Future Work

The first limitation of the classifier is its applicability to certain clinic layouts. Our evaluation explored 2 clinical scenarios: semi-inclusive and fully inclusive. We did not explore exclusive scenarios, even though these scenarios might be encountered in real-world clinical settings. With the proposed classifier, detecting the doctor's computer gaze would not be possible in a fully exclusive scenario since the classifier considers the doctor's head turn to estimate her gaze. We consider this limitation acceptable since inclusive scenarios are already commonplace [25], and we expect an increase in their prevalence to support technology-mediated information-sharing between clinicians and patients. Indeed, previous studies [31,73,74] have shown that clinicians use their computer screens as tools to share information with their patients; therefore, the doctor may turn the screen, along with the camera, toward the patient. If this interaction happens during an ongoing conversation, our tool may classify it as a dialogue between doctor and patient, but the fact that this doctor-patient interaction is mediated by the computer would not be highlighted. Further improvements are needed to detect scenarios where both clinician and patient are interacting with the computer at the same time.

Our work also assumes that clinicians use their computers during consultations, which is not always the case, especially in

XSL•FO
RenderX

secondary care settings. Moreover, the classifier is built and evaluated around the premise that the only people in the clinic are the doctor and the patient and that the only screen is the doctor's computer screen. However, it is possible that patients are accompanied by their family members, friends, or partners [75] and that multiple health care staff are involved in the care of 1 patient and present during the consultation. In addition, extra screens might be installed inside clinics to engage the patient in their care and offer them an easy and clear view of their data. These screens may affect the doctor's behavior in various ways; for example, they might use this screen as an explanation support tool while they converse with the patient or even as their main computer screen. Therefore, another limitation of this work is its nonapplicability in scenarios that include patient screens and stakeholders other than the doctor and patient.

Furthermore, the classifier does not allow us to identify the speaker's identity or the content of the doctor-patient dialogue. Therefore, the classifier does not currently support conversation analysis. To identify the speaker's identity, we would have to perform accurate speaker diarization, a hard goal to achieve especially using a single channel for audio recording and without prior training. Advancements in speaker diarization techniques may render this task feasible in the near future [76]. To identify the content of the dialogue, automatic speech recognition solutions can be used. Though automatic speech recognition solutions have become more robust in the last decade, the performance of automatic speech recognition engines remains limited when applied to conversational clinical speech [77]. Future work could explore the feasibility of automatic conversation analysis in doctor-patient-computer interactions through the application of novel speaker diarization and automatic speech recognition tools.

In other respects, although the direction of the head could be considered a proxy for the direction of attention, the head only communicates short-term attention [78,79]. Pearce et al classified physicians as unipolar, those who maintain the lower pole of their body facing the computer, or bipolar, those who repeatedly alternate the orientation of their lower pole between the computer and the patient [34]. Unipolar physicians experience situations where their body segments are not aligned, also referred to as body torque. Body torque communicates an instability of attention where the most strongly projected resolution involves the upper body getting realigned with the lower body. This means that the orientation of the torso communicates longer-term attention than head orientation, and the orientation of the legs communicates longer-term attention than torso orientation and head orientation [79]. Therefore, to examine the attention of a physician in a clinical scenario, we also need to examine the orientation of their torso and lower body. Future work can use the same pose estimation approach to monitor the direction of the clinician’s torso. This is possible because the shoulders and the torso of the clinician are usually visible to their computer’s camera; however, monitoring the lower part of the body would require setting up extra cameras in the clinic.

Finally, our classifier is model-driven as it derives its decisions from the explicit rules that we set. To be able to classify interactions that do not fit strictly into our specified rules, the classifier has to be driven by data or perhaps be a system that combines model-driven and data-driven logic. Our future work will include collecting and annotating more videos of consultations in order to create a data-driven classifier.

Conclusions

To facilitate human-computer and human-human interaction studies in clinical settings, we presented a computational ethnography tool—an automatic unobtrusive classifier of gaze and dialogue combinations in doctor-patient-computer interactions. The classifier only requires that the doctor record video using their computer’s internal camera and microphone. Our evaluation showed that the classifier's performance was similar to that of a human coder when classifying 3 combinations of screen gaze and dialogue in doctor-patient-computer interactions.

Acknowledgments

This research was supported by Japan Society for the Promotion of Science Kakenhi (grant number JP20K20244).We thank the 5 physicians who provided us with video data. We also thank our reviewers for their valuable comments and suggestions, which helped us improve this work.

Abstract

Background: Cholera poses a significant global health burden. In Bangladesh, cholera is endemic and causes more than 100,000 cases each year. Established environmental reservoirs leave millions at risk of infection through the consumption of contaminated water. The Global Task Force for Cholera Control has called for increased environmental surveillance to detect contaminated water sources prior to human infection in an effort to reduce cases and deaths. The OmniVis rapid cholera detection device uses loop-mediated isothermal amplification and particle diffusometry detection methods integrated into a handheld hardware device that attaches to an iPhone 6 to identify and map contaminated water sources.

Objective: The aim of this study was to evaluate the usability of the OmniVis device with targeted end users to advance the iterative prototyping process and ultimately design a device that easily integrates into users' workflow.

Methods: Water quality workers were trained to use the device and subsequently completed an independent device trial and usability questionnaire. Pretraining and posttraining knowledge assessments were administered to ensure training quality did not confound trial and questionnaire

Results: Device trials identified common user errors and device malfunctions including incorrect test kit insertion and device powering issues. We did not observe meaningful differences in user errors or device malfunctions accumulated per participant across demographic groups. Over 25 trials, the mean time to complete a test was 47 minutes, a significant reduction compared with laboratory protocols, which take approximately 3 days. Overall, participants found the device easy to use and expressed confidence and comfort in using the device independently.

Conclusions: These results are used to advance the iterative prototyping process of the OmniVis rapid cholera detection device so it can achieve user uptake, workflow integration, and scale to ultimately impact cholera control and elimination strategies. We hope this methodology will promote robust usability evaluations of rapid pathogen detection technologies in device development.

Introduction

Cholera is a waterborne disease caused by the bacterium *Vibrio cholerae* that has led to seven major pandemics since 1817 [1]. There are currently 47 countries affected by cholera, leading to 2.9 million cases and 95,000 deaths each year [2]. Cholera is fatal in approximately 60% of untreated cases, but the fatality rate can be reduced to a less than 1% with aggressive rehydration and electrolyte replacement [3]. In total, the disease costs an estimated US $2 billion in lost productivity and health care costs annually [2]. Cholera is a disease of inequity in that it affects the poorest and most vulnerable populations within each affected country [2]. Women of childbearing age and children aged 2 to 9 years are most at risk of infection, with about half of all cases occurring in children younger than 5 years [4,5]. These inequities are attributed to access to safe water and sanitation.

Globally, 844 million people lack access to safe drinking water, and 2.4 billion are without basic sanitation facilities, leading to 2 billion people drinking water with fecal contaminants; these inequities leave billions of people vulnerable to cholera each year [2]. Community members can be asymptomatic carriers of cholera, unknowingly excreting the bacteria and potentially contaminating water supplies [6]. The persistence of *V cholerae* in community water sources leaves local populations continuously vulnerable to infection [7]. Thus, environmental water sources must be monitored for the establishment of reservoirs.

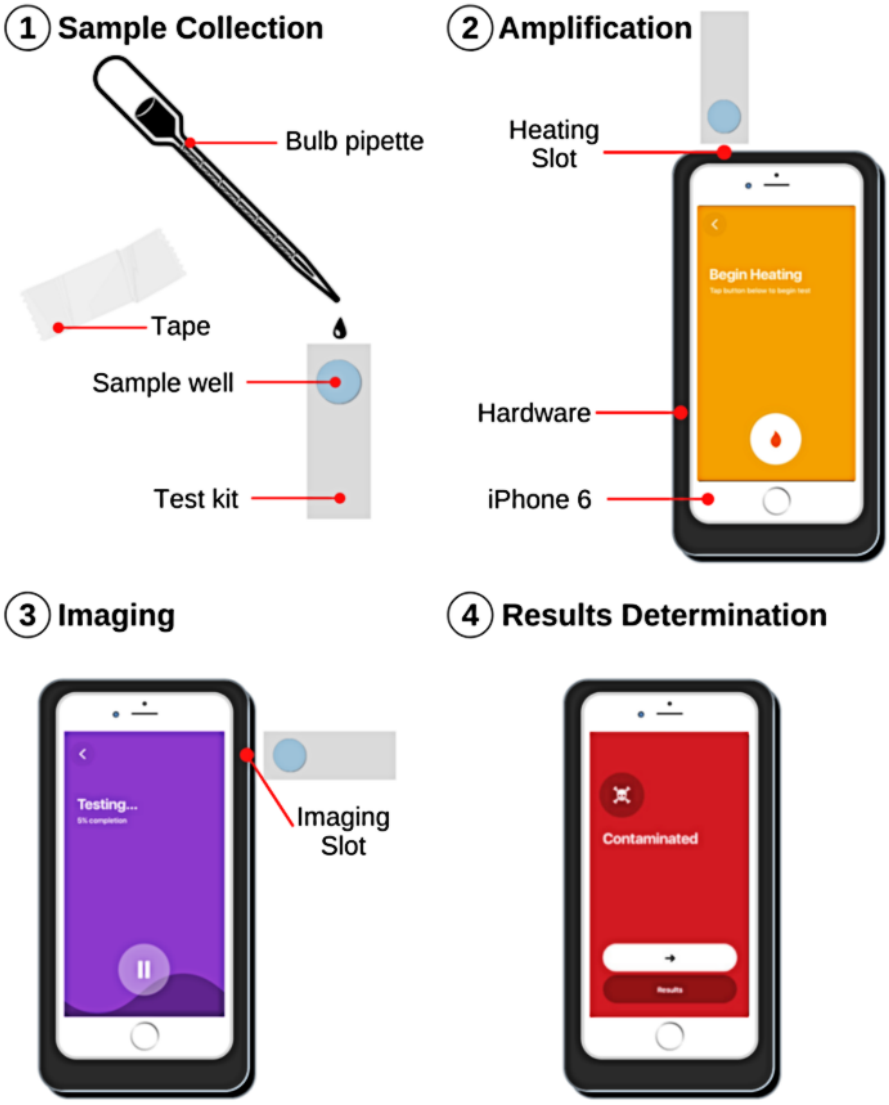
The ability of *V cholerae* to survive in viable but nonculturable states [8] poses a potential danger to public health efforts as the highly selective media used in conventional microbiology can fail to detect the organism in environmental samples [9]. Early pathogen detection is a key component to preventing infection. International efforts call for situational analysis to identify cholera hotspots, primarily through early warning surveillance and stronger laboratory capacities to reduce cholera transmission [10]. While early warning surveillance can encompass both epidemiological and environmental surveillance techniques, using the latter to monitor community water supplies and piped water infrastructure would likely detect pathogens prior to infection and subsequently prevent outbreaks. If *V cholerae* is detected, governments and aid agencies can immediately deploy rapid response teams to distribute household water treatment products and provide community education. Additionally, environmental surveillance can inform government policymaking and implementation strategies by identifying cholera hotspots [2,11]. Rapid detection and environmental surveillance of *V cholerae* could contribute to these goals.

In recent years, the use of mobile technology has dramatically increased globally. Mobile health, or mHealth, is defined by the World Health Organization as “medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants (PDAs), and other wireless devices” [12]. With more than 106 mobile cellular subscriptions per 100 people worldwide, mobile technologies have surpassed 100% penetrance [13]. Mobile technology has infiltrated communities around the world, uniquely positioning mHealth to address global health concerns at a low cost. Rapid pathogen detection technologies could have a significant impact on environmental surveillance efforts [7]. Current mHealth rapid pathogen detection technologies primarily use lab-on-a-chip or microfluidic technology [14]. Because of their camera, GIS, and data storage modalities, mHealth technologies are ideally suited to detect pathogens in environmental water sources and serve as a low-cost alternative to laboratory testing in low-resource settings [14-17].

Recognizing the need for increased point-of-use laboratory technologies in the field and in low-resource settings, OmniVis Inc developed a smartphone-based rapid cholera detection device (Figure 1) [18,19].

XSL•FO
RenderX

Figure 1. OmniVis rapid cholera detection device with inserted iPhone 6 and workstation setup for laboratory personnel trials.



An environmental water sample (approximately 150 µL) is collected in a single-use disposable test kit and inserted into a 3D-printed hardware device with an embedded heating unit and microscope that is built to fit an iPhone 6 preloaded with the OmniVis app (Figure 2). Using particle diffusometry and loop-mediated isothermal amplification, the device detects the presence of cholera from the small water sample [18-20]. Prior to this research, the device was tested only in laboratory settings, demonstrating an estimated time-of-use of 45 minutes.

The purpose of this study was to progress the iterative prototyping process of the OmniVis rapid cholera detection device by evaluating the device's usability with targeted end users, namely water quality workers. As defined by the International Organization for Standardization, usability is the "extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use" [21]. Therefore, this study seeks to determine the effectiveness with which water quality workers can use the OmniVis device, its efficiency in detecting the presence of toxigenic cholera (*V cholerae* with the ctxA gene-encoding cholera toxin) in environmental water samples, and workers' satisfaction in using the device. While the field of mHealth and rapid diagnostic testing for infectious disease is fast-growing, few rapid pathogen detection technologies have been developed for environmental surveillance [12,22]. Moreover, many mHealth usability studies have evaluated interventions such as behavioral change, medication adherence, or clinical decision-making technologies, but there is a literature gap for usability studies evaluating rapid pathogen detection technology [23-26]. By providing input in the device development process, end users can become cocreators and feel ownership in the device design, enabling greater uptake and integration into workflows. Therefore, it is critical to conduct usability evaluations to increase device uptake and ensure the development of culturally appropriate technologies [27]. It is important to assess the usability of the OmniVis rapid cholera detection device with targeted end users in order to contribute to environmental surveillance, control, and elimination efforts.

OmniVis device and app workflow: (1) environmental water sample is collected into well of single-use disposable test kit and channel is sealed, (2) test kit is inserted into hardware heating unit for loop-mediated isothermal amplification, (3) after 40 minutes, sample is placed in microscope imaging slot, (4) OmniVis app displays results: contaminated/not contaminated.

Methods

Study Location

The user-centered study took place in Dhaka, Bangladesh. Dhaka has an estimated population of 14.4 million growing by 1.02% annually and a population density of 19,447 people per square kilometer [28]. Specifically, the study was conducted in partnership with the International Centre for Diarrheal Disease Research, Bangladesh (icddr,b), which has been conducting cholera testing, research, and surveillance in Dhaka since 1960 [29].

Participants

A convenience sample of environmental microbiology laboratory personnel (n=14) and field staff (n=11) employed by icddr,b was recruited into the study during May 2019 by the director of the environmental microbiology laboratory and director of Duaripara field operations via word of mouth at staff meetings. Eligibility was based on participant age (older than 18 years) and job role (field staff or laboratory personnel). Field staff were defined as icddr,b employees responsible for collecting environmental water samples throughout Dhaka city and the surrounding areas using sterile technique and maintaining cold chain transportation from the field to icddr,b laboratories. Laboratory personnel were defined as icddr,b employees who receive environmental water samples and conduct gold standard methods including enrichment, subculturing, and DNA amplification by polymerase chain reaction of *V cholerae* and other waterborne pathogens. Exclusion criteria included minors and nonemployees of icddr,b for adequate homogeneity of job roles. As a small-scale pilot study, only 25 participants were recruited due to funding constraints for participant compensation. All participants provided informed consent before participating in the study. Device training, device trials, and administering the usability questionnaire were conducted at the Duaripara field office for field staff participants and at the environmental microbiology laboratory for laboratory personnel participants. All participants received 820 BDT (US $10) as compensation for their time. This study was approved by the University of Notre Dame institutional review board and the icddr,b research and ethics review committees.

Device Trials

Device Training

Development of a training program was not a specific objective of this research. However, participants needed to have a uniform understanding of the device prior to conducting field trials to minimize confounding variables such as familiarity with technology. Thus, prior to conducting device trials, participants were trained on how to use the device and biosafety protocols for device use. In order to identify any confounding variables resulting from poorly conducted training, the training was evaluated through a 5-question pretraining and posttraining knowledge assessment that included both true/false and open-ended questions (Multimedia Appendix 1). These assessments tested participants' comprehension of personal protective equipment (PPE) use, sample collection, sample analysis, and proper test kit disposal. Pretraining and posttraining knowledge assessments were identical in their content. Participants completed the pretraining knowledge assessment before undergoing a device training session. Following assessment completion, the study investigator demonstrated donning PPE, collecting a water sample with single-use bulb pipette, inserting and sealing the sample into a single-use test kit, powering the device, inserting the test kit into heating and imaging slots at appropriate stages, navigating the app interface, safe disposal of the test kit and sample, and doffing PPE. Spoken English to Bangla translation of this demonstration was provided by a staff member employed by icddr,b. After completion of the training, participants completed the posttraining knowledge assessment to determine if their understanding of how to use the device improved as a result of this training.

Field Trials

Upon entering the laboratory setting or field office setting (hereafter, field), participants were provided with one hardware device, one iPhone 6, one test kit and an accompanying piece of tape to seal the sample well, one single-use bulb pipette for sample collection, and one biohazard bag for sample disposal. Deionized water was used in place of an environmental water sample to reduce the risk of exposure and contamination. Participant time-of-use for each trial was recorded starting immediately prior to collecting the deionized water sample and ending with disposing the test kit into the biohazard bag. Participants performed one trial relying on instructions displayed in the iPhone app and their understanding of the training. The investigator observed participant interactions with the device and recorded written field notes and photographs. Field notes included specific errors observed during each trial. Specific errors were grouped by similarity and summed. Groups were then more broadly coded into user errors and device malfunctions depending on the cause of the error. Photographs were supplied to OmniVis Inc for internal use in developing future prototypes.

Usability Questionnaire

A usability questionnaire (separate from the pretraining and posttraining assessments) was designed to capture user-defined errors, attitudes toward the device, and potential workflow integration pathways. Specific aims included training evaluation, device usability, workflow integration, and community education. Empirically evaluated usability questionnaires including the Mobile Phone Usability Questionnaire and the Poststudy System Usability Questionnaire were analyzed for applicable content when developing the questionnaire [30,31]. Relevant questions were adapted and reworded for applicability to the OmniVis device and testing setting. Questions were carefully ordered to follow device training and use to minimize respondent confusion or recall bias. Special attention was paid to minimize participant cognitive load by ensuring that question language was clear, specific, and nonbiased; redundant questions were omitted, and display and skip logic was used. Demographic questions were added to the end of the questionnaire to capture job role, gender, language competency, education, level of experience, and years worked at icddr,b. Both the English and Bangla versions of this study's questionnaire were input into Qualtrics Surveys Offline Application and administered via a Fire 7 (Amazon) tablet, iPhone XR (Apple Inc), or iPhone 6 (Apple Inc). Participants completed the questionnaire immediately after the field trial via self-administration.

Analysis

Pretraining and posttraining knowledge assessment scores and time-of-use data were input into SPSS (version 26, IBM Corp) for statistical analysis. Field notes were input into Excel spreadsheets (Microsoft Corp) for coding and cleaning before being transferred to SPSS for statistical analysis. Questionnaire data were downloaded from Qualtrics as an SPSS data sheet for statistical analysis. The sample included 25 participants (14 laboratory personnel and 11 field staff). Nonparametric tests were used for analysis due to the limited sample size.

Device Training

Participants were given one point per correct answer on the pretraining and posttraining knowledge assessments. The change in these scores was analyzed on SPSS based on demographics of job role, gender, and language competency.

Field Trials

Field notes were coded by user errors and device malfunctions. Descriptive frequencies were obtained. Aggregate counts of errors and malfunctions were analyzed across participant job role, gender, and language competency using a chi-square test of independence (α=.05) on SPSS.

Usability Questionnaire

Descriptive frequencies for Likert response option format and dichotomous questions were obtained. Chi-square goodness-of-fit tests and Wilcoxon signed-rank tests (α=.05) were performed on SPSS to analyze the distribution of responses around a neutral point for Likert-style questions. Dichotomous questions were analyzed using a Fisher exact test (α=.05) on SPSS to determine if there was an association between demographics and user confidence and comfort with the device.

Results

Participants

The sample included 25 participants, including 56% (14/25) laboratory personnel and 44% (11/25) field staff, 52% (13/25) English speakers and 48% (12/25) non-English speakers, and 80% (20/25) men and 20% (5/25) women. Participant education levels ranged from some secondary school to master's degree (Table 1). Participant years working for icddr,b ranged from 2 months to 15 years, and their years of experience in water quality testing ranged from 3 months to 10 years. Participant demographics are further summarized in Table 1.

Table 1. Participant demographics (n=25).

Characteristic	Value, n (%)
Job role	
Field staff	11 (44)
Laboratory personnel	14 (56)
Gender	
Male	20 (80)
Female	5 (20)
Language	
English	13 (52)
Non-English	12 (48)
Education[a]	
Some secondary school	1 (4)
Secondary school	3 (12)
Some university	3 (12)
University	9 (36)
Masters	9 (36)
Years at icddr,b[b]	
<1	5 (20)
1-5	10 (40)
5-10	6 (24)
10+	4 (16)
Years of experience in water quality testing[c]	
<1	6 (25)
1-5	14 (58)
5-10	3 (13)
10+	1 (4)

[a]Questionnaire responses of some primary school, primary school, and PhD removed as no participants indicated these as the highest level of education.

[b]icddr,b: International Centre for Diarrheal Disease Research, Bangladesh.

[c]One participant declined to answer this question, hence 24 total responses.

Device Training

Pretraining and posttraining assessments were conducted with all participants, and assessment answers were analyzed. After the pretraining and posttraining assessments were scored, it appeared that participants were confused by questions 1 and 2 (Multimedia Appendix 1) because these questions were frequently incorrect on both the pretraining and posttraining knowledge assessments. Question 1 assessed recommended PPE use for device trials. A correct answer listed goggles, gloves, and gown. Question 2 assessed steps to collecting and sealing the environmental water sample into the test kit. A correct answer described use of a bulb pipette to fill the test kit's water channel. Participants expressed confusion to the investigator about differences between US and Bangladesh PPE recommendations and the wording of question 2. Thus, assessments were analyzed with and without these questions. To assess knowledge gain, changes in scores from the pretraining and posttraining assessment were analyzed across demographic features. Table 2 demonstrates that the median change in scores between the pretraining and posttraining assessment was positive (ie, scores were higher on the

XSL•FO
RenderX

postassessment) for all groups when analyzed with and without questions 1 and 2 (5 points vs 3 points). Positive changes suggest that participant knowledge pertaining to the necessary steps for sample collection, sample analysis, and biosafety protocols for the OmniVis device use were gained through the training. Similar scores across demographics suggest that participants obtained approximately the same level of overall understanding from the training regardless of job role, gender, or language competency.

Table 2. Change in assessment scores by demographics.

Change in score	Job role		Gender		Language	
	Field staff	Lab personnel	Male	Female	English	Non-English
5 points, median	2	1	2	2	2	2
3 points, median	1	1	1	1	1	1

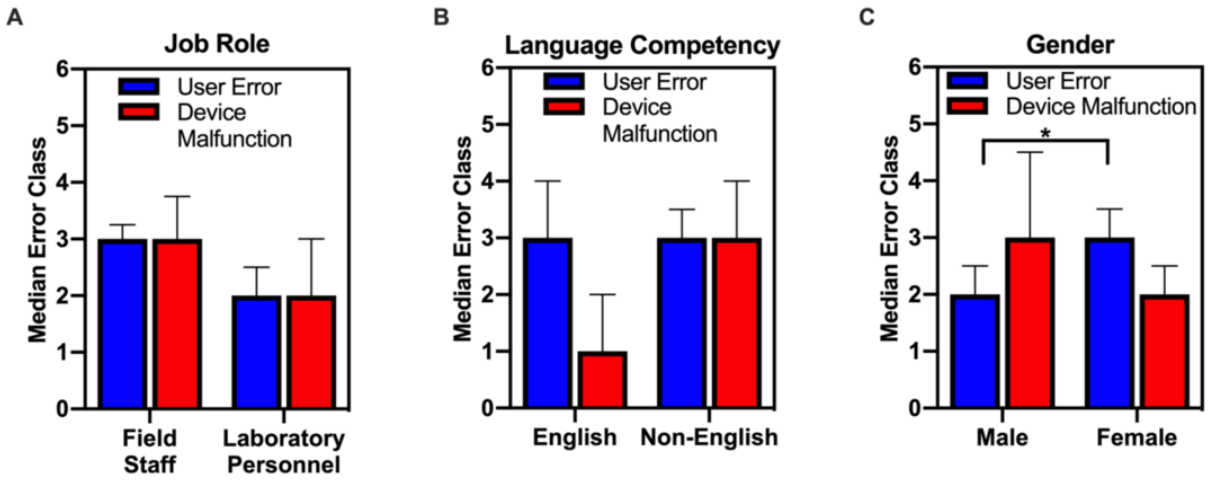
Field Trials

User Errors and Device Malfunctions

Over the course of 25 field trials, 70 user errors and 59 device malfunctions were recorded in total (ie, not per individual user). User errors are defined as improper use of the device dependent on participant actions, and device malfunctions are defined as a failure of the device independent of participant actions. Of the 70 user errors, 21 were unique, and of the 59 device malfunctions, 16 were unique. Unique errors and malfunctions were coded into the categories displayed in Table 3. Unique errors were categorized according to the perception, cognition, action framework for better evaluation [32]. Perception errors occur when users fail to perceive a stimulus (eg, visual or tactile); cognition errors include user memory, rule-based, or knowledge-based failures; and action errors occur when users are unable to act on stimuli (eg, activating a control or applying correct force).

Table 3. Descriptive frequencies of aggregate user errors and device malfunctions.

Error class and type	Value, n (%)	Error category		
		Perception	Cognition	Action
User error (n=70)				
Incorrect tape use	5 (7)		✓	
Incorrect test kit use	12 (17)		✓	
Incorrect app use	11 (16)	✓		
Incorrect test kit insertion into imaging slot	8 (11)	✓		
Failure to perform thumb press	15 (21)			✓
Device powering	19 (27)			✓
Device malfunction (n=59)				
Unresponsive switches	8 (14)			✓
Poor test kit fit	5 (9)			✓
Poor fitting tape	18 (31)			✓
Loss of device power	27 (46)			✓
App closure	1 (2)			✓



Counts of user errors and device malfunctions were compared across job role, gender, and language competency to determine if there was an association between demographics and user errors and device malfunctions. There was a significant association between language competency and error class (χ^2_1=4.2, *P*=.04), suggesting the number of user errors and device malfunctions differed between English and non-English speakers. Comparing aggregate counts across all 25 participants, non-English speakers experienced fewer user errors (non-English=30; English=40) but more device malfunctions than English speakers (non-English=36; English=23).

Further analysis was performed to determine if there was a significant difference in the median number of user errors and device malfunctions per participant according to job role, gender, and language competency (Figure 3). Nonparametric tests were used for analysis because of the limited sample size. To compare the median number of errors across demographics, Mann-Whitney *U* tests (α=.05) were performed. No statistical significance was found for median number of device malfunctions or median number of user errors between field staff and laboratory personnel (Figure 3A) or English and non-English speakers (Figure 3B). Further, no statistical significance was found for the median number of device malfunctions between men and women (Figure 3C). However, there was a statistically significant difference between the median number of user errors per participant between men and women (*U*=20.5, *P*=.04). Although this difference was

XSL•FO
RenderX

statistically significant, the median user errors for men and women differed by only one error per user. Furthermore, the Cramer *V* statistic suggests that the strength of this association is relatively weak (V=0.099). Therefore, this statistically significant yet relatively weak association may be confounded by unequal gender representation in the sample. Because the sample sizes were not equal (men=20, women=5), the median number of user errors by gender and the strength of this association should be evaluated in future studies with larger sample sizes and more equal gender representation.

Figure 3. User errors and device malfunctions compared across demographics. Statistically significant (*P=.04) difference in median user errors between men and women. Errors bars represent semiinterquartile ranges.

Time of Use

Time of use was recorded as the time required for participants to complete one trial of a mock cholera test on the OmniVis device, beginning with picking up the test kit for sample collection and ending with disposing of the test kit in the biohazard bag. Mean time of use was 46:43 minutes (min=41:58; max=53:46). This observed time of use is less than 2 minutes greater than the hypothesized time of use (45 minutes). Compared with current gold standard laboratory methodologies that require nearly 3 days to detect cholera in environmental water samples, this mean time of use demonstrates a substantial reduction in detection time [33].

Usability Questionnaire

Training Evaluation and Device Usability

Ease-of-use questions were formatted as Likert response options. English translation of these questions can be found in Multimedia Appendix 2. Question responses were coded as follows: 1=very difficult/dissimilar, 2=difficult/dissimilar, 3=neither easy/similar nor difficult/dissimilar, 4=easy/similar, 5=very easy/similar. Descriptive frequencies of these questions are shown in Table 4.

The mean and median for each question suggests that participants responded positively to the training components and device features evaluated because these descriptive frequencies are all greater than 3 (neither easy/similar nor difficult/dissimilar). Chi-square goodness of fit tests (α=.05) were performed to determine if question responses significantly differed from a uniform distribution (20% response for each answer choice). Results suggest that responses did not follow a uniform distribution and participants selected certain answer choices more than others (Table 4).

Further analysis was conducted to determine if the median response score for each question in the usability study significantly differed from 3 (neither easy/similar nor difficult/dissimilar), which represents a neutral response. A median response score greater than 3 suggests a positive response, while a response score less than 3 suggests a negative response. Wilcoxon signed-rank tests (α=.05) were performed for each Likert-style question, and results are shown in Table 4. At the 5% level of significance, the median score for each question is significantly greater than 3 (P<.001), suggesting that participants responded favorably to the training session and found the device easy to use overall.

XSL•FO
RenderX

Table 4. Training evaluation and device usability chi-square goodness of fit and 1-sample Wilcoxon signed-rank tests.

Question topic	Minimum	Median	Maximum	Chi-square value[a]	Chi-square significance	1-Sample Wilcoxon signed-rank significance[b]
Training session	3	4	5	19.2	0.001	0
Sample collection training	2	4	5	34.4	0	0
Sample seal training	2	4	5	20.0	0	0
Assembly training	2	4	5	22.0	0	0
Operate training	3	4	5	23.2	0	0
Assembly	2	4	5	20.0	0	0
Screen prompts	3	4	5	33.6	0	0
Words read	3	4	5	42.8	0	0
Color change	2	4	5	33.2	0	0
Interface similarity	2	4	5	25.6	0	0
Water collection	3	4	5	29.6	0	0
Water sample seal	3	4	5	25.6	0	0
Test kit insertion	2	4	5	15.6	0.004	0
Results read	4	4	5	42.4	0	0
Data transfer	3	4	5	42.8	0	0
Disassemble	2	4	5	29.2	0	0

[a]No cells (.0%) have expected frequencies less than 5. The minimum expected cell frequency is 5.0. Degrees of freedom for all chi-square goodness of fit tests are 4.0.

[b]Asymptotic significances are displayed for 1-sample Wilcoxon signed-rank tests. The significance level is .05.

User Confidence and Comfort

Nine dichotomous questions were designed to evaluate participant confidence and comfort using the OmniVis device. English translation of these questions can be found in Multimedia Appendix 2. Descriptive frequencies are displayed in Table 5.

Table 5. Descriptive frequencies of dichotomous questions.

Question topic	Value, n (%)	
	No	Yes
Effective test	0 (0)	25 (100)
Confidence	1 (4)	24 (96)
Device size for transport	0 (0)	25 (100)
Device size for use	0 (0)	25 (100)
Safety in the field	3 (12)	22 (88)
Safety in public	6 (24)	19 (76)
Durability	5 (20)	20 (80)
Proximity to water source	6 (24)	19 (76)
Functions	3 (12)	22 (88)

For each dichotomous question, the majority of participants responded yes, suggesting they are confident and comfortable in their ability to use the device. Participants responded most favorably to the device's size and ability to effectively test the water sample, as indicated by the 100% yes responses. Participants expressed the least confidence and comfort in using the device in public and close to a water source, as 24% of participants answered no to these questions.

Dichotomous question responses were evaluated with Fisher exact tests (α=.05) to test for significant associations according to demographics. Statistical analysis for usability questions "Can you effectively test the water sample with the device?" "Would the device's size be conducive to transporting it in the field or lab?" and "Would the device's size be conducive to using it in the field or lab?" were excluded because 100% of participants responded yes to these questions. The only statistically significant result found was between gender and

XSL•FO
RenderX

participant response to the question "Is the device durable enough to use in the field or lab?" (χ^2_1=6.25, *P*=.04). Of the female participants, 60% (3/5) responded that the device would not be durable enough to use in the field or lab while only 10% (2/20) of male participants gave the same response. Because the frequency difference between gender responses is minimal (3 female participants vs 2 male participants), these results may be confounded by a small sample size and unequal distribution of genders in the sample.

Discussion

Principal Findings

This study evaluates the usability of the OmniVis rapid cholera detection device with targeted end users in Dhaka, Bangladesh. Despite the importance of evaluating usability, many mHealth technologies fail to undergo such evaluations and subsequently fail to scale [12,27]. While many rapid pathogen detection technologies have undergone validity analyses, there is a literature gap of usability analyses for such technologies [14-18]. Many usability studies instead evaluate technologies that aid interventions such as behavioral change, treatment adherence, or clinical decision making [23-26]. Thus, this study can serve as a model of iterative convergent mixed methods research design for device development to further promote usability analysis of rapid pathogen detection technologies and produce rapid detection devices that better fit into user workflows for increased uptake. These results contribute to the iterative prototyping process of the OmniVis device, helping the device to achieve scale and contribute to cholera environmental surveillance. The device trials measured the effectiveness and efficiency of the device by defining common user errors and device malfunctions while also evaluating the length of time required to complete one test. The usability questionnaire elucidated water quality workers' satisfaction with the device with questions regarding ease of use about specific components of device training and use. The questionnaire also evaluated user confidence and comfort in using the device in various settings.

Although device training was not a specific objective of this study, it was necessary to provide uniform training to participants to ensure equal knowledge of the device prior to conducting trials, and thus, minimize confounding variables. Pretraining and posttraining knowledge assessments were administered to detect if poor understanding of training confounded device trial and usability questionnaire results. Overall, participant knowledge increased as a result of the training, as demonstrated by the positive median change in scores across demographics. The only poorly understood competency was proper PPE use. Participants frequently answered question 1 ("What 3 pieces of PPE must you put on before collecting a water sample?") incorrectly by listing different pieces of PPE other than those required by the knowledge assessment. Thus, this error suggests participants are accustomed to different PPE rather than a lack of understanding of the purpose of PPE. Nevertheless, confusion detected in assessment questions 1 and 2 indicate that the training component of this study must be reformed in order to better instruct users how to operate the device for accurate widespread use.

The objective of the device trials was to identify common user errors and device malfunctions in order to correct these errors and malfunctions in subsequent iterations of the device. Results from these device trials suggest that common user errors center around incorrect test kit use when moving from the heating to imaging phases and device powering (Figure 2, Table 3). Common device malfunctions included loss of device power and poorly fitting tape (Table 3). There was a significant association between language competency and error class in which non-English speakers experienced fewer user errors and more device malfunctions than English speakers. Because device malfunctions are defined as failures of the device independent of the participant's actions, this association likely has a temporal confounding variable. Field staff represented a large proportion of non-English speakers in this study. Since all field staff performed their trials on the same day (trials numbers 9 to 19), device malfunctions likely resulted from previous use. For example, the 8 previous trials (trials numbers 1 to 8) likely contributed to decreased battery life, which resulted in more device malfunctions in subsequent trials and contributed to the association between non-English speakers and device malfunctions. These errors elucidate tangible improvements for future device iterations, including removal of the test kit insertion stage and redesign of device powering to make the device effective and usable in field settings.

Additionally, user errors and device malfunctions were analyzed quantitatively to determine if any particular demographic experienced errors at a higher frequency than others. By considering ease of use across demographics, device development will promote equity and accessibility to all, which is critical for widespread use in low-resource settings. The difference in median user errors for men and women was statistically significant but found to have a relatively weak association (Figure 3). Although the proportion of women in the sample was quite low, such analysis provided a gender lens to ensure that the device is not designed more favorably for men or women but rather equally usable by all genders. While there were only 5 women participants in this research, our initial studies warrant further investigation to compare error frequency between men and women in future studies. There were no statistically significant differences in median user errors or device malfunctions per participant when comparing field staff and laboratory personnel or English and non-English speakers. These results suggest that device usability is not biased according to job role or language competency.

Device trials were also used to evaluate the claim that the OmniVis device can detect toxigenic *V cholerae* in an environmental water sample in 45 minutes or less. Time-of-use data suggests that the true median test time is likely greater than 45 minutes, at an average of 46 minutes and 43 seconds. However, no participant required more than 1 hour to complete the test, suggesting that the device dramatically reduces the time required to detect toxigenic *V cholerae* in an environmental water sample. By reducing the time required to determine the presence or absence of cholera in water sources, the OmniVis device can contribute to rapid detection, early warning, and

XSL•FO
RenderX

environmental surveillance of cholera in water sources—methods defined as pivotal for cholera control and elimination [10].

Usability questionnaire results clearly demonstrate that participants perceived the device use positively. Questions regarding training ease of understanding and device ease of use had median scores greater than 3, suggesting participants had positive responses (Table 4). Moreover, participants frequently responded yes to dichotomous questions, suggesting participants expressed confidence and comfort in using the device independently (Table 5). Participants responded most favorably to the device's size and its conduciveness to transport and use in the field or lab. However, safety and durability concerns were noted. Women expressed greater concern for the durability of the device in the field (P=.04). Although the difference was not significant, field staff expressed increased concern for using the device in public (P=.06). Because field staff collect environmental water samples in public more than laboratory personnel do, they could have increased concern about publicly using an expensive device, namely an iPhone, in low-resource areas or near water sources. These concerns prompt reevaluating the use of an iPhone as opposed to a lower cost mobile platform in future iterations because safety concerns could be a barrier to uptake in this population of targeted end users.

Limitations

Limitations of this study include sample size and testing conditions. The study involved only 25 participants, all of whom were employed by icddr,b. All reported a relatively high level of education and training. Participants represented targeted end users in Bangladesh but not all cholera-endemic countries, making the generalizability of the findings for other countries limited, but the intent of the study was to apply the findings to the OmniVis device rather than generalizing results to the population of water quality workers. In this sense, the findings provide insight into the usability of the device. In addition, only 5 women were included in the sample size. Efforts were made to include as many women as possible to achieve equal gender representation, but the sample still comprised an unequal gender distribution. The small sample size also limited the ability to pilot the pretraining and posttraining knowledge assessment and questionnaire (doing so would have depleted the available sample size). Although the questionnaire was based on the Poststudy System Usability Questionnaire, significant adaptations were made to apply the questionnaire to this study. Without such pilots, the reliability and validity of the knowledge assessment and questionnaire could not be evaluated. Additionally, field trials were completed with demonstration test kits that lacked the correct chemistry to complete a pathogen detection test. Because these demonstration test kits had to be reused in subsequent trials, environmental water samples were mimicked with deionized water. Thus, the conditions under which the device was evaluated do not perfectly mirror real testing conditions.

Conclusion

World public health authorities have called for the evaluation of mHealth technologies in order to improve their ability to achieve scale [21]. This usability study is the first step in gaining feedback from targeted end users on the effectiveness, efficiency, and satisfaction of the OmniVis device. By employing an iterative convergent mixed methods design, this study collects user insights into device development and incorporates targeted end user attitudes and perceptions into the development of the OmniVis device [34]. Such methodology increases the likelihood of user uptake of the rapid pathogen detection technology, further contributing to environmental surveillance efforts [27]. The study demonstrated that a portable cholera detection test can be completed in less than 1 hour (mean time of use=46:43 minutes), which is a significant time reduction from the current laboratory protocol [33]. Participants responded positively to the device training and found the device easy to use at each phase of the testing process. Moreover, participants expressed confidence and comfort in using the device independently. While these results are promising for the this prototype, concerns over durability and safety require addressing in subsequent prototypes, particularly across various demographics. Future device iterations can include removing the test kit insertion stage, redesigning device powering, and adapting to a less-expensive mobile platform. Ultimately, this study will help OmniVis further develop the rapid cholera detection device so the device can better contribute to environmental surveillance efforts for cholera control and elimination. Newer generations of the OmniVis device will undergo larger user-centered trials in additional low-resource settings such as field settings in Kenya and Haiti. These studies will provide more feedback as the device is tested in different cultural and language profiles. In addition to advancing OmniVis device development, this study also promotes a feasible methodology for evaluating the usability of rapid pathogen detection technologies. Usability evaluations will help more mHealth and point-of-use environmental surveillance devices achieve scale, integration, and interoperability to further efforts to control, eliminate, and eradicate communicable diseases.

Acknowledgments

The authors would like to thank Dr Miguel Morales for his mentorship leading up to this study and Dr Michelle Ngai for her helpful discussions. Further, we would like to show our gratitude to Mr Jordan Florian for his support and discussions in preparation for the study in Dhaka, Bangladesh, and Mr Dong Hoon Lee for device assembly and preparation. We would like to acknowledge Grand Challenges Canada (grant R-HGC-POC-1803-22784) and the Asmuth Family Foundation Fellowship for their gracious funding of this work. This research study was also funded by core donors who provide unrestricted support to icddr,b for its operations and research, including the governments of Bangladesh, Canada, Sweden, and the United Kingdom. We gratefully acknowledge our core donors for their support and commitment to icddr,b's research efforts.

Authors' Contributions

TLR had full access to all the data in the study and takes responsibility for the integrity of the data and accuracy of the data analysis. TLR and KNC conceived and designed the study. TLR acquired, analyzed, and interpreted the data and drafted the manuscript. Critical revision of the manuscript was provided by CK and KNC. CK, WAK, SA, ZHM, and KNC provided administrative, technical, or material support. KNC also provided supervisory support.

Conflicts of Interest

KNC is a cofounder and full-time employee of OmniVis Inc. The other authors have no conflicts to declare.

Abstract

Background: There is growing interest in identifying and recruiting research participants from health systems using electronic health records (EHRs). However, few studies have described the practical aspects of the recruitment process or compared electronic recruitment methods to in-person recruitment, particularly across health systems.

Objective: The objective of this study was to describe the steps and efficiency of the recruitment process and participant characteristics by recruitment strategy.

Methods: EHR-based eligibility criteria included being an adult patient engaged in outpatient primary or bariatric surgery care at one of 5 health systems in the PaTH Clinical Research Network and having ≥2 weight measurements and 1 height measurement recorded in their EHR within the last 5 years. Recruitment strategies varied by site and included one or more of the following methods: (1) in-person recruitment by study staff from clinical sites, (2) US postal mail recruitment letters, (3) secure email, and (4) direct EHR recruitment through secure patient web portals. We used descriptive statistics to evaluate participant characteristics and proportion of patients recruited (ie, efficiency) by modality.

Results: The total number of eligible patients from the 5 health systems was 5,051,187. Of these, 40,048 (0.8%) were invited to enter an EHR-based cohort study and 1085 were enrolled. Recruitment efficiency was highest for in-person recruitment (33.5%), followed by electronic messaging (2.9%), including email (2.9%) and EHR patient portal messages (2.9%). Overall, 779 (65.7%) patients were enrolled through electronic messaging, which also showed greater rates of recruitment of Black patients compared with the other strategies.

Conclusions: We recruited a total of 1085 patients from primary care and bariatric surgery settings using 4 recruitment strategies. The recruitment efficiency was 2.9% for email and EHR patient portals, with the majority of participants recruited electronically. This study can inform the design of future research studies using EHR-based recruitment.

Introduction

Background

Recruitment of patients for research using electronic health records (EHRs) has potential to enhance the applicability and efficiency of patient-centered research [1,2]. Despite logistical and ethical challenges with recruiting for research using clinical data sources (eg, EHRs) or clinical communication methods (eg, EHR patient portals) [3], researchers are developing strategies that are responsive to both health system and patient stakeholders [4]. In addition, there is interest in designing research studies that include "real-world evidence" (ie, health care information representative of patients, populations, and health care delivery systems from actual clinical settings [5,6]).

In 2014, the National Patient-Centered Research Network (PCORnet) was launched with funding from the Patient-Centered Outcomes Research Institute (PCORI). PCORnet's infrastructure can support EHR-based recruitment and study implementation [7]. The PaTH Clinical Research Network (CRN) originally brought together 4 academic medical centers in the mid-Atlantic region of the United States to build the infrastructure to share EHR data across health systems so that patient-centered clinical questions could be answered in real-world settings [8]. A fifth academic health center (Geisinger Health System) was added to the network in 2015.

Using EHR data from these 5 health systems, standardized to PCORnet specifications [9], we developed a cohort of primary care and bariatric surgery patients called the "Healthy Lifestyles, Body Weight, and Health Care" cohort. The overall aim of the cohort was to complete online surveys about quality of life, healthy lifestyles, and weight management, which could be linked to selected EHR data. Another explicit goal of the CRN was to utilize several different recruitment methods in order to compare sample demographics and survey response rates by recruitment strategy. In this paper, we describe the enrollment process and then compare 4 different recruitment strategies: (1) in-person recruitment by study staff from clinical sites, (2) US postal mail recruitment letters, (3) secure email, and (4) direct EHR recruitment through secure patient web portals. The objective of this paper was to describe the steps and efficiency of the recruitment process and participant characteristics by strategy.

Methods

Institutional review board approval was obtained from PaTH's single institutional review board at The Johns Hopkins University School of Medicine, Baltimore, Maryland. We benefitted from the input of patient stakeholders in the design of the recruitment methods and online survey. Participants who enrolled in this study were not offered any compensation.

EHR-Based Participant Eligibility Criteria

We recruited adult patients from primary care and bariatric surgery clinics to complete surveys and form an EHR cohort from 5 health care systems included in the PaTH CRN—Geisinger Health System, Johns Hopkins Health System, Penn State Milton S. Hershey Medical Center, Temple Health System, and the University of Pittsburgh Medical Center. We identified participants using EHR-based eligibility criteria (ie, the "computable phenotype"). Eligible patients were aged ≥18 years and had a minimum of 2 weight measurements and 1 height measurement recorded between January 1, 2011, and May 31, 2015. Patients in all BMI categories were eligible. Participants were excluded if they were deceased or non–English proficient, as assessed at the time of consent, because the consent form and survey were only available in the English language.

Participant Recruitment and Setting

Each health system used one or more of the following 4 EHR-based research invitation strategies: (1) in-person recruitment by study staff from partnering outpatient primary care and bariatric surgery clinics; (2) US postal mail recruitment invitation letters using the mailing address listed in the EHR, with an online registration link contained in the invitation; (3) email to potentially eligible participants using the email address stored in the EHR, with an embedded registration link in the email; and (4) secure EHR recruitment messages through the patient web portal with an embedded registration link.

Each health system tailored its own strategy to recruit participants from the large pool of potentially eligible patients identified using the computable phenotype. At each site, local norms for integrating research with clinical practice were followed, leading to differences in the number of patients approached by each strategy per site. Importantly, each site's study team partnered with specific clinical practices so that recruitment letters were jointly sent from clinical representatives involved in the patients' care and members of the research team and focused on patients from certain practices. Notably, 2 health systems used direct EHR recruitment through secure patient web portals (sites C and D), while 1 site (site B) was unable to use email because email address was not a data field within the EHR. The content of the recruitment letters and in-person scripts had similar language across all health systems and recruitment strategies.

Each health system had a slightly different recruitment window, but the total recruitment window for all sites was from April 2015 to November 2016. We stopped the recruitment when we met or exceeded the a priori goal of recruiting 1000 participants.

Consent and Enrollment Process

Regardless of the recruitment strategy or method used to complete the baseline survey, all participants completed a web-based consent form, including an initial "consent quiz" designed to ensure that patients understood that they were

XSL•FO
RenderX

agreeing to participate in a research study. Participants consented to complete online surveys and for the research study to access their EHR. Enrollment was determined by consenting and having any data entered into the baseline survey. Participants who were recruited in person used an electronic tablet to access the consent form and complete the baseline survey. For participants recruited through the EHR patient portal, the survey was embedded in the EHR, which required that it had to be completed and "submitted" in order to be accessible and counted as enrolled. We created an enrollment flag in the EHR to identify participants who were enrolled in the cohort study.

Data Collection

Participants completed a baseline survey about sociodemographic background, weight management practices, weight-related interactions with the health system, diet, physical activity, and quality of life using standard survey measures [10-12].

We extracted EHR data (eg, laboratory values, blood pressure, anthropometric measurements, diagnosis, and procedure codes) from each site's PCORNet Common Data Model for all enrolled participants [7,13]. The EHR and survey data were linked for analysis.

Statistical Methods

For this paper, we were primarily interested in describing the patterns of enrollment by recruitment modality, study site, and participant characteristics.

Anthropomorphic data were cleaned to remove unlikely values (eg, BMI ≤15 kg/m^2 or ≥90 kg/m^2; height ≤4 ft or ≥7 ft; weight ≤50 lbs or ≥700 lbs) prior to analyses. We identified the BMI in the EHR data closest to the enrollment date, within a maximum of 3 years, and used a 5-year window to determine comorbidity diagnoses based on International Statistical Classification of Diseases and Related Health Problems codes [14].

We used descriptive statistics (means and standard deviations for continuous measures, frequencies and proportions for nominal measures) to examine differences between the large pool of participants deemed eligible using the computable phenotype and those who enrolled in the study. We defined the "efficiency" of each recruitment strategy as the proportion of the total numbers of participants who enrolled divided by the total number of participants who were approached by the strategy (eg, total enrolled via email divided by total who were sent the email). We performed ANOVA *F* tests and chi-square tests (or Fisher exact tests, where appropriate) to determine if participant characteristics varied by recruitment modality. Because the 5 health systems preferentially designed and utilized different recruitment modalities, we were not able to assess predictors of enrollment by modality using regression models because of complete collinearity by study site. Two-sided $P \leq .05$ was considered statistically significant. Analyses were performed using SAS statistical software (version 9.4; SAS Institute).

Results

Figure 1 shows the enrollment steps and efficiency of enrollment into the cohort by recruitment modality. We identified 5,051,187 eligible patients using the computable phenotype applied to the EHRs from 5 health systems. Based on each health systems' own method of partnering with clinics and recruiting participants, a total of 40,048 patients (33,839 patients from primary care clinics and 6209 patients from bariatric surgery clinics) were then sent recruitment messages or approached in person. Across all sites, the patient recruitment strategies were deployed as follows: 442 (1.1%) patients in person; 12,710 (31.7%) patients by postal mail; 25,224 (63.0%) patients by email; and 1672 (4.2%) patients by EHR patient portals. A total of 1185 participants were enrolled in the cohort, with 907 (76.5%) from primary care practices and 278 (23.5%) from bariatric surgery practices. The efficiency of enrollment by recruitment strategy was by far the highest for in-person recruitment (148/442, 33.5%), followed by email (730/25,224, 2.9%) and EHR patient portal (49/1672, 2.9%), with postal mail being least efficient (258/12,710, 2.0%). Overall, 65.7% (779/1185) were enrolled through electronic messaging (email or EHR portal).

Figure 1. Recruitment flow of participants enrolled into the cohort from 5 health systems using 4 recruitment strategies. EHR: electronic health record.

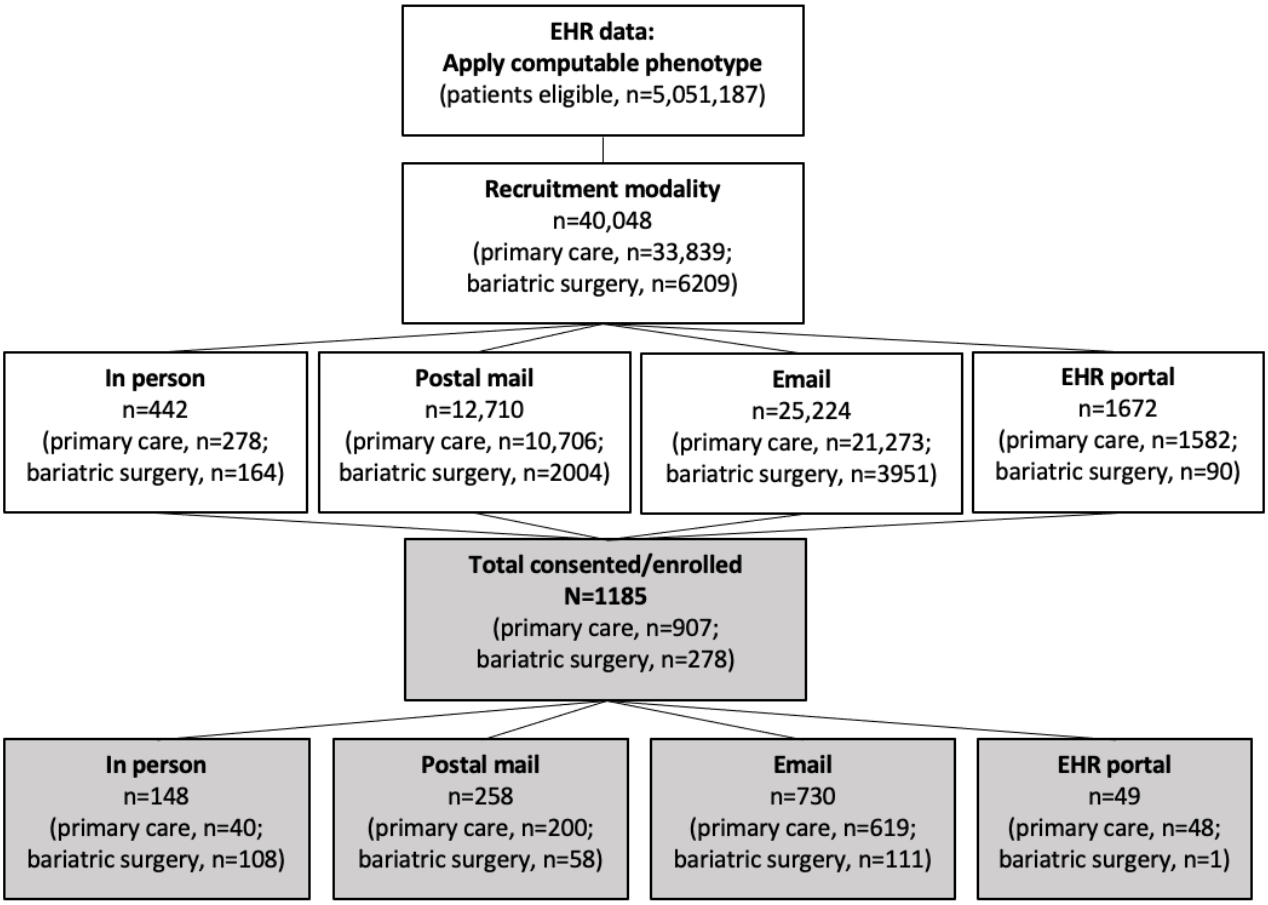

Table 1 compares the demographics and medical conditions between the 1185 participants enrolled in the cohort from primary care and bariatric surgery clinics and the 5,051,187 total patients deemed potentially eligible based on the application of the computable phenotype to their EHRs. Compared with all eligible participants, enrollees were older (aged 58.1 years in primary care clinics and 56.5 years in bariatric surgery clinics versus 43.6 years among all eligible). The bariatric surgery group had the highest proportion of women (207/278, 74.5%) compared with primary care (595/907, 65.6%) and all eligible patients (2,778,178/5,051,187, 55.0%). The proportion of Black individuals among the enrolled patient groups was smaller than that among all patients deemed eligible (81/907, 8.9% enrolled in primary care and 27/278, 9.7% in bariatric surgery versus 558,125/5,051,187, 11.1% from all patients deemed eligible). Overall, very few Hispanic participants were enrolled (14/907, 1.5% in primary care and 1/278, 0.4% in bariatric surgery) compared with the number of Hispanic individuals among the health systems' eligible participants (127,045/5,051,187, 2.7%). Information regarding level of education was not available for nonenrolled patients; in those enrolled from either primary care or bariatric surgery clinics, more than 85% of participants had at least some college education. The mean BMI was highest for the patients from bariatric surgery clinics (34.3 kg/m^2), followed by the patients from primary care clinics (30.2 kg/m^2) and the total population of eligible patients (28.3 kg/m^2). A high proportion of enrollees had hypertension (507/1185, 42.8%) and diabetes (232/1185, 19.6%), but these conditions were even more common among the large sample of eligible patients who were not enrolled (689,925/5,051,187, 52.1% with hypertension and 407,036/5,051,187, 30.7% with diabetes).

Discussion

This study reports the experience of the PaTH CRN's recruitment of patients from primary care and bariatric surgery clinics from 5 health systems into a study cohort. Even though the in-person recruitment had the greatest efficiency (33.5%), this strategy required research staff to identify when patients had upcoming appointments and to be available on site.

XSL•FO
RenderX

Ultimately, only 442 patients were approached in person and 148 enrolled. The majority of participants were recruited using email (730/1185, 61.6%). Although email recruitment required less staff research time, this strategy was limited by having patients' email addresses recorded and available in the EHRs. The secure patient portal was a strategy employed by 2 health systems and had a recruitment efficiency comparable to email (2.9% of those who received a message enrolled in the study). The electronic recruitment strategies may be particularly desirable during times when research staff cannot be present in the clinic, such as under COVID-19–related restrictions.

Traditionally, researchers have relied on postal mailings, newspaper or radio advertising, or random-digit dialing methods for survey-based research as well as for recruitment into clinical trials [15]. EHRs provide an avenue for screening and then directly targeting recruitment at potentially eligible patients for research studies [4,15]. Recruitment of patients from EHRs has the potential to be more inclusive by including patients who might be sicker and those who are undergoing care in real-world health care systems [5,16]. However, no method of recruitment is without the potential for selection biases. With EHR-based recruitment, there are concerns about external validity or generalizability to nonpatient or health care populations, particularly for prevention-oriented studies [17]. In addition, patients with reduced access to care or those who are not regularly followed in the health care setting may be less likely to be approached in person (ie, at the time of a clinic visit) or to receive recruitment messages when they do not have an email address or access the patient portal. While 90% of US adults now use the internet, older adults and Black citizens still show lower rates of internet access [18], but technology usage rates are increasing [19]. A recent study by Walker and colleagues [18] showed that fewer Black patients and patients over the age of 70 had access to an inpatient portal. Notably, in our study, which used a combination of recruitment strategies, approximately 9% of enrolled participants identified as Black compared with 11% among patients identified as potentially eligible. In fact, researchers could leverage the EHR to specifically target patient populations by demographics or medical diagnosis (eg, by race, ethnicity, age, or rare health conditions [20,21]).

Despite the increasing need for effective and less staff-intensive methods of recruitment for clinical trials and surveys, few studies have compared recruitment strategies [22,23]. One study reported and compared response rates from various recruitment methods (postal survey, postal invitation to complete an internet survey, and postal invitation for a telephone survey) for an environmental survey but did not include EHR-based recruitment methods [23]. The study showed the highest response rate (30%) for the telephone survey [23]. The EHR provides a new way to identify potential participants for research studies by applying electronic eligibility criteria to sometimes very large pools of potentially eligible patients [24].

A systematic review by Lai and Afseth [25] assessed the effectiveness and efficiency of EHR-based recruitment methods. They identified 13 articles, of which 11 reported recruitment efficiency and most used alerts sent directly to physicians or staff to notify of participant eligibility [25]. EHRs have multiple functionalities to support recruitment [26]. In our study, we utilized the EHR for several purposes: to generate lists of potentially eligible patients using a computable phenotype, to obtain postal mailing addresses and email addresses, and to send recruitment invitations using the secure patient portal at 2 sites. Some academic research centers have designed patient portal recruitment services to enable, but also limit, recruitment using the portal for certain approved studies [1,21,27,28]. In a 2019 single-institution study that included 13 separate EHR-based recruitment strategies using the patient portal recruitment service, the average response rate for patient portal messages was 2.9%, which was the same as our enrollment rate for both email and patient portal recruitment [21]. Interestingly, we offered no compensation to patients to enroll in our study, yet the studies reviewed by Miller et al [21] did offer compensation.

Although the computable phenotype enabled our teams to identify a very large number of patients who were potentially eligible, each health system designed its own outreach methods to patients by targeting specific clinical sites, thereby greatly reducing the potential number of patients that could have been contacted about this research opportunity. Importantly, institutional review boards at each site prohibited the "cold calling" of patients (ie, directly contacting potential research participants based on prior knowledge of the patients' health information in the absence of a treatment or clinical relationship [29]). Therefore, each site partnered with primary care and bariatric surgery providers, who approached the patients about the study first, either with their signature on the recruitment invitation or through an in-person introduction. However, a recent landscape analysis by McHugh and colleagues [29] highlighted that this universally applied "ban on cold calling" could impose a gatekeeping function and potentially reduce patient autonomy, decreasing access to research and risking the introduction of selection bias into research studies. They suggested alternative approaches to ensuring patient privacy [29], with the goal of broadening access to health research participation [15].

We identified several limitations of this study. First, this was a 5-center, multisite study and the deployed recruitment strategies were dependent on the norms for research recruitment at each site, with the implication that not all samples were directly comparable by site or by strategy. For example, 3 sites did not allow research recruitment using the EHR patient portal and 1 site did not have access to email addresses in the EHRs. Because of the differences in clinical populations' demographics between sites, there was high correlation between the site's choice of recruitment methods and the patients who were recruited, limiting our ability to draw conclusions about whether specific recruitment modalities are more (or less) effective for specific racial/ethnic groups or different age categories. Second, the overall response rate was low; however, it is very comparable to response rates from other studies that relied on EHR-based or email-based recruitment. We were able to assess for selection biases by comparing those patients who were deemed eligible with those who enrolled in the study. We showed lower uptake among Latinx patients, but this was in part because the consent and survey were limited to participants able to read in English.

XSL•FO
RenderX

Third, although this study was low burden for participants, as they consented to having the research team review medical records and complete a 20-minute online survey, we did not offer any compensation for their time, which could have limited enrollment. Therefore, we are not able to draw conclusions about how effective our recruitment strategies would be for more intensive studies, for studies not using online data collection, or for studies offering participant incentives. Fourth, we were unable to estimate cost or cost-effectiveness of the recruitment strategies or describe in detail the staffing time or corresponding resources involved for each health system, such as the effort for the health informatics team to support EHR-based research or the time for research staff to conduct in-person clinic-based recruitment. Fifth, recruitment for this study occurred approximately 4 years ago (2015-2016) and it is possible that response rates and methods for electronic recruitment have improved over time. Sixth, the 5 health systems were all based in the mid-Atlantic region of the United States, which could limit the generalizability of these findings to other regions of the country and outside the United States.

The major implication of our study is to inform the selection of recruitment strategies for the design of future cohort studies, utilizing the capabilities of the modern-day EHR system. We anticipate that other researchers could find this information useful in the design of their recruitment strategies and to estimate the expected yields from "low touch" strategies that require less personnel contact with potential participants. As health systems and institutional review boards become more comfortable and familiar with EHR-based recruitment, it will be possible to achieve greater consistency between the recruitment processes and even sample selection to reduce biases across systems. Ultimately, to facilitate EHR-based research across multiple settings (eg, inpatient and ambulatory), large health systems will need to invest in infrastructure to support and link smaller clinical centers and subsidize their use of a common EHR. An example of a successful academic and community-based network is the OCHIN network, which provides a research infrastructure using EHR data from a national network of smaller community health centers [30].

In conclusion, we recruited a total of 1085 patients from primary care and bariatric surgery clinics to complete a survey and participate in an EHR-based cohort study using 4 recruitment methods. The greatest recruitment yield was achieved using the email-based method, but the greatest efficiency resulted from in-person recruitment. Implementation of low-resource recruitment approaches has important implications for future patient-centered studies in health system settings.

Abstract

Background: With the ever-expanding interconnectedness of the internet and especially with the recent development of the Internet of Things, people are increasingly at risk for cybersecurity breaches that can have far-reaching consequences for their personal and professional lives, with psychological and mental health ramifications.

Objective: We aimed to identify the dimensional structure of emotion processes triggered by one of the most emblematic scenarios of cybersecurity breach, the hacking of one's smart security camera, and explore which personality characteristics systematically relate to these emotion dimensions.

Methods: A total of 902 participants from the United Kingdom and the Netherlands reported their emotion processes triggered by a cybersecurity breach scenario. Moreover, they reported on their Big Five personality traits, as well as on key indicators for resilient, overcontrolling (internalizing problems), and undercontrolling (aggression) personality types.

Results: Principal component analyses revealed a clear 3-dimensional structure of emotion processes: emotional intensity, proactive versus fight/flight reactions, and affective versus cognitive/motivational reactions. Regression analyses revealed that more internalizing problems (β=.33, *P*<.001), resilience (β=.22, *P*<.001), and agreeableness (β=.12, *P*<.001) and less emotional stability (β=–.25, *P*<.001) have significant predictive value for higher emotional intensity. More internalizing problems (β=.26, *P*<.001), aggression (β=.25, *P*<.001), and extraversion (β=.07, *P*=.01) and less resilience (β=–.19, *P*<.001), agreeableness (β=–.34, *P*<.001), consciousness (β=–.19, *P*<.001), and openness (β=–.22, *P*<.001) have significant predictive value for comparatively more fight/flight than proactive reactions. Less internalizing problems (β=–.32, *P*<.001) and more emotional stability (β=.14, *P*<.001) and aggression (β=.13, *P*<.001) have significant predictive value for a comparatively higher salience for cognitive/motivational than affective reactions.

Conclusions: To adequately describe the emotion processes triggered by a cybersecurity breach, two more dimensions are needed over and above the general negative affectivity dimension. This multidimensional structure is further supported by the differential relationships of the emotion dimensions with personality characteristics. The discovered emotion structure could be used for consistent predictions about who is at risk to develop long-term mental well-being issues due to a cybersecurity breach experience.

Introduction

Background

The increasing number of Internet of Things devices (IoT) and their diverse application in private and work lives offer unlimited possibilities for a connected life. However, this has also extended the scope of security breaches and cybercriminal behavior [1]. As cyberattacks became more and more focused on specific companies and individual users [2,3], they increasingly create technological, economic, social, and psychological challenges. Because of the deep penetration of IoT in personal lives, cybersecurity breaches on such devices can have far-reaching personal consequences. Work and livelihood can be disturbed, personal and social spheres can be altered, and these changes can sometimes be irrevocable. The most direct psychological effects of such events, which are intrinsically relevant to the personal goals of the user, are the emotional responses they elicit [4,5]. A leading security company reported that negative emotions including anger, annoyance, frustration, upset, and a feeling of being cheated are the common reactions to being a victim of cybercrime [6]. These emotional experiences could develop into long-term, far-reaching psychological turmoil [7-10]. Despite their central role in psychological well-being, very little is known about emotional reactions in the context of cybersecurity breaches. In this study, we (1) explore victims' emotion processes by employing a scenario study with a cybersecurity breach on a smart security camera, which is one of the most telling examples of invasion of privacy by unauthorized entrance in the private sphere [11,12], (2) explore which personality characteristics predict interindividual differences in emotional reactions to this cybersecurity breach; and (3) designed the explorative research in such a way to generate replicable findings.

Emotion Processes

In emotion research, participants are often asked to report on their own emotions by evaluating emotion and affect terms (eg, the frequently used Positive and Negative Affect Schedule [PANAS] [13]). While this type of research can generate very interesting findings, it does not allow researchers to unearth the emotion processes these affect terms refer to. To get a comprehensive view of the emotion processes that can be elicited by cybersecurity breaches, emotions are currently studied on the basis of the componential emotion approach [14]. This approach has emerged as an overarching conceptual framework within the scientific field of emotion research. According to this approach, emotions are conceptualized as processes that are elicited by goal-relevant events and consist of an interplay between 5 major components: appraisals, action tendencies, bodily responses, expressions, and subjective feelings [5]. Each component has a function. Appraisals are the evaluation of the eliciting event against one's goals, needs, and values. Action tendencies refer to the preparation and direction of adaptive action. Bodily responses refer to physiological changes that prepare the body for actual action. Expressions are the facial, vocal, and gestural reactions through which the ongoing emotion process is communicated. Through subjective feelings, the individual becomes aware of the ongoing emotion process. These feelings are often communicated with the use of emotion and affect terms. Moreover, emotion processes are evolutionary-shaped processes that have evolved from reflex-like reactions to dynamic processes open to regulation [5,14]. All aspects of the emotion process can be regulated, from the impulsive reactions to the cognitive evaluations. Having flexible emotion processes allows us to better adapt to our environment [15].

This componential emotion approach is especially promising for studying emotional experiences, as it has been demonstrated across cultural and linguistic groups that the 5 components, as well as regulation are encoded in daily language. First in 3 samples from the United Kingdom, Switzerland, and Belgium [16] and later in 31 additional samples from 24 countries and representing 20 languages (such as Chinese and Japanese) [14], it was demonstrated that 142 emotion features representing the 5 emotion components and regulation systematically constitute the meaning of 24 frequently used emotion terms [14]. The componential emotion approach forms not only a comprehensive theoretical framework but also represents how people naturally think and talk about their emotions.

Thus, to fully understand emotion dynamics, it is important to go beyond feeling and emotion terms and study all emotion components and regulation processes. In this study, the dimensions that structure the emotion processes elicited by a cybersecurity breach of a smart security camera are exploratively identified by taking all emotion components as well as regulation into account.

Person Characteristics and Emotional Reactions

To better understand the emotion dimensions involved in this scenario, we evaluate whether and how characteristics of personality are related to the reported emotional experience. To this end, we have worked with 2 broad personality models that have been shown in the past to relate to emotional functioning: the Big Five personality model [17] and the resilient/overcontrolled/undercontrolled personality type model [18,19].

Big Five Personality Model

In the first model, personality is described by the Big Five broad personality traits: extraversion, emotional stability, conscientiousness, agreeableness, and openness [17]. These traits have been shown to relate to the duration of emotional states and frequency of specific emotional experiences [20]. A very common finding is that extraversion is positively associated with positive affect and emotional stability negatively with negative affect [21]. Additionally, associations of personality traits with emotion regulation were demonstrated in several studies [22-24]. For instance, extraversion, conscientiousness, and openness were predictive for problem solving and cognitive

XSL•FO
RenderX

restructuring, while agreeableness was predictive for social support and cognitive restructuring [22-24].

Resilient/Overcontrolled/Undercontrolled Personality Type Model

The second personality model classifies people into 3 broad personality types [18,19]. Resilient people are characterized by a tendency to effectively adapt to changes and have the ability to recover well from stress and negative emotional arousal. Overcontrolled people are introverted and emotionally sensitive but also dependable. They are more likely to experience sadness and fear and are at risk of developing internalizing complaints such as depression and anxiety. Undercontrolled people are low on agreeableness and conscientiousness and high on aggressiveness and delinquency. They are more likely to experience anger and are at risk to develop externalizing problems.

Gender and Age

Next to these personality predictors, we have also looked at the relationships with gender and age. Overall gender differences in emotional reactions have been observed, with females having more intense emotional reactions compared with males [25-28]. Regarding age, a general decrease of negative affective experiences [29] and increase of healthier emotion regulation strategies [30-32] have been observed throughout the life span.

Replicability

In light of the replicability crisis in psychology [33] and because of the explorative nature of this research with the innovation to root the study of emotional experiences in the componential emotion approach, the study was executed in two samples from different countries (United Kingdom and the Netherlands) speaking different languages (English and Dutch). Moreover, participants in each country received at random one of two versions of the cybersecurity breach scenario. In one version, the smart security camera showed obvious signs of a cybersecurity breach (nonambiguous condition), and in the other version, it showed unclear signs (the ambiguous condition) that could also potentially be caused by other factors (eg, a bug in the software). By adding the latter scenario, the ecological validity of the research was increased, as in daily life it is also often unclear whether or not a dysfunction of internet-connected devices is due to a cybersecurity breach.

Methods

Sample

A total of 1045 participants were recruited through Qualtrics panel, 524 participants from the United Kingdom and 521 participants from the Netherlands. Before the data analyses, participants showing signs of not properly answering questions were removed. One of the strongest indicators that the validity of responses is at stake is nondifferentiation of the responses [34]. All participants who gave the same response on at least 75% of the GRID items and on 70% of the International Personality Item Pool 50 (IPIP-50) questionnaire items deviated from most participants in scale use and were removed (n=143 deleted cases). This left 902 participants for the analyses. Sample characteristics are presented in Table 1.

Table 1. Study sample characteristics (n=902).

Characteristics	Country of residence, n (%)		Total, n (%)
	United Kingdom (n=435)	Netherlands (n=467)	
Gender			
Female	221 (50.8)	231 (49.5)	452 (50.1)
Male	214 (49.2)	236 (50.5)	450 (49.9)
Condition			
Ambiguous	217 (49.9)	241 (51.6)	458 (50.8)
Nonambiguous	218 (50.1)	226 (48.4)	444 (49.2)

Procedure

The Qualtrics project team organized and coordinated data collection. They recruited samples from both countries based on their Qualtrics panel of participants. Quotas for samples were predefined and balanced by country of residence, gender, and scenario with age range limited from 18 to 65 years. An online questionnaire, located on the Qualtrics survey platform, was presented to participants remotely by sending them a survey link. Each participant electronically signed an online informed consent form prior to completing the questionnaire. Participants had the opportunity to complete the questionnaire within a 1-week period. The average duration of questionnaire completion was 15 minutes. Each participant was presented with an introduction explaining what IoT devices are and specifically what a smart security camera is. This was followed by the presentation of one of the two scenarios (ambiguous or nonambiguous, see complete instructions in Multimedia Appendix 1). Each participant thus evaluated only randomly assigned one scenario.

Measures

Emotion Assessment

Participants were asked to imagine they experienced one out of two cybersecurity breach scenarios. Scenario 1, which represented the ambiguous condition, was formulated as follows: “Imagine that you bought a smart security camera for your home. After some time, you notice that the shutter on your smart security camera starts opening and closing without your instruction, several times for a few minutes, then it stops for a

XSL•FO
RenderX

minute and starts again opening and closing several times and then it stops." In the nonambiguous condition (scenario 2), the formulation was "Imagine that you bought a smart security camera for your home. After some time, you notice that the shutter on your smart security camera opens without your instruction and the camera rotates toward you and then starts following your movement."

Participants were subsequently asked to report the emotional reactions they would have in the situation presented using the Cybersecurity GRID questionnaire (Multimedia Appendix 2). This is an adjusted version of the GRID instrument that was used to study the meaning of emotion words across cultural and linguistic groups [14] and is based on the componential emotion approach [5] including the assessment of the 5 emotion components and emotion regulation. In order to determine and operationalize relevant features of the emotion processes in the specific context of cybersecurity breaches, we executed a preliminary qualitative survey. In this survey, 130 participants reported on their real or expected emotional reactions in cybersecurity breach situations (either from first-hand experience or based on a third-party experience). Participants' reports included a brief description of the cybersecurity breach situation and the emotional reactions they had or would have had in that situation (referring to each of the 5 emotion components and regulation). The new Cybersecurity GRID questionnaire was based on those emotion features that were reported by at least 15% of the participants. The Cybersecurity GRID contains 76 items (19 appraisals, 16 action tendencies, 11 bodily reactions, 8 expressions, 14 subjective feelings, and 8 emotion regulation strategies). Each emotion feature was evaluated on the 7-point Likert scale commonly used in survey research ranging from 1 (strongly disagree) to 7 (strongly agree) [35].

IPIP-50

IPIP-50 [17] is a validated instrument that measures the Big Five personality factors. Participants rated how accurately each statement described them on a 5-point Likert scale ranging from 1 (very inaccurate) to 5 (very accurate). Person mean-centered scores were calculated for IPIP items and reversed according to instructions. Each factor showed good to very good internal consistency (Cronbach alpha): extraversion: α=.85, agreeableness: α=.83, conscientiousness: α=.79, emotional stability: α=.83, and for openness: α=.72.

Depression, Anxiety, and Stress Scale–21 Item

The Depression, Anxiety, and Stress Scale–21 Item (DASS-21) assesses internalizing problems, which is a key feature of the overcontrolled personality type. It is a shortened 21-item version of the Depression, Anxiety, and Stress Scale [36]. Items are rated on a 4-point scale ranging from 0 (does not apply at all) to 3 (applies very much). The total DASS-21 sum scores showed high internal consistency, α=.96.

Short-Form Buss-Perry Aggression Questionnaire

The Short-Form Buss-Perry Aggression Questionnaire [37-39] assesses aggression, which a key feature of the undercontrolled personality type. It is a short version of the Buss-Perry Aggression Questionnaire [40] and consists of 21 items rated on a 5-point scale ranging from 1 (extremely uncharacteristic of me) to 5 (extremely characteristic of me). The scale showed a high internal consistency, α=.92.

Ego Resilience Scale

The Ego Resilience Scale [41,42] is a short, revised version of the Ego-Resiliency Scale [43], measuring self-reported resilience on 10 items on a 4-point scale ranging from 1 (does not apply at all) to 4 (applies very strongly). The Cronbach alpha of the total score was .78.

Ethical Approval

Ethical approval was obtained from the ethical committee of Ghent University, Faculty of Psychology and Educational Sciences in 2017 (number 2016/67).

Results

Internal Structure of Emotional Reactions

Principal component analyses were applied to identify the major dimensions of variability among 76 emotion features. To avoid confusion between emotion components from a substantive point of view and principal components obtained from analysis, the latter will be referred to as dimensions in the remainder of the text.

To identify the number of dimensions, 3 criteria were used: (1) the scree plot based on the Eigenvalues (Multimedia Appendix 1), (2) interpretability, and (3) replicability for each language, scenario, and gender (Multimedia Appendix 1). The theoretically best interpretable rotation was selected. A highly stable and well-interpretable 3-dimensional structure was identified that accounted for 48% of the total variance (see Table 2 for the highest loading features on each dimension and Multimedia Appendix 1 for the full loading matrix).

On the first dimension, accounting for 31% of variance, all emotion features have a positive loading, with the subjective experiences loading highest (eg, I would feel panic, I would feel upset). The higher participants score on this dimension, the more intense negative emotion processes are elicited by the scenario. Therefore, this dimension is named emotional intensity.

The second dimension, accounting for 12% of variance, is a bipolar dimension. One pole is defined by proactive action tendencies to deal with the cybersecurity breach (eg, I would want to regain control over the device/account, I would want to find a solution and fix the problem). The other pole is defined by fight/flight action tendencies (eg, I would want to take revenge, I would want to isolate myself physically) and features from other components that indicate distress (eg, I would have pain in the chest). Therefore, this dimension is labeled proactive versus fight/flight.

XSL•FO
RenderX

Table 2. Results from principal component analysis of the Cybersecurity GRID questionnaire (n=920)[a].

GRID items	Dimension loading		
	1	2	3
Dimension 1: Emotional intensity			
SF5. I would feel panic.	.73	.20	–.30
SF4. I would feel afraid.	.72	.09	–.26
SF7. I would feel worried.	.70	–.15	–.21
SF6. I would feel upset.	.70	.04	–.27
SF14. I would feel uncomfortable.	.67	–.14	–.12
SF11. I would feel angry.	.67	.01	–.15
Dimension 2: Proactive versus fight/flight			
AT14. I would want to destroy whatever was close.	.32	.65	.10
AT15. I would want to take revenge.	.36	.63	.16
BR4. I would have pain in the chest.	.49	.61	–.22
AT1. I would want to stop what was happening.	.43	–.62	.16
AT9. I would want to find a solution and fix the problem.	.34	–.64	.12
AT2. I would want to regain control over the device/account.	.44	–.68	.14
Dimension 3: Affective versus cognitive/motivational			
A19. I would think “It is not safe that this device is connected to the internet.”	.58	–.07	.43
A7. I would think “My trust is betrayed.”	.58	.13	.42
A12. I would think “It is happening because someone is trying to hack and take control over my count.”	.56	–.10	.41
E8. I would be walking around nervously.	.60	.32	–.34
E7. I would be restless (touching face, hair, biting nails, nervously kicking with legs).	.58	.34	–.35
ER3. I would try to calm myself down (eg, by breathing deeply).	.59	–.09	–.37

[a]The 6 highest loadings are presented, and the full loading matrix can be found in Multimedia Appendix 1.

The third dimension, accounting for 5% of the variance, is also bipolar. All appraisal and action tendency features (eg, I would think “It is not safe that this device is connected to the Internet”) have a nonnegative loading, while all subjective experience, bodily reaction, expression, and regulation features (eg, I would try to calm myself down) have a nonpositive loading on this dimension. This dimension is labeled affective versus cognitive/motivational.

Predictors of Emotional Reactions

The scores on each of the 3 identified emotion dimensions were regressed on the personality characteristics. As the Big Five indicators and the resilience, overcontrolled, and undercontrolled indicators show both theoretical and empirical overlap (and the differences and similarities between personality models do not form the focus of this research), their predictive value was investigated separately. Hierarchical linear regression analyses were performed. In the baseline model (model 1), the predictors are country of residence, scenario, gender, and age (with United Kingdom, ambiguous situation, and women being the reference categories). In the second model the personality characteristics were added as predictors: the Big Five personality traits in model 2a and the indicators for resilience, overcontrolled, and undercontrolled personality types in model 2b.

Emotional Intensity

In model 1 (Table 3), it was observed that United Kingdom ($\beta_{TheNetherlands}$=–.20, P<.001), women (β_{man}=–.14, P<.001), and those imagining the unambiguous scenario ($\beta_{unambiguous}$=.12, P<.001) reported the highest emotional intensity. Model 1 accounted for 8% of the variance ($F_{4,901}$=18.28; P<.001). In model 2a (Table 3), it was observed that less emotionally stable (β=–.25, P<.001) and more agreeable (β=.12, P<.001) participants reported a higher emotional intensity. Model 2a additionally accounted for an additional 5% of the variance ($F_{9,901}$=14.64; P<.001). Model 2b (Table 3) showed that those reporting more internalizing problems (β=.33, P<.001) and more resilient participants (β=.22, P<.001) reported a higher emotional intensity. Model 2b additionally accounted for 17% of the variance ($F_{7,901}$=66.32; P<.001).

Proactive Versus Fight/Flight

More fight/flight reactions were reported by younger participants (β_{age}=–.26, *P*<.001), by men (β_{man}=.16, *P*<.001), and by participants responding to the unambiguous scenario ($\beta_{unambiguous}$=.09, *P*=.006). Model 1 (Table 4) accounted for 9% of the variance ($F_{4,901}$=22.59; *P*<.001). In model 2a (Table 4), it was observed that less agreeable (β=–.34, *P*<.001), less conscientious (β=–.19, *P*<.001), and less open (β=–.22, *P*<.001) but more extraverted (β=.07, *P*=.02) participants showed more fight/flight reactions. Model 2a accounted for an additional 32% of the variance ($F_{9,901}$=68.57; *P*<.001). In model 2b (Table 4), it was observed that less resilient participants (β=–.19, *P*<.001) and participants with more internalizing problems (β_{DASS}=.26, *P*<.001) and more aggression (β=.25, *P*<.001) reported more

XSL•FO
RenderX

fight/flight reactions. Model 2b accounted for an additional 24% of the variance ($F_{7,901}$=62.82; *P*<.001).

Table 4. Results of hierarchical regression analyses showing amount of variance in the proactive versus fight/flight reactions dimension accounted for by country of residence, condition, gender, age, Big Five personality traits, DASS-21, aggression, and resilience.

Affective Versus Cognitive/Motivational

Model 1 (Table 5) showed that for older participants (β_{age}=.21, *P*<.001), men (β_{man}=.13, *P*<.001), and Dutch participants ($\beta_{TheNetherlands}$=.08, *P*=.01), the cognitive/motivational reactions were more salient. The model accounted for 7% of the variance ($F_{4,901}$=18.02; *P*<.001). Only emotional stability was a significant predictor of the salience of cognitive motivational reactions in model 2a (β=.14, *P*<.001). Model 2a (Table 5) accounted for an additional 2% of the variance ($F_{9,901}$=10.57; *P*<.001). In model 2b, it was observed that more aggression (β=.13, *P*=.01) and less internalizing problems (β=–.32, *P*<.001)

XSL•FO
RenderX

related to a comparatively higher salience of cognitive/motivational than affective reactions. Model 2b (Table 5) accounted for an additional 5% of the variance ($F_{7,901}$=18.06; P<.001).

Table 5. Results of hierarchical regression analyses showing amount of variance in the affective versus cognitive/motivational dimension accounted for by country of residence, condition, gender, age, Big Five personality traits, DASS-21, aggression, and resilience.

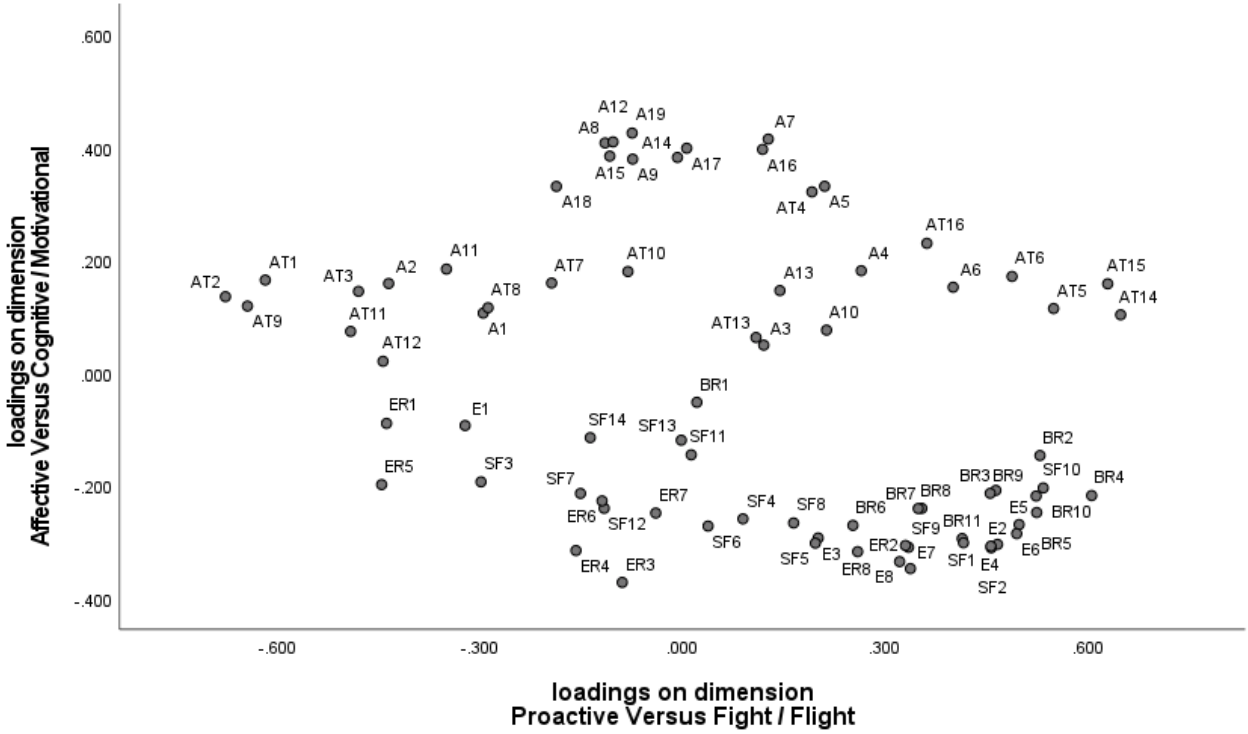
Discussion

Internal Structure

The first and foremost goal of this study was to investigate the structure of emotional reactions in one of the most emblematic situations of cybersecurity breaches of the upcoming IoT devices—the hacking of one's smart security camera—by looking at the full emotion process that can be elicited by this situation. Not a 1-dimensional but a 3-dimensional structure clearly emerges.

XSL•FO
RenderX

On the first dimension, all emotional reactions are loading positively. With the subjective experience items loading the highest on this dimension, this general intensity dimension can be best interpreted as a negative affectivity dimension, comparable to, for instance, the frequently used negative affectivity scale of the PANAS [13].



The second dimension represents the relative salience of proactive versus fight/flight action tendencies. This second dimension underlines the central status of action tendencies for the concept of emotion [44,45]. From an evolutionary perspective, emotion processes are phylogenetically shaped processes that quickly prepare the organism for action. However, depending on the concrete situation, these elicited action tendencies can be more or less constructive. In the new internet environment where we interact from a distance, acting aggressively or withdrawing are not adaptive reactions. One often does not know who is responsible and one's life depends more and more on participating in this interconnected online world. Only the proactive tendencies to stop what is happening and to better protect oneself can be considered adaptive and lead to constructive results.

The third dimension describes the relative salience of cognitive/motivational versus affective (expression, bodily reactions, regulation, and feelings) features. Possibly, this finding can be linked to the different levels of consciousness with which appraisals can occur [46]. When the appraisals are made consciously, one can focus more on what one feels inclined to do and should do. When the appraisals are made unconsciously, the way the emotion is felt and expressed becomes more salient rather than what has elicited the emotion.

When the second and third dimensions are combined, a distinction emerges that has been referred to in the stress and coping literature as problem-focused versus emotion-focused coping [47] (Figure 1). The proactive tendencies in the upper-left quadrant correspond with problem-focused coping. The bodily reactions, subjective feelings, and expressions in the lower-left quadrant indicate that one is overwhelmed and regulation is required.

This 3-dimensional structure is highly replicable: exactly the same structure was found across the two versions of the security breach scenario, across the two countries with their respective languages, and across the two genders (Multimedia Appendix 1).

Figure 1. Plot of the loadings of the emotional reactions on the second and third dimension as a function of the emotion component to which they belong. A: appraisal; AT: action tendency; BR: bodily reaction; E: expression; SF: subjective feeling; ER: emotion regulation.

Predictors of Emotion Dimensions

The second goal was to explore whether personality characteristics predict the empirically identified emotion dimensions, and, if that is the case, which ones (Tables 3-5). The general finding is that the broad personality characteristics from both personality models relate differentially to the 3 emotion dimensions, which confirms that these emotion dimensions are indeed each capturing valid aspects of the emotion processes.

Big Five Personality Model

The two most predictive personality traits are emotional stability and agreeableness. In line with the well-documented negative relationship between emotional stability and negative affectivity [22-24], we observed that emotionally stable participants scored lower on the general emotion dimension and reported a higher

XSL•FO
RenderX

salience of the affective components. Agreeable participants showed more proactive action tendencies and tended also to score a bit higher on the general emotion dimension. It is possible that agreeable people, who value warm interpersonal relationships, appraise negatively intended actions by others, like hacking, as more relevant while at the same time are less inclined to react aggressively, which frees more energy to deal constructively with the situation. Moreover, agreeable people are more likely to use cognitive restructuring and problem-solving approaches [22-24]. Conscientiousness and openness only predicted proactive tendencies. Being diligent, efficient, and orderly, which are characteristics of conscientious people, might help to focus on the action tendencies that can provide support in effectively dealing with the situation. The relationship with the personality trait openness was a bit less self-evident. As IoT is a recent and fast-developing field, people who are more curious and open are possibly more likely to understand the full implications of cybersecurity breaches and act accordingly. Extraversion, which has been found in the literature to be predictive of positive but not negative affectivity [22-24], was virtually unrelated to the emotion dimensions (with the exception of a very small although statistically significant relationship with fight/flight tendencies, probably due to the fact that extravert people tend to express their emotions more) [48].

Resilient/Overcontrolled/Undercontrolled Personality Type Model

Internalization problems, which are important characteristics of an overcontrolled personality type, predicted a higher general emotional intensity, more fight/flight tendencies, and a comparatively higher salience of the affective components. This finding indicates that people who are already vulnerable do not succeed in adequately dealing with the emotional experience. Interestingly, resilience, a characteristic of well-functioning people [43], not only predicts more proactive tendencies but also a higher general intensity of emotional reactions and a higher salience of the affective components. Possibly because resilient people can cope better with stressors, they are less defensive and more willing to appraise the seriousness of the situation and accept their own emotional reactions. Finally, aggression, as an indicator of an undercontrolled personality type, is especially predictive of fight/flight action tendencies and relates to a slightly higher salience of the cognitive/motivational components. People who are high on aggression are more willing to blame others and are primed on aggressive reactions [49,50].

Gender and Age

In addition to the personality predictors, we also found that gender and age played a role. Women had a tendency to have more emotionally intense and affective reactions, while men were more likely to show fight/flight reactions. This is in line with earlier findings that females generally have more intense emotional reactions [25-28], experience more emotions in situations of cyberbullying [51], and have more anxiety in situations of hacking [52] and that males tend to react more aggressively [53].

We also found that older individuals were more prone to have proactive and cognitive/motivational reactions, which fits the observation that older individuals have less negative affective experiences and healthier emotion regulation strategies [29-32]. Additionally, intra-individual differences in emotional reactions to cybersecurity breaches are organized and structured in exactly the same way for males and females (Multimedia Appendix 1).

Ambiguous/Nonambiguous Conditions

While the two cybersecurity scenarios showed exactly the same 3-dimensional structure of emotional reactions, quantitative differences were observed, with the nonambiguous situation eliciting more intense and more fight/flight emotional reactions. The nonambiguous situation is possibly experienced more as though one is confronted with a natural person in real life. The situation becomes more relevant for one's goals and elicits more fight/flight action tendencies rather than the more adaptive proactive reactions.

Country

Finally, while the emotion structure is the same in the two countries, we observed less intense reactions and a higher salience of cognitive/motivational reactions in the Dutch as compared with the UK sample. A speculative explanation could be that the emblematic example of the hacking of a smart security camera has received more media coverage in the United Kingdom [54-57] than in the Netherlands, which has made these scenarios more emotionally salient in the United Kingdom.

Principal Findings

In this study, only the direct emotional reactions to a cybersecurity breach scenario have been studied. A question for future research is whether and to what extent these immediate emotional reactions set the stage for further mental health problems. Being exposed to hacking has been linked to psychopathology [58-61] in the literature and even to suicide in the media [9]. Based on the discovered emotion structure, very different dynamics can be predicted with respect to the role that a hacking situation will play in a person's life in the longer run.

Those with intense emotional reactions, fight/flight action tendencies, and salient affective components are probably more likely to stay confronted with the situation and its negative ramifications. They experience the situation as emotionally highly relevant, but they tend to react in a way that does not resolve the challenges created by the problem. Moreover, they are additionally confronted with affective reactions that need to be regulated and thus require extra energy. This combination can be considered the psychologically least adaptive reaction, which sets the stage for further mental health complaints.

Those who have no or little negative emotional reactions can only be partially considered better off. They do not have to deal with the negative emotional reactions themselves but also lack the inherent pressure created in the emotion process to take action. Emotions are relevance detectors [5]. Appraising the situation as threatening with its ensuing negative emotional reactions can motivate appropriate action and can therefore be considered adaptive. This interpretation is also supported by

XSL•FO
RenderX

the finding that resilient people score higher on the general intensity dimension.

The most adaptive emotional reaction can be considered to be a negative emotional reaction in which the proactive and constructive action tendencies and cognitive-motivational components are the most salient. Such a reaction pattern implies that the seriousness of the situation is adequately appraised and thus that the emotions play their role as relevance detectors. At the same time, actions are prepared that maximize an effective resolution of the situation without the person being overwhelmed by the affective reactions.

Limitations

One of the limitations of this study is that the causal conclusions about the long-term mental health consequences of a cybersecurity breach cannot be investigated with a scenario methodology based on anticipated emotional experiences. However, as experimental research of real emotional experiences is impossible or at least highly limited in this area due to ethical considerations (it is unethical to actually invade the privacy of people by hacking their security camera), scenarios offer an ethically viable and direct way to study the structure of emotional reactions in this uncharted domain. As this study was conducted in Western Europe, further cultural generalizability is yet to be demonstrated. Future research can also study the ecological validity, generalizability, and long-term mental health implications of these findings. Another limitation is the use of self-assessment instruments. While some emotion components can only be studied through self-assessment (like subjective feelings and cognitive appraisals), other components can be studied by objective data (like psychophysiological and expressive changes). In future research, it would be interesting to complement self-reported data with such objective data.

Conclusion

With the increasing interconnections through the internet and especially the recent development of IoT, people are much more at risk of experiencing cybersecurity breaches. Becoming a victim of cybersecurity breaches, with possibly far-reaching consequences for one's personal and professional life, is becoming more and more likely. When all components of the emotion processes elicited by such cybersecurity breaches are investigated, a replicable 3-dimensional structure emerges that goes beyond the well-known negative affectivity dimension. These dimensions relate differentially to broad personality characteristics, which further validates the need for a multidimensional representation. Depending on the position of the emotional reaction on these three dimensions, very different predictions can be made about the long-term mental health implications of hacking experiences. With this study, a key process that links the occurrence of a cybersecurity breach situation with possible long-term mental health effects has been mapped out.

Acknowledgments

This study is part of a larger research project, Emotion Psychology Meets Cyber Security in IoT Smart Homes (Cocoon), funded by EU FP7 CHIST-ERA funding scheme (European Coordinated Research on Long-term Challenges in Information and Communication Sciences & Technologies ERA-NET) corresponding to grants FWO project G0H6416N-FWOOPR2016009701 and EPSRC EP/P016448/1 and NWO project no.651.002.002. Many thanks to native speaker Arpine Hovasapian, PhD, for proofreading the paper. We thank her for her valuable contribution to the manuscript.

Authors' Contributions

SB and JRJF substantially contributed to analyses and interpretation of data, drafted the article, and gave final approval of the version to be published. SB, JRJF, NMAH, AH, GL, and EBR substantially contributed to conception of the study and design and acquisition of data, critically revised the manuscript for important intellectual content, and gave final approval of the version to be published.

Abstract

Background: Novel consumer and lifestyle data, such as those collected by supermarket loyalty cards or mobile phone exercise tracking apps, offer numerous benefits for researchers seeking to understand diet- and exercise-related risk factors for diseases. However, limited research has addressed public attitudes toward linking these data with individual health records for research purposes. Data linkage, combining data from multiple sources, provides the opportunity to enhance preexisting data sets to gain new insights.

Objective: The aim of this study is to identify key barriers to data linkage and recommend safeguards and procedures that would encourage individuals to share such data for potential future research.

Methods: The *LifeInfo Survey* consulted the public on their attitudes toward sharing consumer and lifestyle data for research purposes. Where barriers to data sharing existed, participants provided unstructured survey responses detailing what would make them more likely to share data for linkage with their health records in the future. The topic modeling technique latent Dirichlet allocation was used to analyze these textual responses to uncover common thematic topics within the texts.

Results: Participants provided responses related to sharing their store loyalty card data (n=2338) and health and fitness app data (n=1531). Key barriers to data sharing identified through topic modeling included data safety and security, personal privacy, requirements of further information, fear of data being accessed by others, problems with data accuracy, not understanding the reason for data linkage, and not using services that produce these data. We provide recommendations for addressing these issues to establish the best practice for future researchers interested in using these data.

Conclusions: This study formulates a large-scale consultation of public attitudes toward this kind of data linkage, which is an important first step in understanding and addressing barriers to participation in research using novel consumer and lifestyle data.

Introduction

Background

Poor diet and physical inactivity are known to contribute to millions of early deaths worldwide [1,2]. In the United Kingdom, 1 in 7 deaths are attributed to poor diet, whereas 1 in 6 deaths are attributed to physical inactivity [3,4]. A greater understanding of these risk factors for lifestyle-influenced diseases such as type 2 diabetes, certain cancers, and cardiovascular diseases is needed to improve global health. At the same time, technological advancements have led to increasingly large volumes of *big data* being produced about individual food consumption and exercise habits [5,6].

Historically, a major barrier to research on lifestyle risk factors for noncommunicable diseases has been the availability of accurate, robust, and reproducible data on diet and exercise [7,8]. Big and novel lifestyle data, produced when using services such as supermarket loyalty cards or health and fitness monitoring apps, have many benefits compared with more traditional forms of data collected through surveys, interviews, and food or exercise logs; as these data are collected during everyday activities, they are naturalistic and nonintrusive [9], meaning they do not encounter the selective reporting bias entailed with traditional methods [7]. Furthermore, large volumes of data can potentially be shared with researchers almost in real time, surpassing the scale of traditional methods at a very low cost and requiring little or no effort on the part of the participant [10]. Consequently, these data are uniquely set up for at-scale longitudinal studies with the additional benefit of extending research into traditionally hard-to-reach populations [10].

These data include mobile phone step counts, GPS-tracked exercise, wearable device heart rate monitoring, and store loyalty card records. In health research, few studies have demonstrated the full utility of consumer and personal data of this sort, as they have not typically been available to researchers [7,10,11]. Nonetheless, initiatives such as the Consumer Data Research Center [12] have begun to facilitate access to novel data sources.

In the context of diet and health research, attention has particularly been drawn to the potential of using supermarket loyalty card data (eg, Tesco Club Card) to understand food and drink purchase behavior [7,10,11,13-16] and data from wearable devices (eg, Fitbit and Garmin) or mobile phone fitness apps (eg, MyFitnessPal and Strava) to understand exercise behavior [17-19]. However, studies that have used commercial lifestyle data for research purposes have reported low uptake [10]. Although this may have been influenced by factors such as the methods used to contact participants, there is a clear research need to understand participants' reluctance to share their data.

The combination of data from multiple sources to create enhanced data sets, known as *data linkage*, provides new insights for health research that surpass those provided by the data sets individually. The value of consumer and lifestyle data is further amplified when combined with health outcomes data [10]; for example, Aiello et al [11] used supermarket loyalty card data for small geographic areas to study the association between food purchasing and health outcomes. We believe that similar work linking individual health outcomes and lifestyle data, rather than at the ecological study level, would provide added benefits through greater specificity and personalization. However, an individualized approach may highlight data privacy and ethics barriers, especially in light of understandable historical concerns regarding data linkages, such as those proposed by care.data in the United Kingdom in 2013 and 2016 [20]. In addition, data linkage can create disclosure concerns or can increase sensitivity, which must be addressed by researchers seeking to use such methods [21,22].

Public attitudes toward health data sharing for research appear to be dependent on many factors, with the most prominent being the actual data sharing process, including data security considerations [23], the purpose and social license for the research [23-25], and the level of sensitivity attributed to data [26]. Others have reported high levels of trust in health institutions, lower levels of trust in academics, and the lowest levels of trust in private companies for data sharing initiatives [24,27]. As research using big lifestyle data often involves all 3 of these factors, it is important to address how trust might influence people's willingness to participate in research under these circumstances.

Objectives

Despite the obvious opportunities provided by the proliferation of big data for health research, little is known about public attitudes toward the linkage of lifestyle data with individual health records for research. The *LifeInfo Survey* is the first of its kind at this scale (n=7101 participants) to consult the public on their attitudes toward sharing novel forms of consumer and lifestyle data for linkage with their health records for health research [28]. Moreover, this survey included free-text response questions that allowed individuals, in their own words, to state what actions would alleviate their concerns about data sharing in this setting. Surveys do not frequently allow for unstructured answers of this kind because of the subjectivity and time commitment imposed with the qualitative coding of texts [29]. The use of novel data science methods, including topic modeling, can facilitate the semiautomated analysis of large amounts of textual data to identify latent themes [30].

This study aims to advance the understanding of attitudes toward data sharing by identifying specific barriers that present themselves when linking store loyalty cards or health and fitness app data with individual health records for research purposes. We recommend procedures and safeguards that can be applied to future research linking lifestyle and health data to increase participant support.

We hypothesize that common issues identified in the literature on public attitudes toward data sharing for health research, such as data security and trust, will be evident within survey responses in addition to concerns specific to the type of data to be linked, in this case, store loyalty card and health and fitness app data.

XSL•FO
RenderX

Methods

Data Collection

To gather public opinion on data sharing and linkage, the *LifeInfo Survey* recruited participants between September 2017 and October 2019 across 2 health settings, the Leeds Teaching Hospitals National Health Service Trust and Low Moor Medical General Practice Surgery, and 2 nonhealth settings, the Leeds Institute for Data Analytics and the Leeds City Council Health Communities survey [31]. The *LifeInfo Survey* (Multimedia Appendix 1) addressed a hypothetical scenario—whether, if asked for a future study, respondents would give permission for their consumer and lifestyle data to be linked with their health records for health research. This was conditional on their data being stored safely and not shared with anyone outside the research team. The survey consulted participants specifically about 2 types of data: (1) consumer data from store loyalty cards detailing food and drink purchases and (2) lifestyle data from health and fitness apps, websites, and wearable devices. Basic demographic data and which specific loyalty cards and health and fitness apps respondents used were additionally captured. Additional information about the *LifeInfo* project can be found in the study protocol [32]. Detailed information on the participants and the main survey results are reported elsewhere [28].

Those who responded *no* or *not sure* to whether they would share their data were asked, "what (if anything) might make you change your mind in the future?" concerning their (1) store loyalty card data and (2) health and fitness app data. This study primarily analyzes the qualitative responses to these 2 questions (questions 4 and 9 in the original questionnaire included in Multimedia Appendix 1), henceforth referred to as (1) *the store loyalty card question* and (2) *the health and fitness app question*, to answer the following research question: "What are the reported barriers to linkage of lifestyle data with health records for research?" Responses were given in free-text format, allowing individuals to state, in their own words, potential desired changes that would make them more willing to share such data, although many also used this space to explain their reasons behind more negative responses. Primary analysis regarding overall willingness to share lifestyle and data demographic trends are reported elsewhere [28] and summarized below. The survey questionnaire and all responses were provided in English.

Ethics

This study was granted ethical approval by the London-Brent Research Ethics Committee (reference 17/LO/0622).

Modeling

Latent Dirichlet allocation (LDA) was applied as a method of automated content analysis on unstructured survey responses. This technique was used to identify the underlying factors that contribute to respondents' unwillingness or unsureness to having their consumer or lifestyle data and health records linked for research purposes and potential changes that could influence them to do so. LDA is a generative probabilistic model that is frequently applied to textual data. The model has a 3-level hierarchical Bayesian structure under which each *document* is modeled as several topics, and each topic is modeled as a set of terms [30]. The model uses the Gibbs sampling technique to estimate model parameters. The LDA modeling procedure was applied to free-text responses separately for the store loyalty card question and the health and fitness app question to create a model for each.

Processing

Data cleaning and processing were performed using the R software [33]. Noninformative responses (eg, *N/A* and *no comment*) were removed from the data set. Survey responses that consisted of only a single word were removed from the analysis data set, as the underlying mechanisms of LDA are based on the co-occurrence of terms. These are categorized separately, as attitudes are easily ascertained from single-word responses (shown in Tables 1 and 2).

Table 1. Counts of single-word responses to the question, "What (if anything) might make you change your mind in the future?" about sharing store loyalty card data for linkage with health records (n=396).

Single word	Counts per word, n (%)
Nothing	256 (64.6)
No	98 (24.8)
Privacy	10 (2.5)
None	8 (2.0)
Maybe	5 (1.2)
Private	3 (0.8)
Confidentiality; personal	2 (0.5)
Confidential; discounts; dk[a]; hackers; illegible; incentives; money; unneeded; unlikely; unsure; why; yes	1 (0.3)

[a]dk: don't know.

Table 2. Counts of single-word responses to the question, "What (if anything) might make you change your mind in the future?" about sharing fitness app data for linkage with health records (n=309).

Single word	Count per word, n (%)
Nothing	189 (61.2)
No	71 (23.0)
Privacy; security	7 (2.3)
Maybe; none	5 (1.6)
q4[a]	4 (1.3)
Anonymity; confidential; private; same; yes	2 (0.6)
Benefit; confidentiality; intrusive; might; nil; personal; possibly; relevance; uncertain; unlikely; why	1 (0.3)

[a]q4: question 4.

Preprocessing procedures, standard in natural language processing, were undertaken to create a *document term matrix* (DTM) on which to perform LDA. This included converting all words to lower case and removing white spaces, punctuations, and common *stop-words* from texts to leave only meaningful words. Frequent misspellings were replaced with their correct form, and common equivalent words were standardized (Multimedia Appendix 2).

The *SMART* (System for the Mechanical Analysis and Retrieval of Text) stop-word data set was used to identify uninformative words. However, bigrams (two-word terms) that contain many common stop-words were not removed to uncover attitude positions within responses (Multimedia Appendix 2). Numbers were not removed as numeric bigrams are potentially meaningful (eg, *100 percent* and *3rd party*). Finally, lemmatization of words was undertaken to convert words into their root form (*lemma*) and reduce sparsity within the DTM (eg, *cards* was replaced with *card*; Multimedia Appendix 2). Lemmatization was preferred over stemming, as lemmas are more human-readable than stems, which are not always complete words (eg, *storing* would be replaced with the stem *stor*).

LDA was performed on a DTM of unigrams (one-word terms) and bigrams (two-word terms) within the texts. Bigrams are included in the DTM as this creates more human-interpretable topics, and many words are context-specific, for example, *big brother*/*change mind*, or formulate attitude positions in combination, for example, *would change*/*wouldn't change*. In the example given, the term *brother* alone would provide little insight into data sharing attitudes, yet *big brother* signifies a potential invasion of privacy and distrust. Several papers have reported improved results for including bigrams and higher n-grams in different topic models [34-36]. Only terms that occurred in more than 2 documents were retained, leaving 993 unique terms for the store loyalty card question and 554 unique terms for the health and fitness app question.

Topic Number Selection

Selecting an appropriate number of topics is a key challenge for LDA. According to Green et al [37], "too few topics will produce results that are overly broad, whereas choosing too many will result in the 'over-clustering' of a corpus into many small, highly-similar topics" that are difficult to interpret in a meaningful way. The number of topics (k) is conventionally chosen as the model with the lowest value of *perplexity* when applying different models of candidate k to held-out data [30,38]. This perplexity measure captures how well a probability distribution or probability model predicts a sample, indicating how *surprised* the model is by new data. For LDA, it is equivalent to the inverse of the geometric mean per-word likelihood calculated on the held-out data [30]. For this analysis, ten-fold crossvalidation was used to select an appropriate number of topics (k) from a candidate list of 15 k ranging from 2 to 100, optimizing for perplexity. Candidate k increases in smaller intervals between lower values, as greater change is expected between these values. The crossvalidation process randomly divides the data set into 10 approximately equally sized folds and uses 9 of these to train the model, using the held-out fold to test the model. This process was repeated 10 times such that each fold was used as the testing set once.

Some research has found that the models that produce the most semantically meaningful topics—in that topics are easily interpreted by humans and terms representing concepts are given high probabilities within the model—are not necessarily the models with the best perplexity scores [39]. Hence, a measurement of *coherence*, which research finds corresponds well with human-interpretable topics [40], was also considered. Average topic *probabilistic coherence* measures topic quality based on how commonly topic terms co-occur, controlling for statistical independence [41-43]. This was compared for models of candidate k topics and balanced with perplexity scores.

Once an appropriate number of topics were selected for each LDA model, the final models were created using responses from all individuals for the given question. This method was chosen, rather than using commonly used training and testing approaches, to support the study aim of summarizing survey responses rather than creating a predictive model to categorize new data, as no new *LifeInfo Survey* data will be collected in the future. Moreover, the size of the data set is small compared with many others that use LDA, and splitting the data set into fewer responses could reduce the model quality.

For both topic number selection and the final models, the LDA hyperparameters were set at α=.1, influencing document-topic density, and β=.05, influencing word-topic density. The α prior was set at this relatively low value because *LifeInfo Survey* responses were short (refer to Multimedia Appendix 3 for plots

XSL•FO
RenderX

showing the distribution of response lengths in words, averaging 12 words per document for the store loyalty card question and 9 words for the health and fitness app question), so we would expect there to be only a few topics formulating each document. β was also set to a relatively low value, as we expected a small number of words to be highly influential per topic given the short responses. α is modeled as asymmetrical, as we expected some topics to be more common than others within the survey responses. Previous work has found that asymmetrical α values provide substantial advantages to LDA results, whereas asymmetrical β priors provide no benefit [44].

Hierarchical Clustering

To make the topics more easily interpretable, those created through LDA modeling were further categorized into thematic groups with the aid of hierarchical clustering of topics (Multimedia Appendix 4). These topics were given summarizing names, shown in Tables 3 and 4 by subheadings in bold, based on their content, considering both topic *top terms* and the contextual use of these terms in texts (Multimedia Appendix 5). The Hellinger distance [45] between topics was calculated based on their term φ values, and the 2 closest topics were clustered together. φ values are the probability of a term being used within a text given; therefore, topics that more frequently use the same terms are considered closer. This was done iteratively until hierarchical clusters split topics into meaningful thematic categories. In some cases, topics thematically aligned with a category that was found to be semantically different to the topic according to hierarchical clustering; these are marked with a superscript in the tables and dendrogram and were reassigned to their appropriate thematic category.

Table 3. Topics created by latent Dirichlet allocation modeling of LifeInfo store loyalty card question, showing topic names, top 15 terms per topic according to term φ values, topic prevalence, and topic probabilistic coherence. In total, 9 thematic categories are shown.

Themes and SC[a] topic number	Topic name: top 15 terms selected by highest probability of the term given the topic	Prevalence (estimated survey responses; n=1930)[b], n (%)	Coherence
Nothing would change mind			
SC14	Wouldn't change mind: change, mind, change mind, nothing, would change, nothing would, don't think, make, wouldn't change, nothing change, think would, anything would, make change, think anything, and would make	134.52 (6.97)	0.47
Store loyalty card/don't use store card			
SC16	Store loyalty card/don't use: card, store, loyalty, loyalty card, store card, health, store loyalty, link, card health, don't use, use loyalty, why store, no need, card would, and use store	147.65 (7.65)	0.34
"Big Brother" and privacy invasion			
SC8	Big brother/nanny state: feel, privacy, big brother, brother, nothing, invasion, invasion privacy, regard, don't feel, thing, feel like, state, choice, watch, and nanny	80.10 (4.15)	0.16
SC1	Privacy and cold calling: concern, privacy, concern about, confidentiality, would concern, email, require, call, future, bombard, advertise, market, guarantee, about privacy, and would require	73.15 (3.79)	0.13
Personal information sharing and access by others			
SC2	Concerns about linkage and insurance: information, give, idea, insurance, don't like, health, like idea, good, information could, wrong, reassurance, health insurance, hand, affect, and know about	80.87 (4.19)	0.05
SC19	Data access and others: information, private, personal, access, company, stored, detail, hold, information stored, sell, people, safe, personal information, personal health, and party	103.45 (5.36)	0.04
SC3	Don't want to share personal information: share, information, information share, personal, share information, personal information, don't want, nothing, detail, want information, nothing don't, want share, wouldn't want, don't like, and not share	100.36 (5.20)	0.12
Data inaccuracy			
SC7	Data inaccuracy and bias: buy, shop, make, purchase, family, people, food, eat, lifestyle, relate, supermarket, diet, healthy, product, and good	117.92 (6.11)	0.09
Data security and protection			
SC15	Don't trust organizations with data: data, trust, don't trust, NHS[c], share, organization, system, personal data, data share, hack, personal, guarantee, secure, not trust, and safety	95.34 (4.94)	0.09
SC12	Data protection: data, data protection, protection, data would, data use, access, issue, how data, health data, would use, health, wouldn't want, data link, secure, and link	81.06 (4.20)	0.14
SC9	Data security: security, data, data security, breach, worry, assurance, worry about, security data, data breach, about security, information security, increase, improve, risk, and security information	82.41 (4.27)	0.06
SC5	Guaranteed data safety/security: secure, 100, 100 percent, percent, convince, stored, safely, safe, stored safely, prefer, separate, if could, NHS, control, and how secure	74.88 (3.88)	0.37
Understanding research purpose and process			
SC20	Don't understand benefit: understand, benefit, don't understand, why would, would need, understand why, necessary, link, purpose, need understand, understand benefit, understand purpose, why need, would necessary, and need link	82.41 (4.27)	0.17
SC6	Require demonstratable benefits: benefit, not sure, benefit would, link, explanation, see benefit, explain, appropriate, explanation why, would benefit, explain benefit, if could, sure would, care, and sure why	69.48 (3.60)	0.03

Making Recommendations

The recommended actions that researchers can take to address the key barriers to data sharing and linkage identified through LDA modeling are presented. These recommendations are based on the synthesis of participant suggestions and expertise regarding wider research on data sharing.

Results

Data Collection

The *LifeInfo Survey* recruited 7101 participants. The primary results of this study are reported elsewhere [28]. In brief, of those who reported using the services, 51.50% (2521/4895) responded favorably to sharing their loyalty card data for linkage to health records and 70.80% (1717/2425) responded favorably to sharing data from health and fitness apps or wearable devices to link with their health records. For the store loyalty card question, 62.28% (1489/2391) of respondents who answered *no* to whether they would share their data for linkage provided a free-text response. Of those who answered *not sure*, 66.02% (814/1233) provided a response. For the health and fitness app question, 50.82% (839/1651) of respondents who answered *no* to whether they would share their data for linkage provided a free-text response. Of those who answered *not sure*, 56.8% (565/995) provided a response.

A number of respondents who had either answered *yes* or did not provide an answer to whether they would share their data provided free-text responses that were included in the analysis (n=35 for the store loyalty card question and n=127 for the health and fitness app question). In total, 2338 individuals provided a free-text response to the store loyalty card question and 1531 for the health and fitness app question. Preprocessing steps and removing single-word responses reduced the number of responses to 1930 for the store loyalty card question and 1206 for the health and fitness app question. Single-word responses were considered separately and are shown in Tables 1 and 2.

Health and Fitness Modeling

Topic Number Selection

For the store loyalty card question, perplexity scores for each model of candidate number of topics (k) indicated that the best model has a number of topics within the range of k=20 to k=60, as the perplexity scores plateau at their minimum value within this range (Figure 1). For the health and fitness app question, perplexity scores were minimized to within the topic number range of 20-30 topics (Figure 2). The average probabilistic coherence scores within these ranges of k varied by only very small amounts, indicating that the models had near-equivalent topic quality (Figures 3 and 4). To maximize human interpretation and for comparability between the 2 questions, parsimonious models of 20 topics were chosen for both the store loyalty card question and health and fitness app question.

LDA Topics

Table 3 shows the 20 topics created by the final LDA model of free-text responses to the store loyalty card question. The table includes the 15 top terms most representative of each topic, selected according to their φ values. As φ values are the probability of a term being used within a text given the topic, those terms with the highest φ values are representative of the topic content. The table includes 2 further topic measures: first, topic prevalence, which indicates how common each topic was within the survey responses (eg, prevalence 5.0 indicates 5% of survey responses fell into this topic), and second, probabilistic coherence, as an indicator of the semantic meaningfulness of each topic (this can range from 0 to 1, where higher numbers are more meaningful). Lower values of probabilistic coherence are owing to lower frequencies of topic term co-occurrences within texts and/or topic terms being highly frequent within the data set at large. Low coherence scores are associated with conceptually less defined topics [40]; however, they could also be caused by *fuzzy* topics with many different terms or semantic crossover within other topics. Table 4 shows the same information for the 20 topics created by LDA modeling of the health and fitness app question responses.

LDA modeling also assigns survey responses with probabilities for each topic, known as θ *values* A higher θ value for any given topic indicates that the response should more likely be categorized into that topic (Multimedia Appendix 5 shows example responses most associated with each topic). Some responses, especially those that are very short (consisting of only 1 substantive term), are given equal θ values across all topics, which can be regarded as *uncategorizable* (Multimedia Appendix 6). There are some differences in LDA topic frequency depending on demographic groups (eg, age and gender); further analysis demonstrating demographic patterns can be found in Multimedia Appendix 7. Topic stability is validated by comparing results across multiple LDA runs (Multimedia Appendix 8), indicating that the thematic categories reported are consistently produced in topics created through LDA.

Discussion

Principal Findings

Understanding attitudes toward using big lifestyle data for health research is important for the success of research initiatives interested in using these data in the future. More than half of our participants who generated big lifestyle data reported that they would be happy for these data to be linked to health records for future research. As only individuals who stated that they were unwilling or unsure about sharing their lifestyle data were prompted to respond to what would make them change their mind, these topics identified specific barriers to data sharing. Topic modeling on survey responses produced thematic topics that summarized latent themes of concern to potential data subjects. We believe that the intelligence generated will support researchers in addressing these issues in the future with the appropriate use of safeguards and consent procedures to generate a publicly acceptable study design.

It is also worth noting that, although LDA modeling aims to create distinct topics, individual responses may discuss multiple topics, and many of the topics identified were interconnected and complementary. In addition, topic quality varies and can be inferred by topic probabilistic coherence scores, which indicate how clearly defined each topic is semantically. For example, topic HA2 (Table 4) had a low value of probabilistic coherence (0.05) and primarily focused on the issue of privacy invasion; however, it also discussed the safety and security of data.

Barriers to Data Linkage

The topics uncovered by LDA modeling indicated that many of the same issues arise for both sharing store loyalty cards and health and fitness app data. Many topics can be matched across Tables 3 and 4 or highlight similar themes. Overall, key barriers to the use and linkage of store loyalty cards and physical activity data for health research included data safety and security, personal privacy, the need for further understanding about the research and study purpose, fear that data could get into the *wrong hands*, problems with data accuracy, and not understanding the reason for data linkage. These barriers can potentially be addressed by researchers with varying degrees of ease. However, for some respondents, nothing would make them share these data, whereas others did not use store loyalty cards or health and fitness apps. Many of these issues are common in the literature on health, consumer, and personal data sharing, and as such, these are expected findings; however, new concerns also arise specific to individual data linkages. Example responses most associated with each topic are used throughout this discussion and are labeled with their relevant topic. These responses were selected as those with the highest probabilities of being categorized into a given topic and can be viewed in Multimedia Appendix 5.

Nothing Would Change My Mind

Among those who responded negatively to sharing their lifestyle data for health research, a large proportion would be unwilling to change their mind. This is indicated first by the number of texts that LDA modeling categorized as the topic *nothing would change mind*, which refers to SC14 and HA17, constituting approximately 6.94% (134/1930) and 6.30% (76/1206) of the analyzed responses, respectively, and second, by the single-word answers excluded from the analysis, which were mainly the words *nothing*, *no*, and *none* for both the store loyalty card question and the health and fitness app question (Tables 1 and 2). These 3 single-word answers combined account for 90.3% (361/396) of the single-word responses about store loyalty cards and 85.8% (265/309) of single-word responses about health and fitness apps.

"Don't Use Services"

Others mentioned that they did not use these services and thus would not have data to share. This was most clearly identified within the topics related to health and fitness apps (HA16 and HA11) and was evident for store loyalty cards (SC16). For example:

> *I'm not going to use a wearable device in the future.* [HA16]

XSL•FO
RenderX

Currently don't use store loyalty cards. [SC16]

For this group, only greater participation in big lifestyle data production would allow them to share their data.

"Big Brother" and "Privacy Invasion"

Some respondents reported feeling that the proposed data linkage was a *big brother* and an invasion of privacy (SC8, SC1, HA2, and HA3). However, for the fitness app question, these topics were less clearly defined by LDA modeling, reflected in their low probabilistic coherence scores for these topics (0.05 and 0.06). Answers such as "not interested to a 'big brother is watching' on all aspects of my life" (SC8) and "[I] wouldn't want to feel every area of my life is out of my control and being watched by an institution that already makes me feel like I have no autonomy" (HA3) indicate a dislike and feeling of *surveillance* through the data. Actions by researchers to address these feelings are limited as they are related to a broader distrust of big data; however, greater transparency as to how data are being used and assurance of anonymity may convince some users. Within the responses about store loyalty cards, SC1 specifically identified privacy concerns related to unwanted emails, phone calls, and text that can be addressed through data protection and security actions.

Personal Data and Linkage

Many responses focused on concerns about sharing these data, which respondents perceived as highly personal information (HA20, HA14, SC19, and SC3). References to data being personal and confidential appeared across topic categories, particularly in the context of not wanting to store loyalty card data and health records linked, data protection and security, and concerns about who is able to access these data. For example:

> *Nothing, this information is for my personal use. Access to my private devices can lead to security risks.* [HA14]

The degree to which an individual believes that their data are personal and sensitive influences their willingness to share data and with whom. Medical information is personal, particularly for individuals with complex health conditions. Health and fitness app data and store loyalty card data are personal in different ways. Fitness apps are primarily used for personal monitoring, meaning data are not created with the idea that they might be shared with other actors, whereas for store loyalty card data, individuals exchange information about purchase history with shops in exchange for discounts and points. However, in the case of transaction data, Skatova et al [13] found that people regarded the graduality of transactional data as personal.

"Who Has Access to Private Data?"

Health data are regarded as particularly sensitive and confidential [26], related to the theme of *private information*, and many responses mentioned worries that data would be accessed by other actors without their permission (SC2, HA15, and HA7). For example, "if the information was available only to the research team, and not to others, e.g. insurance companies, mortgage companies, even the medical team" (HA15).

Private companies, third parties, and health insurance companies were frequently mentioned by respondents as actors they feared would gain access to their data. This is expected, as research has found that these institutions are trusted least by the public to use data appropriately [24,27]. Many respondents believed these companies would use their data for profit, to increase the cost of premiums, or to deny treatment altogether. However, respondents also mentioned concerns that health care professionals would be able to access their lifestyle data. For example:

> *It's my information for me. If I want my doc to know it I'll tell him/her or put it on my health record myself.* [HA7]

This finding is less expected, as research finds that health care providers are one of the most trusted actors for data sharing [24,27]. This indicates that there is no straightforward relationship between an individual's willingness to share their data and their trust in the actors involved. A further barrier for data linkage is illuminated in that data are often created for specific purposes, and alternative uses of data outside of this domain can create suspicion.

There was also a common misunderstanding that sharing lifestyle data for research would allow all involved actors to access these data. This was reflected in the previous example and others. For example, one respondent asked, "Why would I want Tesco knowing my health records?" (SC17).

Similar findings were reported by Skatova et al [13] in their research on transaction data sharing. This indicates that one easily achievable action that could influence people to share their data would be to explicitly state that data would not be available to anyone but researchers.

Closely related to data access by others was a reported general belief that health records should not be linked with other data and should be accessed only by health professionals (SC17 and SC11). This again reflects the belief that data should only be used for its designated purpose. For example, one respondent felt that "Health records should be kept in health care" (SC17).

Data Accuracy

Data accuracy was another identified barrier. Many respondents indicated that their purchase history or fitness tracking was only partial, creating misleading data about lifestyle behaviors (SC7 and HA5). Indeed, missingness and data integrity have been identified as a challenge for research using big lifestyle data and a concern for participants [10,26]. Nevertheless, good results have been found by comparing or combining these data with more traditional collection forms, for example, modeling individual consumption from household-level data [10,46].

When looking at responses within this topic, most participants reported concerns that their data would make them appear *less* healthy than their real activity. For example:

> *I buy all my fruit and veg at a farm shop...my data would provide misleading associations.* [SC7]
>
> *[my mobile data] shows a terrible step count, but that's because I don't hold my phone while playing netball, long walks etc.* [HA5]

XSL•FO
RenderX

Implicitly, respondents worried that they would be judged unfavorably on their lifestyle behaviors. Researchers could address these concerns by making explicit in the study protocol that (1) data are not expected to be complete, (2) detailed actions they will take to accommodate for this with modeling techniques or additional surveying, and (3) all data would be made unidentifiable foreclosing the possibility of judgment.

Data Protection and Security

Topics that focused on data protection and security formulated a large proportion of the responses (approximately 17.31% (334/1930) of responses for the store loyalty card question and 19.90% (240/1206) for the health and fitness app question). Changes frequently mentioned were assurances that these data would be stored completely safely and securely and that they would be protected from hacks and data breaches. These are common concerns for data sharing, especially with data that are regarded particularly private or sensitive, such as health data [26]. Although these assurances were given as a condition for data sharing within the question wording (Multimedia Appendix 1), many responses highlighted their importance or were not convinced that this would happen. Action would, therefore, need to be taken to give participants greater confidence, which could be achieved through transparency in the research process and providing details of how these data will be protected.

Understanding More About the Research Purpose, Process, and Benefit

Across both store loyalty cards and health and fitness app data sharing, respondents mentioned that understanding the research better and being given more control over their participation would influence them to change their mind. This includes being provided with more information (SC18 and HA8), giving permission only for specific research projects (SC4 and HA4), and a greater understanding of the reason or benefits of research (SC20, SC4, SC6, HA9, and HA1). These findings are supported by the research of Skatova et al [13], who found that support for data sharing is contingent on its context and purpose, highlighting the importance of well-informed participants. Given that the *LifeInfo Survey* aimed to assess attitudes toward data sharing in the future, rather than requesting participants to consent to data sharing at this time, the participant information sheet (Multimedia Appendix 9) needed to be suitably broad, which would not be the case when recruiting participants to an actual data linkage study.

Researchers have found that a strong social motive, such as improvements to health or treatment, in addition to clearly defining the purpose of research, are key motivating factors for personal data donation [47], whereas using health data for insurance, marketing purposes, or commercial exploitation is unacceptable to the public [23]. This was reflected in the unstructured answers from the *LifeInfo Survey*. A respondent answered that they would be supportive "if the data fed into important public health or similar research and was not used to further commercial gains by these giants of commerce" (HA4).

Again, although LDA separates topics, they are connected, and the involvement of private companies creates concerns about whether these entities will be able to access health data for profit once linked.

Control and consent for health data being used for research have been found to be key for public acceptance [25]. A respondent answered that the data "has to be linked to a condition or specific research project with additional approval provided in advance" (HA2).

This is something that can be adapted into the research process, allowing participants to consent to or deny the use of their data, given the specifications of the study.

In addition to a desire for more understanding, another thematic category was identified of individuals who did not understand the reason or relevance of data linkage (SC13 and SC10). For example, one respondent said, "Do not see any reason why they should be linked" (SC10).

These topics were only produced when modeling the store loyalty card question, although topic HA5 also encompassed responses that stated data are *not relevant*. This perhaps indicates that respondents found the link between purchasing and health to be less relevant than fitness tracking and health.

Strengths and Limitations

The application of LDA modeling has clear strengths, enabling semiautomated analysis of large text corpora to readily identify barriers for data sharing. Nonetheless, some limitations present themselves; the topics identified through LDA modeling may hide rarer topics that do not have highly frequent mentions or a homogenous lexicon; for example, some *LifeInfo Survey* responses mention financial compensation (eg, vouchers), but this is not identified as a topic. In addition, texts that are linked by similar terms but are thematically different are sometimes grouped by LDA modeling; for example, HA6 included responses that require *100 percent* reassurance of certain criteria. However, these criteria span several different issues. These more granular findings may be better identified by human qualitative coding; however, this comes with its own limitations, especially for large data sets.

The *LifeInfo Survey* sample size was large, thereby facilitating the identification of important topics; however, the size of this data set was smaller than those often used for topic modeling, and responses were relatively short. As previously mentioned, those texts that were extremely short were uncategorizable by the model, which is a limitation of this methodology and data. Similarly, the survey was designed to elicit responses only from those unwilling or unsure about sharing their data. This provided benefits as it focused on the scope of topics to identify key barriers; yet, it would be insightful to obtain the opinions of those more supportive of lifestyle data sharing initiatives (which was 52.30% (2521/4820) of loyalty card holders and 70.80% (1717/2425) of health and fitness app users in our study), which should be considered in future studies. In examples where positive and negative responses are captured, it would be useful to explore a sentiment analysis approach to text mining; however, this was not relevant for our study.

Research has found LDA model results to be sensitive to model hyperparameters [44], and it is possible to use methods that

XSL•FO
RenderX

optimize LDA across different α and β values. These methods were not applied in this study as trialing them increased the computational intensity of the analysis and did not provide better solutions.

Due to resource limitations, the *LifeInfo Survey* questionnaires were only available in English. This means that we are unlikely to have reached the <2% of the population who are not able to speak English. However, the *LifeInfo Survey* is overrepresented in the traditionally hard-to-reach, most deprived communities and Asian and other ethnicities [28].

Recommended Actions

Several actions can be taken by researchers to directly address the key barriers to data sharing identified through LDA modeling, a summary of which is detailed in Textbox 1.

Textbox 1. Summary of recommendations to improve support for the linkage of novel consumer and lifestyle data with health records for research purposes.

Motivation

- Provide detailed and specific information about the study purpose and benefit.

Control and consent

- Provide detailed information about research and specific opt-in mechanisms to give participants more control.

Access by others

- Provide an explicit statement that data linkage does not give all parties access to linked data. Lifestyle data will not be shared with health services, and health records will not be shared with supermarkets or technology companies.

Third-party access

- Provide reassurances that data will not be shared with third parties, such as health insurers.

Inaccurate data

- Provide acknowledgment within the study specification that data might be partial and outline mechanisms for how this will be addressed, such as data quality checks, modeling techniques, and supplementary data collection.

Non and/or infrequent use of services

- Increase participation in novel data collection and more complete use.

Data security and protection

- Put in place stringent precautions to keep data protected from hacks or data breaches.

Personal data

- Provide assurances that data will be made anonymous and nonidentifiable.

“Big Brother” and privacy invasion

- Widely used good practice and exemplar studies, which provide a clear benefit to public health, and excellent data security could help increase trust in data sharing initiatives.

Findings and recommended actions incorporate some areas we hypothesized would emerge, for example, data security and protection, but are far more comprehensive and nuanced than the existing literature reflects.

Future Work

There is extensive scope to use LDA in future research, where free-text responses are collected in large surveys. LDA allows the detection of topics in free-text responses to be generated at a scale that is not feasible in more traditional qualitative thematic methods. Other text mining approaches, such as sentiment analysis, may be applicable where identification of positive and negative responses is important.

More work is needed to be able to further unpick concerns within topics such as *who has access to data*, where this could be context-dependent, for example, patients with a complex medical history who are worried about being judged on their lifestyle behaviors by their clinical team, and *big brother*, where it is clear that greater transparency is required regarding data being used for research purposes.

Future research could explore the utility of encouraging patients or research participants to use store loyalty cards and health and fitness apps or wearables as part of their personalized care, extending research that is already being done. This is of particular significance for those relating to the *don’t use services* topic.

There has been significant interest in the use of supermarket loyalty cards and health and fitness app data in health research, in addition to the greater availability of these data in recent years. This provides exciting opportunities to gain new insights into lifestyle risk factors for diseases through individual-linked

XSL•FO
RenderX

data. The growth of this research requires that the common concerns of participants regarding ethics, data security, research aims, and personal privacy, among others, are understood so that they can be addressed by future projects. Researchers may use the findings and recommended actions shared in this paper so that greater trust can be built in practices of data linkage for health research.

Conclusions

Analysis of the *LifeInfo Survey* responses with topic modeling techniques revealed key barriers that prevent people from willingly sharing their novel lifestyle data for health research. This large-scale public consultation provides actionable recommendations that will allow researchers using big lifestyle data to adapt their study design and provide safeguards based on expressed concerns important to the general public that are specific to novel lifestyle data and health record linkage.

Acknowledgments

The authors would like to thank all the LifeInfo study participants. The authors would also like to thank the research teams members at Leeds Teaching Hospitals National Health Service Trust, Kinga Dwornik, Patric Devitt, Linda Bamford, Ian Thompson, Amanda Friend, Linda Roberts, Richard Evans, and Laura Kelly; Leeds Institute for Data Analytics colleagues, Kimberley Wright, Hayley Irving, Chris Carrigan, and Maria Galazoula; Low Moor Medical Practice colleagues, Mark Cade and Maureen Rowland; Leeds City Council colleague, Thomas Woolley; and the UseMyData group. The LifeInfo study has been supported by the National Institute for Health Research Clinical Research Network through portfolio adoption, the Consumer Data Research Centre grant ref:ES/L011891/1, the Medical Bioinformatics Centre ref: MR/L01629X/ and the School of Medicine, University of Leeds, through their Academic Development Fund.

Abstract

Background: HIV disproportionately affects young Black men who have sex with men (YBMSM) in the United States. eHealth holds potential for supporting linkage and engagement in HIV prevention and care and the delivery of HIV information to YBMSM.

Objective: This study aims to investigate HIV information acquisition and use among YBMSM who use the internet.

Methods: A web-based self-administered survey and semistructured interviews were conducted. The survey findings informed the development of the interview guide. Descriptive statistics were used to characterize the survey sample, and interview data were analyzed thematically using modified grounded theory methodologies.

Results: Among the internet sample (N=83), the average age was 29.2 (SD 3.5) years, 41% (n=34) of participants self-reported living with HIV, 43% (n=36) were HIV-negative, and 15% (n=13) were unsure of their HIV status. Most participants (n=79, 95%) acquired HIV information through the internet while using a mobile phone. Web-based HIV information was intentionally sought from consumer health information websites (n=31, 37%), government health information websites (n=25, 30%), and social media (n=14, 17%). Most men incidentally acquired HIV information via advertisements on social media sites and geospatial dating apps (n=54, 65%), posts on social media sites from their web-based social ties (n=44, 53%), and advertisements while browsing the internet (n=40, 48%). Although the internet is the top source of HIV information, health care providers were the most preferred (n=42, 50%) and trusted (n=80, 96%) source of HIV information. HIV information was used to facilitate the use of HIV prevention and care services. The qualitative sample included YBMSM across a range of ages and at different points of engagement in HIV prevention and care. Qualitative findings included the importance of the internet as a primary source of HIV information. The internet was used because of its ease of accessibility, because of its ability to maintain anonymity while searching for sensitive information, and to mitigate intersecting stigmas in health care settings. Participants used HIV information to assess their risk for HIV and AIDS, support their skill building for HIV prevention, inform patient–doctor communication, and learn about HIV prevention and treatment options. Men expressed concerns about their diminishing access to online spaces for HIV information exchange among YBMSM because of censorship policies on social media sites and the *stigmatizing* framing and tone of mass media HIV-prevention advertisements encountered while using the internet.

Conclusions: YBMSM in this sample had high utilization of eHealth for HIV information acquisition and use but diminished access to their preferred and most trusted source of HIV information: health care providers. Future eHealth-based HIV interventions culturally tailored for YBMSM should aim to reduce intersectional stigma at the point of care and support patient–provider communication. The findings demonstrate the need for community-informed, culturally tailored HIV messaging and online spaces for informational support exchange among YBMSM.

Introduction

Background

Young Black men who have sex with men (YBMSM) are disproportionately affected by HIV in the United States, accounting for more HIV diagnoses than men who have sex with men (MSM) of other ethnoracial groups [1,2]. Black MSM have a 50% chance of acquiring HIV in their lifetime, and if the current incidence rates persist, 40% of Black MSM will be diagnosed with HIV by the age of 30 years [3,4]. YBMSM experience disparities across every stage of the HIV prevention and care continuum [5-8]. Compared with MSM of other ethnicities, YBMSM are less likely to have knowledge of their HIV status and are more likely to be infected, yet unaware [1,6]. Biomedical advancements in HIV prevention and treatment, such as pre-exposure prophylaxis (PrEP), provide an opportunity to reduce HIV transmission and related disparities, but awareness and adoption of these advancements remain the lowest among YBMSM [9-14].

Related Literature

HIV-related information is a critical resource for people living with HIV (PLWH) and those at high risk for HIV. Assessing and managing the risk of acquiring or transmitting HIV requires the successful acquisition and application of accurate HIV information. As possessing HIV information does not automatically lead to health behavior change, individuals must be informed before they are motivated and equipped with the skills to perform HIV risk-reduction behaviors [15,16]. Improving our knowledge of how YBMSM acquire and use HIV-related information outside of planned interventions will aid in efforts to disseminate information and messages among this group, which is at an elevated risk for HIV.

There is a growing body of literature that examines health information behavior (eg, health information acquisition, sharing, management, and use) within the domain of HIV [17-20]. Much of the literature examining HIV-related health information behavior has been explored among samples consisting primarily of PLWH, heterosexual youth, and individuals living outside of the United States [21-27]. Consequently, such findings are not generalizable to YBMSM. For instance, because the HIV epidemic disproportionately affects YBMSM, heterosexual young adults often seek information about contraception (eg, pregnancy prevention) and less information about HIV [28-30]. Furthermore, previous research examining HIV information acquisition among Black MSM was conducted at a time when the internet was not as accessible via wireless connection and mobile devices [31].

There is an opportunity to leverage eHealth modalities (eg, the internet, mobile technologies, social media, video games, geospatial networking apps, and text messaging) to provide access to accurate HIV information and support its use among YBMSM [32-36]. Although there are several technology-enabled HIV interventions that provide access to credible HIV information and aim to improve HIV-related outcomes among YBMSM, most are specifically for YBMSM living with HIV [37-40]. Few eHealth or mobile health (mHealth) HIV interventions are inclusive of YBMSM of varying HIV status [41-46]. To inform the design of future eHealth and mHealth interventions that provide HIV-related information and encourage its application among YBMSM, we need a better understanding of how YBMSM currently use these technologies to access and interact with HIV information and services outside of planned interventions. This paper describes a part of a larger study on HIV-related information behaviors of YBMSM and factors affecting their engagement along the HIV prevention and care continuum [47]. This study aims to explore HIV information acquisition and use among YBMSM who use the internet.

Methods

Mixed Methods Study Design

A sequential, explanatory mixed methods design guided this study [48]. During the first phase of the study, a convenience sample of 83 YBMSM completed a web-based, self-administered survey. The survey data were then analyzed to help inform the development of the interview guide. In the second phase of the study, semistructured interviews were conducted among a subsample (n=22) of survey respondents to help elaborate on the survey findings and provide new insights. The survey and interview data were integrated or *mixed* during both the collection and analysis of data. The results from the quantitative and qualitative data analyses were triangulated during interpretation.

Participants and Recruitment

A convenience sample of 83 YBMSM was recruited from December 18, 2018, to May 28, 2019, through a variety of venues such as HIV or sexually transmitted infection (STI) clinics, AIDS Service Organizations, a convenience sample from the UNC Center for AIDS Research, social media sites, geospatial dating apps, bars or clubs, lesbian, gay, bisexual, trans, and queer (LGBTQ) organizations, historically Black colleges and universities, mobile instant messaging apps (GroupMe and WhatsApp), and public postings. The eligibility criteria included the following: self-identification as Black or African American; identification as gay, bisexual, same-gender loving, or a man who has had sex with other men; being aged between 18 and 34 years; residing in the state of North Carolina; willing and able to provide informed consent; and being able to read, write, and speak English. The study received ethical approval from the institutional review board of the University of North Carolina at Chapel Hill. A certificate of confidentiality was obtained from the National Institutes of Health for the study.

XSL•FO
RenderX

Part I: Internet Survey

The survey adapted questions from 3 previous surveys: the National Cancer Institute's Health Information National Trends Survey, the Centers for Disease Control and Prevention's National HIV Behavioral Surveillance Questionnaire, and other published survey items on HIV-related health information behavior [49,50]. The HIV-related health information behavior survey items selected for inclusion were based on theoretical models of information behavior, including an adapted version of the Wilson model of information behavior [51] and the Erdelez model of information encountering [52]. The survey was pilot tested on a community advisory board comprising YBMSM (data not included in the final analysis). The final survey contained 72 possible questions and took an average of 15.7 minutes to complete. In addition to sociodemographic information, the survey content included questions regarding technology ownership or use, HIV information behaviors, HIV or STI testing, HIV or STI treatment, and PrEP use. The web-based survey was administered using Qualtrics software (Qualtrics).

A total of 225 interested parties clicked on the Qualtrics link to read about the survey. Among these, 45.3% (102/225) consented to participate in the survey. Among these 102 participants, 11 (10.7%) were not eligible as they identified as female (5/102, 4.9%), 2 (1.9%) were aged above 34 years, and 4 (3.9%) reported a zip code outside of the state of North Carolina. Of the remaining 91 eligible participants, 83 (91%) completed the survey.

Descriptive statistics of the survey measures were conducted using Microsoft Excel (Microsoft Corporation) to summarize survey data, including sociodemographic characteristics and technology ownership or usage. In this paper, the reported HIV-related information behaviors included information seeking, incidental information acquisition, and information use. To assess HIV information seeking, 3 measures were used: decision to take action (eg, seeking motivators), selection of information source (eg, preference and trust), and sources of HIV information. To measure the frequency of incidental HIV information acquisition, participants were asked to respond how much times ("never," "a little," "some," or "a lot") in the past 2 years they had received HIV information in the following ways: "I learn unexpected things about HIV while browsing the Internet." Additional response options were reflected in the data. HIV information use was measured by asking participants to identify the ways in which they applied the HIV information they acquired.

Part II: Interviews

Between June and July 2019, 22 men who completed a survey in the first phase of the study participated in semistructured interviews using Zoom videoconference software (Zoom software citation [53]). Only survey respondents who consented to being contacted to participate in an interview were considered for selection. Purposive sampling was used to select interviewees based on the following criteria: HIV-positive diagnosis (n=9), HIV-negative and using PrEP (n=7), and HIV-negative and not using PrEP (n=6). Given that most previous studies of HIV-related information behaviors have been conducted among PLWH, the purposive sampling criteria were developed to include the perspectives and experiences of YBMSM at different points of engagement along the HIV prevention and care continuum.

Interviews, which lasted on an average for 1 hour and 16 minutes, were guided by participant responses to survey items and included questions on topics including experiences of using mobile devices and the internet to locate HIV information, incidental acquisition of HIV information while using social networking sites and geospatial dating apps, experiences acquiring HIV information offline, motivators and deterrents of HIV information acquisition, the application of HIV information, use of technologies to overcome barriers to HIV information acquisition, and their criteria for evaluating and selecting HIV information sources. All participants who completed the interview were given a US $35 Amazon e–gift card. Interviews were audio recorded, transcribed verbatim, and member checked. Each participant was assigned a pseudonym.

The interview transcripts were analyzed thematically using Dedoose software (version 8.0.35) using grounded theory methodologies [54,55]. Our thematic analysis was guided by the Wilson model of information behavior, Erdelez model of information encountering, and Kari conceptualization of information use [51,52,56]. The Wilson model of information behavior explores the following:

> *The totality of human behavior in relation to sources and channels of information, including both active and passive information seeking, and information use. Thus, it includes face-to-face communication with others, as well as the passive reception of information as in, for example, watching TV advertisements, without any intention to act on the information given [51].*

The main constructs of the Wilson model of information behavior used for this thematic analysis were *activating mechanisms*, which are the factors motivating a decision to take action to satisfy a need for information (eg, information seeking), and the *sources and channels of information*. The Erdelez model of information encountering focuses on information acquired incidentally rather than through intentional information seeking [52]. We applied Kari conceptualization of information use as the application of a resource in some specific action [56].

Each interview transcript was read, and all texts related to HIV information acquisition and use were highlighted. The selected text was re-read and coded line-by-line to identify the initial emergent themes. Next, the most frequently reappearing initial codes were selected to begin explaining larger sections of data, and codes were condensed based on their thematic similarity. Codes were compared within and across interview text data to yield the most significant themes and provide more detailed information about HIV information acquisition and use among YBMSM.

Results

Internet Survey Sample

The average age of the internet sample was 29.2 (range 19-34) years. Most of the sample (70/83, 84%) consisted of men aged between 26 and 34 years. Most identified as gay (67/83, 80%), with 15% (13/83) identifying as bisexual. More than half of the sample (46/83, 55%) had less than a bachelor's degree and were employed (62/83, 74%; Table 1). Most participants had health insurance (56/83, 67%), and 32% (27/83) reported being uninsured. The annual household income varied with one-third (34%) of the participants earning less than US $20,000 per year. A total of 43% (36/83) of participants self-reported receiving an HIV-negative test result, 41% reported living with HIV, and 15% (13/83) were unsure of their HIV status. Of the men living with HIV, 68% (23/34) were using antiretroviral therapy (ART) at the time of the study, and only 30% (11/36) of the HIV-negative men used PrEP.

Technology Ownership and Use

Participants reported significant access to multiple technological devices and frequent internet use (Table 2). Most participants (83/83, 100%) reported connecting to the internet through a cellular network on a mobile phone, with 94% (78/83) using a wireless connection. Approximately 100% (83/83) of the survey respondents who owned a mobile phone reported using the internet daily. In the web-based survey, the past use of eHealth and mHealth for HIV information was found to be high. Most men had used mobile phones or computers to seek HIV information.

HIV Information Seeking and Source Selection

Most men (28/83, 34%) in the internet sample decided to seek HIV information as they believed it would be need-to-know information for the future (Table 3). Other participants (25/83, 30%) sought HIV information to satisfy their existing information needs and some (20/83, 24%) sought HIV information following a conversation with a member of their social network (eg, a friend, family member, or romantic partner). Approximately half of the participants (42/83, 50%) preferred to acquire HIV/AIDS information from a doctor or health care provider. The internet was the second most preferred source of HIV information at 36% (30/83). The 3 most trusted sources of HIV/AIDS information were a doctor or health care provider, the internet, and libraries, with 96% (80/83), 87% (72/83), and 72% (60/83), respectively, reporting that they trust these sources “a lot” or “some.” When asked, “the most recent time you looked for information related to HIV where did you go first?”, the internet was the top choice reported by 84% (70/83) of the participants. Web-based HIV information seeking was primarily mediated by default mobile phone search engines (eg, Google, Bing, and Yahoo). Consumer health information websites (31/83, 37%), government health information websites (30%), and social media sites (17%) were the top sources of intentionally sought web-based HIV information.

[a]STI: sexually transmitted infection.

Incidental HIV Information Acquisition

Incidental HIV information acquisition was high among the internet sample (Table 3) [57,58]. Respondents (54/83, 65%) most often incidentally acquired HIV information on the web via advertisements on social media sites and geospatial dating apps, postings on social media sites from their web-based social ties (eg, people and organizations they follow; 44/83, 53%), and advertisements encountered while browsing the internet (40/83, 48%). Most participants who incidentally acquired HIV/AIDS information while using social media sites or dating apps did so via Facebook (44/83, 53%), Instagram (40/83, 48%), and the dating app Jack'd (38/83, 46%).

Information Use

Most men in the internet sample applied the HIV information they acquired by looking for HIV or STI testing locations (56/83, 67%) and utilizing HIV or STI testing services (53/83, 64%; Table 3). Among participants who among participants who were living with HIV (34/83), more than half (19/34, 53%) used the knowledge of their status to begin ART within 3 months of receiving a diagnosis. Approximately 55% (46/83) of the internet sample used the HIV information they acquired to discuss HIV status with their sexual partners.

Interview Sample

Interview Sample Characteristics

Semistructured interviews were conducted with 22 YBMSM, aged between 22 and 33 years, who completed the web-based survey during the first phase of the study (Table 4). The interview sample included individuals residing in 9 counties in the state of North Carolina. A total of 9 men were living with HIV, 7 men were HIV-negative and using PrEP, and 6 men were HIV-negative and not using PrEP. The sample criteria were selected to reflect the varying HIV information needs and information interactions of YBMSM at different points of engagement along the HIV prevention and care continuum.

The Internet as a Primary Source of HIV Information

The use of the internet and mobile technology for HIV information was high in both the web and survey samples. All men in the interview sample confirmed using a mobile phone to search for HIV information on the internet. The most common themes were convenience and the ease of accessibility that mobile phones provided for seeking HIV information from multiple sources. Most perceived the HIV information they acquired on the web to be accurate:

> *Mostly because they usually give me the correct answer. It's really easy to navigate and you can find reputable sources like dot orgs or dot gov that's really accurate, something you can believe in as a source. That's why I trust it and then you don't have to go anywhere. Like you can pull out your phone and with quick searching, know the answer in like 10 seconds. Okay. Yep.* [Preston, HIV-negative, using PrEP, 23 years]

Government health information websites and health organization websites were deemed to be the most trustworthy sources of web-based HIV information. Men also valued the ability to seek HIV information privately through the internet while using a mobile phone but expressed concerns about others discovering their browsing history:

> *I usually use my phone and I like go into private browsing. You know like you just start typing something or if someone is using my phone I don't want them to start typing something, then it auto fills and then I hear "hey, what's this?"* [Nathan, HIV-positive, 30 years]

In the interviews, men confirmed that doctors and health care providers were their preferred and most trusted source of HIV information. Despite this preference, mobile HIV information seeking was used by men to circumvent barriers preventing them from accessing it from doctors and health care providers. The most common subthemes included discomfort communicating with health care providers about same-sex sexual behaviors and the underutilization of health care providers as an information source because of the experienced and anticipated intersectional stigma rooted in racism, homophobia, and HIV stigma in health care settings:

> *I didn't tell my doctor that I was sleeping with men, and he didn't ask. I'm already Black, and when they see me, they already treat me like I'm a statistic. I'd rather not talk to them about this stuff, because I don't want them to treat me even worse.* [Rashod, HIV-negative, not using PrEP, 22 years]

HIV Information Use

The internet was used to seek HIV information by men in the interview sample to assess their risk of acquiring or transmitting HIV, support their skill building for HIV prevention, inform patient–doctor communication, and learn about HIV prevention and treatment options (Table 5). HIV-negative and participants living with HIV used resources to build skills to discuss their HIV or STI status and testing history with their sexual partners. One participant described his experience looking for HIV information about PrEP and eventually initiating PrEP to minimize his HIV risk once he started dating someone who was HIV-positive:

> *My expartner was HIV-positive. And I knew that going into that relationship, so I started to do research myself. Just looking online, browsing different online websites. And then, when I wanted to pursue Truvada, I actually spoke with a local PRIDE center.* [Artez, HIV-negative, taking PrEP, 32 years]

Several participants used HIV information to inform patient-doctor communication, including (1) participants *self-diagnosing* themselves before seeing a health care provider, (2) verifying HIV information they acquired on the web by speaking with a health care provider, and (3) seeking information to educate health care providers about PrEP. One participant described his experience of self-diagnosing himself before speaking with a provider because of the presence of flu-like symptoms (Table 5).

XSL•FO
RenderX

Table 5. HIV information use—interview sample (n=22).

Interview sample	Illustrative quotes from participants
Manage or assess risk for HIV/AIDS	"When I learned about medication resistance, it made me really on top of taking my medication. Because previously, I might go in for a sore throat and they'll give you some antibiotics and they'll tell you, 'hey, make sure you take two a day for 10 days, make sure you finish it,' and here we are two months later, and I still have like 4 pills there. So, I wasn't always on top of it. Once I started feeling better, I'd be like, ok whatever. But learning about medication resistance particularly with HIV has def made me very much on top of taking medication as I've been directed to by my doctors. I have to aggressively handle my sexual health myself." [Jerry, HIV-positive, 28 years]
Inform patient-doctor communication	
Self-diagnosis	"Well, a lot of times I do a lot of self-diagnosing first just to kind of give them an idea as to what's going on, give myself an idea of what's going on. And to be able to explain my signs and symptoms more in detail. So that gives them a better view of what potentially could be going on. So, I went ahead and got tested just to make sure it was ok...and then if there was treatment to go along with it, it would be syphilis, the series of three shots, over the course of like six weeks...and I never wanted to go through that again, so I ask my doctor what to look for in myself and in others." [Chris, HIV-negative, non-PrEP[a] user, 29 years]
Information verification	"Whenever there is something new or a new medication or something that I hear about I will research it. And look at it. Or if it's like has to do with different studies, I'll look at the things that's part of the study. And then I will ask that information of my doctor." [Thomas, HIV-positive, 24 years]
Educate health care providers	"I just know I have a few friends that had experiences going to doctors, asking for PrEP or anything like that and the doctor was very closed minded or not very up-to-date on medical history in our aspects. We have to look for stuff on our own to tell them about it. I don't like that. I still mostly trust doctors, but I'll always think I'll have a shred of not doubt, but like I'm gonna double check and make sure you're telling me the best stuff. I'm going to make sure I'm with a good doctor...who is knowledgeable on whatever I need them to be knowledgeable on." [John, HIV-negative, PrEP user, 26 years]
Skill building for HIV prevention	"I started looking for this information because I needed help figuring out how to talk about it with other people. I'm to the point now where in the past if I got burned by somebody, I wouldn't ask them, I would just go get treated. I was afraid of saying something to this person. But I do better now just telling people like, 'hey I just went and got treated you might want to get tested on what's going on.' I was afraid to do so because the first thing you think about is them passing judgment." [Will, HIV-negative, non-PrEP user, 27 years]
Understand HIV prevention and treatment options	"I would like look up, cause I found out there's different strands to HIV, like it's not just one person has HIV, like there's levels to it. So, I'd try to Google and find information about that. And I also heard about PrEP, it was like maybe a cure or whatever I guess to try to prevent you from getting it, or lessen your chance of getting it. To be honest, my doctor had told me about it before, but I wanted to do my own research on it, so I just Googled and read up on that to find out what it's all about." [Patrick, HIV-negative, non-PrEP user, 32 years]

[a]PrEP: pre-exposure prophylaxis.

Use of Social Media for HIV Information Support Exchange

Although participants expressed displeasure with the framing and tone of advertisements on social media sites and geospatial dating apps promoting HIV prevention, they still used the sites as a space for informational support and communication with other Black MSM. Many participants reported acquiring HIV information from Black and other MSM of color who posted about their experiences living with HIV, being in a mixed HIV status relationship (serodiscordant), and the adoption of HIV risk-reduction behavior (eg, PrEP use and HIV self-testing):

> *I guess you can say that with me being on this medication, I do have a best friend that was also pretty much in the same boat as I am dealing with someone that was HIV positive as well. He really didn't know much about PrEP as well, so I talked to him about it, I gave him the same information that my doctor pretty much you know gave to me. I actually pretty much introduced him to my doctor that I'm with right now, and so they've been on PrEP for a while now. I guess you can say that I've been on it, and I hadn't received this information prior, and I was able to share it with someone else that was pretty much unaware of it as well.* [Antonio, HIV-negative, using PrEP, 27 years]

Unfortunately, some participants noted their diminished ability to exchange HIV information with Black and other MSM of color because of censorship policies on social media sites. When probed about where he obtained HIV information on the web, one participant noted his loss of HIV information from Black MSM on Tumblr. Other participants noted the loss of online community due to the suspension of some accounts and content removed because of censorship policies.

Concerns About Incidentally Acquired Web-Based HIV Information

The widespread use of social media sites and geospatial dating apps was confirmed in the interview sample. Encountering HIV information on these platforms was common. All participants expressed concerns about the framing and tone of the HIV prevention information and messages they encountered on the web via mass media HIV-prevention advertisements. Men described the framing of HIV prevention information as "judgmental" and perceived the tone of the information to be "pushy" and "fearmongering":

XSL•FO
RenderX

> *The ads were overreacting, but just in a way that's like, do this or you'll die or do this and you definitely get, you know, you'll definitely get syphilis...do this or you'll end up here or there and it's kind of stigmatizing, because I know I noticed a lot of their targeted audience where it wasn't really straight male, and it isn't fair to the LGBT community cause it's almost like, okay, you're targeting them, like making them feel like they have to get tested because they have something because they're a part of this community versus this guy, he's on the football team or this girl who is a cheerleader. Right. And they have, they may have something, not know it and passing it along to everyone else.* [Rick, HIV-negative, non-PrEP user, 22 years]

Discussion

Principal Findings

The purpose of this mixed methods study among YBMSM who use the internet was to explore their HIV-related health information behavior and to conduct formative work to inform the development of future, culturally tailored eHealth HIV interventions. The study found high technology ownership and use of mobile and social computing technologies to facilitate the utilization of HIV prevention and care services. Web-based HIV information was highly accessible to men in the sample through mobile phones and computers. Men in the interview sample discussed using eHealth to circumvent barriers to obtaining HIV information offline from a health care provider and for the ability to seek this information using private browsers. These findings indicate the importance of considering privacy and confidentiality when developing culturally tailored eHealth HIV interventions for YBMSM.

Men in the internet and interview sample preferred to acquire HIV information from a health care provider. However, men primarily used the internet to acquire HIV information because of barriers, including discomfort disclosing same-sex sexual behaviors to a health care provider, and intersecting stigmas experienced in health care settings. Previous studies with Black MSM have found perceptions of racism and medical mistrust to affect provider communication, health care access, and uptake of prevention services [59,60]. Black MSM have been found to be less likely to report their same-sex sexual behaviors to primary care providers compared with White MSM [57]. Prior research with young men who have sex with men (YMSM) reported barriers to communicating same-sex sexual behaviors and sexual health concerns to providers because of the fear of heterosexist bias, concerns about sexual health information being disclosed to parents, and a general belief that sexual minority youth did not receive equitable treatment in health care settings [58]. As reported in this study, the intersecting stigmas YBMSM experience related to sexuality, HIV, and racism can hinder access to HIV information from reliable and trusted sources of information [61,62]. To support engagement in HIV prevention and care, structural barriers to accessing HIV information such as racism, HIV-stigma, and homophobia must be minimized [63-65]. Future culturally tailored eHealth HIV interventions should aim to reduce intersectional stigma at the point of care and improve communication between providers and YBMSM. The development of these interventions should be community-driven. YBMSM need to be engaged in each step of the research process to identify and prioritize their needs and experiences during health care encounters. Health care providers should also receive training to provide antiracist, culturally competent care to YBMSM [66,67].

Health care providers must be equipped to provide timely recommendations on HIV prevention methods such as PrEP and HIV or STI testing [68]. In the interview sample, YBMSM shared experiences speaking with health care providers who were uninformed about PrEP and other HIV-prevention methods such as undetectable equals untransmittable (U=U; ie, a person who is HIV-positive with a consistently undetectable viral load cannot transmit HIV to a sex partner). To assist health care providers in providing timely HIV-prevention recommendations, the application of machine learning methods could be used to create an HIV risk prediction tool that identifies potential candidates for PrEP and other HIV-prevention strategies [69,70].

Previous research has found that when communicating about sensitive subjects, people may be more comfortable interacting with humans through a computer than through face-to-face interactions [71,72]. Owing to the high use of eHealth for HIV information acquisition and use among YBMSM in this sample, eHealth modalities may be especially advantageous for facilitating shared decision making between men and providers. eHealth interventions for YBMSM should aim to enhance shared decision making by increasing awareness and practical expectations of the advantages and disadvantages of prevention strategies such as PrEP and provide an environment in which they are comfortable communicating with providers [73,74]. This may help mitigate obstacles at the social, structural, and individual levels before enrolling them in health care services [75,76].

Concerns about the framing and tone of web-based, mass media HIV-prevention advertisements targeting YBMSM were raised during this study. Participants perceived the advertisements to be stigmatizing and judgmental of YBMSM. This aligns with research that found public health messaging aimed at reducing HIV disparities to be alienating [77-79]. Pleasure-centric and sex-positive framing of HIV information and messages may be helpful for promoting HIV risk-reduction behaviors among YBMSM [80]. To avoid further stigmatization of YBMSM, future eHealth HIV interventions should include community-informed, culturally tailored HIV messaging [81].

The use of social media sites for sharing and exchanging HIV information with web-based communities of Black MSM was a common theme of this study. Participants valued receiving HIV information from Black MSM who shared their experiences living with HIV, navigating serodiscordant relationships, and using PrEP and HIV self-testing kits. This aligns with the literature that found that social media sites are often used by LGBTQ individuals who may use these platforms to find information that may not be available through their offline social networks, formal education spaces, or health care providers [82,83].

XSL•FO
RenderX

In this study, it was noted that participants experienced diminished access to HIV information from Black MSM on the web because of censorship policies on social media sites such as Tumblr. These censorship policies are a direct result of FOSTA/SESTA legislation, and point to its harmful impact on minoritized communities who relied on these spaces for online social support building [84]. Participants described Tumblr as a platform where they built community and received nonstigmatizing information related to HIV. This finding supports previous research that conceptualized Tumblr as a "queer technology" and explored how the policy change pushed away communities of users, especially communities that relied on the "adult content" banned in this space for medical education and knowledge [85]. Future eHealth interventions should provide online spaces, such as forums, that promote community building and information support exchange among YBMSM.

Limitations

This study has several limitations. First, the findings of this study are limited in their generalizability and thus do not encompass the experiences of all YBMSM, as local and individual differences are also present from this data source. Many participants living with HIV in the study were recruited from HIV clinics and community-based organizations and thus may not be reflective of the population of YBMSM in North Carolina who are out of care. The size of the quantitative sample and qualitative nature of the study also make it difficult to generalize the results to all YBMSM in the United States. Future research would benefit from a larger study sample and a more rigorously recruited study sample. However, this study does show strength over previous internet-based research with YMSM, which has traditionally been limited to mostly White participants in a single geographic region for the sample. Second, internet access familiarity with web-based technology may have influenced the decision to participate in the study. YBMSM who use a different type of electronic device to access the internet may be able to navigate websites easily and may encounter technical challenges.

Although web-based surveys and video chat platforms for qualitative data collection have been found to reduce response bias and minimize barriers for research participation (eg, financial barriers related to travel expenses or time off from work, stigma associated with research participation, and physical disabilities precluding mobility), they do not account for limited literacy. Notwithstanding these limitations, our findings represent a novel characterization of HIV information acquisition and use among YBMSM in the southeastern United States who use the internet—a topic and population that warrants further study given the high rates of HIV diagnoses among this population in this geographic region. The data from this study may provide invaluable information concerning limitations to HIV information access and the potential to use technologies to reduce social, structural, and individual-level barriers to HIV prevention and treatment among YBMSM.

Abstract

Background: Identification of the essential components of the quality of the data collection process is the starting point for designing effective data quality management strategies for public health information systems. An inductive analysis of the global literature on the quality of the public health data collection process has led to the formation of a preliminary 4D component framework, that is, data collection management, data collection personnel, data collection system, and data collection environment. It is necessary to empirically validate the framework for its use in future research and practice.

Objective: This study aims to obtain empirical evidence to confirm the components of the framework and, if needed, to further develop this framework.

Methods: Expert elicitation was used to evaluate the preliminary framework in the context of the Chinese National HIV/AIDS Comprehensive Response Information Management System. The research processes included the development of an interview guide and data collection form, data collection, and analysis. A total of 3 public health administrators, 15 public health workers, and 10 health care practitioners participated in the elicitation session. A framework qualitative data analysis approach and a quantitative comparative analysis were followed to elicit themes from the interview transcripts and to map them to the elements of the preliminary 4D framework.

Results: A total of 302 codes were extracted from interview transcripts. After iterative and recursive comparison, classification, and mapping, 46 new indicators emerged; 24.8% (37/149) of the original indicators were deleted because of a lack of evidence support and another 28.2% (42/149) were merged. The validated 4D component framework consists of 116 indicators (82 facilitators and 34 barriers). The first component, data collection management, includes data collection protocols and quality assurance. It was measured by 41 indicators, decreased from the original 49% (73/149) to 35.3% (41/116). The second component, data collection environment, was measured by 37 indicators, increased from the original 13.4% (20/149) to 31.9% (37/116). It comprised leadership, training, funding, organizational policy, high-level management support, and collaboration among parallel organizations. The third component, data collection personnel, includes the perception of data collection, skills and competence, communication, and staffing patterns. There was no change in the proportion for data collection personnel (19.5% vs 19.0%), although the number of its indicators was reduced from 29 to 22. The fourth component, the data collection system, was measured using 16 indicators, with a slight decrease in percentage points from 18.1% (27/149) to 13.8% (16/116). It comprised functions, system integration, technical support, and data collection devices.

Conclusions: This expert elicitation study validated and improved the 4D framework. The framework can be useful in developing a questionnaire survey instrument for measuring the quality of the public health data collection process after validation of psychometric properties and item reduction.

Introduction

Background

Public health, a data-intensive discipline, relies on high-quality data to monitor the health and well-being of the population, make appropriate policy decisions for intervention, and evaluate intervention outcomes [1-3]. After two decades of development in the design and implementation of information and communication technologies (ICTs) for national public health data management, public health information systems (PHISs) have developed into essential data repositories [1,4,5]. PHISs have been well integrated into many nations' health information management systems, such as those of the United States, Australia, and China [6-9]. The data stored in PHISs, for example, on women's and children's health, aging population, and people living with HIV/AIDS, have enabled public health agencies to formulate evidence-based policies and plan and evaluate program performance to ensure accountability for citizens and countries [1,6,7,10].

As data-driven public health management assumes data are accurate, timely, and reliable, data quality assessment needs to be continuously and rigorously conducted to ensure high-quality data in PHISs [4]. Data quality is a 3D concept that includes the quality of data, data collection process, and data use. Improving the quality of the data collection process is critical for PHIS data quality management [11]. Identification of the essential components of the quality of the PHIS data collection process is the starting point for the design of effective public health data quality management strategies [4,7].

Through appraisal and synthesis of literature that reports the factors affecting the rigor of the PHIS data collection process, we have proposed a preliminary conceptual framework that focuses on four dimensions of the quality of the process [12]. These are data collection management, data collector, information system, and the data collection environment. We name them 4D components, which consist of 12 subcomponents and 149 indicators (Multimedia Appendix 1 [7,12-15]). Data collection management is an administrative process by which data are acquired, validated, stored, protected, and processed [7,13]. Its indicators include appropriate data collection methods, data entry forms, and ongoing quality assurance. At the individual level, data collection personnel (replacing *data collector*) need to have a right attitude, adequate skills, and competence for the job. They must maintain adequate communication with each other. For them to execute their tasks adequately, their organization needs to provide adequate staffing with the right skill mix [12]. A data collection system (replacing *information system*) requires different systems and elements to integrate and assist data capture, data entry, and data logging. Thus, continuous and systemic functionality and technical support are required [14]. A good data collection environment includes training, strong leadership, and funding support for data collection [15]. Given that this preliminary 4D component framework was derived from an inductive analysis of the literature, validation of the framework within a certain PHIS was needed.

Expert elicitation is a research method used to identify and address uncertain subjects, especially when relevant local evidence or information is incomplete [16]. This method has been widely used in public health for policy decisions to generate evidence [17,18] to achieve various research goals, such as environmental health impact assessment [16], health technology assessment [19], and economic evaluation of health gains of antenatal care [20]. Knowledge synthesized from expert opinions can form the foundation for further research.

The main procedures for a formal expert elicitation include characterization of uncertainties, selection of experts, elicitation of expert judgments, and possible aggregation and reporting in a temporary summary [16]. The criteria for expert selection include the following: the person should be representative of the main population of interest and he or she should have sufficient intellectual ability to provide the theoretical definitions, rank the importance of the data items, and explain a potential causal relationship between them [16]. Expert judgments should adhere to the principles of the scientific process. These are accountability, neutrality, fairness, and the ability for empirical control [21]. A facilitator, often a trained interviewer, has *the enormous potentialto reduce bias in expert elicitation* by clarifying the questions to the expert [16,19]. A systematic elicitation session could increase the validity, transparency, and trustworthiness of research [16].

Objectives

Using an expert elicitation approach, this study aims to obtain empirical evidence to confirm the components of the 4D framework and, if needed, to further develop the framework.

Methods

Study Setting

The study was conducted within a country-level PHIS, the Chinese HIV/AIDS Comprehensive Response Information Management System (CRIMS). Acknowledged as one of the milestones for China's HIV/AIDS response programs over the past three decades [22], the CRIMS is a web-based national AIDS information management system that was established in 2008 [5]. The system has been used for routine HIV/AIDS prevention and control data collection from hospitals and all units of the Chinese Center for Disease Control and Prevention (China CDC) in 2893 counties. The data stored in the CRIMS include demographic information, case reporting, antiretroviral treatment, methadone maintenance therapy, behavioral interventions, laboratory testing, counseling, and surveillance. These real-time data can be used for decision making,

XSL•FO
RenderX

monitoring, and evaluating HIV/AIDS prevention and control programs in health bureaus and CDCs at national, provincial, city, and county levels [10]. Therefore, high-quality data in the system are imperative for China's HIV/AIDS program monitoring and evaluation. However, prior studies found that public health professionals lacked trust in the quality of data in the CRIMS and expressed concerns over the quality of the data collection process [17,23,24]. This primary concern of public health professionals in China has also motivated this study.

Data management within the CRIMS includes data collection, data entry, data analysis, data assurance, and data use [25]. The personnel involved in the CRIMS data management include health administrators in health bureaus, epidemiologists and laboratory technicians in CDCs, and clinicians and data registrars in hospitals. They have accumulated rich experiences from long-term empirical work in HIV/AIDS data management and were thus appropriate experts who could provide inputs for this study.

Ethical Approval

This study was approved by the Human Research Ethics Committee at the University of Wollongong and the Institutional Review Board of the National Center for AIDS/STD Control and Prevention at the China CDC. All participants provided informed written consent to participate in the study and to publish individual data.

Design of Interview Guide and Data Collection Form

To ensure the validity of the study, we followed three broad categories of validity for qualitative research in information systems proposed by Venkatesh [26]. These are (1) design validity (eg, descriptive validity, credibility, and transferability), (2) analytical validity (eg, theoretical validity, dependability, consistency, and plausibility), and (3) inferential validity (eg, interpretive validity and confirmability).

During the design phase, an interview guide was developed in consultation with 7 information system researchers at the University of Wollongong: a professor, an associate professor, a lecturer, a research assistant, and 3 PhD candidates. Two open-ended questions were suggested: "What are the components of quality of the CRIMS data collection process?" and "What are the attributes of these components?"

An item represents a component or subcomponent of the 4D component framework in reference to the literature [12]. An item weight table was developed to elicit an expert's opinion about whether an item is a component or subcomponent of the quality of the CRIMS data collection process. To avoid bias in directing the expert to the preliminary 4D component framework, we reconstructed the testing items according to group discussions with consultant researchers. Four items that are not part of the framework but frequently identified in practice were added, including parallel organization, high-level management, social factors, and organizational policy. Four items that are elements of a certain original subcomponent or component were used to represent their parental components. These were data collection forms and data quality assessment strategies of the component data collection management, data collector's data quality audit skills, and demographics of the component data collection personnel. Four original items—funding, data collection personnel's communication, staffing pattern, and integration of different systems—were purposely excluded to test the completeness of the framework item spectrum. Each item was answered as *yes* or *no*. If the answer was yes, the expert was asked to rank the importance of the item for the quality of the CRIMS data collection process. The rankings ranged from 1 (the highest contribution) to 16 (the smallest contribution; Multimedia Appendix 2).

The interview guide and item weight table were translated into Chinese. Three bilingual authors validated the Chinese translation. The interview guide was pilot tested for content validity and face validity with 8 Chinese public health practitioners who worked within the CRIMS. All 8 practitioners agreed with the fit of the interview questions and the item weight table for the study.

Sampling and Recruitment of Study Participants

To ensure generalizability of the study, personnel from all administrative levels in all types of organizations with at least one data management role for the CRIMS were considered as potential experts. They were eligible for inclusion as experts to ensure a comprehensive capture of diverse expert opinions. Those who did not have a role in CRIMS data management were excluded.

Following the aforementioned selection criteria, we used a stratified sampling method to identify the participating organizations [27]. Representativeness was ensured by a lack of significant statistical differences in data quality among provinces [23,24]. A total of 19 organizations were selected, including 3 departments of health bureaus (1 each at the central, provincial, and county levels), 10 departments of the CDCs (1 each at the national, provincial, and city levels and 7 at the county level), and 6 hospitals (4 tertiary, 1 secondary, and 1 primary).

HC was an epidemiologist who specialized in HIV/AIDS prevention and control in a provincial CDC in China. She used a convenient sampling method to recruit participants working in health bureaus and CDCs. A personalized invitation message containing a cover letter and a consent form was sent through the Chinese social media QQ to 20 potential participants. All participants agreed to participate by returning a completed consent form. Web-based interviews were arranged with 18 of them through QQ media. The other 2 withdrew quoting time constraints. Of the 18 participants, 3 were from health bureaus at 3 different levels. The remaining 15 came from 4 tiers of the CDCs: 1 at the national level, 4 at the provincial level, 3 at the city level, and 7 at the county level.

HC recruited potential participants from 6 hospitals via direct contact with hospital management. She explained the project's purpose and research process to the relevant managers in the hospitals and sought their support in recommending eligible data management personnel to participate in the field study. Being introduced by the facility management, HC contacted the potential participant and organized an interview with the person at a designated venue and time. An interview would start only after providing written consent. Overall, 10 potential

XSL•FO
RenderX

participants were recommended and completed interviews. Of the 10 participants, 6 came from 4 tertiary hospitals, 3 from a secondary hospital, and the other from a primary health care center.

On average, the 28 participants had worked in public health or health services for 12 (SD 7) years and in the HIV/AIDS domain for 7 (SD 4) years. Of the 28 participants, 16 (57%) were female; 23 (82%) participants were aged between 30 and 50 years, and the other 5 (18%) were aged under 30 years. Most participants (25/28, 89%) had multiple job roles in HIV/AIDS data management.

Interview Procedure

Both telephone and face-to-face interviews were conducted. An internet voice call was made for telephone interviews with the practitioners during their work break or after hours. Face-to-face interviews were conducted at hospitals. The average duration of the interviews was 44 minutes (SD 23 min).

Each interview started with asking the practitioner to provide answers to the 2 open-ended questions. Answers from 3 of the first 5 practitioners were related to data quality instead of the focused topic of this study, the quality of the data collection process. To clarify the research topic, the researcher started subsequent interviews with the question, “What do you think the differences are between data quality and quality of the CRIMS data collection process?” A further probe clarified any emerging issues raised by the practitioners. Once information saturation was reached, that is, no further issues emerged, the interview was concluded.

After the practitioners answered all the open-ended questions, they were invited to assess the 16 items listed in the weight table. The other 7 items were raised by the practitioners. Their average rankings were not calculated because of the small sample size.

Data Processing and Analysis

All audio recordings were transcribed verbatim. The transcripts were sent to the interviewees for confirmation, translated into English, and back translated. Qualitative data analysis was conducted in accordance with the framework analysis approach suggested by Pope et al [28]. The theoretical (thematic) framework was the 4D component of the quality of the PHIS data collection process. The unit of analysis was each transcript. The data analysis was conducted in 3 steps.

Step 1: Generating the Initial Codes

Each transcript was thoroughly read to identify and understand the meaning of the relevant text. A concise phrase was created to summarize a sentence. For example, “Reward and punishment system, which is important for a working system...This should be in organizational management policy” (C102) was coded as “clear reward and punishment in organizational policy.” “If they (managers) understand the importance to the job (data collection), you will work easily; if they don’t, it is hard” (H306) were coded as “managers should understand the importance of data collection.”

After the first round of transcript encoding, 302 codes were extracted and stored in an Excel database.

Step 2: Mapping the Codes Using the Preliminary 4D Component Framework

All the 302 codes were compared and mapped with the original indicators and subcomponents in the preliminary framework. Three data processing strategies were used in 3 different scenarios.

Scenario 1

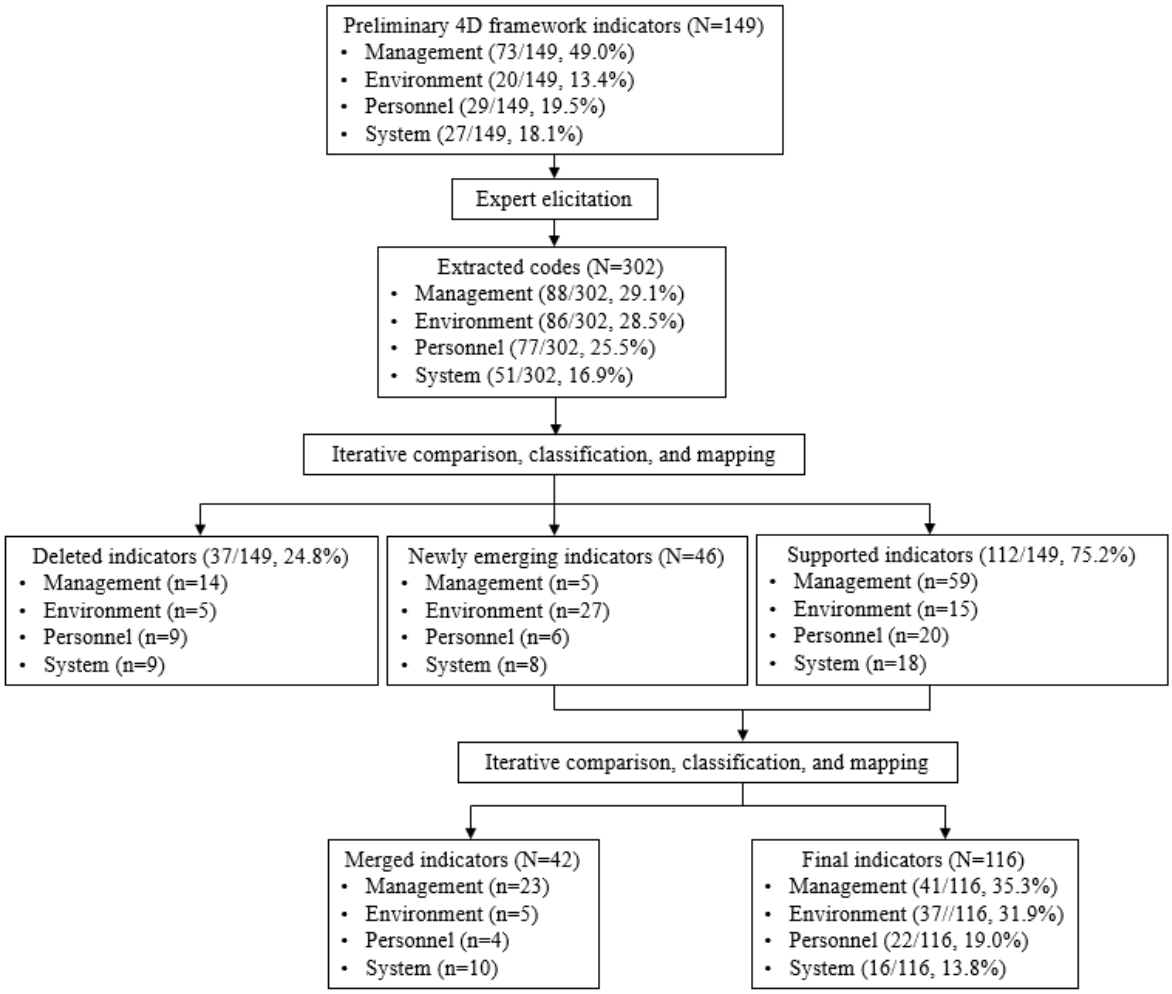
When a code had a similar meaning to an original subcomponent or indicator of the preliminary 4D framework, the original subcomponent or indicator remained or was further refined by merging, condensing, and grouping to represent the code.

Scenario 2

When the meaning of a code was not matched by any original subcomponent or indicator in the preliminary 4D framework, a judgment was made to add the code as a new subcomponent or indicator to the framework.

Scenario 3

When no empirical data could match the meaning of a certain subcomponent or indicator in the preliminary 4D framework, the subcomponent or indicator was deleted from the framework.



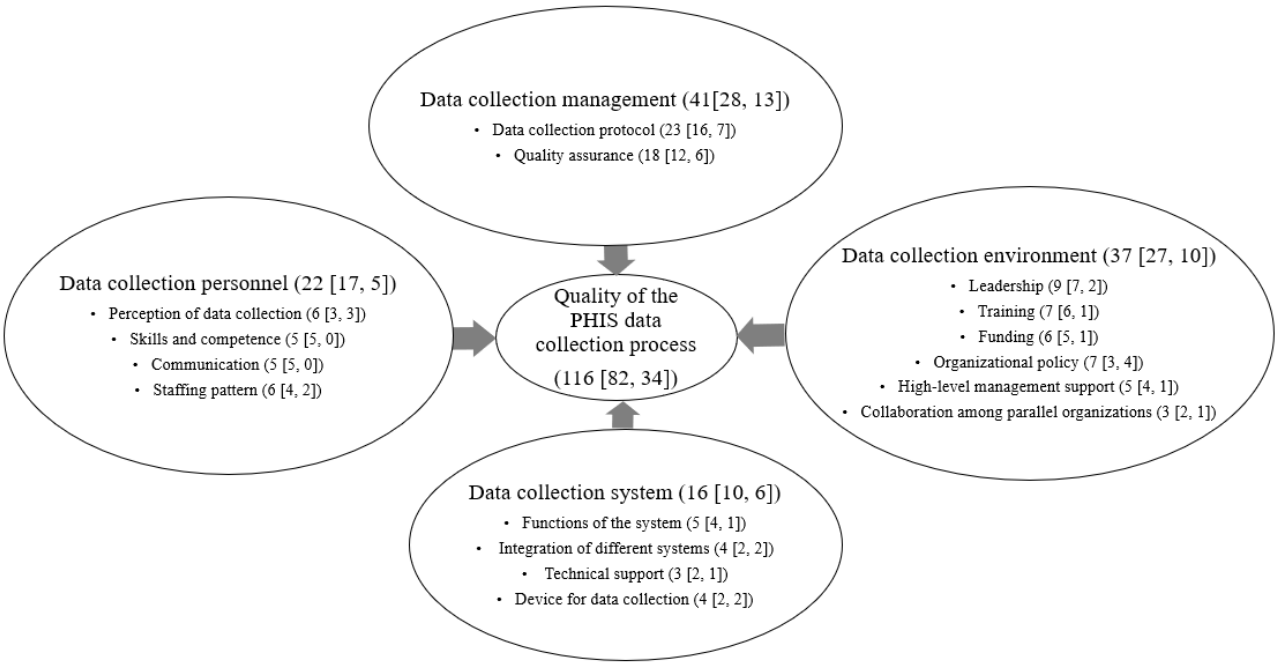
Iterative and recursive coding, mapping, and classification processes were applied continuously between steps 1 and 2. The 302 codes converged to the 4D component framework; 88 were grouped into the component data collection management, 86 into the data collection environment, 77 into the data collection personnel, and the remaining 51 into the data collection system. A total of 46 new indicators emerged from the extracted codes. Of the 149 original indicators, 37 (24.8%) were deleted because of a lack of evidence support and 42 (28.1%) were further merged with codes with similar meaning but different wording. Finally, 116 indicators, 16 subcomponents, and 4 components were synthesized.

Step 3: Interpreting the Framework

The nature of and associations among the components, subcomponents, and indicators were further assessed by the author group. Each indicator was identified as either a facilitator or a barrier for data collection. Data and themes that had been extracted from expert elicitation were constantly compared between hospitals and CDCs with varying data collection processes and contexts and between different data collection roles played by different experts. The data analysis outputs were triangulated and discussed within the team until a consensus was reached (Figure 1).

XSL•FO
RenderX

Figure 1. The validation process for the 4D framework.



Results

Overview

The 4 dimensions of the 4D framework were verified as data collection management, data collection environment, data collection personnel, and data collection system. Three new subcomponents were added: organizational policy, high-level management support, and collaboration among parallel organizations. A total of 16 subcomponents were validated and grouped into the appropriate 4D components. They were measured by 116 indicators, including 82 facilitators and 34 barriers (Figure 2).

XSL•FO
RenderX

Figure 2. Composition of the 4D framework. Parenthesis: (number of indicators [number of facilitators, number of barriers]). PHIS: public health information system.

The next section presents the results using the 4D components to tabulate and elaborate the evidence that supports the subcomponents and indicators of the validated 4D framework situated in the CRIMS.

Data Collection Management

Data collection management includes 2 essential subcomponents: *data collection protocol* and *quality assurance*. Of the 302 interview codes, 88 (29.1%) supported 59 original indicators of data collection management. The remaining 14 were deleted because of a lack of evidence support. Furthermore, 5 new ones emerged from the interview codes. After merging 23 supported original indicators to amalgamate similar meaning with different wording, 41 indicators, including 28 facilitators and 13 barriers, were finalized for measuring the data collection management (Multimedia Appendix 3).

Data Collection Protocol

A total of 56 interview codes were related to the subcomponent *data collection protocol*. They validated 23 indicators, including 16 facilitators and 7 barriers, and fell under the subdimension of data collection form and data collection methods.

Six practitioners (C302, C303, C201, C101, C106, and A101) suggested that the data collection protocol should be aim-focused, operable, scientific, rational, and feasible for frontline data collectors. It should contain comprehensive, step-by-step guidance for the entire process of data collection (A101 and C201). The involvement of frontline data collectors in the development of a data collection protocol was an optimal practice (C302).

A total of 16 practitioners (C101, C102, C103, C104, C105, C106, C107, C201, C203, C303, C304, A101, H302, H305, H101, and H202) stressed that a data collection form needs to be clear, readable, comprehensive, and unambiguous. One of the practitioners mentioned:

> *It [design of the form] needs to be rational to make data collection convenient and simple, and provides comprehensive data, should reduce data collectors burden and reduce unnecessary effort.* [C102]

To ensure that the questions about data collection are articulated in a scientific, rational, and operable manner, 3 CDC practitioners (C201, C202, and C107) recommended the following: (1) to solicit a question, one can ask questions from different angles; (2) the number of questions should be suitable and controlled within the allotted data collection time; (3) the wording of the questions, including options for the multiple-choice questions, must be accurate, direct, understandable, and answerable; and (4) questions should be bound within ethical considerations and should not cause harm to respondents, particularly in places where it is challenging to find confidential and private space for question elicitation.

The data collection methods should be well developed, uniform, applicable, and implementable for data collectors (C302 and C301). A method is considered optimal for data collection if the task is integrated into routine data flow in a health care facility.

Quality Assurance

Overall, 32 interview codes were related to the subcomponent *quality assurance* and validated a total of 18 indicators, including 12 facilitators and 6 barriers. Three topics were elicited: the criteria of quality assurance, the constituency of quality assurance, and the implementation of conduct of quality assurance.

The criteria of quality assurance were consistent with the requirements of data quality, that is, accuracy, completeness, and timeliness. Therefore, quality assurance is “able to

XSL•FO
RenderX

thoroughly, quickly and accurately assess data accuracy, completeness and timeliness" (C203).

Clinicians believed that data quality audits were useful in motivating data collectors because their managers may provide extra funding to incentivize this activity. H201 explained the advantage of a data audit:

> *On one side, it is useful to provide further verification guidance to our routine work, and correct deficiencies inevitable in operational procedures because we are new to this job. On the other side, if they could brief the findings to our manager, it would be even better...For example, if my workplace was equipped with the needed amenities, then it will be easy and convenient. It does not necessarily need further monetary injection.* [H201]

Two health administrators (A401 and A301) who held a position at the national and provincial administration used the CRIMS data regularly for decision making. They relied on the quality of the data quality assessment conducted by all levels of CDCs. "The professionals will ensure the quality of data collection process" (A401), whereas "it is impossible to verify the situation (of data) in the front line" (A301).

A401 expressed his concern about the deliberate falsification of data, especially the *soft* data. Soft data means that its data quality is difficult to assess even with field verification, such as data from high-risk population intervention, follow-up, and health education. *Hard* data are more likely to be *true*, for instance, the methadone treatment data documented on the site, and thus, *hard* data are less prone to errors:

> *It does have difference in level of data accuracy. Some data are relatively accurate, such as the data about methadone treatment because they were recorded when the patient took the medicine; that possibly would not be falsified, right? However, intervention data, the "relatively soft data", are hard to verify in the office. If you do not make an on-site verification, it is hard to control the recording of them.* [A401]

Data Collection Environment

The data collection environment includes 3 original subcomponents (leadership, training, and funding) and 3 newly added ones (organizational policy, high-level management support, and collaboration among parallel organizations). Of the 302 extracted codes, 86 (28.5%) were about the data collection environment, with 32 relating to the 3 new subcomponents. A total of 27 new indicators emerged from these interview codes. Of the 20 original indicators, 5 were deleted because of a lack of evidence and another 5 were merged further for a similar reason. A total of 37 indicators, including 27 facilitators and 10 barriers, were finalized to measure the data collection environment (Multimedia Appendix 3).

Leadership

Of the 28 practitioners, 26 (93%) agreed that leadership is a subcomponent of the quality of the CRIMS data collection process, ranking first among all subcomponents. Twenty-four codes were related to *leadership*. A total of 9 indicators, including 7 facilitators and 2 barriers, were validated for measuring leadership.

Concerning qualification and role, leaders should be role models with professionalism (C103, C105, C106, C203, and H304). They are **"**able to ensure the procedures to be executed up to standards, ensure the implementation of requirements and protocols of data collection, analysis, and use, and thus ensure data quality" (C203). To initiate a new task data collection, the leaders should have a clear roadmap for assigning and executing the task (A101). Leaders should have strong organizational capabilities to push it forward (H301, H303, and C106). Therefore, leaders do not necessarily have to do everything by themselves but should be familiar with the task requirements (C103, C104, and C105). They should have the power to issue policies, clarify and assign duties and tasks, and provide financial support (C302 and C104).

The extent to which a leader attaches importance to data collection determines the quality of this task. "People follow the example of their superiors" (H304 and H305). Clinicians (H202, H203, H301, and H306) mentioned that a significant indicator of adequate notice by a leader in charge is the frequency of his or her attending the meetings or the supervision and inspection events organized by the CDC.

From the practitioners' perspective, a good leader could "lead us well, ensuring those willing to do to have the opportunity to do, and turn those reluctant to do into willing to do; this is good leadership" (H304). The management recognition of the contribution of data collection personnel to data quality is an important motivation factor for data collectors (C102 and H305). It could be in the format of "oral praise to recognize and formal acknowledgement beyond financial incentives" (C102). As commented by H305 and H306, "our leaders all think highly of this job (data collection). Otherwise, the staff would not care." "Data collection personnel need to be respected, trusted, acknowledged, and complemented by leaders" (H304, C104, and C302).

Training

Of the 28 practitioners, 27 (93%) agreed that training is a subcomponent of the quality of the CRIMS data collection process, ranking second among all components. A total of 19 interview codes about training generated and validated 7 indicators, including 6 facilitators and 1 barrier focusing on the objective of training, and the methods to deliver it and evaluate it.

The goal of training is to equip data collectors with qualified work competence and professionalism (C102, C103, C104, C105, C106, and C302):

> *The training objective is to equip the data collectors with work competence, with good work professionalism, such as work abilities and skills.* [C302]

> *I think training is more related to communication of [data collection] skills. Firstly, we must be familiar with the survey, then we will explore how we get good*

XSL•FO
RenderX

> *data. Learning skills is an objective to be reached via training.* [C104]

Therefore, training needs to focus on the standardization and uniformity of the data collection process. These include objective, methods, and time frames for data collection (C203, C103, C104, C106, and H304). The trainees should understand the definition of data to be collected, have good knowledge about all procedures for data collection, and adhere to the standardization.

Interactive training between trainers and trainees has been suggested (C103). During training, trainers should address work issues and help trainees learn what to do and how to do it (C103 and C105). Trainers should not just talk and go and be disinterested in whether the trainees understand or not. Trainers who were welcomed by trainees were those who quickly responded to trainees' questions (C105) and those providing empirical field practice examples in the training session. C103 suggested "if the trainers give more empirical examples for the training, the trainees may obtain a better understanding."

Data collection personnel, especially the newly recruited staff, need training after recruitment and refresh their knowledge every year about what and how to do. On-the-job training, hospital webpage training, and exams have been used in health facilities (H101 and H306). Building up a training network that installs materials and sources under the circumstance of high staff turnover is recommended (C106).

Given that the training results might vary among trainers, a training assessment was recommended, including selecting trainers, training methods, and training contents. C103 claimed that the higher the level of a training organization, such as international organizations and high-level CDCs, the better the training quality.

Funding

Although the subcomponent funding was not included in the item weight table, 10 relevant codes emerged from the interview transcripts and generated 3 new indicators. Three original indicators remained. They gave rise to 5 facilitators and 1 barrier to measuring the subcomponent funding.

From the CDC professionals' perspective, funding should support purchasing data collection devices such as computers, printers, and even vehicles (C301, C103, and C104). Funding should provide compensation, such as gifts for health clients to seek their cooperation (C103). Otherwise, "without funding support, without policy, and without competent personnel, data quality may be problematic, or even a fake product made up in office" (C103). Continuous funding support for previously funded projects is needed to avoid the situation of "when the Demonstration Project finished, funding decreased significantly" (C104).

From the hospital data registrars' perspective, HIV/AIDS work does not bring in profit, an activity that does not support the profit goal of the hospital (H301, H202, and H203):

> *HIV/AIDS prevention activities do not bring in profit, the doctors in the hospital should be committed and have spirit of dedication. However, in market economy, hospital needs profit, and is focused on pursuit of economic cost effectiveness.* [H301]

> *Without funding support, clinicians think they are volunteers for HIV/AIDS data collection. Therefore, sometimes, they are unwilling to do this job.* [H203]

Therefore, given that "funding support can provoke work" (H201) and "the cost of management and treatment can be reimbursed" (H203), "funding support for data collectors must be fully implemented" (H202 and H203). The health administrator (A101) had already recognized this need and promised to further push this agenda:

> *In another aspect, it might be related to boosting work morale to encourage them [data collection personnel] by increasing funding support. For example, they may get some subsidies for the work they are doing or have done. Currently we do have some funding. The performance-based salary system is inflexible. It may be problematic to link their income with their performance. This shortage, maybe, is what we need to tackle, for example, from the perspective of national management. We should be able to do, but not much has been done yet. They should get a better income. This aspect is what we should do.* [A101]

Organizational Policy

Organizational policy is a new subcomponent. Of the 28 practitioners, 23 (82%) agreed to place it in the component of the data collection environment. A total of 13 codes were related to the organizational policy and generated 7 indicators, 3 facilitators and 4 barriers. These indicators were primarily concerned with what organizational policy is desirable for HIV/AIDS data collection.

The organizational policy was critical to ensure the execution of the data collection activities (C104 and H101). "If they attach importance to the job, you will work easily; if they don't, your work is a challenge" (H306). It was regarded as more important than the actual process of data collection because the latter was under the control of the data collector (H303). The organizational policy should "support recognition and reflection of the real situation and encourage analysis of existing issues, a proactive adaptation of scientific findings generated from analysis of high-quality data" (C203).

Desired organizational policies of the CRIMS data collection process included (1) ensuring sufficient funding, staffing and material support, for example, "as long as the workload is increased, more staff is assigned" (H101); (2) embodying good management and coordination; (3) having a built-in reward and bonus scheme (C301 and C202) to "motivate people to work well" (H303).

Indicators of a poor organizational policy relating to data collection included the following aspects: (1) data collection was set up as a part-time job, (2) narrow workspace insufficient for data collection (H302), (3) increased workloads without adequate payment (H201), and (4) the culture of "eating big-pot-rice" (C106).

XSL•FO
RenderX

High-Level Management Support

High-level management support was another newly added subcomponent that 79% (22/28) of the practitioners agreed to. A total of 19 interview codes generated 5 indicators, including 4 facilitators and 1 barrier, to measure this subcomponent of high-level management support.

High-level management support provides assurance (C201); assistance for training; responsibility for policymaking (H305); and being scientific, specific, and rigorous for decision making (C104 and C106). It enforces an appropriate reward and punishment mechanism (H303). High-level management support also means funding support and making essential data collection tools such as vehicles available (C103).

Conversely, high-level management support should "not impose excessive administrative pressure on data collectors because it may compromise data integrity and accuracy in data collection. The management should not affect and intervene in the data collection process and the data. Otherwise, it may cause a negative consequence of manipulating results" (C203). In practice, the policy had a significant impact on the data quality (C104 and C302). The health administrator (A301 from the provincial health bureau) had a different viewpoint: "currently, as for the HIV/AIDS epidemic data collection, indeed there is no intervening in our work, basically it (data) is reliable, no concealment."

High-level management support was recognized as "a strong power that can veto by just a couple of words" (A101 from the county health bureau). The more the emphasis on data quality placed by upper management, the more time would be invested by data collectors toward data quality and vice versa (C102). "No site auditing, no proper work" (H303). However, the more the layers between the high-level management and the frontline data collection organization, the more difficult it is for the organization to execute the data collection process (C104).

The CDCs were considered by H201, a clinician in a secondary hospital, as "supportive" high-level management; they were expected to provide hospitals with support and advocacy. The CDCs were also expected to be of help and to understand "why, what and how" about data collection. H301, a data registrar in a tertiary hospital, suggested that the local CDC should "clarify the work-flow in hospital and do not just require us doing this and doing that without distinction."

Collaboration Among Parallel Organizations

Collaboration among parallel organizations was a third newly added subcomponent, with 82% (23/28) practitioners agreeing. A total of 14 interview codes were related to this subcomponent, which may contribute to HIV/AIDS data collection, for example, through hospitals and CDCs. Furthermore, 3 indicators, including 2 facilitators and 1 barrier, were added to the 4D framework to measure collaboration among parallel organizations.

It was found that sometimes the quality of the data collected by the collaborating organizations may have inferior quality to those collected by the CDCs, if they are without staff in charge. Therefore, if data to be collected were provided by a collaborating organization, C403 suggested a coordinating HIV/AIDS committee would contribute to high-quality data collection. He stressed,

> *"If the parallel organizations with dependency in data do not have a right attitude toward data collection, or conduct data collection in a reckless manner, then the data to be collected would be worse (in quality) and useless.* [C403]

A public health professional (C203) working at a city-level CDC stated that the parallel organization "should not use vicious competition and negative approaches to intervene with public health data collection and organizations. They should cooperate, coordinate and facilitate."

Data Collection Personnel

The component *data collection personnel* included 4 essential subcomponents: *perception of data collection*, *skills and competence*, *communication*, and *staffing patterns*. Of the 302 interview codes, 77 (25.5%) supported 20 of the 29 original indicators of the data collection personnel in the preliminary framework. Six new indicators emerged, and 4 were merged further. There were 22 indicators, including 17 facilitators and 5 barriers for measuring data collection personnel.

Perception of Data Collection

All 28 practitioners agreed that data collectors' perception of data collection is an important subcomponent determining the quality of the CRIMS data collection process. Of the 6 original indicators about the perception of data collection, 4 were supported by the interview transcripts, 1 was deleted because of a lack of evidence, and the other was merged with 2 newly added indicators. Six indicators, including 3 facilitators and 3 barriers, were finalized to measure the perception of data collection.

From some practitioners' perspectives (C102, C103, H306, H202, and H203), the CRIMS data collection process would not be as complicated if the data collection personnel were aware of its importance, which would also lead to better data quality. As H203 said*:*

> *It is a matter of how serious they (doctors) are definitely. Because this (data collection) is a very simple and easy job. If you pay attention to it, you can do it well.* [H203]

H202 and H203, 2 public health data registrars working in a secondary hospital, agreed that the priority given by clinicians and managers in the hospital could significantly improve the quality of the data collection process and thus data quality:

> *It is an issue of whether the doctors and management value it (data collection). If the management values data collection, doctors will also value the activity.* [H203]

It was suggested that the *perception of data collection* should not only be measured by receptibility to data collection but also by 2 new indicators, including commitment of the data collection personnel to data collection and their attitude to integrity (C103, C201, C203, C302, and H203). The manifestation of *good* attitude may be "data were consistent between the paper-based

XSL•FO
RenderX

and the electronic records of the CRIMS" (C103). The fabrication of data or negligence is often caused by poor attitudes rather than incompetence or lack of training for data collection. Burnout demotivates data collection personnel to treat the job as their job responsibility. C106, a public health professional with 8 years of work experience at a county CDC for HIV/AIDS prevention and control, suggested that burnout may appear after working on the same job for a long period. "Now nobody values much about this job, so not many are willing to do it, including me" (C106).

Skills and Competence

All 28 practitioners agreed that data collection skills and work competence were important for data collection personnel. Five indicators, all facilitators, were recommended for measuring subcomponent skills and competence.

This subcomponent was a *must-have* capability for frontline data collectors (C202), which is more important than the data collector's education level (C201, C102, and C103):

> *If they [with high education degree] do not have adequate work experience, if they do not have work skills, they cannot find the solution to the problem.* [C201]

Besides the skills for data quality check, the subcomponent skills and competence includes an accurate understanding of the objective of data collection, contextual knowledge, and the definition of data items (C102, C103, C106, and H102). Data collection personnel should be able to make a rational judgment about the reliability of a data source and ensure data accuracy and completeness (C302, C202, C203, C104, C105, C106, A101, and H302). Communication, organization, coordination, and writing skills were also desired skillsets recommended by practitioners for a competence-based framework (A101, C302, C201, C102, H302, and H305).

The data collection personnel should be professional and receive training in data collection. Interns were not considered qualified for data collection and reporting. H302, a clinician from a tertiary hospital, suggested that work competence means being mature and experienced, which is not what an apprentice is up to. H301 and H306 reported that the interns in tertiary hospitals were asked to fill in the data collection forms for busy clinicians.

Communication

Although communication was not listed in the item weight table, a lack of good communication among data collectors, as described in the preliminary framework with 5 facilitative indicators, was verified by the practitioners, particularly those who need to directly interact with health clients in routine work (H302, H305, H201, and C106).

H201, an HIV/AIDS clinical specialist, felt embarrassed in detecting transmission routes through conversations with AIDS patients. She thought that transmission routes were a private issue, especially for young men. If the data to be collected do not affect treatment, then data quality can be compromised in the interest of preserving the privacy and dignity of patients:

> *All in all, it (knowing whichever transmission route) does not affect treatment. Through conversation with them, I feel that these patients are worried about we, doctors, are discriminating against them. This is the major concern. So, collecting this type of data (transmission route) is neglected in my job.* [H201]

C106, a county CDC professional, felt that it was difficult to communicate with AIDS patients during follow-up:

> *Sometimes, I do not even know how to communicate with them. Like meeting someone new, I am not sure what kind of psychological characteristics the person has. Basically, I feel them difficult to deal with. I do not even know how to talk to them. Sometimes it is fine; this feeling has always been there.* [C106]

She also felt that she was not getting adequate support from her colleagues in a routine job:

> *Having been in this job so long, it is embarrassing to ask others certain problems you encounter. You can only formulate solutions by yourself. You find it difficult to ask others. Better do it yourself.* [C106]

Staffing Pattern

Although the staffing pattern was not in the item weight table, it was mentioned by 11 practitioners. A total of 18 interview codes supported 6 of the 7 original indicators, including 4 facilitators and 2 barriers.

Practitioners frequently mentioned a lack of an adequate number of competent public health professionals:

There are only two staff members assigned to work at the front line of HIV/AIDS control by the Department of HIV/AIDS. These two staff members have to collect all data, and they are under enormous pressure; this indicates the staffing level is inadequate. [C103]

> *I feel the most challenging is staffing level. Lots of work needs people to do. It does not mean there is no staff to do the work but almost everyone has several parallel lines of work happening at a given time. Like us, old employees, all part time regarding data collection.* [C107]

In C107's workplace, employment of contractors was a major approach to fill the vacancy, but it was not favored by local public health professionals because of high turnover. The professionals even refused to train the contractors because they were worried that their efforts would be wasted if the contractors quit the job soon after the training was completed.

Experienced staff and female staff were considered (by C302, C201, C101, C106, and H302) to be the optimal personnel for collecting quality data, rather than young practitioners, because of their experience in interacting with and establishing rapport with AIDS patients. Four practitioners (C302, C105, C106, and H305) suggested that education level, training, experience, personality, and value could affect work competency and, thus, the quality of data collection.

The health administrator from the national Ministry of Health (A401) suggested a need to increase the recruitment of frontline data collectors to cope with the increased workload in HIV/AIDS prevention and control.

XSL•FO
RenderX

Data Collection System

The component data collection system includes 4 subcomponents: functions of the system, integration of different information systems, technical support, and devices for data collection. A total of 51 codes for this component were identified, which supported 67% (18/27) of the original indicators about the data collection system in the preliminary framework and generated 9 new indicators. After comparison, 11 original indicators were further merged. A total of 16 indicators, including 10 facilitators and 6 barriers, were developed to measure the component data collection system (Multimedia Appendix 3).

Functions of the Data Collection System

A total of 17 interview codes were related to the subcomponent *functions of the data collection system.* They supported 8 original indicators of this subcomponent. Two new indicators emerged, and 5 original indicators were merged. A total of 5 indicators, including 3 facilitators and 1 barrier, were finalized to measure the subcomponent functions of the data collection system.

The practitioners agreed that the functions of the CRIMS should facilitate the visualization of routinely collected data. The CRIMS system should be humane, convenient, and error-free for data collection. For example, the system should remind data collectors wherever logic errors or incompleteness appear in data entry. In H304's words, "Machine can do something for human beings."

In recognition of the effect of *smart chart* and drop-down menus, some practitioners (C202, H302, and H305) suggested that the CRIMS should provide a user-friendly interface, allowing clinicians to add descriptive free text data; visualize data; and search by keywords, such as symptoms of a disease. The system should have convenient or automatic functions, such as iPhone's one-click for all end users, and should eliminate tedious extra work. The hospital practitioners were not satisfied with the CRIMS menu allowing limited details. It was inconvenient and difficult for H303 to add additional text data:

Some definitions are too narrow. For example, loss for follow-up could have a variety of reasons in reality, but we could not enter these data. Another example is the patient background. They may have lots of opportunistic infections without clinical symptoms; however,there are not enough options provided by the system to capture all situations. [H303]

An information system without adequate functions may impair data quality. C301 spent nearly 15 minutes, one-third of her interview time, to elaborate on this topic according to her work experience. Ascertain definitions of data items in the system were not in accordance with those of the data collectors, which may lead to missing data or inaccurate data collection.

Integration of Different Information Systems

The interview transcripts supported 4 of the 7 original indicators that discussed the integration of different information systems. Four indicators, 2 facilitators and 2 barriers, were clarified for measuring this subcomponent.

Although the item "integration of different information systems" was not in the weighting table, the negative effects caused by the lack of integration of data across information systems were emphasized by practitioners from hospitals (H302, H303, H304, H305, and H201). Hospital information systems are internal systems that do not connect to external systems via the internet. Access to the CRIMS was only available on a few authorized computers in hospitals via internet connectivity. Clinicians could not read any information from the CRIMS beyond their hospital. Repetition in reporting often happened, causing *a wasted job* that could lead to clinicians' reporting cards being "thrown into a rubbish bin" (H305). Therefore, it is a common sentiment that appropriate integration of the CRIMS with hospital information systems is needed.

In addition, 6 practitioners raised the importance of comprehensive data storage in the CRIMS information system (A101, A401, C106, H302, H303, H305). They suggested the system should include all work functions and topics, and cover all geographic regions from village, county, city to the province and national levels. From the national health administrator's perspective (A401), the CRIMS should be such a system:

> *From the perspective of a specific case reporting system, I think, it is a very comprehensive system; maybe no other disease reporting system can be as comprehensive as it is. The AIDS (CRIMS) should be the most comprehensive one.* [A401]

Technical Support

A total of 12 codes identified from the transcripts discussed technical support. Two new indicators emerged and supported the original indicators in the preliminary framework. Three indicators, 2 facilitators and 1 barrier, were finalized for measuring this subcomponent.

Practitioners (C302, C202, C104, C105, and H101) stated that insufficient technical support could inhibit the quality of the CRIMS data collection process. They emphasized that technical support should also be available for data entry. Technical support differed from training. It should be available before and during data collection. Practitioners from the county CDCs (C104 and C105) recommended that technical support for data entry should include a multimedia-supported electronic network that stores frequently asked questions, allows end users to share experiences, and provides help to use the system. It should offer access to higher level support such as that from national institutions. Technical support must be comprehensive, problem-focused, and formal.

Technical support became exceptionally critical for a data collection task assigned by high-level authority without training. Given that data collection tasks were often directly deployed by the high-level authority through issuing an official notification (C104), A101 believed that a competent team leader could play a role in offering technical support.

Devices for Data Collection

Of the 5 original indicators about devices for data collection, 4 were supported and the other was merged. A new indicator emerged and was added. Four indicators, 2 facilitators and 2

XSL•FO
RenderX

barriers, were finalized to measure the subcomponent. The compatibility of the devices used for data collection with the CRIMS data collection system was a major concern.

The practitioners suggested that data collection devices should be of good quality (C106, C104, C102, and H101), reliable, fast, and fit for surfing the internet and should neither crash nor break down (C302 and C304). Prompts, such as "the system is under maintenance" (C102), were not welcomed by practitioners. They expected that the devices could help them perform their data work even at the peak time of data entry. It should be free from traffic jams (H306, H305, C203, and C102).

Regarding data backup and security, the CRIMS has specific policies requesting the duration of data storage and the frequency of data backup to mitigate the risk of data loss (H306).

Discussion

Principal Findings

This study used the expert elicitation research method to verify a preliminary 4D component framework for measuring the quality of the PHIS data collection process in the context of the Chinese HIV/AIDS information management system, the CRIMS. The 28 public health data management experts for the CRIMS, with varied work experience and roles in their organizations, provided insightful inputs to issues related to the quality of the data collection process. They agreed with the 4 main components derived from the literature [12]. They ranked and commented on the importance of the original subcomponents based on their perceptions of the CRIMS data collection process. The 302 codes identified from the interview transcripts supported 75.2% (112/149) of the original indicators. These results provided the basis for a validated 4D component framework that fits well with the preliminary framework.

The validated 4D component framework was an improvement on the preliminary version. New items were identified in the expert elicitation process and added to the subcomponents of the data collection environment. These were organizational policy, high-level management support, and collaboration with parallel organizations. A total of 46 new indicators were generated and integrated into the framework, showing a wide range of characteristics elicited from the specific research context.

The original indicator statements were further simplified, merged, or deleted based on the 3 data analysis scenarios. The number of indicators in the framework finally decreased from 149 to 116.

There were changes within the framework in the proportions of the indicators for the 4 main components. The proportion of the indicators of the data collection environment increased from 13.4% to 31.9%, that for data collection management decreased from 49.0% to 35.3%, and that for the data collection system decreased from 18.1% to 13.8%. There was no change in the proportion for data collection personnel (19%). The factors that affect the quality of the data collection process are multifaceted from the practitioners' perspective.

Lessons Learned

The detailed feedback from the participants provided deep insights into many issues related to the quality of the data collection process and matters that require ongoing negotiation and development to improve it.

Under data collection management, the methods and protocols with the third ranking among all subcomponents need to be well developed, uniform, and implemented by data collection personnel. Responses on quality assurance emphasized the importance and challenges of this area. In some cases, data collection protocols and quality assurance procedures were developed and issued by high-level management in public health, but frontline personnel were not involved. This might make the data collection protocol and methods not operable or unfeasible in the field. Strategies to improve data collection management should include the involvement of frontline public health data collectors, especially those in hospitals, in the design phase of data collection protocols and quality assurance procedures [29].

A friendly data collection environment is an indispensable component of a high-quality public health data collection process. Participants ranked leadership and training as the two most important items for this component. This is consistent with and corroborated by the International Standard Organization's recommendation that the top management should "demonstrate leadership and commitment with respect to the quality management system" [30].

Various identified organizational issues complemented the subcomponent spectrum for the data collection environment. This included avoidance of data collection intruding unduly on health facilities' operations, such as routine health services in hospitals. This also included the adequacy of communication between different organizations, such as health administration and hospitals, CDCs and hospitals, and between data collection staff and their superiors. Financial and logistical support for the data collection process appeared to be a major issue, as is the case for health care organizations in many countries [29,31-33]. If the level of support is inadequate or not suitably administered, data quality will deteriorate.

On the data collection personnel component, all practitioners agreed on the importance of work attitude, competence, and data audit skills. There was some variation in opinion regarding the difficulty of the data collection process. The priority placed by the management in a hospital that performs the data collection process can significantly affect performance [34]. The fabrication of data or negligence indicated a poor attitude, requiring action by managers and supervisors. *Burnout* exhibited by staff might appear after long-term work in data collection and would require remediation, especially in hospitals [34].

Work competence was considered as a *must-have* capability for frontline data collectors. In addition to data quality audit skills, there should be an understanding of the objective of data collection and the definition of data items. Increasing the number of competent staff would, in principle, help to improve the data collection quality, although a practical difficulty has been the high turnover of recruited contract staff following training [32].

XSL•FO
RenderX

The fourth component, the data collection system, is an area that is influenced by the continuing changes in the performance and availability of ICTs [35]. Functions in the system should facilitate the visualization of routinely collected data. The system should be humane for those who operate it and be convenient and error-free for data collection [35]. An inappropriate function in the system may impair data quality. For example, if the definition of data items in the system does not reflect the reality of the work undertaken, the results will be unconvincing.

As identified in the preliminary 4D component framework, insufficient technical support inhibits the quality of the PHIS data collection process [12]. Additional features suggested by participants included storage of frequently asked questions and shared experiences, help for staff using the system, and access to higher level support such as that from national institutions. They also saw a need for the integration of the data collection system with other information systems because disconnection may result in repetitive reporting and inappropriate use of resources [5,33].

A study contribution is that, for the first time, we confirmed that the 4D components provide a picture of the structure and operation of the HIV/AIDS data collection process in China. The findings suggested that the Chinese HIV/AIDS information management practice provided an effective validation case and enriched the field of the quality of the PHIS data collection process. Three new subcomponents—organizational policy, high-level management support, and collaboration among parallel organizations—were considered to influence the quality of China's public health data collection process. This provided evidence to clarify the effect of the data collection environment on the quality of the CRIMS data collection process. The 4D framework also advocates the involvement of relevant stakeholders in data quality management. This provides an example to suggest the potential of using this framework for root cause analysis to investigate and identify the *real* factors behind poor data quality.

Although this study provides useful inputs to management decisions within the CRIMS and to negotiations with other parties on resources and requirements, it is reasonable to believe that the framework is also applicable to other settings, such as emerging infectious disease surveillance [36], general health care, education, and criminal justice.

Comparison With Prior Work

The context of this investigation was the Chinese HIV/AIDS program. However, many of the issues identified in the 2 sources of validation, the CRIMS and China, are also echoed in other health care systems. Inadequate staff training for data collection and limited support were also reported in birth registration in the United States [37] and in antiretroviral treatment for HIV infection in South Africa [38]. Poor communication across the health care sector and between providers was found in Aboriginal cardiac rehabilitation in Australia [39]. A lack of data linkage and sharing in electronic immunization data collection systems was described in Canada [40]. Job fatigue was found in general practitioners in European countries [34]. Regarding the transferability or generalizability embedded in the findings, this validation study has achieved design validity via a well-organized and executed research process [26].

As there are few extant public health frameworks focusing on the quality of the data collection process, there is a genuine contribution that this research has made to fill a critical gap on this topic. The successful abstraction of the 4D framework components, subcomponents, and indicator statements demonstrates the need for qualitative research in a problem domain without known measurement methods. Therefore, this study has taken the right method and approach given the novelty of the research topic, despite its importance in ensuring public health data quality.

Limitations

A potential limitation of this study is that a relatively small sample of experts participated in the interview, which may be small for statistical probabilistic generalizability. The control strategy was to use the theoretical sampling method, including all levels and types of participating organizations, personnel roles, and experts in the CRIMS system. This eventually brought data saturation for qualitative inquiry and provided comprehensive views of the HIV/AIDS data collection process in China. Given that the purpose of this study was to use a qualitative method to validate a preliminary conceptual framework, we have achieved our aim.

Although the number of indicators was reduced from 149 to 116, these indicators need further item reduction for ease of use in large-scale public health settings. This can be achieved by conducting quantitative questionnaire surveys with public health data management personnel at all levels. This will improve the validity of the 4D component framework and allow the reduction of measurement items to a manageable level.

Conclusions

This qualitative study validated 4D components for the quality of the PHIS data collection process in the context of the Chinese HIV/AIDS information management system, the CRIMS. The findings demonstrate that data collection management, data collection environment, data collection personnel, and data collection system are key components that determine the quality of the Chinese HIV/AIDS data collection process. The 4D component framework was further modified into a new pool containing 16 subcomponents and 116 indicators. They can be further tested and judged by practitioners and researchers in future public health data quality assessment studies.

Abstract

Background: Unlike most virtual reality (VR) training programs that are targeted at homogenous populations, a set of VR games for rehabilitation purposes targeted at a heterogeneous group of users was developed. The VR games covered physical training, cognitive training (classification and reality orientation), community-living skills training, and relaxing scenery experiences. Special considerations for local older adults and people with disabilities were made in terms of hardware choice and software design.

Objective: This study aimed to evaluate the feasibility, acceptance, and efficacy of VR training among users with varying abilities.

Methods: A single-arm pretest-posttest evaluation study was conducted. The participants of the evaluation study were encouraged to undergo 30-minute VR training three times a week for 6 weeks. The 30-minute session consisted of 10 minutes of upper-limb motion games, 10 minutes of lower-limb motion games, and 10 minutes of cognitive games/community-living skills training/relaxing scenery experiences, as appropriate. On completion of each session, usage statistics were documented via the built-in VR software, whereas feedback on the experience of the VR games and adverse events was collected via self-reports and staff observations. Feasibility was reflected by usage statistics, and acceptance was reflected by positive feedback. In addition, health outcomes, including upper-limb dexterity, functional mobility, cognitive function, and happiness, were assessed at baseline, as well as 6 weeks and 3 months after baseline. The primary outcomes were upper-limb dexterity and acceptance of playing VR games.

Results: A total of 135 participants with a mean age of 62.7 years (SD 21.5) were recruited from May 2019 to January 2020, and 124 (91.9%) completed at least one follow-up. Additionally, 76.3% (103/135) of the participants could attend at least 70% of the proposed 18 sessions, and 72.5% (1382/1906) of the sessions had a training time of at least 20 minutes. Linear mixed effect models showed statistically significant effects in terms of upper-limb dexterity (small effect) and cognitive function (moderate effect). Among the 135 participants, 88 provided positive comments. Additionally, 10.4% (14/135) reported mild discomfort, such as dizziness, and none reported severe discomfort.

Conclusions: A set of VR training games for rehabilitation could be applied to users with heterogeneous abilities. Our VR games were acceptable to local older adults and those with different disabilities. Benefits in upper-limb dexterity and cognitive

XSL•FO
RenderX

function were observed despite partial compliance to the training protocol. Service providers could refer to our experiences when developing VR training systems for their clients.

(J Med Internet Res 2021;23(5):e27640) doi:10.2196/27640

KEYWORDS

virtual reality; rehabilitation; older adults, people with disabilities; evaluation

Introduction

Virtual reality (VR) has been widely used in many areas, including education, aviation, medicine, and entertainment. For control and navigation in VR games, users are required to have relatively high cognitive and physical levels. In this regard, researchers and service providers are developing and refining various VR games to extend their applications to older adults and people with disabilities or diseases, who usually have longer response times and cannot handle controllers with buttons because of their weak fine-motor skills. With successful modifications, VR training provides these users the opportunity to engage in motivational training with many repetitions, salient stimuli, and challenging tasks [1]. Examples of VR training, particularly those with a rehabilitation purpose, are well documented in different populations, such as adults with stroke [2], community-dwelling older adults [3], people living with dementia and mild cognitive impairment [4], and children with cerebral palsy and Down syndrome [5].

VR games, particularly those related to living skills training and cognitive training, would be more appealing to users if they are based on local elements and culture that are familiar to the users. Hence, in our local setting (Hong Kong), there are various VR training programs targeting different populations, for example, people with intellectual disability [6,7], acquired brain injury or stroke [8-11], schizophrenia [12], dementia [13], high fall risk [14,15], and different geriatric conditions [16,17].

Despite many VR training programs being developed, they mainly target homogenous populations. There is a lack of an integrated VR training program that suits users with various types of conditions or disabilities. Therefore, there is a need to develop a universal VR training program in Hong Kong to serve a heterogeneous group of users comprising older adults and adults with different disabilities or conditions living in different settings. In 2019, one of the leading nongovernment organizations (NGOs) in Hong Kong took the initiative to develop a universal VR system to supplement the rehabilitation of older adults and people with disabilities, both in the residential care setting and the community setting, with a view to enrich the life experience of service clients and improve their training and treatment outcomes. The common rehabilitation goals of this heterogeneous population were upper-limb dexterity and cognitive status, since these are of utmost importance in maintaining activities of daily living for both institutional and community-dwelling populations. While mobility is also important, it was not one of the common goals, since some of the targeted users already lost this ability. Regarding such development, the efficacy of such VR training in improving health outcomes among users has to be scientifically evaluated. Therefore, the objective of this evaluation study was to investigate the feasibility, acceptance, and efficacy of VR training among older adults and people with different disabilities.

Methods

Study Design

This was a service evaluation study employing a single-arm pretest-posttest design. Although a randomized controlled trial or a quasiexperimental design was preferred, such designs would have to involve at least 145 participants per group in order to detect a small-to-medium effect. As the service units might not be able to support recruitment and intervention of such a large sample, these designs could not be adopted.

Participants

The target population included clients of the service units for rehabilitation or the service units for older adults of one NGO in Hong Kong. The inclusion criteria were service clients of the selected units, covering both residential care settings and community settings; age 18 years or above; ability to understand instructions in VR training; and presence of at least one of the following disabilities: functional impairment, mobility limitation, cognitive impairment, intellectual disability, and visual impairment. The exclusion criteria were conditions that restricted participation in VR training and severe discomfort with VR training.

The VR facility was expected to serve at least 130 clients. Depending on the functional status, cognitive status, and possible attrition among users, it was expected that at least half of the users (ie, 65 participants) would be eligible for outcome assessments. This would result in about 80% power and 5% level of significance to detect a small-to-medium effect size (Cohen d=0.35) in pre-post difference.

Interventions

A set of multipurpose immersive VR games was developed for VR training. These programs fit the language, content, and VR scenes specially designed for Hong Kong individuals, which enhanced usage experience. Various elements, including hardware, virtual setting, gaming operation, and game setting, were specially considered during program development to cater to users with different disabilities and functional levels, so as to ensure user friendliness and comfort for users (Table 1).

The components of the VR games included physical training, cognitive training (classification and reality orientation), community-living skills training, and relaxing scenery experiences (Table 2). To date, the types of VR training, as well as training intensity and frequency to achieve desired outcomes, have not been consistent. Benchmarking with other VR

XSL•FO
RenderX

programs for rehabilitation [18-21], the participants of the evaluation study were encouraged to undergo a 30-minute VR training three times a week for 6 weeks. The 30-minute session consisted of 10 minutes of upper-limb motion games, 10 minutes of lower-limb motion games, and 10 minutes of cognitive games/community-living skills training/relaxing scenery experiences, as appropriate.

Table 1. Some of the key considerations during program development to cater to the different conditions and disabilities of the users.

Element	Considerations
Hardware	Fully immersive simulation was adopted, with head-mounted display (HMD) devices and limb motion trackers used as the display method and control interface, respectively. Through the HMD, the images of virtual reality (VR) games were manifested in front of the users' eyes. It enabled users with low vision to see the VR scenery clearly. Moreover, the HMD device was highly portable and could be used with minimal space requirement, which fitted well for a densely populated place such as Hong Kong. Button-free limb motion trackers allowed the users to participate in VR games by simple limb movements without relying on fine-motor control.
Virtual setting	An approximately 180-degree interaction zone within the VR environments was adopted, where interactive objects or training tasks were set at arm's length or attached to users' virtual hands. Hence, users could play the games safely in a sitting posture without moving or bending forward. Agile body and head movements were excluded or minimized from the gaming design to alleviate cybersickness such as dizziness and nausea. The backdrop and characters of VR games were not too fancy or stimulating to cater to users with limited cognitive and visual perceptions.
Game operation	Users only needed to move the button-free trackers with their limbs to a target position and hold for about 2 seconds. Then, a preprogrammed action would be triggered. Moreover, some of the VR games allowed users to either stand up or sit down to play, whereas some permitted the use of one or more limbs to play selectively (eg, left, right, or both), whichever suits the user, such that even those with mutilation could enjoy VR games. Motion-detection sensitivity was tailor made to the capability of users so that even the smallest movement of their limbs and the slowest reaction time could be detected. Then, those with minimal mobility could also easily participate in VR games using button-free trackers.
Game setting	Most of the games were designed with three levels of difficulty so that users and/or staff could choose the most suitable one according to their abilities. All games have timely and encouraging feedback and cues. By providing immediate feedback, users would realize that what they do in the real world could trigger something in the VR games. In addition to feedback, cues were provided in the form of images, words, and sounds, which served as guides to help users understand what they should do in the VR games. Staff could also use their own cues as additional guidance. Only positive reinforcement was adopted in the game design, allowing users to freely explore the VR games without any sanction and penalty (eg, score deduction). It also provided a sense of achievement to users and encouraged them to continuously engage in VR training.

Table 2. Virtual reality games in the training session.

Component	Virtual reality (VR) games
Physical	The games involved the upper limbs (*handball*), lower limbs (*football*), or full-body motions (*gatekeeping*). Users repeatedly mobilized their limbs and used their muscles, which aimed to help slow down the deterioration of bodily functions.
Cognitive (classification skills)	Nostalgic elements were employed to appeal to the users. Three signature games/scenes from a local amusement park that operated from the 1940s to the 1990s were included. The games, namely *Elephant Feeding*, *Feather Duster Throwing*, and *Coin Tossing*, were familiar to most Hong Kong older adults. They could provide not only cognitive stimulation but also a reminiscence of the old days. Another game, named *Home Items Locating*, simulated a home setting and required users to identify the appropriate items in the corresponding rooms.
Cognitive (reality orientation)	In the game named *Hong Kong Footprint*, users were virtually brought to familiar local places, including Shek Kip Mei, Man Mo Temple, Wong Tai Sin Temple, and Chun Yeung Street. Each scene was played with a soundtrack that briefly introduced the place. Along the VR journey, a trained staff member discussed the place that the user was watching. The experience allowed older adults to revisit familiar places and widened the horizons of residential care clients. These aimed to elicit pleasure and satisfaction, improve communication, and enhance self-esteem and social skills.
Community- living skills	The game *Seven Must-Dos Before Leaving Home* aimed to promote users' awareness (especially older adults) of the seven safety measures that keep them and the living environment safe before leaving their homes. Another game named *MTR GO GO GO* aimed to help those with disabilities to develop skills in taking public transport and going to different places in Hong Kong by themselves. It simulated a Mass Transit Railway (MTR) station scene and aimed to familiarize users with travelling via the MTR under various conditions repeatedly and purposefully.
Relaxing scenery experiences	Four relaxing scenes, including *diving*, *river*, *starry sky*, and *grassland*, accompanied by relaxing music, were provided. The experience aimed to relieve users' physical tension, calm their agitated mood, and engage with them in an interactive virtual environment. In the virtual scenes, various interactive objects were merged with a real 3D scene. Users could interact with them and trigger a particular preprogrammed effect. Additionally, the scenes aimed to provide dramatic multisensory stimulation for some frail users who could not engage in real sceneries that require limb motions.

Procedure

Trained staff of the NGO identified and recruited potential participants to join the evaluation study. Upon recruitment, written informed consent was sought from the participants or their legal guardians. Eligibility screening and assessment were conducted by trained research assistants. Then, eligible participants engaged in 30-minute VR training three times a week for 6 consecutive weeks (giving a total of 18 sessions). Deviations were allowed according to the actual situation of the users. For example, if a week of training was missed due to sickness, the user was allowed to continue the program in the seventh week.

For each session, a trained staff member always accompanied the participant in the same room. The staff member was responsible to assist the user in putting on the head-mounted display (HMD) device and limb motion trackers (both hand and foot), to guide the user in playing the VR games, and to closely monitor the conditions of the user during game play to ensure safety. In between different training components, the participants could take off the HMD device and rest if needed. Any training component that was not applicable to the users would be skipped, for example, those with total loss of lower-limb function would not engage in lower-limb motion training. The participants could terminate the session whenever they wished. Adverse events were monitored and recorded as appropriate. After each session, the staff asked the participants for feedback on their experience of the VR games in that particular session.

Data Collection and Outcome Measures

Demographic and medical information, which included age, gender, living arrangement (community-dwelling vs institutional setting), education level, dependence status, mobility status, cognitive status, intellectual disability status, visual impairment status, medical history (eg, stroke and fracture), and medical conditions (eg, mental illness and autism), were extracted from the records of the residents/members at baseline.

Health outcomes, including upper-limb dexterity, functional mobility, cognitive status, and happiness, were assessed by the trained research assistants at baseline (T0), 6 weeks after baseline (T1), and 3 months after baseline (T2). Participants with conditions that prohibited them from performing certain assessments were excluded from the analysis for that outcome.

Upper-limb dexterity was measured by the standard Box and Block Test (BBT). The BBT has been shown to be a valid measure of dexterity in the older population [22]. The participants were asked to transfer blocks from one compartment to the other in 1 minute according to a standard procedure [23]. The number of blocks transferred to the second compartment is counted, and a larger number indicates better dexterity.

Functional mobility was measured by the Timed Up and Go Test (TUG). The participants were asked to get up from an armchair, walk 3 meters, turn back, and return to a seated position according to a standard protocol [24]. The time required to finish the task at each round was recorded. Three measurements were made. Shorter walking time indicated better balance. The best (fastest) time of the three TUG trials was used [25].

Cognitive status was measured using the Montreal Cognitive Assessment 5-Minutes (Hong Kong Version) (HK-MoCA 5-Min) protocol. The validated assessment test covered the following four domains: attention, executive functions/language, orientation, and memory [26,27]. The total score ranged from 0 to 30, with a higher score indicating better cognitive status. The alternate version was not used in subsequent assessments, as literature suggested that the results were unlikely to be affected if the same assessment tool was used over the follow-up period [28]. If the participants were incapable of answering the HK-MoCA 5-Min, they were examined using the Benton Temporal Orientation Test (BTO), which involves only questions about orientation to time (including identifying the year, month, day, day of the week, and time of the day) [29]. An error score was calculated according to the Benton Temporal Orientation Scale (BTOS), with a lower error score indicating better cognitive status [30].

Happiness was measured using a single question “for most of the time, do you feel…” [31], accompanied with a 11-point Likert-scale ruler or 5/3/2 facial expression pictures about happiness [32]. Following the pretest protocol suggested for the Personal Wellbeing Index–Intellectual Disability (Chinese-Cantonese), the intellectual ability of respondents was assessed to determine the response options [32]. The options (for respondents with descending order of ability) included an 11-point scale (0-10), a 5-point scale (0-4), a 3-point scale (0-2), and a 2-point scale (0-1). Then, the score was standardized into units of “percentage of scale maximum,” with a possible range of 0 to 100 and higher scores indicating higher levels of happiness [32].

Usage time of VR training was collected via the built-in VR software system to ensure data accuracy. At the end of each session, the trained staff who accompanied the participants in the VR training collected qualitative feedback on the training experience, using the question “Do you like or dislike the VR training? Why?” The participants could provide multiple feedback responses, both positive and negative, if they wished. Any adverse health effects (such as dizziness) induced after playing the VR games were also recorded through self-reports and staff observations. The staff accompanying the participants in the VR training closely observed any discomfort experienced by the participants, in addition to explicitly asking the participants about any discomfort.

Statistical Analysis

The primary outcomes were upper-limb dexterity and acceptance of VR training. The secondary outcomes were usage statistics, functional mobility, cognitive status, and happiness. SPSS version 25 (IBM Corp) was used for statistical analyses. A 5% significance level was adopted.

The participant characteristics were summarized using descriptive statistics. Characteristics of dropout participants were examined using a logistic regression model. VR training usage statistics in terms of the number of weeks engaged in VR training, number of total sessions of VR training attended, and duration of each VR training session were calculated and used to reflect the feasibility of the intervention. Linear mixed effect models were used to analyze the change in health outcomes,

XSL•FO
RenderX

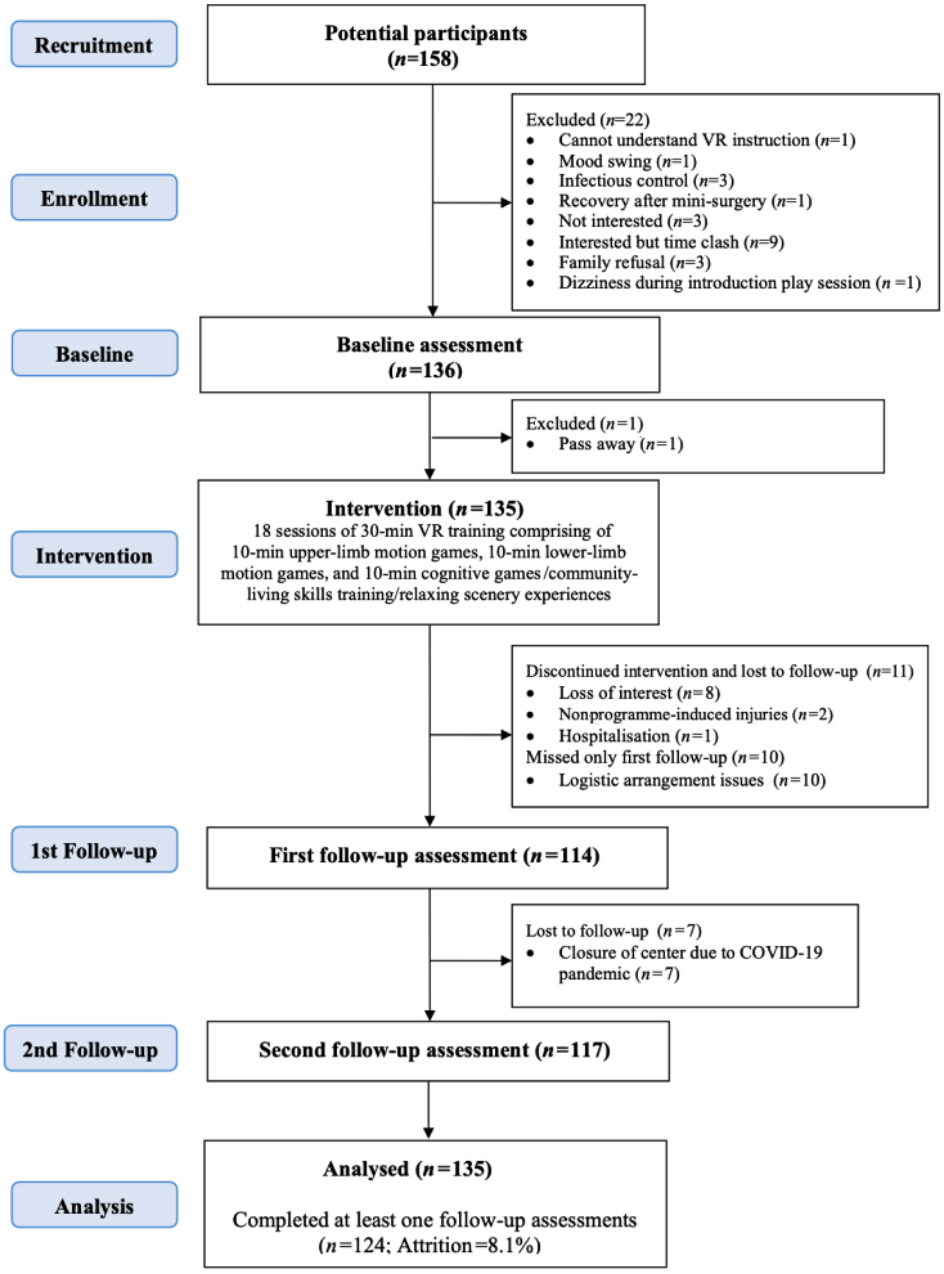
adjusting for age, gender, education level, living arrangement, disability, and medical history/condition. Assessment time was used as the independent variable, and its fitted coefficients indicated the temporal change in health outcomes in T1 and T2 as compared with T0. Missing data at follow-up were not imputed as the linear mixed effect models could cater for missing data. The standardized effect size in terms of the Cohen *d* index was calculated using the adjusted mean difference divided by the standard deviation [33]. Cohen *d* index values of 0.2, 0.5, and 0.8 indicated small, moderate, and large effect sizes, respectively.

Content analysis was performed for the qualitative feedback on the experience of VR training. First, the presence of concepts related to positive and/or negative comments was determined. Then, the presence of keywords and related concepts, such as tiredness, equipment, excitement, and exercise, was counted. Lastly, the frequency and percentage were calculated accordingly. The acceptance level of VR training experience was reflected by the number of participants providing positive comments, with a larger proportion indicating a higher level of acceptance. As the participants could provide multiple feedback responses, both positive and negative, when we calculated the proportion of participants using the total number of participants as the denominator, the proportion could exceed 100%. Therefore, in order to investigate factors associated with a higher level of acceptance, participants had to be further classified into the following three mutually exclusive groups: (1) only or mostly positive comments, (2) only or mostly negative comments, and (3) no comments or equal positive/negative comments. The proportions of participants in each group were calculated. Multiple multinomial regression was conducted to identify the associated factors. Adverse health events were also summarized.

Ethics Approval

This study was approved by the Institutional Review Board of the University of Hong Kong/Hospital Authority Hong Kong West Cluster (reference number: UW19-336).

Results



Characteristics of the Participants

A total of 158 participants were recruited from both institutional and community settings, including four homes for the severely disabled, eight homes for the intellectually disabled, six homes for the visually impaired, one old-age home, one community center for the intellectually disabled, and three elderly community centers. Of the 158 participants, 23 (14.6%) were not eligible, giving a total of 135 participants for the evaluation study (Figure 1). Table 3 summarizes the baseline characteristics of the 135 participants. The participants had a mean age of 62.7 years (SD 21.5). Additionally, 50.4% (68/135) of the participants were male, 76.3% (103/135) had an education level of primary school or below, or special educational needs, and 70.4% (95/135) were living in residential care settings. All participants had at least one type of disability, with 52.6% (71/135) having moderate-to-severe functional dependence, 78.5% (106/135) requiring walking aids or wheelchairs, 28.1% (38/135) having mild-to-severe cognitive impairment, 54.8% (74/135) having mild-to-severe intellectual disability, and 45.9% (62/135) having mild-to-severe visual impairment. Moreover, 9.6% (13/135) of the participants had a stroke history, 9.6% (13/135) had a fracture history, 13.3% (18/135) had mental illness, and 9.6% (13/135) had autism.

Additionally, 91.9% (124/135) of the eligible participants completed at least one follow-up. Some of them dropped out because of loss of interest (n=8), while a few of them did so because of nonprogram-induced injuries (n=2) and hospitalization (n=1). The logistic regression model showed that none of the participant characteristics was associated with dropout.

Usage Statistics of VR Training

A total of 1906 VR training sessions were conducted during the study period. Table 4 shows the summary of the usage statistics of VR training. Ninety-one individuals participated in the VR training for 6 weeks consecutively and another 15 participated for at least 6 weeks intermittently, giving a total of 106 participants (106/135, 78.5%) that met the suggested usage

XSL•FO
RenderX

duration of 6 weeks. Over three quarters (103/135, 76.3%) of participants attended at least 13 sessions of VR training (ie, at least 70% of the proposed 18 sessions), and the majority (n=1382, 72.5%) of the 1906 sessions had a training time (excluding set-up time and rest time) of at least 20 minutes. The median total training time of the participants was 316.8 minutes. All of them participated in physical training games for a median of 275.0 minutes, and 116 of them participated in cognitive training (classification) games for a median of 33.8 minutes (Table 5). As for the difficulty level, 84.7% (1512/1786) of the *handball* game sessions, 88.7% (1295/1460) of the *football* game sessions, and 66.7% (909/1363) of the *classification* game sessions were at the easiest level (level 1) (Table 6). On the other hand, participants were able to play more advanced levels in *MTR GO GO GO*. Reasons for not complying with the usage protocol, including medical appointments or other engagements, limited resources, bad weather, technical problems, disability constraints, mood swings, sickness, and tiredness, were encountered in the scheduled sessions.

Health Outcomes

According to their conditions, the participants received varying health outcome assessments at baseline, with the BBT (n=134 for the dominant hand and n=128 for the nondominant hand), TUG (n=104), HK-MoCA 5-Min (n=94), BTO (n=30), and happiness scale (n=130) (Table 7). Among the health outcomes, significant improvement over time was noted in upper-limb dexterity (P=.008 for the dominant hand and P=.043 for the nondominant hand) and cognitive function (P<.001 for overall performance) (Figure 2), whereas there was no significant change in functional mobility (P=.14), orientation to time (P=.72), and happiness (P=.34).

Table 7. Baseline outcome measures of the participants (N=135).

Outcome measure	Number of participants	Value, mean (SD)
BBT[a] (in blocks)		
Dominant hand	134	27.7 (14.1)
Nondominant hand	128	28.0 (14.7)
TUG[b] (in seconds)	104	15.4 (11.8)
HK-MoCA 5-Min[c] score		
Overall performance	94	13.7 (7.8)
Attention domain	94	2.3 (1.4)
Executive functions/language domain	94	3.9 (2.3)
Orientation domain	94	3.6 (2.1)
Memory domain	94	3.9 (3.2)
BTO[d] score (in error scores)	30	37.8 (25.9)
Happiness score	130	79.1 (30.0)

[a]BBT: Box and Block Test.

XSL•FO
RenderX

Figure 2. Change in health outcomes over three measurement time points (baseline [T0], 6 weeks after baseline [T1], and 3 months after baseline [T2]). (A) Block and Block Test (BBT), a larger number of blocks transferred indicates better upper-limb dexterity; *P* values for time difference: .008 (dominant hand) and .043 (nondominant hand). (B) Montreal Cognitive Assessment 5-Minutes (Hong Kong Version) (HK-MoCA 5-Min), a higher score indicates better cognitive status; *P* values for time difference: <.001 (overall performance), <.001 (attention domain), <.001 (executive functions/language domain), .004 (orientation domain), and <.001 (memory domain).

Based on the linear mixed effect models (Table 8), the number of blocks transferred by the dominant hand significantly increased by 2.4 blocks (*P*=.007, Cohen *d*=0.17) and that by the non-dominant hand increased by 1.9 blocks (*P*=.04, Cohen *d*=0.13) when comparing T2 with T0. However, no significant differences in the number of blocks transferred were observed for both the dominant and nondominant hands when comparing T1 with T0.

In terms of the HK-MoCA 5-Min, the overall performance score significantly increased by 2.5 (*P*<.001, Cohen *d*=0.31) when comparing T1 with T0, and increased by 3.5 (*P*<.001, Cohen *d*=0.45) when comparing T2 with T0. Significant differences were also detected in T1 and T2 compared with T0 for all domains, except the orientation domain where an insignificant difference was reported for the comparison between T1 and T0. When comparing T2 with T0, the Cohen *d* of the domains ranged from 0.24 for orientation to 0.65 for attention.

XSL•FO
RenderX

Table 8. Change in health outcomes over the three assessment time points.

Outcome measures[a]	T1[b] vs T0[c]			T2[d] vs T0		
	Change[e] (95% CI)	Effect size[f]	*P* value	Change[e] (95% CI)	Effect size[f]	*P* value
BBT[g] (in blocks)						
Dominant hand	0.7 (−0.9 to 2.3)	0.05	.39	2.4 (0.9 to 4.0)	0.17	.002[h]
Nondominant hand	0.7 (−0.7 to 2.2)	0.05	.33	1.9 (0.4 to 3.3)	0.13	.01[h]
TUG[i] (in seconds)	−0.5 (−1.6 to 0.6)	−0.04	0.39	−1.1 (−2.2 to −0.007)	−0.09	.048[h]
HK-MoCA 5-Min[j] score						
Overall performance	2.5 (1.7 to 3.2)	0.31	<.001[h]	3.5 (2.8 to 4.3)	0.45	<.001[h]
Attention domain	0.5 (0.2 to 0.7)	0.33	.001[h]	0.9 (0.6 to 1.2)	0.65	<.001[h]
Executive functions/language domain	0.8 (0.4 to 1.1)	0.33	<.001[h]	1.0 (0.7 to 1.3)	0.43	<.001[h]
Orientation domain	0.3 (−0.005 to 0.6)	0.14	.054	0.5 (0.2 to 0.8)	0.24	.001[h]
Memory domain	1.0 (0.5 to 1.4)	0.30	<.001[h]	1.2 (0.7 to 1.6)	0.37	<.001[h]
BTO[k] score (in error scores)	2.6 (−7.4 to 12.6)	0.10	.61	−1.5 (−11.4 to 8.3)	−0.06	.76
Happiness score	−4.4 (−10.6 to 1.9)	−0.15	.17	−3.5 (−9.8 to 2.7)	−0.12	.26

[a]A better condition is represented by an increase in transferred blocks in the BBT, a decrease in time in the TUG, an increase in the HK-MoCA 5-Min score, a decrease in error scores in the BTO, and an increase in the happiness score.

[b]T0: baseline.

Feedback From Participants

Among the 135 participants, 88 (65.2%) provided positive comments and 63 (46.7%) provided negative comments (multiple comments allowed), whereas 30 (22.2%) did not provide any comment. Among the 88 participants who provided positive comments, 53 (60.2%) reported the VR experience as innovative, interactive, fun, or exciting, 49 (55.7%) found the experience motivating, and 30 (34.1%) perceived the VR games as exercises. Meanwhile, among the 63 participants who provided negative comments, 26 (41.3%) complained about the VR equipment (such as the HMD device), 25 (39.7%) felt bored, 24 (38.1%) felt physically tired, 17 (27.0%) described the experience as scary, tense, or worrying, and 16 (25.4%) reported the usage as complicated. Moreover, 38 (60.3%) of those who indicated negative comments expressed such comments during the first two game sessions.

In terms of enjoyment, most participants enjoyed the *elephant feeding* game (n=11), followed by the *handball* game (n=5), *football* game (n=5), *diving scenery experience* (n=5), *feather duster throwing* game (n=3), *home items locating* game (n=3), and *coin tossing* game (n=1). At the same time, in terms of dislike, most participants disliked the *elephant feeding* game (n=11), followed by the *diving scenery experience* (n=3) and *seven must-dos before leaving home* game (n=1).

The participants were further classified into the following three groups: those who provided only or mostly positive comments (n=61, 45.2%), those who provided only or mostly negative comments (n=34, 25.2%), and those who had no comments or provided equal positive/negative comments (n=40, 29.6%). Based on multiple multinomial logistic regression, home-dwelling participants (*P*<.001) and those without autism (*P*=.008) had a much higher chance of providing positive comments. On the other hand, none of the participant characteristics was associated with a higher chance of expressing negative comments.

Apart from the general feedback, reports on mild discomfort were obtained in 25 of the 1906 (1.3%) game sessions (14 of 135 participants, 10.4%). The most common mild discomfort

XSL•FO
RenderX

was dizziness (nine sessions from seven participants), followed by eyestrain (six sessions from three participants), hand/leg pain (three sessions from two participants), blurred vision (two sessions from one participant), eye redness (two sessions from one participant), hand tremors (two sessions from one participant), and cramps (one session from one participant). Over half (13/25, 52.0%) of these mild discomforts occurred in the first four sessions of the VR training. None of the participants reported severe discomfort. Moreover, staff reported technical problems in 63 of the 1906 (3.3%) game sessions.

Discussion

Overview

This evaluation study explored the feasibility and acceptability of a universal set of VR training games for users with different abilities and conditions. Additionally, the improvement in health outcomes over time was assessed. The findings from this study can inform the future development and application of VR training to heterogeneous users in different settings.

Feasibility of Providing VR Training to Users With Different Disabilities

Few VR games have been designed for the broad coverage of different populations. Our experience revealed the possibility that people with different disabilities could enjoy the same set of VR games. With different training components, clients with different disabilities could participate in suitable types of training. Nevertheless, manpower resources had to be invested in addition to the VR system, since close supervision of the users by trained staff was required.

With a rehabilitation goal, we proposed a training protocol of 3 days a week for 6 weeks, with a target of 18 sessions. Over 76% of the participants attended 13 or more sessions. Adherence to the proposed number of training sessions was comparable to that reported in the literature [34]. Flexibility for makeup training was allowed if participants were not able to attend certain sessions. Usage statistics showed that the majority of sessions could offer at least 20 minutes of game time. However, the game time for cognitive training/community-living skills training/relaxing scenery experiences was substantially less than that for physical training. One explanation could be the limit of the session time. These components were placed as the last training components of each session, and thus, they might have been terminated if time was running out. Scheduling was a critical element to the successful implementation of the program. To facilitate a 30-minute training time, the manpower, equipment, and venue had to be made available for at least 45 minutes to allow for the necessary time for setup, instructions, and breaks. Moreover, as reality orientation, community-living skills training, and relaxing scenery experiences were available for use at a later stage, usage statistics were substantially less than those for the classification game. Despite the users' inability to attend all 18 sessions or spend 30 minutes of training time per session, there was a significant improvement in cognitive function and upper-limb dexterity. Hence, we propose to retain the current usage protocol until a new one with reduced usage is tested.

In our experience, mild discomfort was reported by 14 of 135 participants (10.4%). In a local study examining the effects of VR cognitive stimulation activity among community-dwelling older adults (n=236), 1.4% of them reported severe discomfort regarding fatigue and eye strain, blurred vision, and dizziness after 20 to 25 minutes of VR exposure [17]. However, mild discomfort was not reported. In another study conducted by US researchers, it was reported that 12% of older people with Alzheimer disease/mild cognitive impairment and 19% of older people without such conditions dropped out from the VR game because of simulation sickness [35]. The proportion of participants reporting adverse outcomes among our users was comparable, if not lower, than the proportions reported in the literature. Therefore, participants with disabilities would not put themselves at a higher risk of adverse events. At the same time, some participants reported physical tiredness after VR training. While this study did not quantitatively investigate tiredness as an outcome, a meta-analysis suggested an insignificant difference in terms of the presence of tiredness after VR training as compared with participants engaging in traditional exercises [36].

Acceptance of VR Training Among Users at an Advanced Age or With Various Disabilities

Generally, most of the participants accepted the use of the VR training, as 65.2% of the participants indicated positive comments. Those living in the community and those without autism tended to provide more positive remarks. This might be because these participants were more expressive of themselves. On the other hand, the HMD device and limb motion trackers might have induced discomfort, which was the major reason for negative comments. To enhance their experience and satisfaction in terms of fit and comfort, hardware designers may develop lighter devices. To accommodate the special needs of clients with limitations in head and neck movements, sensors should also be further adjusted so that clients do not need to maintain an upright position throughout the sessions.

Some participants also perceived the VR games as complicated, but they could still complete the session under the supervision of trained staff. Although some users claimed the VR training was boring, there was no evidence showing that such negative remarks were related to the proposed VR training for 18 sessions. Indeed, those who made negative comments had such perceptions in the first two sessions. This might suggest the need for more briefings or orientations prior to the use of VR training. In the current program, the scoring regime had been modified to increase the users' sense of achievement. However, there was no personalized scoring regime to differentiate game difficulty levels for different disabilities over time. In future development, such features should be incorporated for motivating clients to continue training and promoting a higher sense of achievement where progression could be felt by users.

The VR games that involved physical activity training were well received by users. It was interesting to learn that the VR cognitive-training game featuring the elephant kept in a zoo in Hong Kong in the 70s received both favorable and unfavorable reviews from the users. Some loved it probably because it recalled memories of the old days, while some disliked it

probably because they were scared by the elephant's trumpet, which was close to that in real life. Future design of VR scenery should take a balanced approach among excitement, calmness, and boredom.

Efficacy of VR Training in Improving the Health Outcomes of Participants

Using a single-arm pretest-posttest design, the evaluation study showed significant improvement in upper-limb dexterity assessed by the BBT and cognitive function assessed by the HK-MoCA 5-Min. According to the literature, an increase of 2 points in the MoCA full version score was generally considered as a minimal clinically important difference (MCID) for older adults or stroke survivors, which was about 0.5 standard deviations as defined by the distribution-based approach [36-38]. However, the MCID in terms of the MoCA 5-Min version has not been discussed in the literature. Hence, we used a distribution-based approach of 0.5 standard deviations, and considered a Cohen *d* index of 0.5 as the MCID. In our evaluation study, the HK-MoCA 5-Min overall score increased by 3.5 units as compared with baseline. In terms of the standardized effect size, the HK-MoCA 5-Min score had a Cohen *d* index of 0.45, which aligned with this reference. As understanding and following instructions to play VR games involve cognitive processing, the improvement in cognitive function might be enhanced by playing all the games and not necessarily restricting playing to the sessions involving cognitive VR games.

As for the BBT, there was no well-established MCID. Literature suggested that a difference of 6 to 8 blocks is considered as the smallest real difference beyond measurement error among stroke survivors [39], which would translate to a Cohen *d* index of 0.4 to 0.6 based on the standard deviation estimated in our study. Since the effect size of the BBT achieved in our study was only 0.13 to 0.17, we had to be cautious in interpreting the clinical significance of such a change. For functional mobility, although there was a favorable trend in improvement, such improvement did not reach statistical significance. It appeared that training intensity, particularly when participants took a sitting position when playing the games, was not sufficient to achieve improvement in functional mobility.

Our results are consistent with recent reviews, which found that VR training attained small-to-moderate effects in terms of physical performance [40] and cognitive function [41]. Despite the significant improvement in the oriental domain of the HK-MoCA 5-Min scale, there was an insignificant change in the BTO score. Further research is suggested to examine the reasons. Nevertheless, we would be cautious about clinical significance in terms of the improvement in the BBT. Our insignificant results in terms of mobility are also consistent with the absence of an effect in terms of gait as reported by a review [40].

The evaluation study did not show any significant change in the happiness level. This is consistent with a recent systematic review of VR exercise training that reported insignificant effects on psychological outcomes such as calmness and enjoyment [40]. The review also suggested that immersive components of VR training and longer follow-up periods tended to be associated with smaller benefits, but statistical significance was not found. As VR games are designed to promote functional and cognitive ability, if happiness is to be enhanced, the content of VR games might need to be adjusted and a regular playing schedule might not need to be applied.

A supplementary analysis testing the interactions between different subgroups (dependence level, mobility status, cognitive status, intellectual disability status, visual status, stroke history, fracture history, mental illness, and autism) and time points was performed using linear mixed effect models. Insignificant interaction terms were found for all those explored, except a few, which might have occurred by chance. There was insufficient evidence for the difference in the change of outcomes between different subgroups, and future studies could revisit this with a more vigorous design.

Strengths and Limitations

The strengths of this evaluation study were its large sample size, adoption of validated scales as outcome measures, and long follow-up period. Qualitative feedback from the participants also informed the strengths and weaknesses of the VR training program. However, the study has some limitations. First, the lack of a control group might have limited the interpretation of the results that only efficacy instead of effectiveness could be investigated. Second, people with hearing impairment, those who were bed bound, and those with disability in turnaround were not included in the study, as the current system could not cater to their special needs, and the potential benefits or adverse effects in these users are unclear from this study. The uses of various cognitive training components, community-living skills training, and scenery experiences were not standardized, and some games were not available at the beginning of the program, resulting in vast variations in game time for the components. In addition, progression of the game difficulty level was not standardized in the usage protocol, and this should be considered in future studies. As qualitative feedback responses were collected at the end of each game session, investigation by game components could not be performed. A future study should continue to investigate the optimal modalities in the domains of physical, cognitive, and psychological training for people with different vulnerable health conditions, and a controlled trial would be preferred.

Conclusions

A set of VR training games for rehabilitation could be applied to individuals with heterogeneous abilities. Our VR games were acceptable to local older adults and those with different disabilities. Benefits in upper-limb dexterity and cognitive function were observed despite partial compliance to the training protocol. Service providers could refer to our experiences when developing VR training systems for their clients.

Abstract

Background: Cognitive training can potentially prevent cognitive decline. However, the results of recent studies using semi-immersive virtual reality (VR)-assisted cognitive training are inconsistent.

Objective: We aimed to examine the hypothesis that cognitive training using fully immersive VR, which may facilitate visuospatial processes, could improve visuospatial functioning, comprehensive neuropsychological functioning, psychiatric symptoms, and functional connectivity in the visual brain network in predementia.

Methods: Participants over 60 years old with subjective cognitive decline or mild cognitive impairment from a memory clinic were randomly allocated to the VR (n=23) or the control (n=18) group. The VR group participants received multidomain and neuropsychologist-assisted cognitive training in a fully immersive VR environment twice a week for 1 month. The control group participants did not undergo any additional intervention except for their usual therapy such as pharmacotherapy. Participants of both groups were evaluated for cognitive function using face-to-face comprehensive neuropsychological tests, including the Rey-Osterrieth Complex Figure Test (RCFT) copy task; for psychiatric symptoms such as depression, apathy, affect, and quality of life; as well as resting-state functional magnetic resonance imaging (rsfMRI) at baseline and after training. Repeated-measures analysis of variance was used to compare the effect of cognitive training between groups. Seed-to-voxel–based analyses were used to identify the cognitive improvement–related functional connectivity in the visual network of the brain.

Results: After VR cognitive training, significant improvement was found in the total score ($F_{1,39}$=14.69, *P*=.001) and basic components score of the RCFT copy task ($F_{1,39}$=9.27, *P*=.005) compared with those of the control group. The VR group also showed improvements, albeit not significant, in naming ability ($F_{1,39}$=3.55, *P*=.07), verbal memory delayed recall ($F_{1,39}$=3.03, *P*=.09), and phonemic fluency ($F_{1,39}$=3.08, *P*=.09). Improvements in psychiatric symptoms such as apathy ($F_{1,39}$=7.02, *P*=.01), affect ($F_{1,39}$=14.40, *P*=.001 for positive affect; $F_{1,39}$=4.23, *P*=.047 for negative affect), and quality of life ($F_{1,39}$=4.49, *P*=.04) were

XSL•FO
RenderX

found in the VR group compared to the control group. Improvement in the RCFT copy task was associated with a frontal-occipital functional connectivity increase revealed by rsfMRI in the VR group compared to the control group.

Conclusions: Fully immersive VR cognitive training had positive effects on the visuospatial function, apathy, affect, quality of life, and increased frontal-occipital functional connectivity in older people in a predementia state. Future trials using VR cognitive training with larger sample sizes and more sophisticated designs over a longer duration may reveal greater improvements in cognition, psychiatric symptoms, and brain functional connectivity.

Introduction

Dementia is a major neurodegenerative disorder, affecting approximately 10% of older people [1]. Cognitive, psychological, and behavioral deterioration are typical manifestations of dementia, ultimately resulting in functional impairments and disability [2]. The individual and societal burden of dementia is accelerating rapidly compared to other diseases [1,3]; however, due to the unclear mechanisms and multifactorial pathology underlying the development and progression of dementia, only symptomatic treatments are currently available [4].

To date, many researchers have suggested that prevention is crucial, and have identified risk and protective factors associated with dementia, as well as preventive strategies [5]. According to a recent large study, one-third of Alzheimer disease (AD) cases are attributable to potentially modifiable risk factors such as educational attainment, vascular factors, and depression [6]. Additionally, lifelong exposure to cognitively and mentally engaging activities has been shown to protect against cognitive decline [7], and performance of cognitively stimulating activities in advanced age was associated with better cognitive function [8]. Accordingly, recent cognitive training studies have shown that repeated practice of exercises to restore brain and cognitive reserves resulted in small to moderate positive improvements in cognition in patients with mild to moderate dementia [9].

Advances in computer sciences and information and communication technology (ICT) have resulted in increased availability and accessibility of computerized cognitive training. Although conclusive results have yet to be found, preliminary studies have reported improvements in trained and nontrained cognition, and enhanced brain activity in related regions after computerized cognitive training in individuals with mild cognitive impairment (MCI) [10-12]. Working memory training was effective in improving verbal memory and hippocampal activation in patients with MCI [11], and exposure to a driving video game resulted in increased ability to control the vehicle that was related to midline frontal theta power in older people [12]. Moreover, emerging ICT applications using virtual reality (VR) have resulted in evolutions in health care, including cognitive and behavioral therapy [13]. VR can offer interventions in flexible and real world–like environments, facilitating visuospatial function through learning and transference outcomes [14], highlighting a role for cognitive training in a virtual environment in basic research and clinical practice. Owing to the lack of knowledge and dearth of experiments on VR-based cognitive training, especially the fully immersive type [15,16], further studies are needed to ascertain its potential therapeutic efficacy.

Recently, the number of neuroimaging studies attempting to reveal the underlying neural mechanisms associated with cognitive decline has increased [17,18]. Functional connectivity studies using resting-state functional magnetic resonance imaging (rsfMRI) have identified networks temporally coinciding with spatially distant neurophysiological events that are intrinsically coherent during a resting state such as the default-mode network [19]. We considered that functional connectivity studies using rsfMRI may be able to reveal the neural mechanism, especially in the visual network, responsible for the observed cognitive improvements following VR cognitive training, as such training is based on the cognitive reserve hypothesis associated with functional neural networks [20].

To test this hypothesis, we performed a preliminary randomized controlled trial to determine the efficacy and mechanisms of VR cognitive training in a predementia state. We aimed to ascertain the effects of VR multidomain cognitive training on visuospatial function, comprehensive neuropsychological function, and psychiatric symptoms in predementia. Moreover, we examined the hypothesis that cognitive improvement could be related to increased functional connectivity in the visual network of the brain.

Methods

Participants

Participants over 60 years old in a predementia state (ranging from subjective cognitive decline to MCI) were prospectively recruited between May and December 2019 from the memory clinic of Gachon University Gil Medical Center, Republic of Korea. Among 58 individuals who were assessed for eligibility using structured clinical interviews and brain MRI, four participants were excluded due to cerebral infarction on MRI (n=2), severe white matter hyperintensity on MRI (n=1), and history of a recent dental implant surgery (n=1). Nine participants voluntarily withdrew from the study due to an acute medical condition (n=2), hospitalization of a family member (n=1), scheduling conflict (n=1), and unknown personal reasons

XSL•FO
RenderX

(n=5). Finally, a total of 45 participants were randomly assigned to either the VR group or the control group.

All participants had subjective cognitive complaints, including memory decline, but did not meet the criteria for diagnosis of a major neurocognitive disorder based on the Diagnostic and Statistical Manual of Mental Disorders (5th edition) [2]. Participants were classified as having subjective cognitive decline according to the corresponding research criteria and five cognitive domain scores such as attention, language, visuospatial, memory, and frontal executive functions above –1.5 SD [21,22]. Participants were classified as having MCI according to the Petersen criteria [23]. Screening evaluation of the participants was performed by a board-certified psychiatrist (JK) and a clinical neuropsychologist (SL).

The exclusion criteria for the participants were as follows: (i) Korean version of Mini-Mental State Examination (MMSE) score <20; (ii) impaired activities of daily living; (iii) comorbidity of severe medical or surgical conditions; (iv) major psychiatric disorders; (v) history of any kind of dementia; (vi) history of neurodegenerative disorders, including Creutzfeldt-Jakob disease, Pick disease, Huntington disease, Parkinson disease, inflammation associated with HIV, and syphilis; (vii) structural abnormalities on MRI such as intracranial hemorrhage, cerebral, cerebellar, or brainstem infarction, hydrocephalus, traumatic brain injury, severe white matter hyperintensity, tumors, multiple sclerosis, or vasculitis; and (viii) inability to use the VR system.

Information on study objectives, group allocation, cognitive intervention, brief study protocol, risks and benefits, and confidentiality was given to all participants before enrollment. All participants provided offline written informed consent, and the Institutional Review Board of Gachon University Gil Medical Center approved this study (GCIRB2018-396).

Study Design

This was an open-label, randomized controlled trial (KCT0005243) that aimed to investigate the efficacy of a fully immersive VR cognitive training program on visuospatial function in older people with risk for dementia (Multimedia Appendix 1). Participants were randomly assigned to either the VR or the control group. The unblinded randomization was performed by drawing lots with the participants present. Participants in both groups were evaluated for visuospatial function, comprehensive neuropsychological function, and psychiatric symptoms, and underwent rsfMRI before and after the 1-month cognitive training. The participants in the VR group underwent VR cognitive training twice a week for a total of eight sessions in addition to their usual therapy such as pharmacotherapy for the prevention of dementia (eg, choline alfoscerate and cholinesterase inhibitor); the participants in the control group did not undergo any additional intervention except for their usual therapy such as pharmacotherapy.

VR Cognitive Training

The multidomain VR cognitive training program was developed between November 2018 and April 2019 by the authors who are board-certified geriatric neuropsychiatrists and clinical neuropsychologists with expertise. The VR cognitive training program consisted of multiple games involving multidomain cognitive tasks to assess: (i) attention (to find differences), (ii) executive function and memory (to select items needed to perform certain tasks), (iii) working memory and ability to perform mathematical calculations (to prepare an exact amount of money), (iv) visuospatial orientation (to find a path using a memorized map), (v) visuospatial function (to spatially place furniture exactly based on a memorized drawing), (vi) verbal memory (to remember certain words), (vii) visual memory (to remember specific flags and symbols), and (viii) processing speed and working memory (to catch animals in a certain order). All virtual environments were fully immersive 3D settings allowing for feelings of increased presence and visuospatial stimulation; training was accompanied by game elements to increase the interest and motivation of the participants. Representative images of the VR training program are presented in Multimedia Appendix 2.

Each session lasted approximately 20-30 minutes. The VR training took place using a head-mounted Oculus Rift CV1 display, with Oculus Touch controllers held in both of the participant's hands. Each training session was performed with the participant in a seated position, and the difficulty level increased throughout the study period from easy to difficult (levels 1-4), with two sessions at each difficulty level. All procedures were performed in the memory clinic of Gachon University Gil Medical Center and were guided by a certified clinical neuropsychologist (SL) in addition to automatic verbal and visual messages from the program. There were no revisions, updates, or breaches of the program during the study period. This program was used exclusively in this study and is not available for commercial use.

Procedures and Outcome Measures

All participants underwent face-to-face comprehensive neuropsychological tests and evaluations using psychiatric scales, as well as rsfMRI at baseline and after the VR cognitive training period. Baseline evaluations of diagnostic criteria included global and functional scales such as the Korean version of the MMSE, Clinical Dementia Rating (CDR), CDR Sum of Boxes (CDR-SOB), global deterioration scale, and instrumental activities of daily living scales.

The primary outcome was the effect of the VR cognitive training on visuospatial function measured by the Rey-Osterrieth Complex Figure Test (RCFT) copy task, which has been validated in the Korean population [24,25]. Basic components, including a large rectangle (1 point), diagonal cross (1 point), horizontal midline of a large rectangle (1 point), and vertical midline of a large rectangle (1 point), were also evaluated because they are considered important in qualitative aspects [26,27]. The neuropsychologist (GP) who scored the RCFT copy task was blinded to the randomization.

The secondary outcomes concerned the effect on comprehensive neuropsychological function; psychiatric symptoms such as affect, apathy, quality of life (QoL), and depression; and functional connectivity in the visual network of the brain.

The neuropsychological tests consisted of the MMSE and subtests from the comprehensive neuropsychological test battery

XSL•FO
RenderX

[25]. Attention was assessed by the digit span forward and backward test and Trail Making Test (TMT) part A [25]. The Korean version of the Boston Naming Test (K-BNT) was used to assess language ability [25,28]. Memory was assessed by measuring performance on three tasks of the Seoul Verbal Learning Test (SVLT): immediate recall, delayed recall after 20 minutes, and recognition [25]. Frontal executive function was assessed by phonemic word fluency testing, the TMT-B, and the Stroop Color Test [25]. All neuropsychological test results were adjusted for age and years of education, and are presented as standardized *z*-scores.

Noncognitive psychiatric symptoms that typically start to decline in the early dementia stage were also assessed [29]. Depressive symptoms were evaluated by the validated 30-item Geriatric Depression Scale (GDS), including questions pertaining to mood, anxiety, energy, satisfaction, hopefulness, inattention, and sleep quality [30,31]. The GDS comprises a series of binary yes/no questions (scored as 1 or 0, respectively), with higher scores indicating severe depression. Apathy was evaluated by the validated 18-item Apathy Evaluation Scale (AES), including items pertaining to emotional affect, behavior, and cognitive apathy [32,33]. Items of the AES are rated on a 4-point Likert scale, with a low score indicating severe apathy. Affect was evaluated by the Positive and Negative Affect Schedule (PANAS), which consists of 10 items to assess positive affect (PANAS-P) measures such as alertness and enthusiasm and 10 items to assess negative affect (PANAS-N) such as lethargy and feelings of sadness [34,35]. Each of the PANAS items is rated from 1 (not at all) to 5 (very much), with higher scores indicating higher affect. Participants' QoL was evaluated by the QoL-AD scale, which has been validated for use in people with dementia, including 13 subjective rating items to assess physical health, living situation, relationships with friends, and the ability to engage in leisure activities [36,37]. Items of the QoL-AD are assessed on a 4-point Likert scale, with higher scores indicating better QoL.

The Simulator Sickness Questionnaire (SSQ) was administered after each session to evaluate tolerability of the VR cognitive training program [38]. Simulator sickness refers to side effects from virtual environment usage, and is also called cybersickness [39,40] and VR sickness [41]. The SSQ consists of 16 items yielding three subscales (nausea, oculomotor, and disorientation) and a total severity score, with high scores indicating increased symptoms. The levels of interest and satisfaction were also assessed on a Likert scale ranging from 0 to 100 after the period of VR cognitive training in a face-to-face manner.

MRI Acquisition

A 3-Tesla whole-body Siemens scanner (TrioTim syngo) was used for functional image acquisition with an interleaved T2*-weighted echo-planar imaging gradient echo sequence (repetition time/echo time=2500/25 milliseconds, flip angle=90°, slice thickness=3.5 mm, in-plane resolution=3.5×3.5 mm, matrix size=64×64) with a 12-channel birdcage head coil. For each participant, 160 functional volumes were acquired at the pretraining and posttraining time points. After rsfMRI, an anatomical image was acquired using a high T1-weighted 3D-gradient echo pulse sequence with magnetization-prepared rapid gradient echo (repetition time/echo time/inversion time=1900/3.3/900 milliseconds, flip angle=9°, slice thickness=1.0 mm, in-plane resolution=0.5×0.5 mm, matrix size=416×512). T1-weighted images were acquired only at the pretraining time point.

Functional Connectivity Analyses With rsfMRI

Preprocessing of the rsfMRI data was performed using Statistical Parametric Mapping software version 12 (Wellcome Trust Centre for Neuroimaging). First, a slice-timing correction was applied and the center of each image was relocated near the anterior commissure. Second, rsfMRI and T1-weighted images were imported into CONN FC toolbox v19c [42] for further preprocessing. To correct for between-scan rigid body motion, the functional images were realigned to the first image in the time series. The functional images were coregistered with anatomical images and spatially normalized to the Montreal Neurological Institute space using a transformation matrix derived from the T1-weighted anatomical image segmentation. The functional images were then resliced to 2×2×2 mm and spatially smoothed using an 8-mm full width at half maximum Gaussian kernel.

All preprocessed rsfMRI images were bandpass-filtered (0.008-0.09 Hz), and physiological and other spurious noise sources in the blood oxygenation level–dependent signal were removed using the anatomical component-based noise correction strategy implemented in CONN [43]. Outliers were calculated using the Artifact Detection Tools toolbox [44], and six motion correction parameters obtained from realignment were also modeled as nuisance covariates. The seed-to-voxel analyses were performed in the visual network with four cortical seed regions (right visual lateral, left visual lateral, visual medial, and visual occipital cortices) with predefined regions of interest based on the Harvard-Oxford atlas (fMRIB Software Library) [45]. Seed-based analyses were adjusted for age, years of education, sex, CDR-SOB, depressive symptoms, and pharmacotherapy. The mean time series for each seed region was calculated and then correlated with the time courses of all other voxels in the brain for each participant.

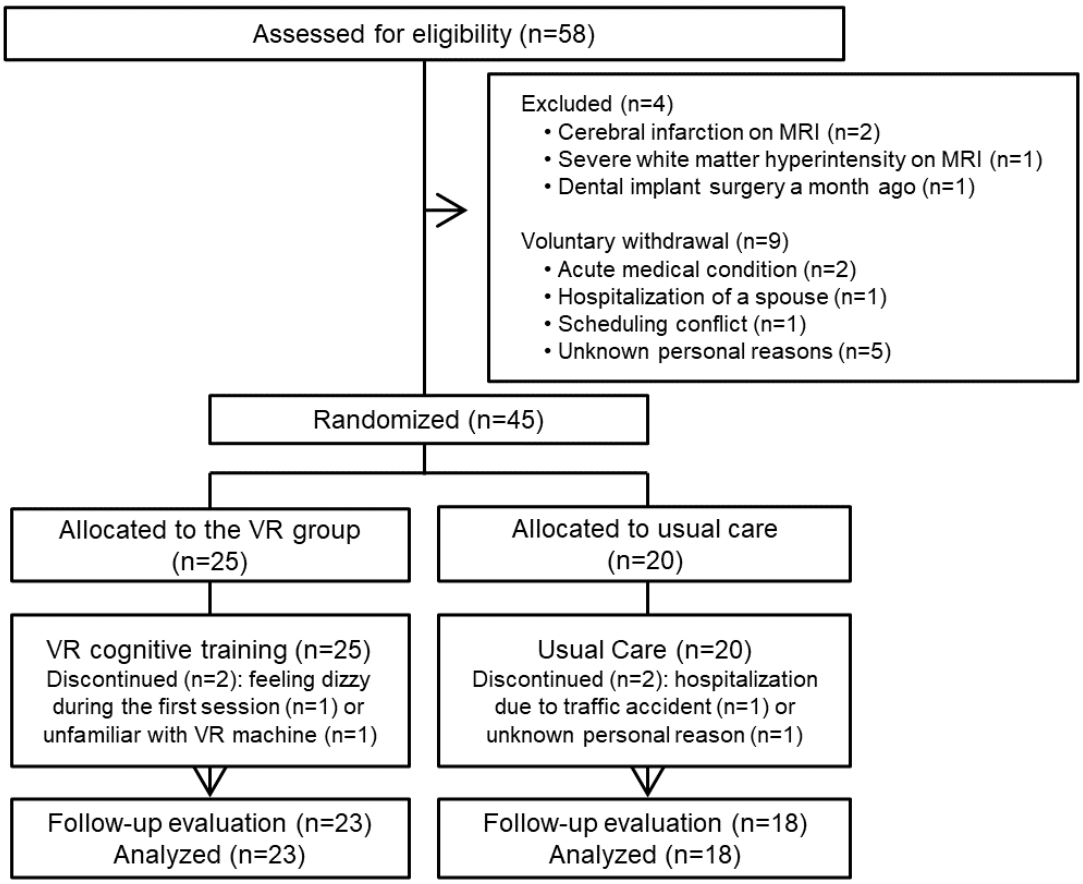
Sample Calculation and Statistical Analyses

Sample calculation was based on a recent meta-analysis on the effectiveness of VR for people with MCI or dementia that produced small-to-medium effect sizes using a random-effects model (effect size=0.29) from a total of 11 studies [15]. Assuming an attrition rate of 20%, a total sample size of 32 patients (16 per treatment group) would provide 0.8 power at a two-sided α error of .05. Power analysis was performed with G*Power software version 3.1.9.2.

Comparisons of demographic and clinical variables between the two groups were performed using independent *t* tests, the Mann-Whitney *U* test, or the χ^2 test. The paired *t* test was used in within-group comparisons of pretraining and posttraining measures. Repeated-measures analyses of variance was used to find the group interaction of the VR cognitive training on neuropsychological function and psychiatric symptom scales after adjusting for age, years of education, sex, CDR-SOB, depressive symptoms, and pharmacotherapy. Age and years of

XSL•FO
RenderX

education were not adjusted in analyses with comprehensive neuropsychological test results that are presented as age- and years of education–adjusted *z*-scores. All statistical analyses were performed with SPSS software version 23 (SPSS Inc), with a significance level assessed at $P<.05$ (two-tailed).



For rsfMRI data, Pearson correlation coefficients were converted to normally distributed scores using the Fisher *r*-to-*z* transformation. Group-level comparisons between the VR and control groups were performed using a general linear model in which improved cognitive task score was used as an explanatory variable and the posttraining minus pretraining *z*-transformation value was used as a dependent variable after adjusting for age, sex, years of education, CDR-SOB, depressive symptoms, and pharmacotherapy. The statistical thresholds for significance were set at voxel-wise uncorrected $P<.001$ and cluster-wise corrected $P<.05$ to correct for false-positive rates.

Results

Participants

Of the 45 participants who were randomly allocated to the VR (n=25) or the control (n=20) group, 41 participants completed the study. After allocation, two participants of the VR group dropped out of the study due to dizziness (n=1) and unfamiliarity with the VR machine during the first session (n=1). Two participants of the control group dropped out because of hospitalization due to a traffic accident (n=1) and unknown personal reasons (n=1). Ultimately, 41 participants were included in the analyses. The trial flow chart is presented in Figure 1.

Figure 1. Trial flow chart. VR: virtual reality; MRI: magnetic resonance imaging.

Demographic and Clinical Characteristics

Table 1 presents the detailed demographic and clinical characteristics of the study participants. Among the 41 participants, 23 (56%) and 18 (44%) were assigned to the VR and control groups, respectively. Participant age was around 75 years, and they were predominantly women. No group differences were found in the baseline diagnostic evaluation.

Effect of VR Cognitive Training on Visuospatial Function

Table 2 shows the comparisons of the pretraining and posttraining visuospatial function within groups, as well as group interactions in the effects of VR cognitive training. VR training resulted in significant improvement in the RCFT copy task compared to the control group. Basic components of the RCFT copy task also improved in the VR group compared to the control group.

Table 2. Group comparisons of visuospatial function pre and post virtual reality (VR) cognitive training.

Function score	Pretraining	Posttraining	Within groups pretraining vs posttraining		Between groups interaction[a]		
			t (df)	*P* value	$F_{1,39}$	*P* value	η^2

Effect of VR Cognitive Training on Comprehensive Neuropsychological Function

Table 3 shows the comparisons of pretraining and posttraining comprehensive neuropsychological function within groups, as well as group interactions in the effects of VR cognitive training. K-BNT, SVLT delayed recall, and Controlled Oral Word Association Test phonemic fluency showed improvement in the VR group, but the group interaction was not significant.

Simulator Sickness, Interest, and Satisfaction Associated with the VR Training Program

Table 5 shows the simulator sickness measured by the SSQ after each training session, reported on a Likert scale ranging from 0 to 100, in the VR group participants after the training period. The mean SSQ total score was 12.86 (SD 11.82), and the summary subscale mean score for nausea, oculomotor, and disorientation was 7.02 (SD 6.40), 11.15 (10.56), and 17.16 (16.91), respectively.

Interest and satisfaction had mean scores of 79.78 (SD 14.18) and 78.04 (SD 12.50) on a Likert scale ranging from 0 to 100, respectively.

Table 5. Mean (SD) simulator sickness questionnaire scores associated with the virtual reality cognitive training (n=23).

Session	Nausea	Oculomotor	Disorientation	Total score
1	9.95 (14.80)	14.83 (14.18)	22.39 (22.89)	17.24 (17.53)
2	6.22 (10.61)	11.53 (16.30)	15.13 (18.25)	12.20 (15.59)
3	9.13 (12.69)	11.21 (16.62)	16.95 (25.51)	13.66 (18.86)
4	6.64 (9.73)	9.89 (14.89)	10.29 (19.78)	10.24 (14.97)
5	6.64 (10.54)	7.91 (13.02)	13.92 (23.37)	10.24 (14.63)
6	2.45 (7.17)	9.56 (15.70)	20.58 (26.83)	11.22 (16.18)
7	5.39 (6.94)	9.89 (12.61)	19.37 (27.12)	12.20 (14.93)
8	9.97 (11.20)	14.82 (17.27)	18.98 (27.35)	16.32 (19.47)

Increased Functional Connectivity in rsfMRI

We investigated brain functional connectivity in the visual network associated with the improvement in the RCFT copy task. The areas with significantly increased connectivity in the seed-to-voxel visual networks are presented in Table 6: (a) from the right visual lateral cortices to the left paracingulate gyrus, right paracingulate gyrus, left frontal pole, left superior frontal gyrus, anterior cingulate gyrus, and white matter; and (b) from the visual medial cortices to the right insular cortex, right frontal pole, right frontal operculum cortex, right caudate, left caudate, right putamen, left insular cortex, and white matter.

Figure 2 depicts the increased regional functional connectivity in the brain cortices and the white matter that are related to improvements in the RCFT copy task in the VR group compared to the control group.

Figure 2. Seed-to-voxel analyses based on the right lateral region (a) and the medial region (b) of the visual network (blue circles). Increased frontal-occipital functional connectivity related to the Rey-Osterrieth Complex Figure Test copy task improvement after virtual reality cognitive training. False discovery rate–corrected *P*<.05 for cluster threshold; uncorrected *P*<.001 for voxel threshold.

Discussion

Principal Findings

This study found that 1-month multidomain cognitive training using fully immersive VR was effective in improving visuospatial function and frontal-occipital functional connectivity, as well as apathy, affect, and QoL in older people in a predementia cognitive state.

The first major finding of this study is that VR cognitive training resulted in improvements in the RCFT copy task. Despite the inconsistent results reported in the literature, training-related changes in cognition have been repeatedly found in older people with cognitive disorders [9,10]. Neuropsychological test score improvements after traditional pen-and-paper or computerized cognitive training have been found in measures of global composite cognition [46-48], verbal memory [11,46,49,50], verbal letter fluency [46,47], verbal fluency [51,52], and visuospatial function in the clock-drawing test [46,53]. It has also been reported that VR cognitive training was effective in improving frontal executive function in individuals with MCI [54], as well as attention and visual memory in older people [55,56]. In line with these previous studies, our results also showed that multidomain cognitive training in a virtual environment was effective in visuospatial function measured by the RCFT copy task in total and basic components comprising the gestalt of the feature showing the ability to approach [26,27]. Although not significant, improvements in naming ability, verbal memory delayed recall, and frontal executive function were also found in the training group compared to the control group. It is possible that the relatively short 1-month training period might have resulted in the lack of group difference, as a learning effect may have impacted the posttraining neuropsychological test results in the control group. However, the improvement in visuospatial function in the VR group, even after the short period of cognitive training, might be attributed to the ecological nature of the fully immersive VR environment. In the enriched auditorily and visually stimulating environment, processing of visual orientation, visuospatial construction, and visual selective attention likely occurred [57,58]. In recent studies with VR evaluation, investigators have been able to effectively differentiate between the navigational [59] and visuospatial deficits observed in patients with MCI and healthy older people [60,61]. In studies with VR interventions, VR cognitive training was found to be effective [55,62] or ineffective [56,63] in improving visuospatial function

XSL•FO
RenderX

in older people or those in an early dementia stage. We believe that the cognitive training performed in the maximally immersive environment with the head-mounted display, headphones, and hand movement trackers in our study might have increased visuospatial functioning in those at a predementia stage [64]. The immersion methods utilized in previous studies investigating VR cognitive training in older people have employed desktop-based systems [55,56], screen and sensors [62], screen and glasses [65,66], and head-mounted display and fixed joystick setups [63]. Although heterogeneity in study populations and methodological differences among prior studies have resulted in inconsistent findings, this study provides further evidence to support the benefits of VR cognitive training in eliciting improvements in visuospatial processing through the repeated presentation of real-world, dynamic, multisensory, and interactive environments.

Another novel finding was the increased functional connectivity observed in the frontal-occipital cortical network after VR cognitive training, which was associated with improved performance in the RCFT copy task, consistent with the associations between cognitive improvements and neuronal plasticity that have been observed previously [67]. In patients with MCI, significant associations have been observed between verbal memory improvement and left hippocampal activation in task-related fMRI after 8-week training to improve auditory processing speed and accuracy [11]. Other studies have shown that 6 weeks of episodic memory training in patients with MCI resulted in the manifestation of new associations between improved delayed word recall test performance and brain activation in the right inferior parietal lobule in fMRI during memory encoding [68]. In healthy older people, 8 weeks of exposure to a cognitive control training program led to an increased frontoparietal network related to cognitive control ability [69]; another study found that verbal recall was associated with an increased left hippocampal volume in healthy older people after 8 weekly verbal recall memory training sessions [70]. Thus, in this study, repetitive cognitive training in a novel fully immersive environment might have increased the frontal-occipital activation in accordance with improved visuospatial function. We also observed increased functional connectivity in white matter areas, which are known to exhibit a lower hemodynamic response than the grey matter. Although fMRI studies have focused on grey matter until recently, the increased functional connectivity in the white matter close to the grey matter supports the growing neural evidence of fMRI white matter changes induced by VR cognitive training [71,72].

This evident link between visuospatial construction and frontal-occipital functional connectivity might be explained by the acquired cognitive system engagement induced by the RCFT copy task, which requires the participant to copy a complex geometric figure [73]. Visuoconstructive ability is based on the Van Sommers model of drawing [74]; according to this cognitive model, the RCFT copy task consists of (i) visual recognition of a 2D Rey-Osterrieth complex figure; (ii) visual representation of the figure in long-term or temporary memory; (iii) graphical output processes such as those related to depiction decisions (eg, context, orientation, viewpoint, details, and boundary) or reproduction strategies (eg, copying orders, dimensions, shapes, diagonals, crosses, line sets); (iv) graphical planning (eg, routine or contingent planning); and (v) articulation and economic constraints during motor output. Through these steps, multiple brain regions have been found to be associated with performance in the RCFT copy task, including the temporal, parietal, occipital, and frontal cortices in both hemispheres or in the right hemisphere alone [75-77]. Although we observed increased activity only in the primary visual cortices (visual medial) and the right associative visual cortices (right visual lateral) connecting to the areas in the middle frontal cortices, these regions are known to be involved in the visual recognition and graphic output planning processes required to complete the RCFT copy task [74], and are associated with visuo-motor transformation and multistep object use in the task [77]. A recent study reported that lesions in the right superior parietal lobe and the middle occipital gyrus were associated with poor RCFT copy task performance [78], which is in accordance with our results. Furthermore, there have been reports on improvements in nontrained cognitive functions, also known as transfer effects, in memory training in older people with MCI [79,80]. Previous studies have shown that repeated memory-focused training might have enhanced the processing speed of memory retrieval and the efficiency of working memory, assuming that frontal executive function was the main recipient of the transfer effects [79,80]. Although recent studies have applied cognitive training with novel computerized tools and involvement of multiple cognitive domains, existing programs have only applied cognitive training in a 2D environment with an emphasis on language abilities [9,53,79,81]. Since frontal executive function plays a major role in all cognitive domains and higher-order cognitive controls [82], the improved performance on the RCFT copy task may be supported by increased functional connectivity in the frontal-occipital network.

The psychiatric benefit of VR cognitive training in individuals in a predementia state should be considered. In this study, participants in the VR group showed improved apathy, affect, and QoL scores after training compared with those in the control group. A recent review reported that computerized cognitive training resulted in long-term improvements in psychological outcome measures [16]. Although methodologies vary across studies, 3D VR cognitive training was effective in improving depressive symptoms in patients with MCI compared with an active control group receiving music therapy [63]. Moreover, a few feasibility studies have reported improved alertness, pleasure, apathy, and security following one-time exposure to a less immersive VR environment [65,66]. We postulate that apathy, affect, and QoL might be improved by the VR cognitive training, as these are some of the early symptoms of dementia [83]. Immersive virtual environments might facilitate the limited functioning of patients with cognitive disorders that affect communication, interaction, motivation, engagement, and positive attitudes toward others [84]. Thus, the importance of virtual environments should be considered in cognitive training because the feeling of presence itself in a 3D space can enhance volitional motivation, allowing one to constantly process external stimuli and cognitively adjust to changing environments [85].

XSL•FO
RenderX

Simulator sickness reported after every session was minimal in the VR cognitive training group. In this study, the SSQ total score (mean 12.86, SD 11.82) indicated minimal symptoms (score 5-10) according to the suggested categorization established in flight simulators [86]. Although the SSQ was originally developed and validated in military personnel using flight simulators, it is the most commonly used measure of sickness in a virtual environment [40]. A recent meta-analysis of the SSQ in virtual environments reported total and subscale scores and dropout rates according to VR conditions (total 28.00, SD 1.71; nausea 16.72, SD 0.77; oculomotor 17.09, SD 0.55; disorientation 23.50, SD 1.17; dropout rate 15.6%) [87]. Compared to the results in a VR environment, our results on the SSQ scores and dropout rates (8%) showed better tolerability, with moderate interest and satisfaction. The SSQ scores have been reported to be higher in VR than in a flight simulator environment [86] and with gaming content than without it [87]. Despite the characteristics of VR in this study, such as fully immerse, game and training components, and old users at an early stage of cognitive decline, these results may imply that fully immersive VR can be a safe and interesting method for cognitive training.

Limitations

Our study had several strengths and limitations. This is one of the largest VR cognitive training studies to use a fully immersive 3D VR program. Compared to 2D or semi-immersive VR programs, our results highlight the positive effects of employing fully immersive 3D VR in cognitive training, as we found neural evidence supporting the improvement in visuospatial function. However, there are several limitations and lessons learned in this study. First, the small sample size and short training period were the main limitations. Although sample sizes in studies investigating the effects of cognitive training are increasing [88], most VR trials still rely on small sample sizes and are performed over a short duration, especially those using fully virtual environments [15]. Short clinical trial periods in previous studies investigating the effect of computerized cognitive training programs have also been a limiting factor in the field as a whole [88]. Thus, future studies should aim to increase the sample sizes and extend the duration of training to better evaluate the effect of VR cognitive training. Second, we considered that the per-protocol analysis could bias the results of this randomized controlled trial, although the number of participants who dropped out of the study was the same in both groups. Third, the lack of an active control group in this study is another limitation. Some previous trials have included active control groups receiving psychoeducation, cognitive therapy, face-to-face music therapy, or pen-and-paper cognitive training for comparisons with the VR training group [15,63]. In the future, various active control groups should be considered to confirm the effectiveness of VR cognitive training. Fourth, the lack of examination for AD biomarkers such as cerebrospinal fluid analysis or brain imaging for amyloid detection can be a limitation because it is unclear whether the participants in our study will develop AD, which is the most prevalent cause of dementia. Future studies involving AD biomarkers could clearly explain the pure effect of cognitive training in individuals in a preclinical or prodromal dementia state. Lastly, heterogeneity among patients, practitioners, program content, and accessibility to the VR system can limit the generalizability of the results to other populations.

Conclusions

We found that fully immersive VR cognitive training improved cognition and psychiatric symptoms in a predementia state. Visuospatial function improved in such individuals relative to controls, and this finding was supported by increased frontal-occipital functional connectivity assessed by rsfMRI. These findings suggest that VR training can enhance visuospatial ability by exposing patients to an enriched virtual environment, leading to improved apathy, affect, and QoL. Our results support the neurotherapeutic use of VR cognitive training as an effective nonpharmacological intervention for those who are at risk for dementia; however, more rigorous trials should be performed to confirm the effects and identify the associated neural mechanisms.

Acknowledgments

We would like to thank C2MONSTER for help in designing and manufacturing the multidomain VR cognitive training program. This research was funded by the support program for Development of Dementia Care Service using Advanced ICT Technology 2018 funded by Korea Radio Promotion Association (RAPA) and the Ministry of Science and ICT (MSIT), Korea, under the Information Technology Research Center support program (IITP-2021-2017-0-01630) supervised by the Institute for Information & Communications Technology Promotion. The funding sources had no role in the study design; collection, analysis, and interpretation of data; writing of the manuscript; or decision to submit the article for publication.

Authors' Contributions

JK, NK, and SL conceived and designed the study, acquired and analyzed the data, interpreted the study findings, and drafted the manuscript. SW, GP, and JP analyzed the data. BY, JL, JY, and SR designed the study, interpreted the study findings, supervised and directed the conduct of the study, and critically reviewed the manuscript. SC conceived and designed the study, acquired and analyzed the data, interpreted the study findings, supervised and directed the conduct of the study, and critically reviewed the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Complex regional pain syndrome (CRPS) is a rare and severe chronic pain condition, with effective treatment options not established for many patients. The underlying pathophysiology remains unclear, but there is a growing appreciation for the role of central mechanisms which have formed the basis for brain-based therapies such as transcranial magnetic stimulation and mirror visual feedback (MVF). MVF has been deployed in the treatment of CRPS using both conventional mirrors and virtual reality (VR).

Objective: The aim of this study was to further investigate the use of VR in the treatment of patients with unilateral upper limb CRPS. VR has the potential advantage of more flexible and more motivating tasks, as well as the option of tracking patient improvement through the use of movement data.

Methods: We describe the development, acceptability, feasibility, and usability of an open-source VR program MVF module designed to be used with consumer VR systems for the treatment of CRPS. The development team was an interdisciplinary group of physical therapists, pain researchers, and VR researchers. Patients recruited from a pain clinic completed 3-5 visits each to trial the system and assessed their experiences in pre- and post-treatment questionnaires.

Results: All 9 (100%) participants were able to use the system for 3, 4, or 5 trials each. None of the participants quit any trial due to cybersickness. All 9 (100%) participants reported interest in using the module in the future. Participants' reported average pain scores in the affected limb were not significantly different from baseline during treatment or after treatment (P=.16). We did not find a statistically significant effect on participants' self-reported average pain scores.

Conclusions: We propose that this module could be a useful starting point for modification and testing for other researchers. We share modifications to make this module usable with standalone headsets and finger tracking. Next steps include adapting this module for at-home use, or for use with participants with lower limb pain.

Introduction

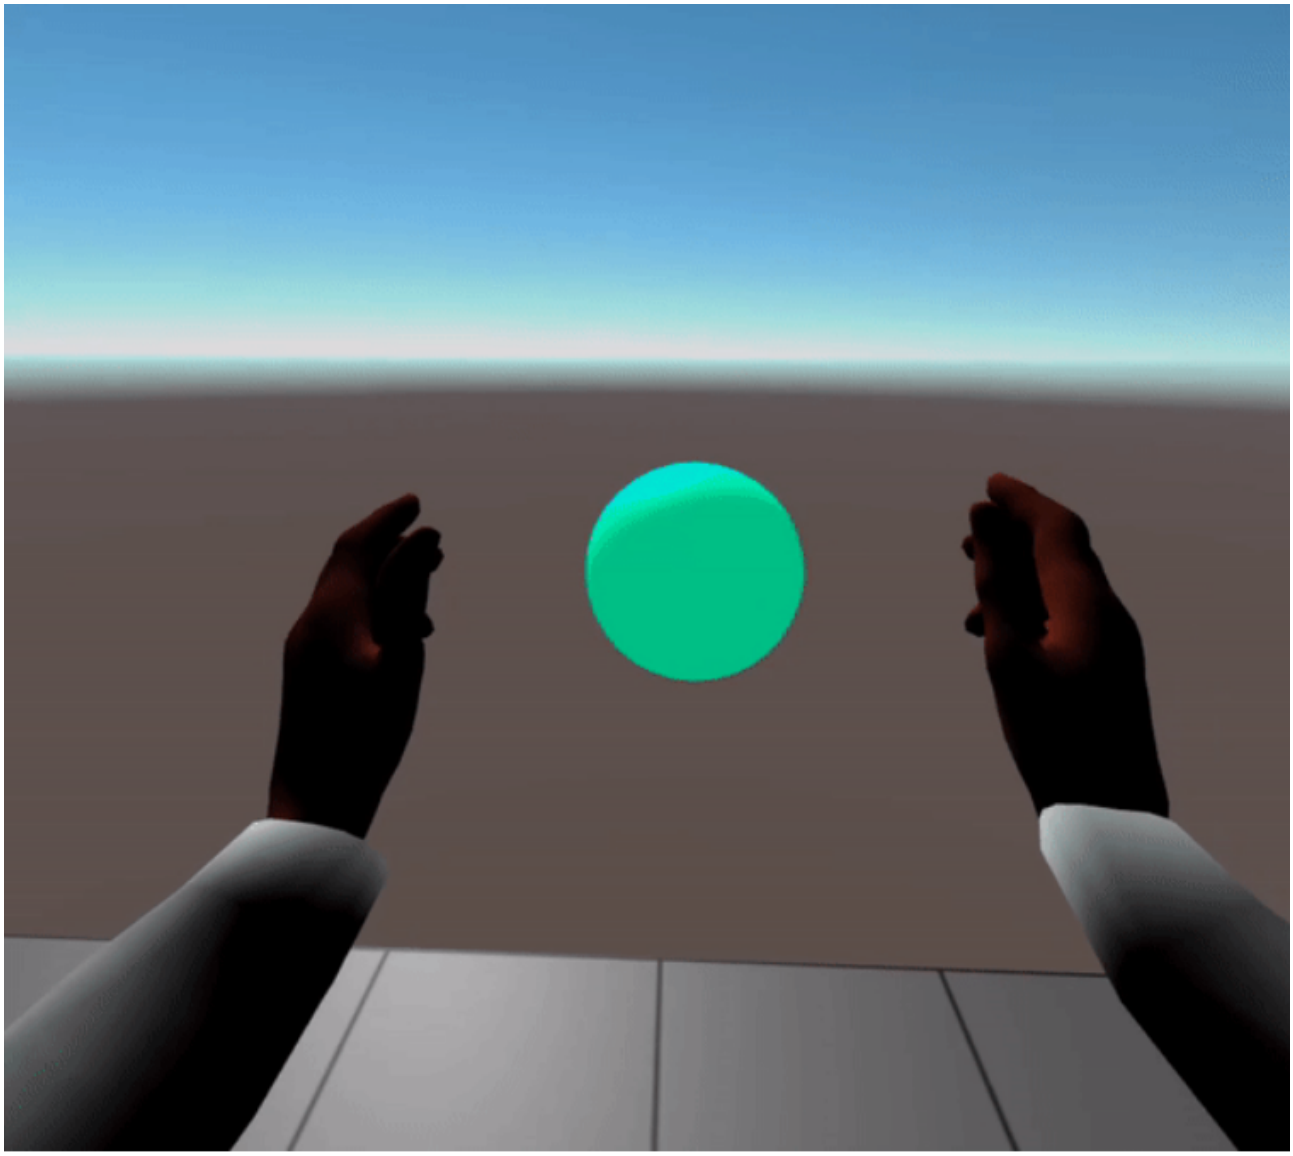
Complex regional pain syndrome (CRPS) is a rare and severe chronic pain condition, defined as "continuing pain...disproportionate to any inciting event," accompanied by an array of varying signs and symptoms (sensory, vasomotor, sudomotor/edema, or motor/trophic features) which do not fit other diagnoses [1-3]. A Cochrane Review found low level of quality of evidence for CRPS treatments [4], with current treatment guidelines based largely on expert experience, case reports, open-label trials, and pilot studies [3]. Thus, many patients are without established, effective treatment options [5]. While the underlying pathophysiology remains unclear, there is a growing appreciation for the role of central mechanisms which have formed the basis for brain-based therapies such as transcranial magnetic stimulation [6] and mirror visual feedback (MVF). MVF [7] has been deployed in the treatment of CRPS using both conventional mirrors [8] and virtual reality (VR) [9-11]. VR has the advantage of more flexible and more motivating tasks [10-12], the ability to be used at home [13], and the option of tracking patient improvement through the use of movement data [11,12,14]. However, barriers of cost and difficulty of adoption have prevented this technology from being widely used.

Given the advent of inexpensive, portable consumer VR systems, systematically testing the potential of these systems for the treatment of CRPS and other disorders has become a possibility for many researchers who have not previously used VR in medicine. Virtual environments for therapeutic purposes can be created using game engines such as Unity 3D or Unreal. These virtual environments can be modified to allow researchers to investigate the effects of avatar realism, limb swapping, changing the appearance of the targets, changing the environment around the targets, etc. However, because many researchers working with clinical populations have limited experience building virtual environments, there is a significant barrier to entry.

To provide a tool for the research community as well as for our own research, we developed an open-source VR mirror module that could be used for our own experiments. We deployed this module in a pilot study for patients with chronic unilateral upper limb CRPS.

This pilot study was a feasibility study to test the usability of the VR system and its acceptance, ease of use, and patient willingness to engage. We evaluated these goals by examining participant retention, as well as qualitative comments on general usability and interest in engaging with the module at home. Participants' reported average pain scores in the affected limb were not significantly different from baseline after treatment (P=.16). Furthermore, all participants completed the required sessions for this study and qualitative measures indicated that participants were interested in continuing the therapy at home.

Methods



Virtual Reality Application

A team of pain researchers and VR researchers created a simple open-source VR application for patients with CRPS using the game engine Unity 3D. This application is compatible with a range of consumer VR systems that use head-mounted displays and hand controllers or hand tracking to allow users to interact with virtual content by controlling avatars. Figure 1 shows an example of a user's view of their avatar's hands which are controlled by their movements.

As in conventional MVF, movement from the patient's uninjured hand was transformed over the midline to symmetrically animate their avatar hand on the injured side. Thus, patients' uninjured hands could control the movements of both avatar hands, just as in conventional mirror therapy.

Figure 1. Image representing participant in VELOS MVF with a mono version of their first person perspective.

Participants

In the summer of 2017, 110 adult patients in the database of a pain clinic at a large United States university with a diagnosis of unilateral CRPS in an upper extremity were contacted to ask if they would be interested in participating in a pilot study to test the feasibility of a novel VR intervention. Eligible patients had average pain level reported on a Visual Analog Scale as greater than or equal to 4 out of 10, were on a stable treatment plan for the month preceding the study, and could commit to multiple visits. A total of 9 patients (6 female and 3 male) were recruited within the 2-month time span set for the study. Among the 9 patients, 7 (78%) identified as Caucasian, 1 (11%) as Asian, and 1 as “other” (11%). Their ages ranged from 19 to 60 years, with the median being 42 and mean 44. Their education level ranged from a high-school diploma to graduate degrees, and their income ranged from under US $10,000 to US $80,000 or more. All 9 patients were right handed, with 3 having CRPS on the left upper extremity and 6 with right upper extremity CRPS. All patients signed informed consent in the clinic, received US $20 per hour of visit time, and the experiment was approved by the Stanford Institutional Review Board. The consent form, along with all other study materials, is shown in Multimedia Appendix 1.

Table 1 shows participants’ symptom onset and duration.

Table 1. Participants' CRPS symptom onset and duration.

Patient ID	Symptom onset date	Duration (from the onset of CRPS[a] to the baseline assessment date)
2	August 16, 2008	8 years and 11 months
3	May 15, 2010	7 years and 2 months
4	December 12, 2012	4 years and 7 months
7	January 11, 2015	2 years and 6 months
8	June 1, 2013	4 years and 2 months
9	September 6, 2016	10 months and 29 days
10	August 7, 2016	1 year and 16 days
11	March 28, 2013	4 years and 4 months
12	February 2, 2015	4 years and 6 months

[a]CRPS: complex regional pain syndrome.

Materials

To make this environment as accessible to as many users as possible, it was built to accommodate both the hardware systems currently supported by the Steam VR plug-in in the Unity game engine. At the time of the experiment, these were the Oculus Rift/Touch system [14] and the HTC VIVE system [15], both of which cost less than US $400 and could be deployed using a "VR-ready" laptop as seen in Multimedia Appendix 2. The application can accommodate, but does not require, room-scale tracking. Since this initial study, the project has been revised to be used with standalone headsets that include hand and finger tracking. Original and revised projects and documentation can be found in [16].

Baseline Survey

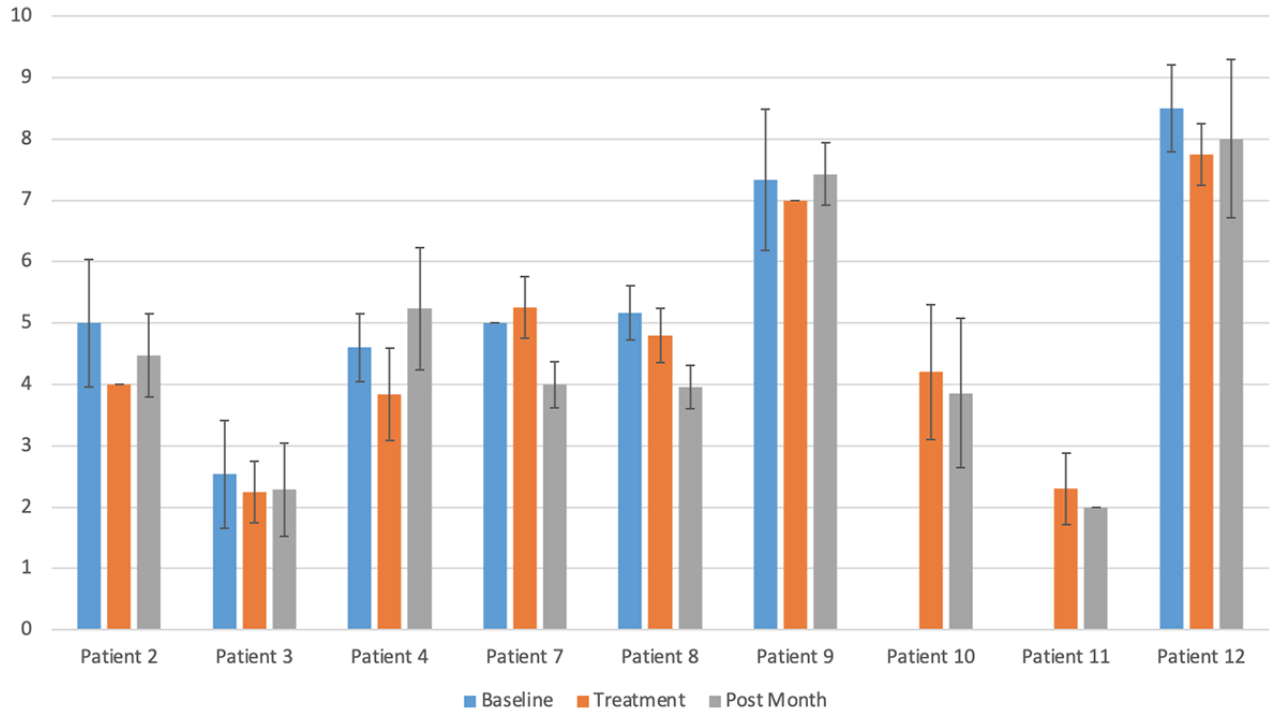
All visits took place in July and August of 2017. After the screening interview, participants completed a baseline survey at the clinic through the institution's REDCap account. This survey consisted of a set of demographic and baseline measures, including the PROMIS measures of pain and daily function [17]. This survey was repeated after the last session, and 1 month after the study. All survey instruments are provided in Multimedia Appendix 1.

Procedure

Participants then returned to the clinic weekly for a minimum of 4 sessions of immersive VR, with an optional fifth visit based on participant interest and availability. After each session, participants completed a daily pain survey (modified from the Brief Pain Inventory [18]) and a presence questionnaire derived from Witmer and Singer [19].

Participants were seated in a swivel chair in front of the computer and a researcher (AB) helped them to don the headset and hold the hand controller in their unaffected hand. Avatars were scaled to the participants' seated height and the color of the arms and hands was selected at the beginning of each session. For participants suffering from CRPS of the right upper limb, both avatar hands were controlled using the left controller. For participants suffering from CRPS of the left upper limb, this was reversed and both avatar hands were controlled using the right controller. It was too painful for some participants to hold the tracker with their injured hand, so all participants held only 1 tracker on their uninjured side.

The researcher (AB) then began the session by pressing the spacebar key. Each time the key was pressed, one of a series of 18 targets of 3 different sizes (6 large, 6 medium, and 6 small) appeared in random order in the midline of the participant's field of view. Participants were asked to bring both the injured and uninjured hands together to contact the target. When an avatar hand contacted the target, a chime sounded, and the target object disappeared. Participants completed as many sets of target hitting as they wished (mean 7.5 [SD 2.25]). For the first 2 participants, the protocol differed slightly for their first 2 visits, in that they were only allowed to complete 2 sets.



Measures Taken at Each Session

Pain, Physical Activity, Mood, and Quality of Sleep

Before completing the target-hitting task, participants reported their average level of pain throughout their body and in their affected CRPS limb, their level of physical activity, their mood, and the quality of their sleep over the past 24 hours, as well as their CRPS-related pain at that moment and any qualitative responses (Figure 2). These data are described in Multimedia Appendix 3.

XSL•FO
RenderX

Figure 2. Patient ratings of average pain in affected CRPS limb. Ratings were on a 0-10 scale, with 10 being the most pain. Ratings were averaged before treatment, during treatment, and at one month post-treatment.

Movement Data

Participants' movements were recorded at a rate of 30 times per second. As each target was hit, the time and the position of the trackers at the time of contact were also recorded.

Cybersickness Measures

When considering the effectiveness of such a system in a clinical setting, it is important to assess its usability. Thus, we included a measure of cybersickness, also known as simulator sickness, which occurs when exposure to a virtual environment causes symptoms similar to motion sickness.

Results

All 9 participants completed 3, 4, or 5 sessions, and all were interested in continuing the therapy at home. Detailed results are presented in the following sections.

Baseline Survey

The results of the baseline surveys can be found in Multimedia Appendix 3.

Pain, Physical Activity, Mood, and Quality of Sleep

Several participants commented positively on the sessions, for example "VR helped hand pain!" and "I'm more likely to use my affected arm than I was before the study. Even my family noticed." However, using a linear mixed model with Bonferroni-corrected α of .01 for multiple comparisons, there were no statistically significant differences over time on average or highest pain of the affected limb or body, or on physical activity, mood, or quality of sleep. Table 2 shows these results.

Table 2. Nonsignificant effects of time on patient self-reported outcomes using linear mixed models, predicting each outcome measure averaged at each time point and including participant ID as a random effect. Alpha adjusted to .007 using Bonferroni correction for multiple comparisons. We note that this study was not powered to detect efficacy.

Outcome measure	*P* value
How would you rate your average level of pain in your affected CRPS limb over the past 24 hours?	.13
How would you rate your average level of pain in your throughout your body over the past 24 hours?	.76
How would you rate your highest level of pain in your affected CRPS limb over the past 24 hours?	.04
How would you rate your highest level of pain throughout your body over the past 24 hours?	.64
How would you rate your level of physical activity over the past 24 hours?	.75
Rate your overall mood for the past 24 hours.	.60
How would you rate the quality of your sleep over the past 24 hours?	.84

RenderX

Movement Data

Most consumer VR systems contain trackers on the head-mounted display and 2 hand controllers, each of which captures both position (X,Y,Z) and orientation (pitch, yaw, roll) data at each frame. The default setting in our current module is to record every third frame, for a rate of approximately 30 frames per second. However, the frame rate can be modified to record at a higher or lower rate. We saved movement data for each tracker to a separate CSV file at the end of the experiment. We note that the data we recorded reflect the actual positions of the single tracker held by the participants, and the head-mounted display that they wore on their heads.

In this pilot study, participants' head and uninjured hand movements were tracked. Participants were not asked to hold or attach a hand sensor to their injured hand, on the grounds that this might exacerbate their injury. Thus, the data collected from these sensors cannot inform us about how participants may or may not have moved their injured arm during the experiment. Data collected from the other 2 sensors can be used to examine changes in movement over the course of the following sessions, and can also be compared with other, self-reported measures. A representative example of movement data can be found in Multimedia Appendix 4.

Cybersickness

The majority (7 participants) reported no cybersickness, with 2 participants rating their cybersickness as "slight." No participants quit any trial due to its effects.

Discussion

Principal Findings

In this pilot study, we tested the feasibility, ease of use, and patient willingness to engage with an open-source MVF VR module for CRPS. All 9 participants were able to use the system for 3, 4, or 5 trials each, all participants stated that they were interested in an at-home trial if one were made available, and no participants stopped any trial due to cybersickness. We did not find a statistically significant effect of trial on participants' self-reported average pain scores, but this is not surprising given that the study was not intended or powered to detect a clinical signal for efficacy.

Limitations

Because of the small number of participants, we cannot draw conclusions about efficacy nor do we have enough information to discuss generalizability. In addition, participants were not blinded to treatment, and the researcher working directly with the patients (AB) was also not blind to the purpose of the study.

Next Steps

Because in this study, participants only held the trackers in their *un*injured hand, we could not directly track improvement in movement on the injured side.

Although hand tracking was not available at the time this study was conducted, we have since updated the project to include markerless hand tracking, including finger tracking through the Oculus Quest. This can facilitate tracking of the injured hand, and may also improve the overall patient experience. Future work should examine whether markerless tracking and finger tracking improve patient outcomes.

Other potential easy modifications include changing the appearance of the avatar body, changing how the avatar limbs are controlled, and changing the appearance and placement of the targets. We have made this project open source with the goal of encouraging further exploration of deploying MVF in immersive VR using consumer systems.

This pilot study measured participant pain scores using a daily pain survey modified from the Brief Pain Inventory [18]. Future studies may use other standardized pain indicators, for example, Pain Self-Efficacy Questionnaire (PSEQ) [20], EuroQol-5D (EQ-5D) [21], or Pain Catastrophizing Scale (PCS) [22], as well as analyzing improved function as an indicator of positive outcome.

All 9 participants in our initial pilot study were interested in an at-home trial if one were made available. While at-home VR systems are still out of reach for most consumers, such systems can increase accessibility [23]. An at-home module would allow patients to use the module at will and could also be a useful channel of communication between the clinician and the patient. In such a system, safety and social interaction must be fully considered. Thus, any consent form for such an environment should reiterate potential risks and protection of patients' data must also be assured [24].

We note that this software is not a commercial system or patient-ready application. Rather, it is designed to be used as a potential starting point for research for other clinicians interested in exploring potential therapeutic uses of immersive VR for visual feedback on movement. We look forward to the contributions of other researchers in this area.

Abstract

Background: Connected devices are dramatically changing many aspects in health care. One such device, the virtual reality (VR) headset, has recently been shown to improve analgesia in a small sample of patients undergoing transcatheter aortic valve implantation.

Objective: We aimed to investigate the feasibility and effectiveness of VR in patients undergoing atrial fibrillation (AF) ablation under conscious sedation.

Methods: All patients who underwent an AF ablation with VR from March to May 2020 were included. Patients were compared to a consecutive cohort of patients who underwent AF ablation in the 3 months prior to the study. Primary efficacy was assessed by using a visual analog scale, summarizing the overall pain experienced during the ablation.

Results: The AF cryoablation procedure with VR was performed for 48 patients (mean age 63.0, SD 10.9 years; n=16, 33.3% females). No patient refused to use the device, although 14.6% (n=7) terminated the VR session prematurely. Preparation of the VR headset took on average 78 (SD 13) seconds. Compared to the control group, the mean perceived pain, assessed with the visual analog scale, was lower in the VR group (3.5 [SD 1.5] vs 4.3 [SD 1.6]; *P*=.004), and comfort was higher in the VR group (7.5 [SD 1.6] vs 6.8 [SD 1.7]; *P*=.03). On the other hand, morphine consumption was not different between the groups. Lastly, complications, as well as procedure and fluoroscopy duration, were not different between the two groups.

Conclusions: We found that VR was associated with a reduction in the perception of pain in patients undergoing AF ablation under conscious sedation. Our findings demonstrate that VR can be easily incorporated into the standard ablation workflow.

(J Med Internet Res 2021;23(5):e26349) doi:10.2196/26349

KEYWORDS

connected devices; virtual reality; atrial fibrillation; pain management

Introduction

Atrial fibrillation (AF) ablation is an established therapy for patients with symptomatic AF [1]. The number of AF ablations is increasing year on year, but the availability of general anesthesia does not meet demand [2]. As such, it is now commonplace for procedures to be performed under conscious sedation. However, patients' pain and discomfort during AF ablation may be associated with poorer outcomes [3].

Connected devices are dramatically changing many aspects in health care [4-7]. While in cardiology, the majority of devices are intended to monitor heart rhythm, others have a therapeutic

XSL•FO
RenderX

purpose [8-10]. One such device, the virtual reality headset, is the subject of numerous studies [11-15] and has recently shown to improve analgesia in a small sample of patients undergoing transcatheter aortic valve implantation [16,17]. To our knowledge, this device has not been tested in other cardiac procedures.

We aimed to investigate the feasibility and effectiveness of VR in patients undergoing catheter ablation of AF under conscious sedation.

Methods

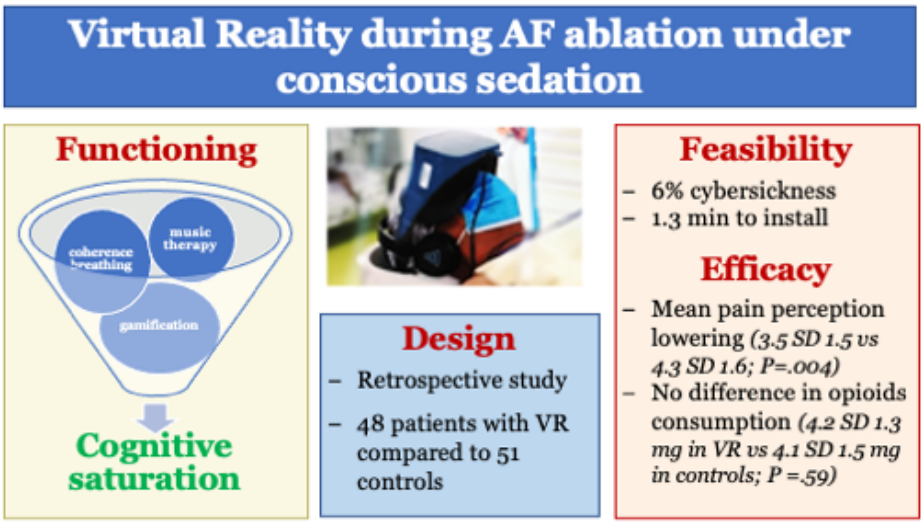
Recruitment

From March to May 2020, all consecutive patients in whom an AF ablation was performed using cryoballoon (Arctic Front Advance; Medtronic) at the University Hospital of Poitiers were included. All participants received VR using a Deepsen headset on top of the usual analgesia protocol. The VR technique uses cognitive saturation in association with cardiac coherence breathing, music therapy, and gamification [18]. At the beginning of the session, 5 minutes of cardiac coherence breathing was delivered. Then, the patient was immersed in 1 of 5 3D computer-simulated scenarios. During the whole procedure, music therapy and gamification were also used. The patient played an active role as he or she interacted with the virtual environment, which aimed to deepen the immersion to unconsciously disconnect the patient from painful moments in the procedure. Our analgesia protocol consisted of 1 g of intravenous (IV) paracetamol, 20 mg of IV nefopam, 1 mg of IV midazolam, and 3 mg of IV morphine just before the start of the procedure. Patients could also request additional analgesia, in which case further boluses of 1 mg of morphine were given. Patients who underwent AF ablation with VR were compared to a consecutive cohort of patients who received routine AF cryoablation in the 3 months prior to the study using the standard analgesia protocol.

Outcomes

The feasibility of VR was assessed by the number of patients who refused this technique, the tolerance of the VR headset, and the time taken to install the device. Primary efficacy was assessed by using a visual analog scale (VAS), shown to the patient 45 minutes post procedure when they were asked to select a single point on the scale to summarize the overall pain experienced during the ablation [19]. The maximum pain intensity perceived was also recorded using a VAS score. Finally, the patient's comfort was assessed using a numerical scale, with 0 being "the most uncomfortable procedure you could have" and 10 being "the most comfortable procedure you could have." Oral informed consent was obtained from all participants. According to French legislation, this study was declared to the Commission Informatique et Libertés and did not require the approval of an Ethics Committee as this device is CE marked and is already used in routine clinical practice in some centers in France.

Statistical Analysis



Continuous variables were expressed as mean (SD) and categorical variables were presented as numbers and percentages. Comparisons between groups were performed using the Student *t* test or the Mann-Whitney *U* test for continuous variables as appropriate, and the chi-square test for categorical variables. Analyses were performed using SPSS 22 (IBM Corp) statistical software.

Results

Feasibility

A total of 48 patients were enrolled to receive VR during AF cryoablation procedure (mean age 63.0, SD 10.9 years; n=16, 33.3% females). No patient refused to use the device, although 7 (14.6%) terminated the VR session prematurely. Four patients had a vasovagal reaction and 3 experienced cybersickness (vertigo: n=2; headache: n=1) (Figure 1). Preparation of the VR headset took on average 78 (SD 13) seconds.

Figure 1. Virtual reality (VR) use during atrial fibrillation (AF) ablation.

4.1 [SD 1.5] mg; *P*=.59). In addition, procedure and fluoroscopy duration were not different between the two groups. Lastly, 3 (6.3%) patients had transient phrenic palsy in the VR group vs 6 (11.8%) in the control group (*P*=.34) and vagal reaction occurred in 4 (8.3%) patients in the VR group vs 2 (3.9%) in the control group (*P*=.60).

Figure 2. Mean pain, maximal pain, and comfort assessment in the virtual reality and control groups.

Discussion

Principal Findings

To our knowledge, this study is the first to evaluate the use of immersive VR to improve pain perception during cryoballoon AF ablation. Less than 10% of patients experienced cybersickness, and the device was set up in under 2 minutes. Compared to the control group, VR during AF ablation was associated with pain reduction and comfort improvement but did not lead to a reduction in opioid consumption.

Effect of VR During the AF Ablation Procedure

Several studies have assessed the feasibility and/or effectiveness of VR in different clinical settings [20-22]. However, the number of patients included in these studies was small. The present study showed that in patients undergoing AF ablation, VR uptake was high and well tolerated, suggesting that it can be widely adopted during AF ablation procedures performed under conscious sedation. Moreover, setup can be carried out by the operator or the nurse, and increased the total duration of the procedure by less than 2% [23], which is acceptable, as the device was associated with lower pain with the same level of opioid consumption. It can be speculated whether the absence of a placebo in the control group could have influenced the results. However, we could argue that the placebo effect of VR is still valid because it is really this subjective assessment of pain reduction and comfort increase that are the endpoints we are trying to achieve. Nevertheless, the reduction in pain perception seen in this study did not result in reduced opioid use since morphine consumption was not different between the two groups. This lack of difference might be related to the low level of additional opioids required after the initial bolus of morphine. Indeed, only a mean of 1.2 mg and 1.1 mg were needed on top of the initial bolus in the VR and control groups, respectively. Overall, our results are in line with the literature [24]. In a recent systematic review, Smith et al [24] suggested that VR was effective for analgesia in a variety of different clinical settings but could also have disadvantages.

Advantages and Drawbacks of VR

Other alternative techniques such as music therapy and hypnosis have been developed to relieve pain during conscious sedation anesthesia, but each have their drawbacks and advantages [25,26]. As the brain can only process a limited amount of information, mind saturation using VR aims to increase nonpainful input and limit the transmission of pain information according to the gate control theory [27]. Moreover, contrary to hypnosis, VR has a minimal learning curve and does not require specialist training, which may facilitate widespread adoption by other health care centers [19]. On the other hand, VR may elicit unpleasant reactions, such as cybersickness, in patients prone to vertigo or seasickness caused by conflicting sensory signals [28]. While the patient receives visual signals informing him or her that he or she is moving, no corroborating information is provided by the vestibular organs. Cybersickness has been described to occur in 20% to 80% of cases [29], although it occurred in only 18.8% of the sample in Bruno et al's [17] study. In our study, the occurrence of this side effect was even lower (6.3%) and may be due to younger age, fewer comorbidities, and better hemodynamic stability in patients undergoing AF ablation compared to those who underwent the transcatheter aortic valve implantation procedure.

Limitations

This study was a nonrandomized, single-center study. Nevertheless, the relatively high number of patients in each group and consecutive inclusion have limited bias. Moreover, baseline characteristics were not different between groups. Finally, patients' prior experience with interactive games may have influenced the effect of VR and its associated side effects, which was not systematically assessed or taken into account in our study.

XSL•FO
RenderX

Conclusion

Our study demonstrates that VR can be easily incorporated into the standard AF ablation workflow. Further, it was associated with a reduction in the perception of pain, even if it did not result in less opioid consumption, and improved patient experience. Larger randomized studies are needed to confirm these promising findings.

Abstract

Background: Digital health technologies (DHTs) generate a large volume of information used in health care for administrative, educational, research, and clinical purposes. The clinical use of digital information for diagnostic, therapeutic, and prognostic purposes has multiple patient safety problems, some of which result from poor information quality (IQ).

Objective: This systematic review aims to synthesize an IQ framework that could be used to evaluate the extent to which digital health information is fit for clinical purposes.

Methods: The review was conducted according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) guidelines. We searched Embase, MEDLINE, PubMed, CINAHL, Maternity and Infant Care, PsycINFO, Global Health, ProQuest Dissertations and Theses Global, Scopus, and HMIC (the Health Management Information Consortium) from inception until October 2019. Multidimensional IQ frameworks for assessing DHTs used in the clinical context by health care professionals were included. A thematic synthesis approach was used to synthesize the Clinical Information Quality (CLIQ) framework for digital health.

Results: We identified 10 existing IQ frameworks from which we developed the CLIQ framework for digital health with 13 unique dimensions: accessibility, completeness, portability, security, timeliness, accuracy, interpretability, plausibility, provenance, relevance, conformance, consistency, and maintainability, which were categorized into 3 meaningful categories: availability, informativeness, and usability.

Conclusions: This systematic review highlights the importance of the IQ of DHTs and its relevance to patient safety. The CLIQ framework for digital health will be useful in evaluating and conceptualizing IQ issues associated with digital health, thus forestalling potential patient safety problems.

KEYWORDS

digital health; patient safety; information quality

Introduction

Background

Digital health—the use of digital technologies for health—is increasingly recognized as a major driver of quality in health care [1]. Digital health technologies (DHTs), such as telemedicine, electronic health records (EHRs), clinical decision support systems (CDSS), mobile health, computerized physician order entry, electronic prescribing systems, and web-based health services, can improve access and quality of health care services [2,3]. DHTs generate a copious amount of information used in health care for administrative, educational, research, and clinical purposes [4,5]. However, the clinical use of digital information for diagnostic, therapeutic, and prognostic purposes has multiple patient safety problems, including significant harms and death, some of which result from poor information quality (IQ) [6-9]. For instance, a patient in the United Kingdom experienced a life-threatening allergic reaction following a medication error because of inaccessible allergy information in the EHR [6].

IQ refers to the extent to which information is fit for a specific purpose [10,11]. IQ is multidimensional, with each dimension describing a unique aspect of information [10,12]. For example, accuracy describes the extent to which information is correct, and accessibility describes the extent to which information is easily obtainable [12]. Dimensions relating to a specific context are traditionally integrated into a framework for evaluating IQ within the context [10,11]. One IQ framework for EHRs [13] has 11 dimensions and 3 categories, as shown in Textbox 1. The framework depicts the relationship between the dimensions by categorizing statistically measurable dimensions as objectivity, security-related dimensions as integrity, and dimensions relating to the usefulness of information to intended users as utility [13].

Research Problem and Objective

Currently, there is no consensus on the definition of IQ dimensions in the context of the use of digital health information for clinical purposes. There is a lack of consistency in the terminology and definition of dimensions in existing IQ frameworks, limiting a common understanding of IQ requirements for DHTs [14]. Although previous literature reviews have attempted to define the IQ dimensions of digital health information, they focused on the use of digital health information for administrative and research purposes [14,15]. Identifying and defining IQ dimensions in the context of the use of digital health information for clinical purposes is especially important considering the patient safety implications of poor IQ, as discussed earlier [6-8]. This study aims to use an evidence-based approach to integrate dimensions from existing IQ frameworks, thus promoting a common understanding of IQ requirements. In addition, safety concerns may discourage health

XSL•FO
RenderX

care professionals from adopting DHTs. Although many general practitioners in the United Kingdom would support the deployment of more DHTs in primary care, they are concerned about the safety of digital health information [16]. Thus, there is a need for a framework that can be used to evaluate the extent to which digital health information is suitable for clinical purposes. The aim of this systematic review is to identify and define dimensions within existing IQ frameworks for DHTs and synthesize an IQ framework that can be used to evaluate the extent to which digital health information is fit for clinical purposes, either diagnostic, therapeutic, or prognostic.

Methods

Review Checklist

The systematic review is reported based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) checklist [17] presented in Multimedia Appendix 1.

Review Questions

The systematic review will address the following questions:

1. What IQ frameworks currently exist for evaluating DHTs?
2. How are dimensions within these existing IQ frameworks defined?
3. Which IQ dimensions indicate how well digital health information is fit for diagnostic, therapeutic, or prognostic purposes?
4. How are these digital health IQ dimensions related to one another?

Eligibility Criteria

The eligibility criteria of this review were based on a specific approach for identifying frameworks, theories, and models in a systematic review using behavior of phenomenon of interest, health context and model or theory [18,19]. The traditional population, intervention, comparator, and outcome approach was not suitable as we synthesized frameworks rather than interventions.

We included IQ frameworks for assessing DHTs used for clinical purposes but excluded frameworks for nonclinical or administrative purposes because they are less likely to affect patient safety. For example, an incidence reporting system within a hospital setting can be used for administrative purposes. Similarly, we excluded IQ frameworks for web-based health-related information and electronic learning because they are not directly used in the clinical management of patients at the point of care. We excluded self-management apps used by patients mainly for health education and disease tracking purposes, as their IQ requirements are probably different from those used for clinical purposes by health care professionals [20]. We included multidimensional frameworks, but not individual IQ dimensions, as IQ is an interrelated multidimensional concept. Both published and gray literature were included. The included studies were not restricted based on publication date, and all eligible studies until October 2019 were included. Restrictions based on publication status, study type, and publication date may inadvertently lead to the exclusion of potentially relevant IQ frameworks. A summary of the eligibility criteria is presented in Table 1.

Table 1. Inclusion and exclusion criteria.

Concept	Inclusion	Exclusion
Behavior of phenomenon of interest	Information quality or data quality	Information quality or data quality of administrative and nonclinical data
Health context	Use of digital health information for clinical purposes (ie, diagnostic, therapeutic, or prognostic)	Web-based search for health-related information, electronic learning, and digital health apps for self-management
Model or theory	Multidimensional framework	Individual dimension
Language	English	Non-English
Publication status	Published and gray literature	None
Date of publication	Any	None
Type of study	Any	None

Information Sources

We searched bibliographic health care databases, including Embase, MEDLINE, PubMed, CINAHL, Maternity and Infant Care, PsycINFO, and Global Health. We also searched Scopus to identify digital health publications in non–health care disciplines, such as engineering and computer science. In addition, we searched HMIC (the Health Management Information Consortium) and ProQuest Dissertations and Theses Global, which are regarded as good sources of gray literature [21,22]. We manually searched the references of the included studies and tracked their citations to identify other eligible studies using Scopus and Google Scholar.

Search Strategy

The search terms are related to 3 main concepts: (1) IQ (behavior of the phenomenon of interest), (2) digital health (health context), and (3) framework (model or theory) [18,19]. The search terms relating to each of these concepts were combined using the *OR* connector. The results of the 3 categories were then combined using the *AND* connector. A librarian was consulted for input on the search strategy. Medical Subject Headings and free-text terms were used. Truncation and adjacency searching were used to increase the sensitivity of the search, as appropriate. The search strategy is presented in Multimedia Appendix 2.

XSL•FO
RenderX

Data Management

We removed duplicates using Endnote Reference Management Software (Clarivate), and additional duplicates not identified by the Endnote function were removed manually. The deduplicated data were then imported into Covidence (Veritas Health Innovation Ltd), a review-management software program that operates in partnership with Cochrane Collaboration and allows multiple reviewers to work on study selection simultaneously and independently.

Study Selection

The eligible studies were identified in 2 stages: title and abstract screening and full-text review. Titles and abstracts of the studies were screened for eligibility by 2 independent reviewers (KPF and JTA) using the criteria outlined in Table 1. Conflicts were resolved by discussion between the 2 reviewers and adjudicated by a third independent reviewer (JOD) when necessary. The full-text review of all studies selected during the screening was independently conducted by 2 reviewers (KPF and SOC), with disagreement resolved as described previously.

Data Extraction

Overall, 2 reviewers (KPF and SOC) independently extracted data from each eligible study using a prepiloted Microsoft Excel data extraction form. Other reviewers (JOD, CC, PAW, JG, JC, and AM) reviewed the extracted data to ensure the accuracy and completeness of the data. We extracted the study details, including authors, year of publication, country, affiliation, study aim, study design, and publication status. We also extracted IQ framework–related data, including the method of framework development, method of framework validation (when available), type of DHT, IQ dimensions and their verbatim definition, categories of IQ dimensions (when available), and metrics of IQ dimension measurement (when available).

These data elements were defined as follows:

- IQ frameworks for DHTs: A systematic integration of IQ dimensions to evaluate health information technologies used in the diagnosis, treatment, and prognosis of patients.
- IQ dimensions within the frameworks in digital health: These are the evaluation criteria within the IQ frameworks that specify the extent to which health information technologies are fit for clinical use.
- Definition of IQ dimensions in digital health: A clear description of what aspect of information each dimension assesses.
- Categories of dimensions within IQ frameworks in digital health: IQ dimensions are often categorized to depict the relationship between IQ dimensions in an IQ framework.
- Metrics of measurement of IQ dimensions in digital health: How each IQ dimension is measured, for example, questionnaire and mathematical formulas.

Quality Assessment

We assessed the quality of the included studies using the Critical Appraisal Skills Programme (CASP) checklist for qualitative studies [23]. Selecting this tool was difficult, as the included papers comprised a range of methodologies, including ethnography study, literature review, practice brief, and framework development, with some of the papers not explicitly stating their methodology. Therefore, some of the questions on the checklist were not applicable. Scores were not assigned, as this was not recommended by the checklist [23]. Studies were not excluded based on quality assessment outcome, as this was unlikely to have any major impact on the ultimate definition of the dimensions and the resulting IQ framework. However, the assessment provided a general idea about the quality of the development processes of the existing IQ frameworks and, therefore, the strength of the evidence [24].

Data Synthesis

In this review, the IQ framework was developed using a thematic synthesis approach comprising 3 key stages: coding, descriptive synthesis, and analytical synthesis [25]. Although codes and descriptive themes were generated directly from the extracted definition of IQ dimensions, analytical themes were interpretations that went beyond the original data.

In the first stage, we coded the verbatim definitions of IQ dimensions extracted from the existing IQ frameworks in the included papers. Coding was done by identifying the unique concepts from each definition of the IQ dimension and highlighting them using the text highlight function of Microsoft Word (Microsoft).

Second, we categorized the codes based on their similarities and differences and created a descriptive theme to capture the meaning of each category. Each descriptive theme was defined based on the meaning of the original code from which it was created. The descriptive themes created were regarded as the IQ dimensions of the new IQ framework for digital health. Coding and descriptive synthesis were performed by 2 independent reviewers (KPF and JTA) with adjudication by a third independent reviewer (JOD).

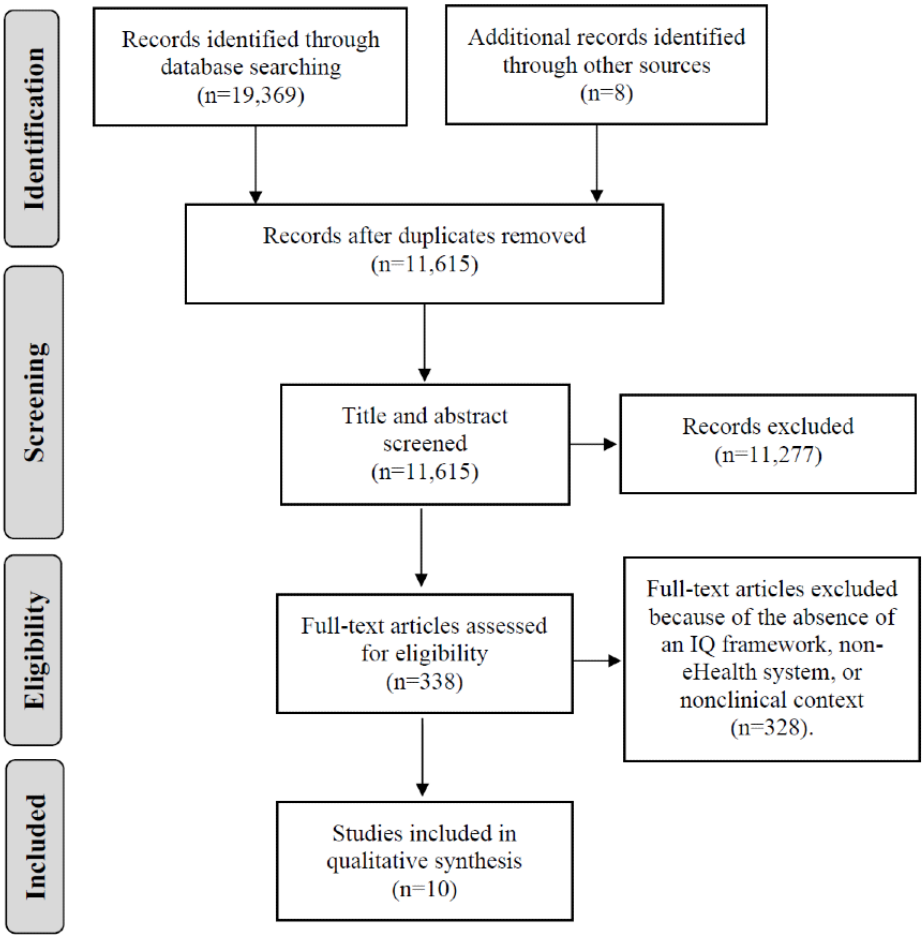
Finally, we conceptualized analytical themes by considering the interrelationship between the descriptive themes (IQ dimensions) based on their definitions. The conceptualization of the analytical themes from the descriptive themes in thematic synthesis has been described as controversial because it is influenced by the insight and judgment of the reviewers [25]. This stage was quite challenging because of the subjective nature and varying perspectives of the reviewers. The following procedures were used to avoid bias and to achieve a consensus. The lead author (KPF) categorized the IQ dimensions without revealing his proposed categories to other reviewers. The other reviewers were then invited to categorize the IQ dimensions individually and email their suggested categories with rationale to the lead author without copying other members of the team. The reviewers were specifically asked to reflect on the suitability of digital health information for clinical purposes and its impact on patient safety while categorizing the IQ dimensions. Overall, 2 reviewers (KPF and JOD) then collated the inputs and carefully assigned a category to each of the dimensions based on the most popular suggestions considered along with the rationale. The framework was then shared with all the members of the team for further inputs and adaptation, if necessary.

Thus, a new digital health IQ framework was developed by synthesizing existing IQ frameworks for DHTs. The IQ

XSL•FO
RenderX

dimensions in the new framework are descriptive themes that were generated directly from the definition of IQ dimensions within existing frameworks, whereas the IQ categories were generated from the higher-order analytical synthesis of the descriptive themes.

Ethics



Ethical approval was not required for this systematic review, as the primary data were not collected. The review was registered in PROSPERO [26], and the protocol was published [27] to promote transparency.

Results

Selection of Studies

A total of 19,377 records were identified from the literature search. These were reduced to 338 after the removal of duplicates and screening of titles and abstracts. Only 10 papers were included in the study after a full-text review. Although 3 of these papers [14,28,29] were in the context of secondary use of digital health data for research, they were included, as their IQ frameworks were relevant to the clinical context of digital health information. However, we performed a sensitivity analysis by conducting a thematic synthesis with and without these 3 papers [30]. The sensitivity analysis revealed that the inclusion of the 3 papers did not affect the component dimensions in the resulting framework, but their inclusion produced a better understanding of the definition of the dimensions. The PRISMA flow diagram is shown in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) flow diagram. IQ: information quality.

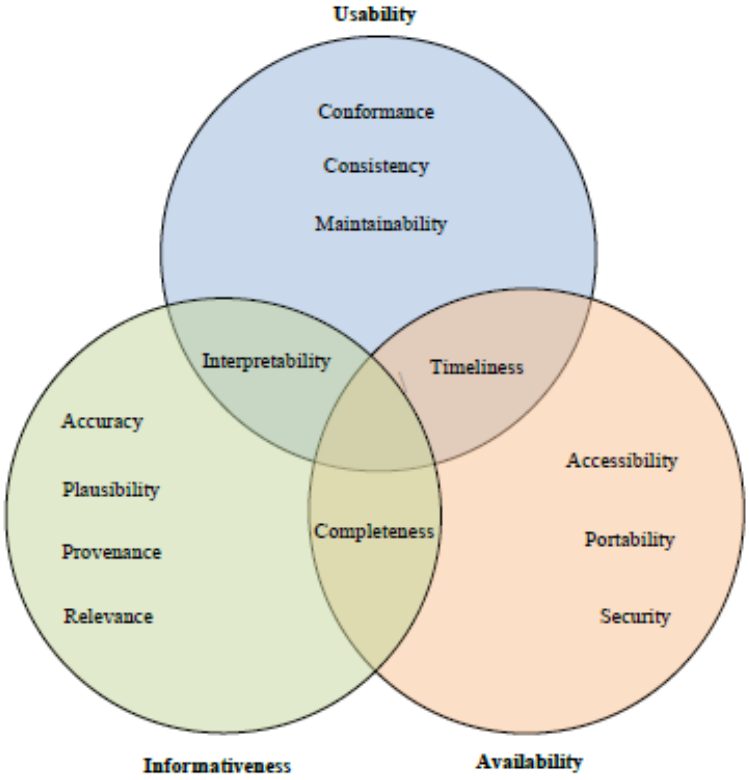
Included Papers

The 10 included papers were published between 2007 and 2017. Of the 10 papers, 5 (50%) were published in the United States [14,28,31-33], 3 (30%) were published in the United Kingdom [13,29,34], and one each was published in Canada [35] and Japan [36]. One of the studies published in the United Kingdom was conducted in Saudi Arabia [13]. Of the 10 papers, 4 (40%) were journal publications [14,28,32,36], 3 (30%) were conference papers [29,31,34], 2 (20%) were institutional reports [33,35], and 1 (10%) was a PhD thesis [13]. Of the 10 studies, 5 used qualitative methods, either alone [31,36] or in combination with other methods [13,14,29]. Similarly, 40% (4/10) studies used literature review alone [28,34] or combined with other methods [13,14]. Overall, 30% (3/10) studies modified the existing frameworks [29,32,36]. One study reported to have updated the previous framework [33], but it was unclear how this was achieved. In addition, 10% (1/10) study [35] did not state how the framework was developed. About 50% (5/10) of the frameworks were on EHRs [13,14,28,32,33], one each

XSL•FO
RenderX

on electronic medical records [35], primary care databases [29], CDSSs [31], mobile and web-based apps for telemedicine [36], and cloud-based health information systems [34]. Thus, it appears that IQ framework research is unable to keep pace with the rapid evolution of DHTs with obvious underrepresentation of newer DHTs such as mobile health. The details of the included papers are presented in Multimedia Appendix 3 [13,14,28,29,31-36].

Quality of Included Studies



The quality assessment indicated that most of the studies described an IQ framework for DHT without reporting a robust framework development process. The Critical Appraisal Skills Programme checklist is not applicable to 2 studies [33,35], which are institutional publications. Only 1 qualitative study [13] reported on the recruitment strategy. Similarly, studies with literature reviews did not report on the search strategy or study selection process [13,14,28,34]. Only 3 studies [13,31,32] addressed ethical issues and reported sufficiently rigorous data analysis. These findings further justify the need for this study, which used a robust systematic review approach to develop a preliminary IQ framework for digital health. The quality assessment results are provided in Multimedia Appendix 4 [13,14,28,29,31-36].

Clinical Information Quality Framework for Digital Health

A total of 38 IQ dimensions and 70 verbatim definitions were extracted from the 10 included frameworks. The list of dimensions and their definitions are provided in Multimedia Appendix 5 [13,14,28,29,31-36]. The coding of these definitions led to the identification of 160 codes. Aggregation of similar codes resulted in a total of 13 unique IQ dimensions that mirrored all the relevant dimensions in the existing IQ frameworks while eliminating related but redundant dimensions. The resulting dimensions include accessibility, completeness, portability, security, timeliness, accuracy, interpretability, plausibility, provenance, relevance, conformance, consistency, and maintainability. These dimensions were defined based on the codes from which they were generated and classified into higher categories of availability, informativeness, and usability during the analytical synthesis. It is worth noting that some of the dimensions fit into more than one category but were placed into the best-fit category after carefully considering the inputs of all reviewers. For example, completeness was considered fit for both the availability and informativeness categories but was placed in the informativeness category, as this was the most popular category suggested by the reviewers. Similarly, timeliness was considered more fit for the availability category compared with the usability category, and interpretability was placed in the informativeness category rather than the usability category. The resulting Clinical Information Quality (CLIQ) framework for digital health is shown in Figure 2.

XSL•FO
RenderX

Figure 2. Clinical Information Quality framework for digital health.

Informativeness directly concerns the usefulness of digital information for clinical purposes.	Accuracy	The extent to which information is correct.
	Completeness	The extent to which no required information is missing.
	Interpretability	The extent to which information can be understood.
	Plausibility	The extent to which information makes sense based on common knowledge.
	Provenance	The extent to which the source of information is trustworthy.
	Relevance	The extent to which information is useful for the intended task.
Availability concerns the functionality of the system holding clinical information.	Accessibility	The extent to which existing information is easily obtainable.
	Portability	The extent to which information is accessible in different systems.
	Security	The extent to which information is protected from unauthorized access and corruption.
	Timeliness	The extent to which current information is available on time.
Usability concerns the ease of use of clinical information.	Conformance	The extent to which information is presented in the desired format.
	Consistency	The extent to which information is presented in the same format.
	Maintainability	The extent to which information can be maintained.

Metrics of Measurement

Metrics of measurement for the IQ dimensions were given in only 30% (3/10) of the included papers [13,29,35]. The remaining papers only conceptualize IQ without providing guidance on its measurement. Objective and subjective measures were used in these studies. Objective measures involved mathematical calculations, such as ratio, percentages, and fraction to quantify the IQ dimension [37]. Subjective measures, on the other hand, rely on the perspectives of the information users, which are usually assessed using a Likert scale questionnaire or qualitative interviews [10].

Objective measures were reported for accuracy, validity, timeliness, completeness and interpretability, comprehensibility, reliability, validity, timeliness, relevance, integrity completeness, concordance, informative sufficiency, consistency, consistency of capture, and consistency of form [13,29,35]. These dimensions were measured by determining whether a desired

XSL•FO
RenderX

or undesired attribute was present or absent. For example, Almutiry [13] identified quality problems (undesired attributes) related to accuracy as misspelling, out-of-range values, erroneous values, etc. The quality score for accuracy was then calculated by determining the proportion of the total data units without each quality problem. Similarly, Dungey et al [29] measured accuracy by calculating the proportion of implausible values (undesired attributes). Bowen [35], on the other hand, used the percentage of data units with the desired attribute. Correctness was measured by determining the positive predictive value, which is the proportion of true positives (desired attributes).

Subjective measures were reported for usability, relevance, provenance, secure access, confidentiality, and privacy [13]. Each dimension was measured using multiple Likert scale questions. For example, relevance was assessed by the information users' rating of how far the information was relevant, useful, applicable, and appropriate to the task at hand [13]. The quality score for each dimension is the aggregate of all ratings for these different measures.

Discussion

Principal Findings

We identified 10 existing IQ frameworks for DHTs, and from these, we developed the CLIQ framework for digital health with 13 unique dimensions, including accessibility, completeness, portability, security, timeliness, accuracy, interpretability, plausibility, provenance, relevance, conformance, consistency, and maintainability, which were classified into 3 meaningful categories—availability, informativeness, and usability—based on our conceptualization of *fitness* of digital health information for clinical purposes.

The informativeness category directly concerns the usefulness of information for clinical purposes and has the greatest implications for patient safety. Problems with the dimensions in the category can directly lead to significant harm, as previously reported in the literature [6,8]. Accuracy is the most popular IQ dimension. However, this systematic review echoes the literature that IQ is not only about accuracy but also a multidimensional phenomenon [38]. Provenance and plausibility are unique IQ dimensions that can be regarded as proxies for accuracy, especially in situations where immediate and objective determination of accuracy is impractical. Provenance and plausibility can be easily determined subjectively. For example, knowing that the source of digital health information is a reputable institution (provenance) such as the World Health Organization would be reassuring, and an implausible value, such as a body temperature of 100°C (plausibility), would raise a serious concern. Interpretability is critical to the clinical use of digital information, as an incorrect interpretation may lead to significant harm. Hence, the inclusion of reference values with most laboratory results enhances the safe interpretation of the values.

The availability category of IQ dimensions concerns the functionality of a system that holds clinical information. These dimensions are critical as they can affect the efficiency of service delivery and are regarded as important by users of digital health information. Inaccessible digital information offers no real value to health professionals, as it cannot be used in the clinical management of patients. In addition, accessibility of clinical information wherever it is required (portability) and whenever it is required (timeliness) could be lifesaving, especially in emergency situations when the knowledge of a patient's medical history and current medications are essential. Timeliness, in the clinical context of digital health, also requires that health information is up to date. On the other hand, restriction of access to clinical information only to authorized users (security) protects the privacy and confidentiality of the patient and protects the information from corruption. Availability dimensions are illustrated by the UK's Summary Care Records [39], which contain up-to-date personal medical and medication history of patients and are accessible at the point of care (timeliness and accessibility) across different health care settings only to authorized health care professionals (security).

The usability category concerns the ease of use of health information. Consistency and conformance are akin to 2 sides of a coin, with consistency referring to the presentation of information in the same format within a system and conformance referring to the presentation of information in the desired format based on local guidelines or international standards. For example, it is important for an app to present blood glucose consistently using either gram per deciliter or millimoles per liter and conform with the recommended units in the local guidelines to avoid confusion, which may compromise patient safety. The last dimension in this category is maintainability. This refers to the extent to which the information can be maintained. Maintenance, in this context, covers a range of activities, including review, audit, update, and storage of clinical information to ensure that all other IQ requirements are met. For example, timeliness can be improved by updating the information in the DHTs, and accuracy can be improved through regular audits of the information generated by the DHTs.

Strength and Limitations

The main strength of our framework lies in the rigorous systematic review approach that was used to identify, define, and categorize IQ dimensions. In addition, our approach of synthesizing definitions rather than the traditional practice of simply cross-matching dimensions from different frameworks is more meaningful, as the definition expresses the real meaning of each dimension, and a dimension usually has heterogeneous definitions across different frameworks. In addition, focusing on the clinical context rather than the ever-changing DHTs, as in previous frameworks, we have developed a context-specific IQ framework that would be applicable or at least adaptable to a range of DHTs used in the clinical context, including novel ones that are currently underrepresented in IQ framework research. This approach differs from previous frameworks that focus on individual DHTs, such as EHR [13] and CDSS [31]. The consideration of the clinical purposes of DHTs is in consonance with the *fit-for-purpose* definition of IQ [10]. Moreover, the traditional practice of using the same clinical information across different DHTs (eg, the use of EHR information for CDSS) further justifies the need for a common IQ framework for the clinical context of DHTs.

XSL•FO
RenderX

However, the lack of information about the relative relevance of the IQ dimensions in the CLIQ framework and the optimal means of their measurement are limitations. Although these dimensions could be considered as indices of fitness of digital information for clinical purposes, we acknowledge the need to consult with clinical information users, such as doctors, nurses, and health service managers, as recommended in the literature [10,12]. Thus, the current CLIQ framework for digital health could be regarded as a preliminary framework to be tested in primary research studies. To build on this preliminary research, an international eDelphi study is currently underway to obtain consensus among clinicians on the approach to assessing the quality of clinical information produced by DHTs. The eDelphi study addresses the prioritization of the dimensions and the metrics for measuring the dimension.

Comparison With Validated IQ Frameworks

The CLIQ framework for digital health shares several characteristics with validated IQ frameworks within and beyond the health care domain. One such validated IQ framework, developed by Wang and Strong [38], has been used as a reference point in IQ research. Out of its 15 dimensions, 7 (accuracy, relevance, completeness, timeliness, interpretability, security, and accessibility) are also included in the CLIQ framework. The rest of its dimensions, such as believability and understandability, were assimilated by other dimensions in our framework during thematic synthesis. On the other hand, novel dimensions such as portability and maintainability are included in our framework but not in the framework developed by Wang and Strong [38]. This reflects technological advances in the last three decades, with an increasing amount of digital information. In addition, our framework was developed for the clinical context, whereas Wang and Strong focused on the business domain [38].

Similarly, the dimensions in our framework overlap with the product quality properties of the International Organization for Standardization/International Electrotechnical Commission (ISO/IEC 25010), which include 8 characteristics: functional suitability, reliability, performance efficiency, operability, security, compatibility, maintainability, and transferability [40]. Of these characteristics, 2 (maintainability and security) were also included in the CLIQ framework. Other dimensions in the CLIQ framework (eg, availability, accuracy, and completeness) are included as subcharacteristics of product quality. This overlap is not unexpected, as DHTs are also software products, with IQ being a subset of product quality [40]. However, ISO/IEC 25010 addresses Systems and Software Quality Requirements and Evaluation from a computer engineering perspective, whereas the CLIQ framework addresses IQ from a health care perspective with consideration of its impact on patient safety [6-8]. Although we recognize the importance of other aspects of product quality, such as user-interface esthetics, these are beyond the scope of this study, which is focused on IQ in the clinical context of DHTs.

Conclusions

This systematic review highlighted the importance of the IQ of DHTs and their relevance to patient safety. Future research is needed to determine the relative relevance of each dimension in the CLIQ framework and their metrics of measurement, with inputs from clinical information users. The CLIQ framework for digital health will be useful to health care organizations, health care professionals, digital health solution developers, and medical device regulators in conceptualizing and evaluating IQ issues associated with digital health, thus forestalling potential patient safety problems. This is more relevant than ever, as the health care community is increasingly turning to DHTs, and the need for and value of such systems in the context of health emergencies is becoming ever more apparent.

Acknowledgments

The authors would like to thank Rebecca Jones, library manager and liaison librarian at the Charring Cross Library, Imperial College London, for useful advice on strategies for the literature search. This review is part of the PhD of the lead author (KPF) sponsored by the Federal Government of Nigeria. This review is an independent research supported in part by the National Institute for Health Research (NIHR) Applied Research Collaboration Northwest London. The views expressed in this publication are those of the authors and not necessarily those of the National Institute for Health Research or the Department of Health and Social Care.

Authors' Contributions

KPF and JOD conceived the study. KPF drafted the manuscript. JTA, SOC, PAW, CC, AM, JC, JG, and JOD revised the manuscript for important intellectual content and contributed to the review, including search strategy, study selection, data extraction, and data analysis. AM is the clinical lead, and JOD is the guarantor of the review.

Abstract

Background: The delivery of standardized self-report assessments is essential for measurement-based care in mental health. Paper-based methods of measurement-based care data collection may result in transcription errors, missing data, and other data quality issues when entered into patient electronic health records (EHRs).

Objective: This study aims to help address these issues by using a dedicated instance of REDCap (Research Electronic Data Capture; Vanderbilt University)—a free, widely used electronic data capture platform—that was established to enable the deployment of digitized self-assessments in clinical care pathways to inform clinical decision making.

Methods: REDCap was integrated with the primary clinical information system to facilitate the real-time transfer of discrete data and PDF reports from REDCap into the EHR. Both technical and administrative components were required for complete implementation. A technology acceptance survey was also administered to capture physicians' and clinicians' attitudes toward the new system.

Results: The integration of REDCap with the EHR transitioned clinical workflows from paper-based methods of data collection to electronic data collection. This resulted in significant time savings, improved data quality, and valuable real-time information delivery. The digitization of self-report assessments at each appointment contributed to the clinic-wide implementation of the major depressive disorder integrated care pathway. This digital transformation facilitated a 4-fold increase in the physician adoption of this integrated care pathway workflow and a 3-fold increase in patient enrollment, resulting in an overall significant increase in major depressive disorder integrated care pathway capacity. Physicians' and clinicians' attitudes were overall positive, with almost all respondents agreeing that the system was useful to their work.

Conclusions: REDCap provided an intuitive patient interface for collecting self-report measures and accessing results in real time to inform clinical decisions and an extensible backend for system integration. The approach scaled effectively and expanded to high-impact clinics throughout the hospital, allowing for the broad deployment of complex workflows and standardized assessments, which led to the accumulation of harmonized data across clinics and care pathways. REDCap is a flexible tool that can be effectively leveraged to facilitate the automatic transfer of self-report data to the EHR; however, thoughtful governance is required to complement the technical implementation to ensure that data standardization, data quality, patient safety, and privacy are maintained.

KEYWORDS

REDCap; electronic health record; systems integration; measurement-based care; hospital information systems

Introduction

Background

A key component of measurement-based care (MBC) in mental health relies on the ability of patients to complete self-assessments. These assessments can be used in conjunction with evidence-informed practice guidelines to monitor patient progress and inform clinical decisions for patient-centered care plans. MBC can improve outcomes by rapidly detecting patients with deteriorating symptoms and by effectively quantifying persistent symptoms [1]. The Centre for Addiction and Mental Health (CAMH) is the largest mental health hospital in Canada, supporting over 34,000 patients per year across diverse clinical programs. CAMH has developed and deployed a number of integrated care pathways (ICPs), which include MBC as the main, evidence-based aspect of care. Broadly used across many clinical domains, ICPs are structured care plans that follow evidence-based guidelines to improve patient outcomes [2] and may include definitions for specific medications or treatment strategies [3,4].

In addition to providing clinical care, CAMH is Canada's leading mental illness research facility. In recent years, REDCap (Research Electronic Data Capture; Vanderbilt University) has been instrumental to this research effort [5]. REDCap is a secure, Health Insurance Portability and Accountability Act–compliant, web-based application for building and managing electronic surveys and assessments [6]. Developed in 2004 by researchers at Vanderbilt University, REDCap was designed to provide a straightforward means of data management for the local research community [7]. Since its inception, the platform has evolved through several phases, first through select development partnerships and then through a growing international consortium that currently represents a diverse global community spanning over 3600 institutions in more than 130 countries with more than a million users worldwide [8]. The platform is available to academic, nonprofit, and government organizations through a no-cost consortium model, whereby partner institutions are provided the source code and installation files for REDCap after agreeing to the end user license agreements terms outlined by Vanderbilt University.

REDCap was launched at CAMH in 2015 for research data collection and operational support. Since then, the platform has grown to more than 1000 users who have created over 1800 projects culminating in more than 200,000 individual records. In 2017, a second, fully validated instance of REDCap was launched to support data collection for Health Canada regulated clinical trials. In 2018, because of the growing familiarity with REDCap at CAMH and knowledge of its flexibility, customizability, and community support, a demand for a version of REDCap to support clinical data began to emerge. Specifically, this version of REDCap would be used for ICP delivery. It was posited that REDCap's flexibility and its ability to manage complex workflows would significantly improve the previously paper-based methods used for ICP delivery. Importantly, however, this version of REDCap would need to be integrated with the CAMH electronic health record (EHR), a CAMH-branded version of Cerner Millennium called I-CARE.

CAMH achieved the Healthcare Information Management Systems Society (HIMSS) Adoption Model for Analytics Maturity Stage 6 in 2018 and the Electronic Medical Record Adoption Model Stage 7 in 2017 [9], indicating excellent hospital-wide adoption and compliance. Electronic data capture is used throughout the hospital and coordinated as the *sole source of truth* legal health records. To enhance the flexibility of electronic data collection for MBC, a *clinical* instance of REDCap was launched and connected to Cerner via a systems integration layer to facilitate the automatic transfer of completed assessments to the patient chart in both PDF and discrete formats. This integration extends capabilities for complex survey queues and branching assessments as needed by clinical pathways while maintaining the integrity of the health record.

Objectives

In this development and usability study, we describe the technical implementation and governance model of a clinical instance of REDCap to support digital MBC in multiple clinical environments. We detail the technical requirements for real-time transfer of self-assessments collected in REDCap to the patient's chart in Cerner in both PDF and discrete variable formats. In addition, we describe the clinical governance structure necessary to sustain high-quality clinical data and support standardized implementation across clinics. A pertinent clinical use case is outlined to illustrate the utility and applicability of REDCap to support scalable and extensible structured mental health MBC at CAMH and beyond.

Methods

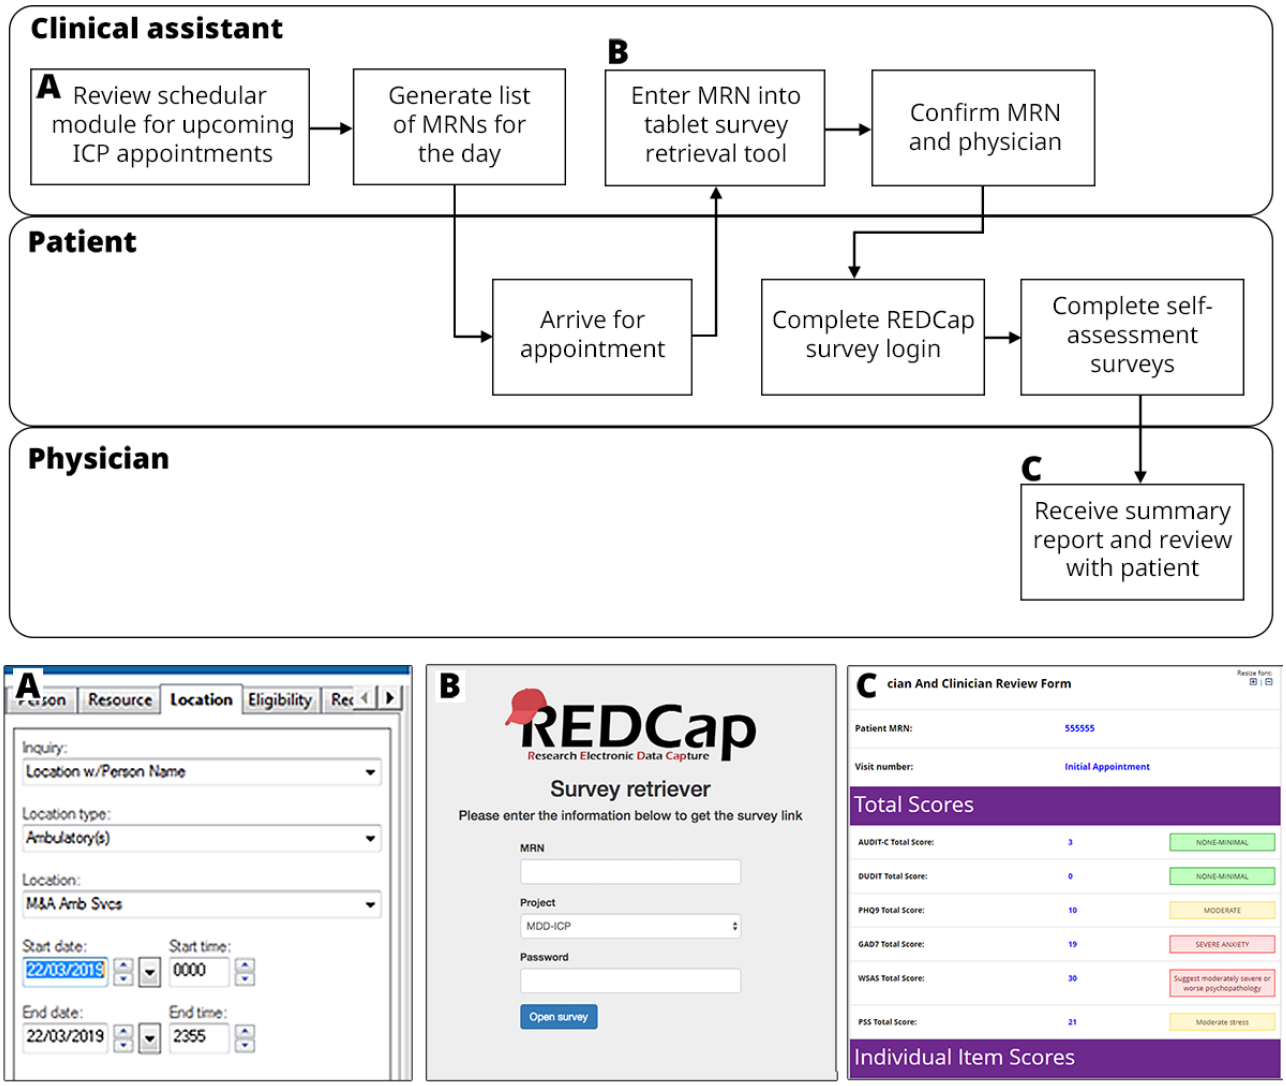
Overview

Evaluation of the ICPs at CAMH identified a need to deploy complex bundles of assessments over time that could be dynamically adjusted based on indicators such as severity or frequency of symptoms. The functionality of REDCap is well suited to meet these requirements. By delivering standardized assessments longitudinally, modified through branching and survey queue logic as appropriate, necessary psychological dimensions could be sampled to inform physician decision making throughout the course of care. The clinical instance of REDCap (Clinical REDCap) was the third installment of REDCap at CAMH, preceded by a research instance and a fully validated instance for regulated clinical trials. REDCap version 9.1 was used for this implementation.

Technical Implementation

The technical implementation to integrate REDCap with Cerner included (1) tablet deployment in the clinic; (2) automated transfer of completed self-assessments in a PDF format to the patient chart; and (3) automated transfer of completed self-assessments in a discrete format to the patient chart for

XSL•FO
RenderX



trending, analysis, and more complex physician decision support.

Tablet Deployment and Automated Survey Retrieval Tool

Samsung Galaxy Tab Android tablets were provided to clinical assistants to facilitate patient self-assessment data entry into REDCap. As a technical safeguard, a kiosk app (Kioware) was configured to limit tablet use to preapproved apps and webpages, in this case, Google Chrome and REDCap, respectively.

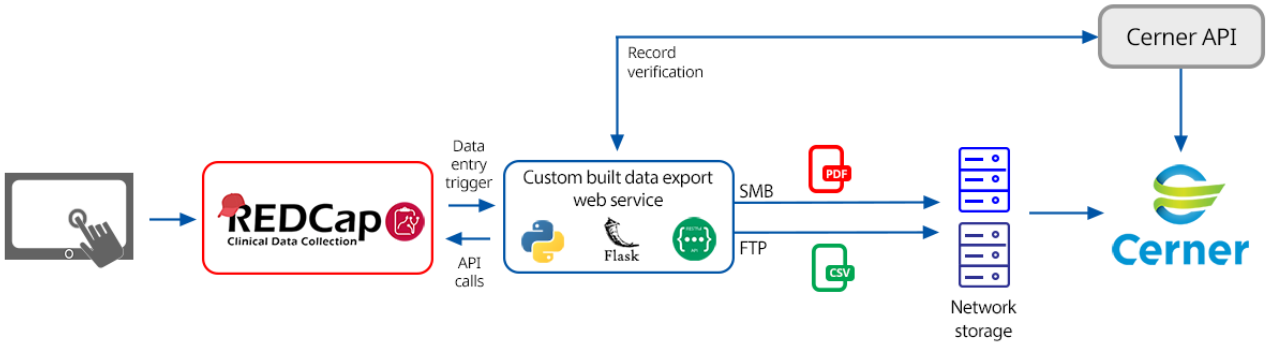
In collaboration with the clinic managers and physician teams, work was undertaken to streamline the administration of tablets and surveys for patients and staff. To simplify the clinical workflow (Figure 1), a custom *survey retriever* web app was developed using the REDCap application programming interface (API). This tool accepts the patient medical record number (MRN) and ICP name and retrieves the unique survey queue link from the *next available* set of self-assessments in the care pathway for a particular patient. Using this tool, the clinical assistant may load the appointment's set of assessments, beginning with a confirmation survey asking the clinical assistant to confirm the MRN, appointment date, and the patient's physician to ensure compliance and accuracy. The physician field on this confirmation form is populated using a dynamic SQL (Structured Query Language) field, which draws from a separate REDCap project that lists all ICP physician names or emails and their current status (eg, active or inactive). It allows clinical end users to easily update the physician list without needing to dynamically modify a dropdown list directly in the Online Designer. As a final patient verification step before data entry, the REDCap survey log-in feature is used to prompt the patient to enter a personal identification number (PIN) based on their date of birth.

Figure 1. Clinical REDCap workflow and example screens for a typical follow-up appointment. (A) Cerner scheduler view. (B) Custom survey retriever tool used as a tablet homepage. (C) Summary report built as a REDCap survey. ICP: integrated care pathways; MRN: medical record number; REDCap: Research Electronic Data Capture.

Transfer of PDFs to Cerner

To ensure the integrity of the health record, individually completed self-assessments were automatically transmitted as PDFs to the patient's EHR in Cerner and were filed in the *documents* section, specifically under *assessments and plans*. For convenience, an aggregate report is automatically generated within REDCap by piping values into a standalone REDCap

XSL•FO
RenderX



survey emailed to the primary clinician or physician upon assessment package completion (Figure 1). These reports summarize patient response data onto a single page; however, they are not sent to Cerner, as the data have already been transferred as individual files.

As the patient completes assessments, a REDCap data entry trigger (DET) delivers the project ID, record ID, event name, instrument, and form status to a custom-built data export web service. The service listens for DETs and sends a request back to REDCap, thus providing real-time data export functionality. Following the DET, the service makes a request to REDCap using the API method *export PDF file of data collection instruments* to retrieve a PDF document of the completed assessment (eg, the Patient Health Questionnaire-9 [PHQ-9]), and the document is written into a securely shared directory. Each PDF is given a unique file name that follows a predefined convention, as follows:

[mrn]_[encounter]_[assessment_code]_[date]_[time].pdf

This process ensures further compatibility with the Cerner interface, which uses a purpose-built Cerner AXRM COLD Feed (Cerner) [10] to import the document into the patient chart (Figure 2).

Figure 2. Clinical REDCap workflow and example screens for a typical follow-up appointment for a patient in the major depressive disorder integrated care pathway. API: application programming interface; FTP: file transfer protocol; REDCap: Research Electronic Data Capture; SMB: server message block.

Transfer of Discrete Data to Cerner

Similar to PDF export from REDCap, the transfer of discrete values also uses DETs and the REDCap API. In this case, the *export records* API method was used. This method returns the values of the completed assessment fields (eg, PHQ-9) and system variables, such as timestamps. Once the discrete data are retrieved, the web service executes the code to format this information as a comma-separated values (CSV) file that follows a specified convention, as follows: [timestamp].csv for the name and [mrn],[encounter],[uid],[assessment_code],[timestamp],[assessment_field1],[assessment_field2],...,[assessment_fieldN] for CSV content.

UID is a unique identifier of a completed assessment within the REDCap instance generated using the project ID, record ID, instrument code, and visit code. This identifier ensures that the correct form is updated in Cerner if the data in REDCap are modified. At this step, assessment variables are also renamed to be correctly mapped to the corresponding Cerner fields. The CSV file is then written to a directory on a file transfer protocol server. This directory is periodically scanned by a custom Cerner interface, which converts the CSV data into an HL7 unsolicited results (ORU) message. The interface then routes the HL7 to the standard Cerner external systems inbound servers for processing and passes the values into the results view of the chart, where the data are displayed in a table format. Currently, the interface only accepts numerical results, but future updates may include the processing of REDCap data sent in JavaScript Object Notation (JSON) to allow greater flexibility for data import.

Record Verification and Linkage

The primary verification mechanism for data transfer relies on correctly entering the MRN and a Cerner-specific appointment identifier called the *Encounter* number into REDCap. A custom Cerner API (Figure 2) was built, which accepts these parameters, checks whether these values are valid and belong to the same patient, and returns a JSON-formatted response. Upon submitting a data entry form in REDCap, a DET initializes a custom-built data export web service that sends the MRN and *Encounter* number to the custom Cerner API. If all the criteria are met and a successful response is received, the web service proceeds to create the document and discrete files. If the criteria are not met, the transfer is terminated, and an error message is logged and sent via email to the study contact. The message can be one of the following: “Missing MRN,” “Missing Encounter,” or “MRN and Encounter mismatch.”

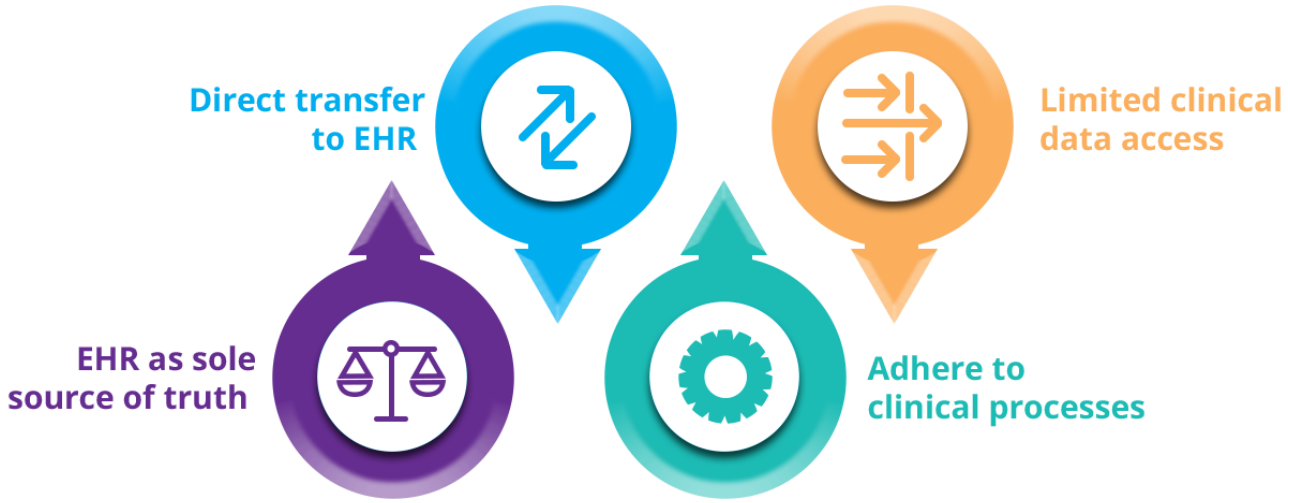
Clinical REDCap Governance

To support technical development and integration, a robust and consistent governance model was necessary to ensure compliance with the legal health record and maintain the standardization necessary to effectively support scalable and reproducible MBC. We outline the governance practices adopted by our institution in a format that can be applied to other similar hospitals.

Clinical Governance Structures

The Clinical REDCap governance structure and principles were codeveloped with clinical and privacy stakeholders to establish core operating constraints. The underlying theme of these principles establishes Clinical REDCap as an extension of normal EHR data collection capabilities and establishes that

XSL•FO
RenderX



clinically relevant information must pass through the primary EHR to maintain a consistent health record. Changes to the care pathway within REDCap must be reviewed and approved by clinical governance committees, consistent with the review process for changes to Cerner. In general, institutional clinical governance committees are accountable for final decisions relating to platform governance and approval of forms used for clinical care; REDCap administrators are accountable for system administration and all project development, and the clinical applications (Cerner) team is accountable for final integration with the EHR. All parties were consulted or informed at various points where necessary.

The collaboration between all stakeholders established a list of 4 key operating principles (Figure 3) that were used to inform all decisions relating to Clinical REDCap, as follows:

1. The hospital EHR will remain the *sole source of truth*.
2. Clinical data collected in REDCap will be transferred directly to the EHR.
3. Clinical REDCap will follow existing clinical measure or pathway approval processes.
4. Access to data collected through Clinical REDCap will follow existing processes pertaining to clinical records.

Although the specifics of principles 3 and 4 will differ depending on the institution and regional legislation, the high-level principle of clinical governance alignment is strongly recommended.

Figure 3. Four key principles of REDCap (Research Electronic Data Capture) integration with the Centre for Addiction and Mental Health EHR. EHR: electronic health record.

Controlled Access and Data Retention

Access to the clinical instance is limited at both the server and individual roles or permissions levels. The clinical instance sever is situated behind the CAMH firewall and is not accessible externally. At the application level, user management is tightly regulated under structured clinical roles established by privacy and health record experts to meet the needs of the clinical workflows and limit unnecessary data access.

Users of the platform fall into 2 broad categories: administrator and clinical (Textbox 1). *Administrators* are responsible for project creation, instrument design, and API configuration and are strictly limited to central REDCap operations staff. In the *clinical* category, 3 subcategories exist: clinical data lead, a clinical staff member who acts as the *owner* of a project and provides in-clinic training and basic support (eg, data corrections); clinical care provider, the role assumed by clinicians and physicians who may enter new records and clinical data; and clinical assistant, a support staff who retrieve survey access codes, load survey queues, and supply tablets to patients for self-assessment. Account provision and project access are handled solely by administrators. Each new user must complete mandatory training by reviewing the policies of Clinical REDCap, including the differences between clinical and research platforms, permitted user roles, and privacy considerations when using the system. User roles are assigned following a hierarchical process: users who request a clinical data lead role must have their request approved by the institutional clinical director. For subsequent clinical roles, account or project access is approved by the respective clinical data lead, who also determines the user role (clinical care provider or clinical assistant) for the project. This approval is required before the user account or project access is provided by an administrator. This hierarchical approval process conforms to the internal organizational structure for consistency and varies in other institutions; however, this approach provides a template for developing permissions modes that are sufficiently restrictive but allow secure access as necessary.

At present, Clinical REDCap project data reside in REDCap for a period aligned with institutional clinical data retention periods unless otherwise removed by a REDCap administrator by request of the clinical team and privacy office.

XSL•FO
RenderX

Textbox 1. Clinical REDCap (Research Electronic Data Capture) user roles and responsibilities.

Clinical REDCap administrator

- Clinical REDCap staff responsible for account creation, modification, and suspension for all user types. Responsible for moving projects and draft changes to production. Limited to 2-3 staff members.

Project developer administrator

- Clinical REDCap staff responsible for creating REDCap projects and associated forms or surveys. Leads project validation to be carried out in collaboration with clinical stakeholders.

Service administrator

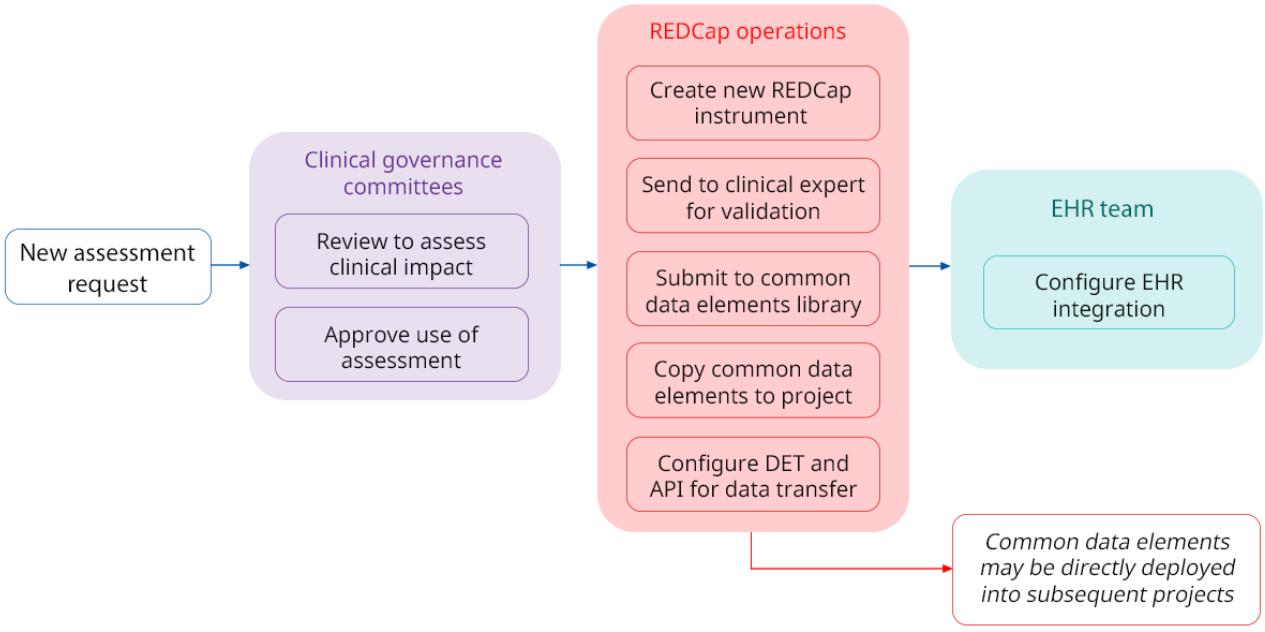
- Specialized account for managing secure services post data collection (eg, application programming interface data export to electronic health record).

Clinical data lead

- Clinical staff responsible for monitoring the integrity of the data, providing clinic-specific training to clinic users, supporting minor technical issues in the clinic, facilitating project validation, submitting project change requests, approving subordinate account requests, and serving as the main point of contact for developers and administrators.

Clinical care provider

- Clinical staff responsible for the administration and review of clinical assessments; can enter data that have been collected on paper into REDCap.



Clinical assistant

- Clinical support staff responsible for administering patient survey queue in the clinic and providing simple technical assistance.

Centralized Assessment and Project Development

All Clinical REDCap projects are built by a dedicated internal team of administrators that follow standardized naming and versioning practices for assessments and variables. All new assessments are clinically validated by CAMH clinicians or physicians and undergo strict approval processes through the hospital's clinical data governance committees to ascertain alignment with existing clinical instruments and standard practice. Once validated, assessments are deployed into a *common data elements* library to support the rapid development of parallel and complementary pathways (Figure 4). The use of common data elements across all projects ensures clinical consistency and provides a standard set of elements that can be transmitted to the hospital EHR with little additional setup. Ancillary forms such as project or participant tracking, reporting, or summary forms are built ad hoc as requested on a project-by-project basis.

Figure 4. High-level workflow for clinical instrument development on the Clinical REDCap instance. The review is conducted by clinical committees to align assessments. API: application programming interface; DET: data entry trigger; EHR: electronic health record; REDCap: Research Electronic Data Capture.

XSL•FO
RenderX

Evaluation of Impact

The clinical impact was assessed by determining the number of physicians who adopted the ICP before and after implementing the Clinical REDCap project. In addition, the monthly enrollment of patients was determined by counting the number of patients enrolled in the paper-based process compared with the Clinical REDCap process on average per month after 6 months.

A short user acceptance survey was developed and sent to Clinical REDCap users in the clinical care provider role to assess clinicians' and physicians' attitudes toward Clinical REDCap. The survey drew questions from the technology acceptance model, which seeks to measure users' perceived usefulness and perceived ease of use and how these factors may affect acceptance of new technology [11]. The survey consisted of 10 items measured on a 5-point Likert scale and included 3 free-text options for respondents to comment on their likes and dislikes and make suggestions for system improvement.

Results

Example Use Case: Major Depression Disorder Integrated Care Pathway

The major depression disorder integrated care pathway (MDD-ICP) provides a multidisciplinary and structured care management strategy, including interprofessional collaboration, standardized assessments, and evidence-based treatment algorithms. The pathway has been active at CAMH for 3 years, and a Clinical REDCap project was created as an alternative to paper-based data collection to digitize and support the clinic-wide implementation of the pathway in the fall of 2018. The data collected in Clinical REDCap (which are subsequently made available in the EHR) are used to support the MBC component of the MDD-ICP, which is used to inform treatment decisions.

Data Entry Workflow

Figure 1 shows a typical Clinical REDCap workflow for patients in the MDD-ICP. Every morning, a clinical assistant reviews the EHR scheduler module to compile a list of patients scheduled for an ICP appointment. When a patient arrives for their appointment, the clinical assistant retrieves a tablet and enters the MRN into the survey retriever tool. Provided that a valid MRN (ie, an existing record in REDCap) is entered, the retriever tool will open the first survey of the next available follow-up event. In this case, the first survey is a confirmation page that asks the clinical assistant to confirm the patient's MRN and their ICP physician(s). Next, the tablet is passed to the patient who enters the verification PIN (using the survey log-in feature in REDCap) based on their date of birth. Following successful verification, the patient may then complete their self-assessments, including the PHQ-9 [12], the Generalized Anxiety Disorder-7 [13], a substance use compliance screener, and a side-effects screener. Additional self-reports are completed at the initial and discharge appointments and include patient history, sociodemographics, the World Health Organization Disability Assessment Schedule 2 [14], the World Health Organization Quality of Life Instruments [15], and the Ontario Perception of Care [16] survey. In some use cases, the REDCap survey queue may be used to conditionally deploy certain assessments based on the responses provided in certain screener assessments. Once the patient has completed their assessments, a notification is emailed to the ICP physician with a link to a summary page in REDCap. This allows the physician to quickly review the results before and during the appointment without having to log into REDCap.

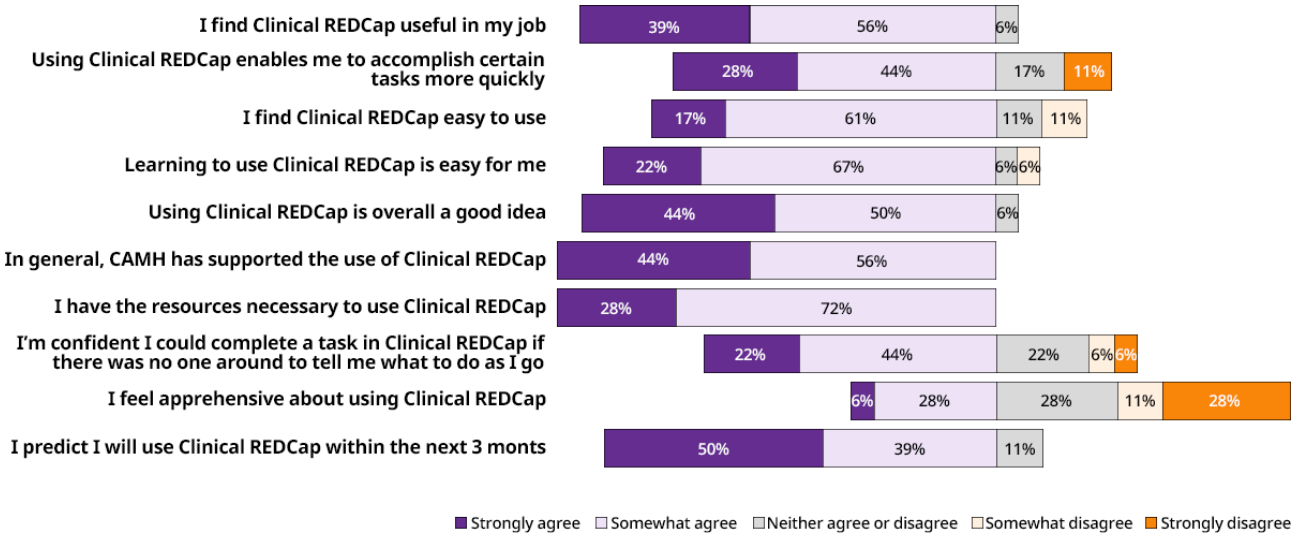
Impact of Digitization

The digitization of the MDD-ICP MBC component contributed to a 4-fold adoption rate by physicians in the clinic compared with the paper-based pilot implementation phase (Table 1). Digitization resulted in an efficient and streamlined process that automatically calculated assessment scores and the ability for psychiatrists to access and review results before a patient's appointment. This practice change, along with clinic-wide implementation, has contributed to the more than tripling of MDD-ICP patients seen by the clinic and has improved data quality. The use of Clinical REDCap ensures a standardized collection of assessments from patients at each visit and minimizes missing data. This systematic data collection method has resulted in the accumulation of high-quality data that may be used to inform quality improvement projects and to answer research questions with approval from the CAMH research ethics board.

XSL•FO
RenderX

Table 1. Overview of the impact and outcomes of Centre for Addiction and Mental Health major depressive disorder integrated care pathway digital transformation.

Measure	Digitization outcome	Impact
Physician adoption[a]	• Contributed to a 4-fold increase in-clinic physician adoption rate • Contributed to adoption by 20 physicians upon digitization compared with 5 physicians during the paper-based pilot implementation in the clinic	Increased capacity
Patient enrollment[a]	• Contributed to a 4-fold increase in total patient enrollment on average per month • After 6 months of digitization, an average of 49 patients enrolled monthly compared with 12 patients enrolled monthly during the paper-based pilot implementation	Increased capacity
Data entry time	• Elimination of paper transcription by support staff • Elimination of manual calculations	Increased workflow efficiency
Completeness	• Major reduction of missing values and incomplete assessment packages • Automatic date-stamping of all forms	Increased data quality
Standardization	• 3 new assessments submitted to the common data elements library for future deployment	Increased data quality



[a]Impact and outcome of clinic-wide major depressive disorder integrated care pathway implementation and digitization.

User Acceptance

All MDD-ICP clinical care providers were sent a 5-point Likert scale survey to assess their attitudes toward Clinical REDCap. A total of 18 responses were received, and Figure 5 shows the results of this survey.

Overall, respondents were satisfied with the system, with 94% (17/18) of respondents stating that they found Clinical REDCap useful in their job. Some apprehension was noted with ease of use, wherein 22% (4/18) to 33% (6/18) of respondents did not agree that the system was easy to use, that it allowed them to complete their work more quickly, or that they could complete a task without help. Despite these reservations, however, most respondents indicated that they planned to use the system within the next 3 months (use of the system is voluntary). From the free-text responses included in the survey, many respondents commented that electronic data capture presented major time savings compared with the previous paper-based entry method, especially in terms of the automatic calculation of scale scores. Conversely, many respondents noted that the interface could be more flexible and user-friendly with better tools for tracking patient trajectories.

Figure 5. Clinical REDCap user acceptance questions and responses. CAMH: Centre for Addiction and Mental Health; REDCap: Research Electronic Data Capture.

Discussion

Principal Findings

Ensuring sustained high-quality data collection is critical for supporting actionable MBC and clinical decision making. REDCap has proven to be highly valuable for deploying complex self-assessment workflows in diverse clinical environments. A governance model was established consistent with the HIMSS 7 designated processes that ensure regulatory compliance and integrity of the health record. System integration between REDCap and Cerner established real-time data flow for completed self-assessments.

Almost all clinical care provider users of Clinical REDCap indicated that they perceived the system to be useful; however, the survey revealed some concerns with the perceived ease of use of Clinical REDCap. These concerns are worth noting given

XSL•FO
RenderX

that a user's motivation to use technology is higher if the system is perceived as easy to use [17,18]. However, despite these concerns, all survey respondents indicated that they felt supported by the institution and that they had the resources available to use the system.

Efforts are underway to streamline workflows and improve integration and reporting. Currently, customized summary reports on questionnaire results are generated by Clinical REDCap and sent to physicians to review ahead of the patient's appointments for clinical decision making. This process has also had a positive impact on patient-physician communication and interaction during visits. However, the current presentation of self-report questionnaire results and EHR data focuses on point-of-care evaluation; the accessibility and presentation of complete treatment response trajectory over time would further enhance clinical decision support. To this end, enabling interactive data visualization methods (ie, dashboards) to convey knowledge about an individual's treatment trajectory would provide health care providers a tool for rapidly processing and interpreting the patient's chart and enhancing individualized clinical treatment decisions. Such a tool would free physicians from searching and filtering through the patient's chart, which can be challenging in a time-pressured clinical setting. Thus, both Clinical REDCap and EHR dashboards will be codeveloped with physicians using human-centered design methodology and embedded within the EHR to ensure streamline access during patient appointments. For the MDD-ICP, this dashboard will feature self-report measures trended over time along with corresponding treatment such as medication.

One of the core features of REDCap is the ability to send survey invitations via email, thereby allowing respondents to complete self-assessments at their convenience using their own devices. With the recent pandemic and temporary suspension of in-person clinic visits, the demand for such functionality (along with other virtual care solutions) has never been greater. An approach to this use case using Clinical REDCap may be configuring external access only to REDCap survey pages while prohibiting project backend access. This approach would allow off-site patients to complete their self-assessments while simultaneously protecting the project data and setup pages on the internal network. Although this strategy may precipitate novel privacy concerns surrounding the use of unsecured email (eg, sending to the wrong email address or guardians having access to their dependent's email account), this concern may be mitigated by using a patient verification PIN and other verification methods. Moreover, only blank self-assessment forms would be sent by email, and no sensitive health data or identifying information would be included. Consent language informing patients of these potential risks would be another key element in risk mitigation. A new process using this approach is currently being explored in several clinics that aim to send patients their self-assessment package 3 to 5 days before their appointment, followed by a reminder the day before. The self-assessment summary report can then be reviewed by the clinician or physician during a virtual appointment. It is anticipated that this new process will be able to leverage existing workflows and should not incur a significant increase in workload on the clinical staff compared with the original tablet-based approach.

The design of MBC pathways in Clinical REDCap will facilitate the rapid deployment of these pathways in other CAMH clinics. In addition, the scalable and extensible design of Clinical REDCap presents an opportunity for CAMH to partner with community sites to jointly implement MBC pathways in primary care settings. The use of assessments drawn from the common data elements library will enable standardized data collection practices consistent across the institution(s), thereby facilitating the accumulation of harmonized data that will allow clinicians and researchers to make meaningful comparisons over time and across otherwise independent clinical environments.

Conclusions

REDCap has been successfully deployed for the structured collection of standardized self-assessments to coordinate and accelerate the implementation of MBC in clinical practice. Systems integration was achieved between REDCap and Cerner to automatically transfer PDF and discrete variables from completed assessments into the patient's chart. This transfer maintained the integrity of the legal health record and enhanced clinician or physician decision-making ability. Thus, both a novel technical infrastructure and a comprehensive governance model aligned with institutional clinical committees were created to implement this new technology within the clinic. REDCap was demonstrated to be an effective tool for the implementation and expansion of MBC and ICPs by supporting an efficient and standardized process to deliver complex longitudinal bundles of assessments for the duration of a patient's treatment and by delivering real-time accessible information to health care providers to inform clinical decisions. This digitization process and integration has been designed to be extensible to other organizations practicing MBC in mental health and other disciplines.

Acknowledgments

This work was supported in part by the CAMH BrainHealth Databank, which is funded by the CAMH Discovery Fund. The work on the MDD-ICP was supported by the Max Bell Foundation and the University of Toronto Department of Psychiatry Academic Scholar Award. The authors would also like to thank the various clinical administrative staff members, clinical care providers, the clinical applications team, the enterprise data warehouse team, the information and privacy team, and the health records team for their work and feedback when designing and implementing this system.

Conflicts of Interest

None declared.

Abstract

Background: Information and communication technologies (ICTs) are becoming increasingly popular in supporting the fight against low physical activity (PA) levels among adolescents. However, several ICT solutions lack evidence-based content. Therefore, there is a need to identify important features that have the potential to efficiently and consistently support the PA of adolescents using ICT solutions.

Objective: This study aims to create evidence-based models of requirements for ICT solutions supporting PA by combining scientific evidence from literature and health experts. In addition, we test the suitability of agent-oriented goal models in this type of modeling process.

Methods: A literature search of PubMed, Web of Science, and Scopus databases was conducted to identify evidence-based functional, quality, and emotional goals that have previously been proven to be relevant in supporting PAs among youth using ICT solutions. The identified goals were presented in the form of goal models. These models were used to collaborate with health experts to receive their input on the topic and suggestions for improvement. The initial goal models were improved based on the feedback from the experts.

Results: The results indicated that agent-oriented goal modeling is a suitable method for merging information from the literature and experts. One strength of agent-oriented goal models is that they present emotional requirements together with quality and functional requirements. Another strength is the possibility of presenting results from a literature review in a systematic manner and using them thereafter in the communication process with stakeholders. Agent-oriented goal models that were created were easy to understand for health experts without previous experience in requirements engineering, which facilitates and supports collaboration with nontechnical stakeholders.

Conclusions: The proposed agent-oriented goal models effectively merged information from scientific literature and experts in the field and presented early functional, quality, and emotional requirements in a holistic and coherent manner. We believe that the created models have high potential to help requirements engineers and developers to provide more efficient ICT solutions that support PA among adolescents in the future.

Introduction

Background

Despite the numerous health benefits of physical activity (PA) on mental, social, and physical health [1-3], countries struggle with low levels of PA among children and adolescents [4]. According to data from 32 European and North American countries, only 23% of adolescent boys and 14% of girls meet the recommended daily PA levels [4], which is a minimum of 60 minutes of moderate- to vigorous-intensity PA every day [5]. According to the studies, PA declines during adolescence [6,7]. At the same time, many health-related behavior habits are established during adolescence that carry on to adulthood [8,9]. Therefore, adolescence is a sensitive period that can influence health behavior in later life, and greater attention should be paid to supporting the PA of adolescents [9].

Numerous interventions have been developed to support PA among children and adolescents, with most of them being conducted in a school setting [10], where it is easy to reach all children despite their age or socioeconomic background. In recent years, interventions using a variety of technological solutions have emerged, which can be explained by the high level of technology use among children and adolescents as well as by the vast possibilities of information and communication technologies (ICTs) that enable more individualized behavior change interventions [10]. It is also important that through ICT solutions, it is possible to provide health information to people who would otherwise not have access to health education resources [11]. According to adolescents themselves, supporting PA by using technology makes PA more appealing and helps to increase their awareness of the actual activity levels [12]. Previous ICT interventions have shown promising results [10,13-20], irrespective of the technological mechanisms used to deliver or support the delivery of an intervention. Some examples of the mechanisms used are the internet [14,15,21], text messaging, email [19-21], and phone apps [22]. However, the development process of ICT solutions supporting PA includes several challenges, which is highlighted by the fact that not all ICT interventions have been proven to be effective or successful [22,23]. It has been pointed out that a stronger collaboration between scientists and technologists who develop the solutions is needed [22,24,25], as ICT interventions are more likely to be successful when combined with theory, such as behavior change theory [15,21]. Collaboration with health experts and scientists during the problem identification and requirements engineering phase helps to elicit evidence-based functional, quality, and emotional requirements for ICT-based intervention solutions that have the potential to support the behavioral change of the target group. Such collaboration with scientists and experts would also increase the quality of information, and according to a review, several apps lack evidence-based content and focus mainly on functionality, aesthetics, and engagement [22].

In addition to functional requirements, the quality and emotional side of the software application must also be considered because the adaptation of the application depends on the emotions of the user [26]. The lack of user-friendliness and being unappealing to the target group has been marked as a significant cause of dropout and low levels of involvement in previous interventions [23,27]. Therefore, it is crucial that the development process includes both end users [27] as well as different stakeholders, health experts, and scientists, which ensures that the end product will have an expected impact on the end users [25,28-30]. The method used to involve different stakeholders must be easy to comprehend, as stakeholders often lack previous experience in requirements engineering. At the same time, it should capture as many functional, quality, and emotional requirements that constitute an important input for requirements engineers and developers.

Agent-Oriented Goal Modeling

One method for presenting emotional requirements for sociotechnical systems (STSs) is agent-oriented goal modeling [29-32]. STS is a software-intensive system that has defined operational processes followed by human operators and operates within an organization and comprises both social and technical aspects [33]. The STS consists of humans, software, and hardware [34]. According to the preceding definitions, ICT solutions supporting PA among adolescents fit into the category of STSs. Agent-oriented goal modeling [31,32,35] is a state-of-the-art method for eliciting and representing the requirements of STSs. In this method, the starting point is something to be achieved or done, whereas it is not yet important *who* or *what* does it. A distinct feature of motivational modeling is its explicit support for eliciting and representing emotional requirements [30,36]. The method enables the representation of functional, quality (nonfunctional), and emotional requirements for STSs in a holistic manner as a hierarchical goal tree, consisting of functional, quality, and emotional goals [30-32,35,36]. Agent-oriented goal modeling has been applied previously in several studies, which have shown that this approach is suitable and comfortable for including both technical and nontechnical stakeholders [30,31,36-38]. Moreover, this approach supports communication with nontechnical experts and other stakeholders whose input is required for the design process. Agent-oriented goal models provide a thorough description of possible solutions for the problem in question. The created models are not final technical requirements but rather offer an overall picture of the necessary elements and features that should be considered during the development process. On the basis of the agent-oriented goal models, requirements engineers can form more concrete requirements in the form of, for example, user stories [39], which can then be used in the further development process. Often, the creation of goal models includes a workshop or focus group with stakeholders to identify functional, quality, and emotional goals and the roles required for the attainment of the goals [30-32,36], which is followed by creating goal models based on the information gathered. However, in the current situation caused by the spread of COVID-19, the possibilities for face-to-face workshops have become limited, and alternative solutions have to be considered. In addition to expert opinions, more scientific evidence is emerging with regard to the features and factors that increase the effectiveness of ICT solutions supporting PA, which should also be considered in goal models.

XSL•FO
RenderX

Objective

The main aim of our study is to create evidence-based models for ICT solutions supporting PA by combining scientific evidence from the literature and opinions of health experts. For this purpose, we also aim to pilot the use of agent-oriented goal modeling in the process of communicating the results of the literature review and involving experts with nontechnical backgrounds. Interestingly, we have previously used a similar approach in problem domains where arranging co-design workshops would be complicated, impossible, or even dangerous [37,38].

Methods

Overview

Previous studies using agent-oriented goal models have often gathered their input for goal models only from stakeholders through interviews or workshops [30,32,35,36]. For the topic under discussion, there is some scientific evidence on the features that have the potential to increase the effectiveness of ICT solutions supporting PA among adolescents and reduce dropout. Therefore, to combine the findings from previous ICT intervention studies with information from experts, this study was designed in the following steps:

- Identification of evidence-based features of ICT solutions that have the potential to support the behavioral change and PA of adolescents based on a literature review
- Development of initial goal models
- Inclusion of experts, model validation, and improvement

Literature Review

First, we identified from the scientific literature evidence-based features of ICT solutions that have the potential to support the behavioral change and PA of adolescents. For this purpose, we searched for articles in the PubMed, Web of Science, and Scopus databases. Separate searches for three topics were conducted for each database. The topics and keywords used are listed in Textbox 1. The first search focused on reviews that covered ICT-based interventions with adolescents. The results of the first search indicated that behavior change techniques (BCTs) have the potential to positively influence the behavior of the target audience [15,21]. Considering this, the following search focused on identifying the most prevalent and effective BCTs used in ICT solutions aimed at adolescents. To gain more thorough insight into the needs and preferences of adolescents concerning ICT solutions and PA, the third search focused on qualitative studies. The reference list of each identified article was also searched for relevant reviews and studies.

The reviews that addressed ICT-based interventions with adolescents included different study methodologies, such as randomized controlled trials, quasi-experimental studies, and feasibility studies [14,15,17-21,24,40-43], providing a good overview of the features that have the potential to support PA levels. Information about BCTs was mostly elicited from studies or reviews describing ICT solutions using BCTs [22,25,44-46]. Finally, qualitative studies helped to identify possible facilitators and barriers perceived by the adolescents themselves [7,12,23,47-58].

Textbox 1. Search topics and keywords.

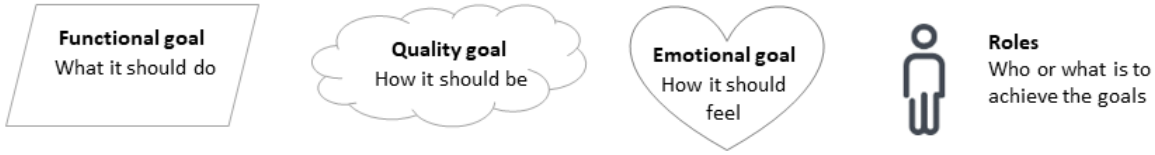
Search: reviews covering information and communication technology–based interventions with adolescents

- "(adolesc*[Title/Abstract]) AND (review[Title/Abstract]) AND ('physical activity'[Title/Abstract]) AND ((technology[Title/Abstract]) OR (web[Title/Abstract]) OR (E-Health[Title/Abstract]) OR (eHealth[Title/Abstract]) OR (mHealth[Title/Abstract]) OR (app*[Title/Abstract]))"

Search: behavior change techniques used in information and communication technology solutions aimed at adolescents

- "((adolesc*[Title/Abstract]) OR (young [Title/Abstract])) AND ('physical activity'[Title/Abstract]) AND ('behaviour change'[Title/Abstract])"

Search: qualitative studies to identify factors valued by adolescent users



- "('physical activity'[Title/Abstract]) AND ((qualitative[Title/Abstract]) OR ('focus group'[Title/Abstract])) AND ((app*[Title/Abstract]) OR (mHealth[Title/Abstract]) OR (eHealth[Title/Abstract])) AND (adolesc*[Title/Abstract])"

Development of Initial Goal Models

The data gathered from the literature were used to create the initial version of goal models, which included three types of goals: *do*, *be*, and *feel* goals. *Do* goal is a functional goal that indicates what the system should do. *Be* goals or quality goals present the nonfunctional requirements of the system, which describe the quality aspects of the system—how the system should be. *Feel* goals are emotional goals that describe how the user should feel when interacting with the system. In addition, *roles* are identified, which represent who is responsible for the attainment of which goals. This information is eventually presented as a simple graph in which the functional goals are rendered in a tree-like hierarchy. In the hierarchical goal model, each subgoal represents a particular aspect of achieving its parent goal. The functional goals are represented with tilted rectangles, whereas roles, quality, and emotional goals are attached to the appropriate functional goals and are represented by stick man icons, clouds, and heart symbols, respectively (Figure 1). Therefore, it is important that roles, quality, and emotional goals attached to the given functional goal apply to that goal and to all of the functional goals located below it in the goal tree. The described method enables the representation of functional, quality (nonfunctional), and emotional requirements for an STS in a holistic manner [30-32,35,36].

XSL•FO
RenderX

Figure 1. Notation for goal modeling.

The initial functional, quality, and emotional goals identified in the literature are presented in Textbox 2.

The features identified from the literature were combined into a hierarchical goal model, with *move* as the highest-level goal—purpose of the ICT solution—and *report background info*, *set goals*, *monitor activity*, *receive feedback*, and *increase awareness* as first-level functional goals. These first-level functional goals were elaborated into lower-level functional goals and attached to their quality and emotional goals. The initial goal model derived from the literature review was presented to the experts, who elicited additional functional, quality, and emotional goals. In the final goal models, the functional, quality, and emotional goals identified from the literature are marked with an asterisk (*), and those elicited by the experts are marked with a number sign (#).

The goal models can be further elaborated into the format of user stories [39], which is one of the most prevalent ways of representing requirements in agile software engineering [73,74]. We made use of the following format of user stories, which has been adapted from Cohn [73]: “As a [user performing a certain role], I need [to perform action] to support [achieving a certain goal]”. We will introduce an example of elaborating goal models into user stories in the *Elaboration to User Stories* subsection.

Textbox 2. Initial goals identified from the literature.

Functional goals

1. Report background information [20,40,44,59-61]
2. Set goals [21,24,42,45,52-54,60,62]
3. Monitor activity [21,24,42,45,62]
4. Receive feedback [21,24,42,45,51,54,62]
5. Participate in challenges [44,46,53,63]
6. Increase awareness [54,60,64,65]
7. Select challenge [12,47,50,66]
8. Create groups [15,48,63,67-69]
9. Invite friends [15,48,64,67-69]
10. View results [55,60]
11. View comparison with others [46,55,56,60,64]
12. Show health benefits [22,55]
13. Receive activity suggestions [22,55]
14. Receive links to materials [22,55]
15. Help to interpret the data [52,64]

Quality goals

1. Actively [5]
2. Regularly [5]
3. Personal [21,45,46,51,52,60]
4. Achievable [12,47,50,53,66]
5. Challenging [12,47,50,66]
6. Scientific [18,20,22,54,60]
7. Supportive [22]
8. Attractive [43,46,54,60,69]
9. Easy-to-use [43,46,54,60,69]
10. Automatic [43,46,54,60,69]

Emotional goals

1. Enjoyment [47,49,50,53,70-72]
2. Fun [47,49,50,66,70-72]
3. Involved [44,46]
4. Feel achievement [53,66]
5. Engaged [44,46,53,56,64]
6. Thrilled [53]
7. Be aware [18,20,22,54,60,64,65]

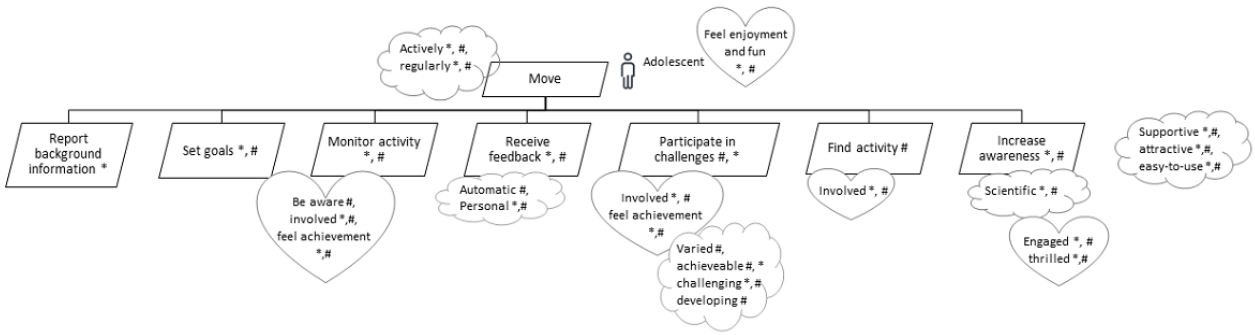
Inclusion of Experts, Model Validation, and Improvement

The initial goal models were validated by the experts. Although previous studies with goal models have used workshops or focus groups to gather input from stakeholders [30,32,36], due to the COVID-19 situation, in this study, one-on-one interviews in the outdoors and web-based meetings were used instead. We consulted sports scientists and physical education experts (n=5) to identify the features of ICT-based interventions that can support the PA of adolescents. Some of the included experts had previous experience in the development and implementation of PA interventions in a school setting; therefore, they could highlight several aspects and experiences from the field. All the included experts were also parents, which enabled them to reflect the expectations of parents. The initial goal models were

XSL•FO
RenderX

sent to the experts before the interviews, together with an explanation of the notations and the aim of the models. These aspects were repeated by the interviewer at the beginning of each interview. Thereafter, the interviewees' thoughts about the goal models rooted in the literature and their possible improvements were obtained. All suggestions provided by the experts were documented by the interviewer in written form. In addition, feedback concerning the clarity, usability, and comprehensiveness of the agent-oriented goal models was provided. All interviews were conducted by the same researcher.

The final versions of the goal models resulting from both the literature review and the interviews with the experts are presented and explained in the *Results* section. Goals in goal models include markings that distinguish between the ideas originating in the literature and the ideas proposed by the experts. As both the ideas appearing in the literature and the ideas proposed by the experts reached a detailed level, the resulting goal models also cover the functionalities of ICT solutions that are usually represented as detailed requirements in the form of user stories [39]. In the goal models presented in the *Results* section, such functionalities are distinguished with a different color of rectangles denoting functional goals. For completeness, in the *Participate in Challenges* subsection, we also present user stories.



Results

Overview

The outcomes of the literature review, complemented according to the opinions expressed by the experts, were represented by the goal model shown in Figure 2. The highest-level goal expressed by the goal model is that adolescents should move or, in other words, be engaged in PA. In terms of health benefits, PA should be performed actively and regularly because according to the recommendations for PA [5], adolescents should acquire every day a minimum of 60 minutes of moderate-to vigorous-intensity PA. This is reflected by the *actively* and *regularly* quality goals associated with the main goal. We also attached the emotional goals *feeling enjoyment* and *feeling fun* to the main goal, as there is an abundance of evidence that enjoyment and fun contribute to increased PA among children and youth [47,49,50,70-72]. The highest-level goal was elaborated into seven subgoals, each representing a particular aspect of achieving the highest-level goal, together with the associated quality and emotional goals.

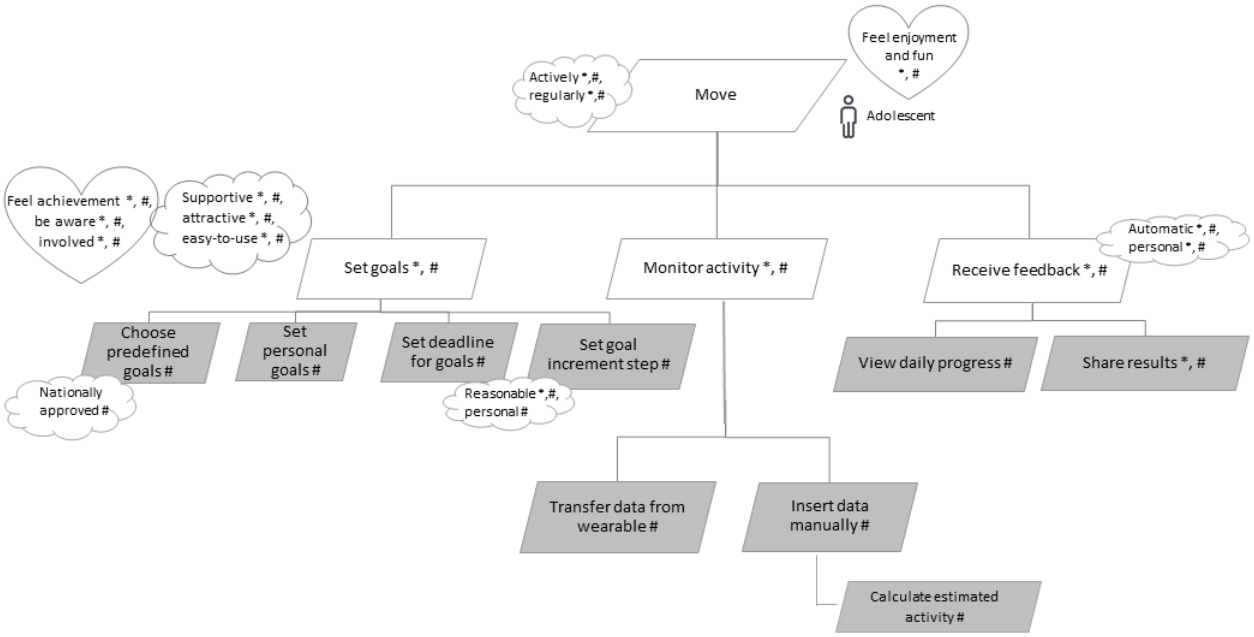
In the following five subsections, we will explain the seven second-level functional goals represented in Figure 2 and their subgoals along with the quality and emotional goals pertaining to the functional goals.

Figure 2. Overall goal model for information and communication technology solutions supporting physical activity levels of adolescents. The "*" in the model represents findings from the literature; the "#" represents suggestions by experts.

Report Background Information

The first activity when starting to use an ICT solution should be providing background information to offer personalized experience based on the adolescent's personal objectives, previous PA experience, age, or gender. Using information provided by the adolescent allows the provision of messages that are more relevant to the recipient, thereby reducing information overload and supporting long-term engagement [44,59-61], while receiving personalized encouraging messages increases the effectiveness of the intervention [20,40]. A qualitative study with students confirmed that tailored information is preferred by young users [60]. Having sufficient background information can be applied for nudging [75] and directing users to healthier choices.

Set Goals, Monitor Activity, and Receive Feedback



The inclusion of BCTs in ICT solutions for supporting PA has been emphasized by several authors, as they seem to have a significant impact on the effectiveness of the solution [15,21,22,40,41,45]. However, there is no consensus on the optimal number of BCTs that should be included in an effective ICT solution. It has been pointed out that the inclusion of multiple BCTs increases the attractiveness and effectiveness of the app [22,76]. At the same time, some reviews with adults indicate that too many BCTs can have a negative impact on effectiveness [62,77]. On average, six BCTs have been included in the apps aimed at children and adolescents [22], with the most popular BCTs being *provide instructions*, *provide general encouragement*, *provide contingent rewards* [22], *prompt specific goal setting*, *prompt self-monitoring of behavior*, and *provide feedback on performance* [21,45]. The importance of setting goals, monitoring activity, and receiving feedback was also highlighted by the experts involved in the modeling. Adding these three BCTs to the ICT-based solution can have a positive impact on the effectiveness of the solution [24,42,62]. The experts also pointed out that the inclusion of the functionalities *set goals*, *monitor activity*, and *provide feedback on performance*

XSL•FO
RenderX

makes it possible to incorporate the ICT solution into teaching activities at school (eg, physical education and health education lessons), which would have multiple advantages. For example, in addition to helping students gain knowledge about their actual activity levels, incorporating the solution into in-school or in-curricula activities has the potential to increase its effectiveness [14,21] and ensure that less-motivated students also use the solution [15].

On the basis of the literature review and feedback from the experts, we added *set goals*, *monitor activity*, and *receive feedback* as the second-level functional goals. The emotional goals associated with these functional goals are *be aware*, *feel achievement*, and *involved*. The second-level functional goals are elaborated into sublevel functional goals, as shown in Figure 3.

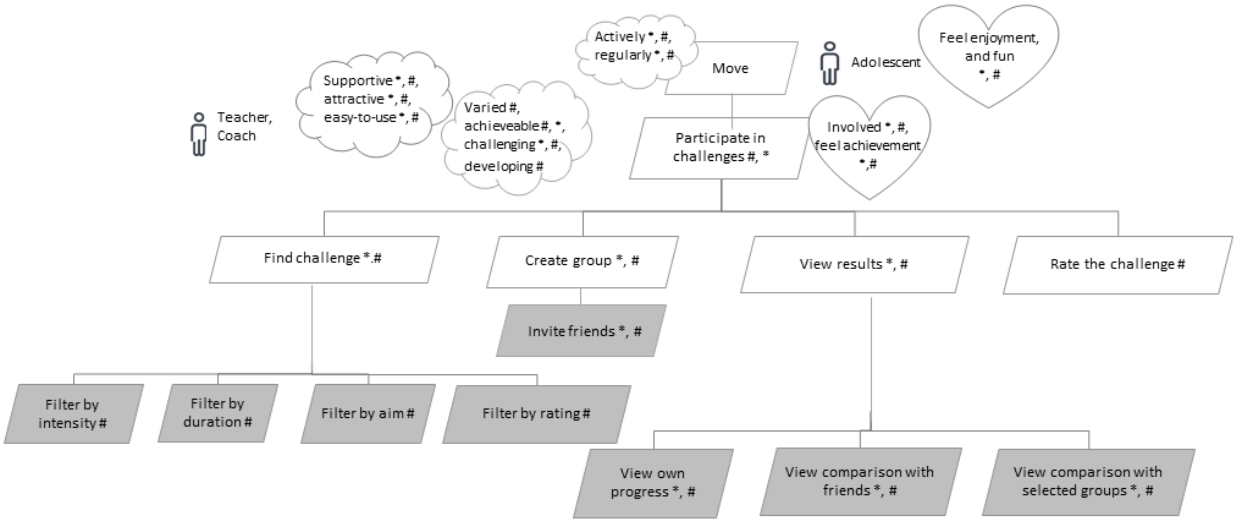
Figure 3. Sublevel models for the functional goals "set goals," "monitor activity," and "receive feedback." The "*" in the model represents findings from the literature; the "#" represents suggestions by experts; gray rectangles represent functionalities at the level of user stories.

For the second-level functional goal, *set goals*, shown in Figure 3, we identified that it should be possible to select from among predefined goals that are based on national and international PA recommendations as well as define one's own goals. The benefit of defining personalized goals is that such goals match the user's abilities and daily routines [46,51,52,60] and offer a sense of enjoyment from achieving one's own goals [53]. Personalized goals are especially useful when goals based on national or international PA recommendations seem to be too demanding and, because of this, constantly failing to reach them would be demotivating. It is important that the goals that have been set are achievable because perceived competencies are associated with the feeling of fun [66], which, in turn, supports the continuous usage of the ICT solution and behavior change. Therefore, defining one's goals that seem realistic and achievable supports the self-efficacy, autonomy, and motivation of adolescents. The importance of providing goal setting functionality was also highlighted by students and adolescents [52-54,60]. The experts pointed out that the possibility of setting goals enables the solution to be incorporated more easily into a school setting and use it in physical education lessons. As achievement goals should be accompanied by deadlines and sometimes it is beneficial to set subgoals with reasonable increment steps, we believe that such functionalities should be included in ICT solutions.

Goal setting functionality is strongly associated with the self-monitoring functionality to evaluate compliance with the goals that have been set. In Figure 3, this functionality is represented by the *monitor activity's* second-level functional goal. On the basis of the literature, self-monitoring seems to be a functionality that is crucial in ICT solutions aimed at supporting PA levels [24,42,54,60,62]. Young users value self-monitoring as it helps to increase their awareness of the actual PA levels and review their progress over time [54,60,64,65], which, in turn, has been associated with increased PA levels [43,64,78]. There are many ways to measure one's PA by, for example, using subjective ratings and questionnaires or objective data from pedometers, accelerometers, or heart rate monitors. The strength of transferring data from wearable trackers is to provide objective PA information that is more accurate compared with the information obtained by means of questionnaires and more comfortable gathering. The ICT solution should connect with wearables from different manufacturers and convert the data into an easily understandable format. However, activity trackers might underestimate some activities (eg, skiing and cycling), or it can be impossible to wear them during activities such as swimming and wrestling. In addition, users sometimes forget to wear the tracker or forget to start tracking at the beginning of the workout [55]. Therefore, it is possible to manually enter training or activity data into the ICT solution.

The third second-level functional goal shown in Figure 3—*receive feedback*—is tightly associated with goal setting and monitoring PA to evaluate performed activities and plan

XSL•FO
RenderX



future ones. Providing feedback is a necessary feature pointed out by young app users [51,54], and one way to increase engagement with the solution [44] is to enhance the user's motivation and self-efficacy [46]. Knowing that healthy PA levels have been reached increase the feeling of being healthy among adolescents [52]. However, the way feedback is given should be carefully planned and targeted so that it would not bring about negative emotions, such as guilt and disappointment [60], which can discourage and cause dropout.

Sharing results was also added to the model as one of the functional goals because sharing can increase the motivation of adolescents by receiving social support. Sharing also increases the feelings of belonging [46,56,64] and contributes positively to the effectiveness of the solution [40]. According to the experts involved in the modeling process, sharing can widen the usage of an ICT solution because it can be incorporated into physical education lessons by sharing the activity goals and results with teachers. In such a case, the physical education teacher can also serve as the provider of tailored feedback, thereby increasing the motivation of the students to be physically active. However, this possibility should be prevalidated with adolescents, as it might be perceived by them as a controlling mechanism resulting in a loss of autonomy, which can, in turn, cause resistance to using the ICT solution by adolescents [52].

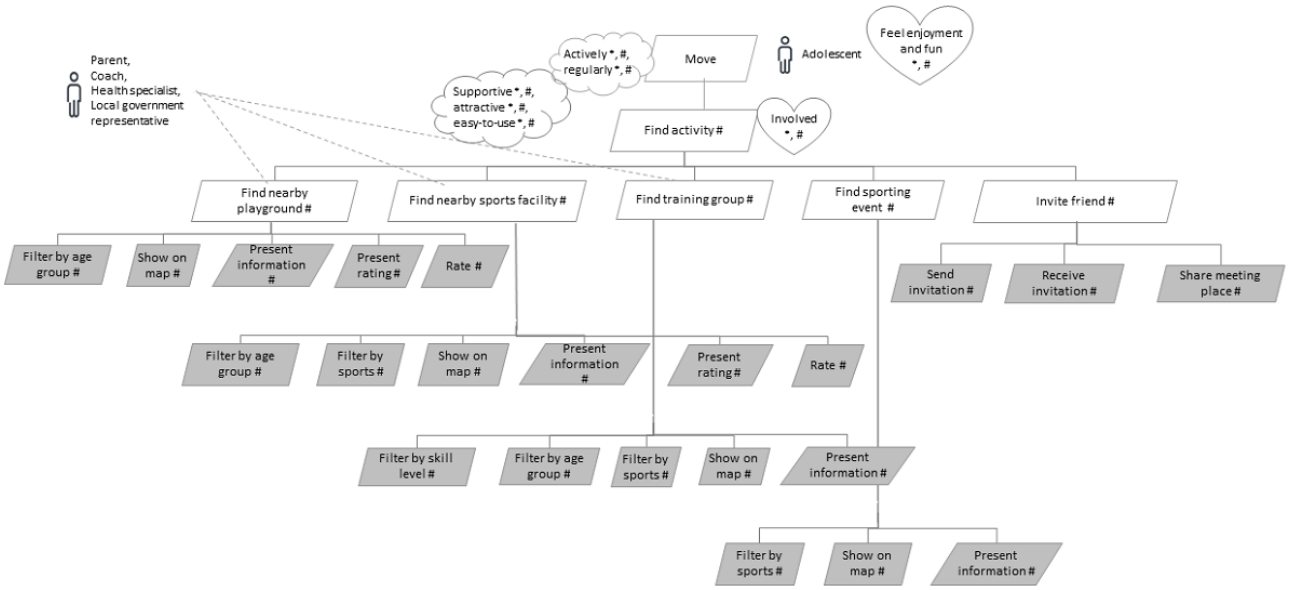
Participate in Challenges

Challenges and competitions have been found to be the elements of game design that can increase engagement and reduce dropout [44,53]. In addition, participating in challenges and competitions increased the PA of the participants [46,63]. At the same time, not all people are interested in participating in challenges and competitions [12,40,46,52,53]. The studies indicate that participation in challenges is associated with PA and self-efficacy levels, as those with higher activity levels are more prone to participate in challenges [46]. It has been pointed out that competitors should have similar precompetition activity levels so that the competition effect would not drop [63] as a constant feeling of failure and no hope of winning reduces the motivation of participants [52,53]. Therefore, in addition to finding challenges, it should be possible to create groups of participants with similar PA levels or skills. This is reflected in the goal model shown in Figure 4. In addition, the ICT solution should include a variety of challenges for adolescents with different PA levels, interests, and skills, which make the participants feel competent [12,47,50,66] and would support their feeling of autonomy [50]. Moreover, the challenges have to be versatile, as similar challenges become boring for adolescents [53].

Figure 4. Sublevel models for the functional goal "participate in challenges." The "*" in the model represents findings from the literature; the "#" represents suggestions by experts; gray rectangles represent functionalities at the level of user stories.

As challenges that extensively prioritize only successful performance can create subgroups of nonparticipants [56], it was suggested by the experts that the challenges should involve different kinds of targets. For example, in addition to finding the most active participants, an achievable daily threshold of a goal set by the adolescent should also be established with the aim of reaching it on all or most of the days comprised by the challenge. This approach would provide the participants with the possibility to feel a sense of achievement, increase self-efficacy, and retain anticipation to reach the goal. This also complies with the views expressed by the adolescents that not only excelling in particular sports but also merit of effort should be awarded or noticed [12]. Moreover, focusing on achieving healthy daily PA levels instead of maximum performance helps to avoid extreme PA behaviors that have been reported by some adolescents as a result of participating in PA challenges [52].

Participating in challenges is a social activity that involves interactions with other participants. The evidence suggests that participation in the challenges might be more effective when friends are engaged because there is an abundance of evidence that both the motivation to be active and actual PA levels are increased when friends are involved [15,48,67-69]. Moreover, it is more fun to be physically active together with friends [47], and peer involvement has been previously identified as a feature



XSL•FO
RenderX

that adolescents like and use in ICT solutions [64]. Therefore, one should be able to invite a group of friends with whom to participate in the challenge. This is reflected by the corresponding fourth-level functional goal, *Invite friends*, shown in Figure 4. Another way of interaction during the challenge is to share information with coparticipants or a selected group of people. This is represented in Figure 4 by the third-level functional goals *view results* and *rate the challenge*. On the basis of the literature review, sharing PA information with familiar people supports PA levels, whereas sharing with strangers seems to be ineffective [46]. There are mixed feelings about comparing the results of meeting the challenge, similar to the case of participating in challenges. Some users of ICT solutions have found sharing demotivating when a comparison is made with more active people, and they rather prefer to compare themselves with lower performers to obtain assurance and confidence [55,60], whereas others find the comparison with more active people motivating [55]. According to the suggestions of the experts, we also complemented the goal model shown in Figure 4 with the roles *teacher* and *coach*, so that performers of these roles could incorporate suitable challenges into their teaching activities and would be able to view the outcomes.

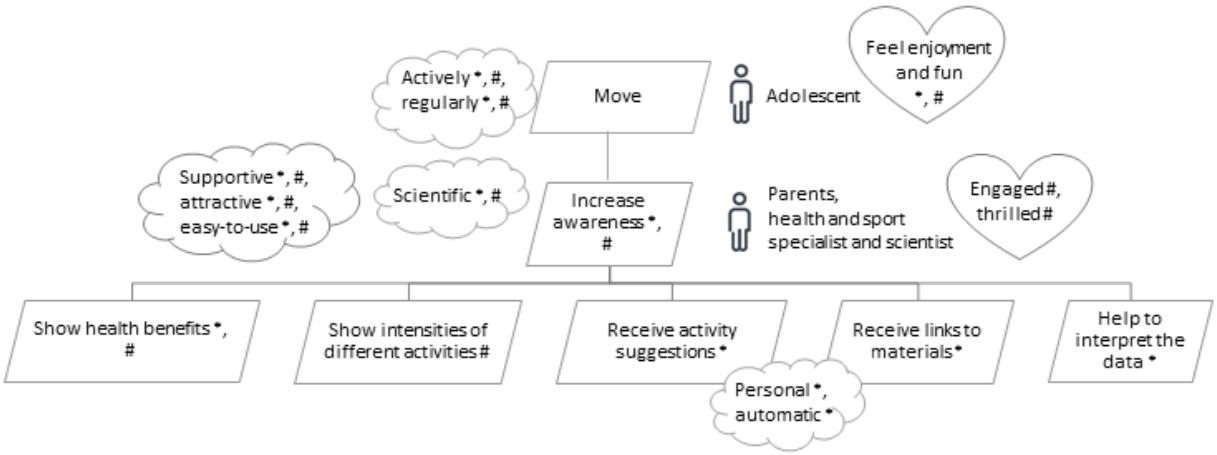
Find Activity

According to a socioecological model [79], one's PA is also influenced by the built environment. To increase the awareness of PA opportunities available in the neighborhood, we have added, based on the literature, the functional goals *find nearby playground*, *find nearby sports facility*, *find training group*, and *find sporting event*. These functional goals along with their subgoals are presented in Figure 5. Although university students considered the feature of providing information about facilities and possibilities provided by the environment as unimportant [55], the experts involved in our study suggested that compiling a comprehensive overview of the PA opportunities in the neighborhood can support PA because free and easily accessible sports and activities are more appealing to adolescents [12]. By means of this feature, adolescents can also find places to practice nonorganized and lifestyle sports activities, such as workouts, slackline, parkour, or skateboarding, which are becoming increasingly popular among youth [80]. At the same time, this type of feature can be beneficial for different stakeholders. For example, among those who can benefit from such features are parents who want to be active with their children, teachers and coaches who want to find training places, coaches who want to be visible to their target group, and experts in public health who would like to introduce different PAs to inactive adolescents. In addition, representatives of the local government can also benefit from these features, as the ICT solution can help to identify the existing opportunities for PA and plan additional developments, considering that both proximity and accessibility of facilities affect participation in PA [47,57,66]. In addition, the presence of green spaces has the potential to increase the PA of children [81]. Therefore, the *find activity* feature would help the local government to apply nudging [75] by making healthy choices more accessible to the target group. Providing a neighborhood with opportunities for PA also reduces children's dependence on their parents, which has been identified as one of the factors hindering adolescents from participating in sports [12].

Figure 5. Sublevel models for functional goal "find activity." The "*" in the model represents findings from the literature; the "#" represents suggestions by experts; gray rectangles represent functionalities at the level of user stories.

It should be kept in mind that the preferences of adolescents vary greatly—some prefer competitive and some others prefer noncompetitive activities, and some prefer team sports and some others prefer individual sports [12,47,58]. Moreover, nonorganized and lifestyle sports activities are gaining popularity among youth [80]. To support the PA of all adolescents, different types of sports with different levels of competitiveness should be offered, as providing a choice can increase the motivation and willingness to participate [50,56]. According to the qualitative studies, adolescents value activities that are diverse, challenging, social, and support their autonomy [50] and offer the possibility to try new activities [12,82].

XSL•FO
RenderX



Adolescents should be able to distinguish between training groups based on their expected level of skills (eg, beginners, advanced, or high level) because joining a training group with more skilled participants lowers self-efficacy, reduces motivation, and increases the odds of dropout.

Increase Awareness

Current apps aimed at youth lack health content and concrete recommendations [22,25], and only a few apps are aligned with PA recommendations [22]. The need for evidence-based content has been emphasized both by researchers [18,20,22] as well as by users of ICT solutions [54,60]. Therefore, one focus of an ICT solution should be presenting the benefits of PA. This need is reflected by the functional goal *increase awareness* and its subgoals, along with the relevant quality and emotional goals, as shown in Figure 6. This should not only include the benefits for physical health but also the benefits for social and mental health and academic achievements [1], which are less known to the wider public according to the experts who were involved in the goal modeling process of our study. In addition, developing positive attitudes toward PA and informing stakeholders on possible health gains can increase adherence to ICT solutions [24,61]. Students also reported that they would like to receive tips on how to reach their achievement goals, make activities more fun, exercise safely, and get recommendations on when it is best to exercise [55].

The feature of increasing awareness should also include providing advice on the interpretation of the collected data, as adolescents tended to neglect the information about their PA behaviors that they did not understand [52]. Providing support for data interpretation, especially at the outset of using the ICT solution, may be of critical importance to encourage adolescents to continue using the solution [64].

Figure 6. Sublevel models for the functional goal "increase awareness." The "*" in the model represents findings from the literature; the "#" represents suggestions by experts.

Other Associated Aspects

To strengthen the effect of ICT solutions, attention should be paid to the user experience and the usefulness of the information provided, as both have been demonstrated to strengthen the effect of the solution [46,69,83]. The need for a positive user experience through a simple and well-ordered design that is pleasant to use has also been highlighted by the users involved in previous studies [43,46,54,60,69].

The opinions of adolescents concerning different gamification elements are contradictory, as some studies with adolescents have found rewarding to be an irrelevant feature [64], whereas some other studies emphasize the importance of rewards [58]. It has been suggested that different gamification elements such as avatars and rewards to achieve a goal or meet a challenge increase the attractiveness of and engagement with an ICT solution and reduce dropout [44,53]. It has also been pointed out that rewards have the potential to foster motivation and increase self-efficacy [46]. However, the logic behind receiving award points must be clear to the participants [55,69], and the reward system should be carefully planned so that it would support intrinsic motivations because intrinsically motivated behaviors are derived from enjoyment and interest by the performer [64,84]. This, in turn, supports long-term behavior changes [85]. Adolescents have pointed out that it is not just the goal achievement that should be rewarded but also the improvements and progress toward goal achievement [58].

It is widely accepted that the learning process should support the autonomy of a child, as it affects the achievement and motivation of the child [84,86]. The goal models proposed by us include elements of support for all three categories of autonomy: organizational, procedural, and cognitive. Support for organizational autonomy involves students in decision making on management issues [84], which in our goal models is expressed by the possibilities to choose group members for challenges or set dates for achievement goals. Support for procedural autonomy enables one to choose their own way of finding a solution [84], which is in our model addressed by, for example, providing information about different PA opportunities and challenges that the adolescent can choose from to achieve their goals. Support for cognitive autonomy encourages student ownership of the learning process and is considered the most important type of autonomy to be supported in the learning process [84]. Some examples of the features supporting cognitive autonomy included by our goal models are providing

XSL•FO
RenderX

feedback, enabling the formulation of personal goals, and providing means to reach one's goals independently.

Elaboration to User Stories

In this subsection, we describe how goal models can be further elaborated to more detailed technical requirements for an ICT solution in the form of user stories [39], which is one of the most prevalent ways of representing requirements in agile software engineering [73,74]. Table 1 presents user stories associated with the submodel *Participate in challenges* shown in Figure 4, following the user story format adapted from Cohn [73], as follows: "As a [user performing a certain role], I need [to perform action] to support [achieving a certain goal]".

Feedback From Experts

The experts considered an agent-oriented goal model to be an effective representation artifact to present the features that support the PA of adolescents and facilitate an understanding of the problem domain. The models created in our study also proved to be effective communication tools because expressing the existing scientific evidence by means of clear and simple goal models, together with just short explanations, helped the experts to understand the ideas expressed by the models and focus on analyzing and enhancing them. The created goal models provide a good overview of the necessary features of ICT solutions. The experts pointed out that although the notation of the models was easy to understand, to fully understand the presented ideas, additional information provided by the researcher was useful. It was also highlighted that the goal models created in the process could serve as input for developing ICT-based interventions because goal models presented all important and evidence-based factors in a holistic and systematic way. This would make the agent-oriented goal modeling an easily usable method for selecting and planning further intervention activities.

Discussion

Principal Findings

This study proposes a novel approach to create agent-oriented goal models by combining a literature review and qualitative information from experts. According to our experience, this approach is a promising and feasible method for identifying the functional, quality, and emotional goals of ICT solutions for supporting PA in adolescents. The literature review conducted by us as the first step enabled the collection of existing scientific evidence and expressed it through holistic goal models capable of representing functional, quality, and emotional aspects and relationships between them. The resulting goal models helped to obtain and present an overview of the existing problems and possible solutions and easily communicate them to nontechnical experts. As a result, the experts could focus on the aspects that were missing from the models, and they did not have to spend time or effort to point out the existing theories or previously identified possibly effective features. Such an approach also saved experts a lot of time, which is an important aspect considering the need to retain fruitful cooperation with experts and therefore cannot be underestimated. As most of the experts involved had previous experience in implementing PA interventions in a school setting or practical work experience from school, they could focus on adding valuable knowledge

XSL•FO
RenderX

from the field and pointing out aspects that have a high potential to support the usability and effectiveness of ICT solutions in the target group. Examples and experiences from real life provided by experts constitute invaluable information to better understand the existing problems and possible solutions.

Several goals included by the goal models emerging from the study indicate that ICT solutions aimed at supporting PA can benefit greatly from applying machine learning methods. For example, machine learning methods can contribute to a better user experience by providing tailored advice and information. Moreover, well-timed support by the ICT solution can reduce the odds of exercise relapse or dropout [87]. In addition, machine learning algorithms can help to adjust personalized goals [87] or form adaptive goals that, according to randomized controlled trials with adults [88,89], are more effective than static goals. Therefore, future ICT developments should consider applying different machine learning methods to support the PA of users.

In this study, we preferred to conduct one-on-one interviews with experts instead of workshops or focus groups, which were often used in previous studies to identify the functional, quality, and emotional goals to be represented by goal models [30,32]. The main reason for this decision was the COVID-19 situation, which has set restrictions on physical indoor meetings in larger groups. Therefore, the interviews were conducted on the web or outdoors, where the risk of infection was lower. Such an approach certainly has its advantages and disadvantages. During one-on-one interviews, the experts were able to freely express their opinions and ideas without being interrupted, having additional discussions, or experiencing the need to further justify the ideas presented by them. In addition, the situation created by COVID-19 enabled us to refrain from *reinventing the wheel*, as the starting point of the discussions consisted of goal models created by the researcher based on a thorough literature review. On the other hand, workshops support the cocreation process in which an idea or example by one stakeholder can be developed further by the other stakeholders. The research conducted by us was a pilot study, and further studies should validate our findings and improve the goal models with a wider range of stakeholders, such as parents; coaches; and naturally, the main target group—adolescents. However, we believe that the models included in this study lay a strong foundation for further development.

Conclusions

This paper presents the first attempt to create agent-oriented goal models of ICT solutions that support the PA of adolescents by combining evidence-based information and the opinions of experts and practitioners. The desired ICT solutions have the potential to contribute to the fight against low PA levels among adolescents by including in ICT solutions the features supported by the evidence. The strength of the proposed model is, in addition to including information from the scientific literature and experts in the field, a holistic and coherent presentation of early functional, quality, and emotional requirements. Our approach seems to be efficient in communicating the results of literature reviews to experts and supporting collaboration with nontechnical stakeholders. We believe that the created models have a high potential to help requirements engineers and developers to provide more efficient ICT solutions in the future.

Acknowledgments

The authors would like to thank all the experts who provided invaluable input to the models. This research was supported by the *Pilots for Healthy and Active Ageing* (Pharaon) project (1.12.2019-30.11.2023) funded by the European Union's Horizon 2020 research and innovation program under grant 857188.

Abstract

Background: The evidence base for internet-based cognitive behavioral therapy for insomnia (iCBT-I) is firm; however, little is known about iCBT-I's health-economic effects.

Objective: This study aimed to evaluate the cost-effectiveness and cost–utility of iCBT-I in reducing insomnia among schoolteachers.

Methods: Schoolteachers (N=128) with clinically significant insomnia symptoms and work-related rumination were randomized to guided iCBT-I or a wait list control group, both with unrestricted access to treatment as usual. Health care use, patient and family expenditures, and productivity losses were self-assessed and used for costing from a societal and a public health care perspective. Costs were related to symptom-free status (score <8 on the insomnia severity index) and quality-adjusted life years (QALYs) gained. Sampling error was handled using nonparametric bootstrapping.

Results: Statistically significant differences favoring the intervention group were found for both health outcomes (symptom-free status yes or no: β=.30; 95% CI 0.16-0.43; QALYs: β=.019, 95% CI 0.01-0.03). From a societal perspective, iCBT-I had a 94% probability of dominating the wait list control for both health outcomes. From a public health care perspective, iCBT-I was more effective but also more expensive than the wait list control, resulting in an incremental cost-effectiveness ratio of €650 per symptom-free individual. In terms of QALYs, the incremental cost-effectiveness ratio was €11,285. At a willingness-to-pay threshold of €20,000 per QALY gained, the intervention's probability of being cost-effective was 89%.

Conclusions: Our trial indicates that iCBT could be considered as a good value-for-money intervention for insomnia.

Introduction

Insomnia is characterized by difficulties in initiating or maintaining sleep and/or early morning awakenings that occur 3 nights or more per week, for at least 3 months, resulting in poor sleep quality and significant daytime impairment [1]. Insomnia is one of the most common sleep disorders among adults. Prevalence estimates range from 6% for insomnia disorder [2] to 25% for insomnia symptoms [3].

Insomnia is associated with a range of adverse health consequences for individuals, including poor daytime functioning [4] and reduced health-related quality of life [5]. In view of its high prevalence and its debilitating nature, insomnia is related to a substantial health and economic burden. As such, it increases the risk of future mental disorders (eg, major depressive disorder) [6]. Economic costs stem from both absenteeism and reduced productivity while at work (ie, presenteeism) [7] as well as increased health care utilization, (eg, medication prescription [8,9]).

In order to reduce the personal and economic burden of insomnia, it is essential to implement interventions that can improve sleep. American and European guidelines recommend cognitive behavioral therapy (CBT) as first-line treatment for insomnia disorder [10,11] due to its substantial clinical evidence base [12]. However, despite this recommendation, CBT for insomnia (CBT-I) is not widely available, mainly due to a shortage of therapists and available resources [13]. In addition, only 37% of those suffering from insomnia seek professional help [3].

Internet-based CBT intervention for insomnia (iCBT-I) has been touted as a solution that can bridge this gap in health care [14]. Meta-analytic evidence demonstrated that iCBT-I is effective in treating insomnia with large effect sizes at posttreatment (eg, Cohen's d = 1.09; 95% CI 0.74-1.45) for insomnia severity [15]. Effect sizes are comparable to those found in individual face-to-face delivered CBT-I (eg, d=1.11; 95% CI 0.94-1.28) [12].

Although the effectiveness of (i)CBT-I has been demonstrated, research on its economic costs and benefits is still limited [16]. Previous reviews have argued that treating insomnia costs less compared to doing nothing [17,18]. A recent review on CBT-I interventions (N=7) using a dominance ranking framework showed that CBT-I was cost-effective compared to pharmacotherapy or no treatment [19]. However, only 2 studies have evaluated the economic effects of an iCBT-I intervention, but they suggested that iCBT-I provides superior health improvements at reduced costs [20,21]. To the best of our knowledge, no study has yet investigated the economic merits of iCBT-I from a societal perspective (including reductions in direct medical costs, patient and family costs, and indirect costs stemming from productivity losses) and from the public health care perspective (including only direct medical costs).

The aim of the this paper was thus to assess, from a societal and public health care perspective, the cost-effectiveness and cost–utility of a guided iCBT-I intervention to reduce insomnia symptoms in currently employed schoolteachers. The health economic evaluation presented here was conducted alongside a randomized controlled trial [22]. A previous publication reported the clinical effects of the iCBT-I intervention (6-month follow-up: Cohen d=1.43; 95% CI 1.04-1.82) [23].

Methods

Study Design

We conducted and reported the health-economic evaluation in agreement with the Consolidated Health Economic Evaluation Reporting Standards (CHEERS) statement [24] and the guidelines from the International Society for Pharmacoeconomics and Outcomes Research (ISPOR) [25]. The economic evaluation was performed from a societal perspective (ie, all relevant costs) and a public health care perspective (ie, direct medical costs) alongside a pragmatic 2-armed randomized controlled trial to establish the cost-effectiveness and cost–utility of a guided iCBT-I intervention as an adjunct to treatment as usual (TAU) for schoolteachers with insomnia compared to a wait list control condition with unrestricted access to TAU. Self-report questionnaires to assess costs and effects were collected at baseline, posttreatment (only health effects; 8 weeks after randomization), and 6-month follow-up via a secured online-based assessment system (Advanced Encryption Standard, 256-bit encrypted). Full details of the trial design can be found elsewhere [22]. The study was approved by the ethics committee of the University of Marburg (reference number: 2013-01K) and is registered under DRKS00004700 in the German clinical trial registry.

Procedure

Participants were recruited in Germany from March 2013 to September 2013 using email distribution lists to primary, secondary, and vocational schools, which were provided by the Ministry of Education in the German state of Nordrhein–Westfalen. Currently employed schoolteachers aged 18 and above with clinically significant insomnia symptoms (Insomnia Severity Index [ISI] >14) and elevated work-related rumination (Irritation scale, subscale "Cognitive Irritation" >14) were included in the study [22]. The exclusion criterion was current psychotherapy for insomnia and/or suicidal ideation (Beck Depression Inventory item on suicidality >1). People taking sleep medication were not excluded from the study but were required to keep their medication on a stable dose during the study period. The Consolidated Standards of Reporting Trials (CONSORT) study flowchart and participants' characteristics at baseline can be found elsewhere [23]. In brief, 128 schoolteachers were recruited into the trial with 64 randomized to the intervention and 64 to the wait list control condition. The average participant was female (95/128, 74%),

XSL•FO
RenderX

48 years of age (SD 10), married or in a partnership (92/128, 72%), and had a diagnosis of a primary insomnia (100/128, 78.1%) with moderate severity, and 14% (18/128) had a comorbid major depression [23]. Randomization took place at the individual level in a ratio of 1:1 and was conducted centrally by an independent research staff member not otherwise involved in the study using an automated web-based program (randomisation.eu). Study participants were not masked to their treatment allocation due to the nature of the psychological intervention.

Interventions

In this pragmatic trial, all study participants had unrestricted access to TAU. In Germany, TAU for elevated insomnia symptoms usually includes visits to the general practitioner followed by more intensive interventions, such as cognitive behavioral therapy and medication if insomnia symptoms persist or worsen.

iCBT-I Intervention (GET.ON Recovery)

The iCBT-I intervention (GET.ON Recovery [22,23]) has been specifically tailored to schoolteachers experiencing work-related stress and insomnia. The intervention was mainly based on cognitive behavioral methods (eg, sleep restriction therapy, stimulus control therapy, relaxation, sleep hygiene, and cognitive interventions) [26]. These methods were supplemented by techniques effective in reducing work stress and fostering mental detachment from work-related problems derived from behavioral activation [27], metacognitive therapy [28], gratitude research [29], and research on boundary management [30]. The intervention consisted of 6 weekly modules. Overall, of the 64 participants, 61 (95.3%) completed all 6 modules [23]. Participants received written feedback on each completed module by an eCoach (ie, a trained clinical psychologist), who followed a standardized coaching manual. To maximize the comparability of the participants and maintain the guidance at a minimal level, eCoaches were advised that the time spent on each participant per module should not exceed 30 minutes; thus, the total amount of time spent on each participant was approximately 3 hours for the total duration of the intervention [23]. eCoaches were supervised by a clinical psychologist.

Wait List Control Condition

In addition to TAU, individuals in the control group were eventually granted access to the unguided version of the intervention after completing the final assessment at 6 months post baseline.

Outcomes

ISI Symptom-Free Status

The health outcome in the cost-effectiveness analysis was symptom-free status defined as a score <8 on the ISI [31]. The ISI is a 7-item instrument answered on a 5-point Likert scale with a total score ranging from 0 to 28. The psychometric properties of the online version of the questionnaire have been well established [32]. In the current study, internal consistency was set at Cronbach α=.91.

Quality-Adjusted Life Years

Quality-adjusted life years (QALYs) were used as a health outcome in the cost–utility analysis (CUA). QALYs were based on the 6D Health State Short Form (SF-6D; a subset of 6 items of the Short Form Health Survey Version 1 [33]). The SF-6D contains 6 dimensions (each with between 2 and 5 levels) and can generate 7500 different health states. Utility values were derived using Brazier's algorithm [34]. QALY health gains were estimated by calculating the area under the curve of linearly interpolated SF-6D utilities between measurements to cover the whole 6-month follow-up period. The SF-6D was used in this study because the instrument is known to be more sensitive to changes in mild to moderate physical and mental health conditions than is the EQ-5D-3L questionnaire [35,36].

Resource Use and Costing

We used the Trimbos and Institute for Medical Technology Assessment "Treatment Inventory of Costs in Patients with psychiatric disorders" questionnaire (TiC-P) to collect data on health care utilization, patient and family costs, and productivity losses [37,38]. The TiC-P is a retrospective questionnaire with a 3-month recall period. The TiC-P was adapted for use in Germany and has been used in a large number of cost-effectiveness studies [39-41]. Costs were expressed in euros and indexed for the year 2013, the year the study was conducted, based on the German consumer price index (index factor 1.04) [42]. A reference to the National Institute for Health and Care Excellence willingness-to-pay (WTP) threshold of £20,000 (€23,529) to £30 000 (€35,294) per QALY gained was made where appropriate [43]. Costs were converted to pound sterling (£) using the purchasing power parities reported by the Organization for Economic Cooperation and Development. For the reference year 2013, €1 was equated to £0.85.

Intervention Costs

At the time of conducting the study, the market price of the iCBT-I provided by the GET.ON Institute was €299 (£254) per participant including all costs for developing (eg, tailoring intervention content to the target group) and delivering the intervention (eg, eCoaches providing individual feedback to participants).

Health Care Costs

We used 2 German guidelines for calculating health care costs [44,45]. A list of unit cost prices (ie, outpatient care) was used to compute the total health care costs on a per-participant level. Unit cost prices indexed for the year 2013 were as follows: €20.92 (£17.78) for a visit to the general practitioner, €68.06 (£57.85) for an internal medicine consult, €46.55 (£39.57) for a session with a psychiatrist, and €81.44 (£69.22) for a session with a psychotherapist. Hospital stays were computed at €335.52 (£285.19) for an in-patient day in a psychiatric hospital and €306.41 (£260.45) for an in-patient day in a hospital for psychosomatic medicine and psychotherapy. Costs were estimated by multiplying the units of resource use with corresponding unit cost prices.

XSL•FO
RenderX

Medication

The costs of prescribed medication were based on the German drug registry (Rote Liste [46]). Costs of prescribed medication are calculated as the pharmacy retail price, with the pharmacist's "clawback" (ie, wholesale margin) being accounted for. The rates of discount vary between private and statutory (public) health insurances. Therefore, we weighted the mean costs of the 3 largest packages with the same agent based on the daily defined dose by the statutory population share (89% of the German population are statutorily insured).

Patient and Family Costs

Out-of-pocket expenses were directly obtained from participants. Costs for traveling were valued at €0.30 (£0.26) per kilometer for making trips to access health services. Time spent on the intervention and costs of informal care were valued using the opportunity cost method and were estimated at €23.10 (£19.64) per hour [44,45].

Costs of Productivity Losses

Productivity losses can be caused by absenteeism (ie, days not worked) and presenteeism (ie, reduced efficiency while at work). We followed the human capital approach to value costs due to absenteeism [47]. Lost workdays due to absenteeism were valued at the corresponding gross average of participants' income per day. Lost workdays due to presenteeism were computed by taking into account the number of work days for which the participant reported reduced functioning weighted by the reported corresponding inefficiency score for those days (Osterhaus method) [48]. Productivity losses from unpaid work (ie, household work) were valued using the replacement cost method [49]. The estimated value was €18.33 (£15.58) per hour (eg, the average hourly gross wage of domestic help).

Analysis

The study was not powered to statistically test differences in health-economic outcomes. Therefore, we took a probabilistic decision-making approach to make health-economic inferences [50]. We did not discount costs and effects because the analysis was limited to a 6-month time horizon.

In evaluating clinical and cost outcomes, we reported all analyses in accordance with the CONSORT statement [51]. Data were analyzed according to the intention-to-treat principle. Missing data in ISI were imputed via multiple imputation using a Markov Chain Monte Carlo multivariate imputation algorithm (SPSS 21, IBM Corp) with 10 estimations per missing value [23]. To account for missing data in the cost and utility data, we used the regression imputation procedure in Stata version 16 (StataCorp) to obtain the required predicted values [52]. Predictors of outcome and dropout were identified by (logistic) regression analyses. Identifying predictors of outcome helped us to obtain the most likely values of the outcome, whereas identifying predictors of dropout allowed us to correct for bias that might arise by differential loss to follow-up. Differences in effectiveness between study groups at 6-month follow-up were estimated using ordinary least square regression analyses. Due to baseline imbalances, QALYs were adjusted for baseline values [53]. To compare cumulative costs between study groups, a generalized linear regression model with a gamma family distribution and an identity link function was fitted and adjusted for baseline depressive symptom severity and age. The family distribution was selected based on the modified Park test [54]. The identity link function was chosen because an additive effect of the covariates was expected.

Societal costs included all cost categories, while direct medical costs used in analyses from the public health care perspective comprised intervention costs, health care costs, and medication costs. In the cost-effectiveness analysis, the incremental cost-effectiveness ratio (ICER) was calculated by dividing incremental costs (total per-participant costs or direct medical costs) by symptom-free status gained. In the cost–utility analysis, incremental costs were divided by QALYs gained. The corresponding equation was as follows: ICER = (CostsINT – CostsCTR) / (EffectsINT – EffectsCTR), where INT is the intervention group and CTR is the control group [47]. Although costs were gamma distributed, the difference of 2 nonnormally distributed variables (eg, incremental costs) followed a remarkably normal distribution. Hence, to handle sampling uncertainty, we bootstrapped the seemingly unrelated regression equations model ("sureg" command in Stata) to generate 2500 simulations of incremental cost and incremental effect pairs while allowing for correlated residuals of the cost and effect equations and adjusting for potential confounders (eg, baseline utilities in the effect equation; age and baseline depressive symptom severity in the cost equation) [55]. Based on the bootstrapped seemingly unrelated regression equation model, bias-corrected and accelerated 95% CIs were obtained for incremental costs and effects. In addition, 95% CIs around ICERs were obtained by the bootstrap acceptability method [56]. The bootstrapped cost and effect pairs were graphically represented on a cost-effectiveness plane with effects along the horizontal axis and costs along the vertical axis [47]. To assess the probability of the intervention being cost-effective at varying WTP thresholds, cost-effectiveness acceptability curves were plotted [57]. Except for the imputation of missing ISI scores, all analyses were performed using Stata version 16 (StataCorp) [52].

Sensitivity Analyses

Three sensitivity analyses were performed. Presenteeism has been previously identified as one of the main cost drivers in insomnia [20]. As there is no gold standard to measure costs due to presenteeism, we used a different approach to assess presenteeism costs in the first sensitivity analysis. Here, we calculated costs due to presenteeism based on the Health and Labor Questionnaire (HLQ) method. The Osterhaus method, used in the main analyses, tends to overestimate costs due to presenteeism because this method concentrates on the work capacity of the individual. In contrast, the HLQ method focuses on production loss that is recoverable and is not yet made up for, thus generating a lower estimate of costs [58]. In a second sensitivity analysis, we varied the costs of the intervention by plus and minus 20% and 50%, respectively, to reflect uncertainties about the actual market price also including a lower price due to scaling effects. Finally, we conducted a "completers-only analysis" based on the data of the participants who completed the 6-month follow-up assessment.

XSL•FO
RenderX

Results

Study Dropout

At posttreatment, 92.2% (118/128) of the participants completed the follow-up questionnaires, whereas at 6-month follow-up, 88.3% (113/128) did. Dropout rates did not differ between the intervention and control conditions ($\chi 2_1$=1.89; *P*=.17). Study dropout was neither associated with baseline insomnia severity nor with any sociodemographic factors (lowest *P* value=.18 for treatment allocation). There were no missing data due to item nonresponse.

Effects

In the intervention group, 27 out of 64 participants (42%) reached a symptom-free status, whereas in the control group, 4 out of 64 participants (6%) were symptom-free at 6-month follow-up [23]. Statistically significant differences favoring the intervention group were found between the intervention and control group in symptom-free status (incremental effect, (Δ[E]=0.30; 95% CI 0.16-0.43). On average, participants in the intervention group gained 0.36 QALYs (95% CI 0.35-0.37) during the study period, while participants in the control condition gained 0.35 QALYs (95% CI 0.34-0.36). Differences in adjusted incremental QALYs were statistically significant (Δ[E]=0.02; 95% CI 0.01-0.03).

Costs

Both groups showed similar total costs within the 3-month recall period before randomization (intervention group: €2902 [£2467], 95% CI €2111-€3693; control group: €3112 [£2645], 95% CI €2321-€3903). Table 1 presents the 6-month accumulated per-participant costs separately for different cost categories by treatment allocation. Mean direct medical costs were higher in the intervention group (€592 [£503]; 95% CI €444-€740) compared to the control condition (€389 [£331]; 95% CI €242-€537), which could largely be explained by the intervention costs that were only involved in the iCBT-I group. In contrast, both patient and family's costs, along with productivity costs, were lower in the intervention group compared to the control group, with costs related to productivity losses having the largest impact on overall societal costs. Mean per-participant total costs accrued over the 6-month follow-up period were €4030 (£3426; 95% CI €3125-€4934) for the intervention group and €5021 (£4268; 95% CI €3394-€6147) for the control condition. Adjusted incremental differences in total costs were in favor of the intervention group (Δ[C]=–€895 [–£761]; 95% CI –€2155 to €364; ie, lower by €895 in the intervention group).

Table 1. Mean cumulative per-participant costs (in €) by condition over a 6-month follow-up period (based on intention-to-treat sample; N=128).

Costs	Intervention group (n=64), mean (95% CI)	Control group, (n=64), mean (95% CI)	Incremental costs, difference (95% CI)
Direct medical costs			
Intervention costs	299[a]	—[b]	299[a]
General practitioner	36 (21 to 51)	51 (36 to 66)	–15 (–36 to 6)
Mental health care	150 (56 to 244)	163 (69 to 257)	–13 (–146 to 120)
Antidepressants	2 (0 to 5)	5 (2 to 8)	–3 (–7 to 1)
Allied health services[c]	105 (34 to 176)	170 (99 to 241)	–65 (–166 to 36)
Patient and family costs			
Informal care	884 (226 to 1541)	1260 (602 to 1918)	–376 (–1306 to 554)
Domestic help	310 (147 to 474)	(132 to 459)	15 (–217 to 246)
Out-of-pocket expenses[d]	45(7 to 84)	73 (35 to 112)	–28 (-82 to 27) [a]

Economic Evaluation

Societal Perspective

Table 2 shows the incremental cost, effects, and cost-effectiveness ratios (based on 2500 bootstrap simulations) for the main analyses. Cost-effectiveness analysis revealed that the iCBT-I intervention resulted in more symptom-free individuals (Δ[E]=0.30; 95% CI 0.16-0.43) and that these health gains were achieved at lower costs (Δ[C]=–€1121 [£953]; 95% CI –€3012 to €64). With regard to the cost-effectiveness plane, most of the replicated ICERs (94%) fell in the south–east quadrant, indicating a 94% probability that the intervention would dominate the control condition (Figure 1). Cost–utility analysis revealed similar results compared to the cost-effectiveness analysis (Table 2). Again, most of the bootstrapped cost and effect pairs (94%) fell in the south–east quadrant, indicating the dominance of the intervention over the control condition (Figure 2). When the societal WTP per additional QALY gained was €0, the iCBT-I intervention had a 94% probability of being more cost-effective than the control condition.

Table 2. Results of the main analyses (based on 2500 bootstrap simulations) based on societal and public health care perspectives.

Type of analysis	Incremental costs (in €), mean (95% CI)[a]	Incremental effects, mean (95% CI)[a]	ICER[b], mean (95% CI)	Distribution over the cost-effectiveness plane (%)			
				NEQ[c]	NWQ[d]	SEQ[e]	SWQ[f]

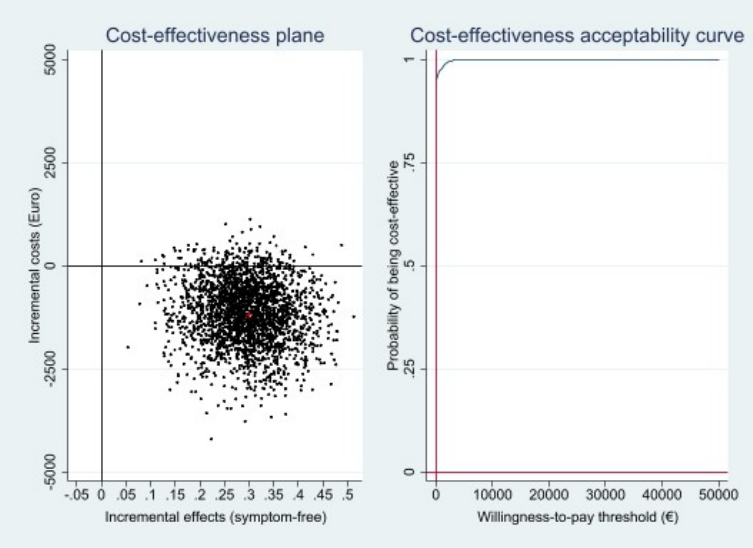
Figure 1. Scatterplot of 2500 replicates of the incremental cost and effect pairs (eg, symptom-free status) from the societal perspective on the cost-effectiveness plane: internet-based cognitive behavioral therapy versus wait list control condition and cost-effectiveness acceptability curve.



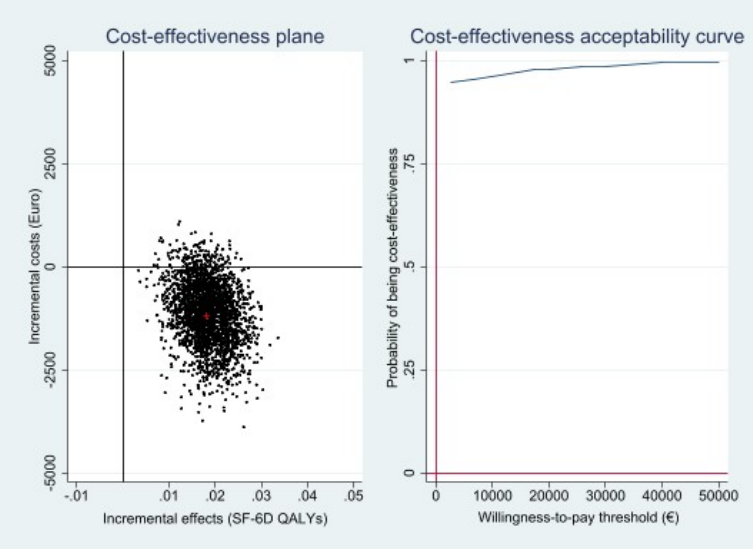


Figure 2. Scatterplot of 2500 replicates of the incremental cost and effect pairs (eg, QALYs gained) from the societal perspective on the cost-effectiveness plane: internet-based cognitive behavioral therapy for insomnia versus wait list control condition and cost-effectiveness acceptability curve. QALY: quality-adjusted life years; SF-6D: 6D Health State Short Form.

Public Health Care Perspective

From a public health care perspective, health benefits were achieved at higher costs (€189 [£161]; 95%CI –€97 to €350). The ICER was €650 (£553; 95% CI –€215 to €1652) for 1 additional symptom-free individual. At a WTP threshold of €0, the iCBT-I intervention's probability of being cost-effective was 6%. With an increase in the WTP to €1500 (£1275) per symptom-free status gained, the probability rose to 96% (Figure 3). Cost–utility analysis revealed an ICER of €11,285 (£9592; 95% CI –€1750 to €27,493) per QALY gained. The corresponding cost-effectiveness acceptability curve shows a probability of 4% and 89% that the intervention would be cost-effective at WTPs of €0 and €20,000 (£17,000) per QALY gained, respectively. With a National Institute for Health and Care Excellence WTP threshold of £20,000 (€23,529) to £30,000 (€35,294) per QALY gained [43], the probability would increase to 95% and 99%, respectively (Figure 4).

QALY: quality-adjusted life years; SF-6D: 6D Health State Short Form.

Sensitivity Analyses

Cost-effectiveness estimates based on the completer-only sample were almost identical to the main analyses, indicating that the imputation procedure did not bias the results (Table 3). From a societal perspective, results of the sensitivity analyses showed that neither using the HLQ method to assess costs due to presenteeism nor increasing intervention costs affected the overall conclusion that the iCBT-I intervention produces greater health gains at lower costs compared with a wait list control condition (Table 3). Using the HLQ method, the intervention's probability of being cost-effective was 72% at a WTP of €0 for both health outcomes. This probability rose to 86% at a WTP of €20,000 (£17,000) per QALY gained (Multimedia Appendix 1 Figure S1). Increasing or decreasing intervention costs by 20% or 50% did not affect the intervention's probability of being cost-effective compared with the main analysis (Table 3). From a public health care perspective, with intervention costs decreased up to 50%, health effects were still gained at slightly higher costs. Increasing the intervention costs by 20% and 50% resulted in an ICER of €14,380 (£12,223) and €19,360 (£16,456) per QALY gained, respectively (Table 3). At a WTP of €20,000 per QALY gained, the intervention's probability of being cost-effective was 80% and 60% (Multimedia Appendix 1 Figure S2), respectively.

[j]CUA: cost–utility analysis: quality-adjusted life years.

Discussion

Principal Results

Our study was set out to evaluate the cost-effectiveness and cost-utility of a guided iCBT-I intervention as an adjunct to usual care to reduce insomnia symptoms in schoolteachers in comparison with a wait list control condition with unrestricted access to TAU from a societal and a public health care perspective. Statistically significant differences favoring the intervention group were found for both health outcomes (symptom-free status and QALYs). From a societal perspective, the iCBT-I intervention dominated the wait list-control condition, meaning that the iCBT-I intervention has better health effects for less costs than does usual care in schoolteachers with insomnia. From a public health care perspective, the ICERs were €650 and €11,285 for a symptom-free individual and QALY gained, respectively. At a WTP threshold of €20,000 per QALY gained, the intervention's probability of being cost-effective was 89%.

Comparison With Prior Work

Although the effectiveness of iCBT-I is well established [15], there is a critical gap in health-economic evidence for iCBT-I. To our knowledge, this is the first trial-based economic evaluation of an iCBT-I intervention to reduce insomnia symptoms using a societal and public health care perspective. As such, results from our trial add to the converging evidence pointing to the cost-effectiveness of CBT interventions for insomnia. Thiart et al [20] used the same study to evaluate the cost and benefits of the iCBT-I intervention as seen from an employer's perspective. Results of the current health-economic evaluation line up agreeably with these findings. Baka et al [21] compared a guided iCBT-I intervention to care as usual for insomnia patients in general practice. Analogous to our findings, mean societal costs were lower in the intervention group than in the care as usual group, and, in contrast to our results, the cost–utility analyses revealed a lower probability (69%) of the intervention being cost-effective compared to care as usual at a ceiling ratio of €30,000 per QALY gained. This difference could be due to different types of control conditions used (care as usual vs wait list control). Applying an employer's or societal perspective seems to generate incremental costs favoring interventions groups when participants are employees, or at least in the productive age groups. In addition, our findings match with available health-economic evidence from a recent systematic review (N=7) showing that CBT-I was cost-effective compared to pharmacotherapy or no treatment [19].

Our findings from the public health care perspective showing that the iCBT intervention resulted in better health effects but achieved this at higher costs are also in line with findings from this systematic review [19]. Three trial-based economic evaluations employing a public health care perspective showed that CBT-I led to greater health improvements at higher costs compared to either TAU [59,60] or a wait list control condition [61], with time horizons ranging from 8 weeks to 6 months. In terms of QALYs gained, studies reported a low (34%) [61] and high (99%) [59] probability of CBT-I being cost-effective at a maximum WTP of £30,000 (€31,727) in the United Kingdom. Watanabe et al [60] reported a 90% chance of CBT-I being cost-effective at a WTP threshold of US$40,000 (€29,400) per QALY gained. In contrast, one study conducted from a public health care perspective showed that CBT-I was cheaper and more effective than TAU. However, there was large uncertainty around cost estimates resulting in a moderate probability (70%) of being cost-effective at a WTP of £30,000 (€31,727) [62].

Limitations

This study has some limitations. First, the time horizon of this study was limited to 6 months. However, results of an economic model investigating the long-term cost-effectiveness of CBT-I among long-term hypnotic drug users with chronic sleep difficulties compared to TAU indicated that any increase in the timeframe of the economic evaluation produces substantial reductions in the incremental costs per QALY gained. The cost-effectiveness of CBT-I improved even when treatment effects were reduced radically over time [59]. Further studies should thus assess the long-term clinical and cost-effectiveness of iCBT-I to reaffirm its long-term cost-effectiveness. Second, the iCBT-I intervention was compared to a wait list control condition in the present trial. Although patients in the control group had full access to treatment as usual, we cannot rule out a potential nocebo effect in the wait list control condition [63]. In addition, pharmacoeconomic guidelines recommend standard care (eg, face-to-face CBT-I) as comparator [64]. Future studies should thus directly compare the cost-effectiveness of iCBT-I versus face-to-face CBT-I. Third, although the sample size in this trial was sufficient to demonstrate clinical effectiveness, it needs emphasizing that much larger sample sizes are required for hypothesis testing in economic studies due to the skewness of costs relative to normally distributed health effects [65]. Therefore, it is recommended that future studies employ larger sample sizes to allow for better evaluation of cost changes and sustainability of interventions like iCBT-I. Fourth, we only used the SF-6D to compute utilities and QALYs. However, the choice for the SF-6D (rather than its alternative the EQ-5D-3L [66]) matters, even to the point where decision-makers have to regard

XSL•FO
RenderX

a new intervention as cost-effective or not [67]. In the current study, we flanked the cost–utility analysis (with QALYs) by a cost-effectiveness analysis (with improvements in insomnia) and both economic evaluations led to the same conclusion of the iCBT-I intervention being the preferred option. Nevertheless, future studies should employ different instruments to compute QALYs. Fifth, our results may only be generalized to professions with similar characteristics, such as flexible working hours, loose boundaries between work and private life, and work-home interference. Sixth, the trial has been conducted in a highly educated sample. Hence, we cannot predict the uptake of such an intervention in participants with a lower education level or among those with lower-income status. A recent individual participant data meta-analysis revealed, however, that education was not associated with differential treatment effects of an iCBT intervention to prevent depression [68] although other evidence suggests that better treatment adherence is predicted by higher education [69]. Attrition has been suggested to be an issue, especially in internet-delivered interventions [70]. It is thus warranted to conduct research into the willingness of specific population segments to fully engage in such interventions (ie, how uptake and adherence rates of iCBT interventions could be increased among individuals with less education). Finally, the research context might have led to a self-selection of individuals who might have been more motivated and committed to engage in the iCBT-I intervention than is assumed outside a research context. As a result, findings might not be generalizable to the wider population, but might be representative of specifically those willing to use internet-based interventions in the first place.

Clinical Implications and Future Research

American and European guidelines recommend CBT as the first-line treatment for insomnia disorder [10,11]. Our study supports this recommendation by showing that a guided iCBT-I intervention may reduce insomnia symptoms and improve health-related quality of life. iCBT interventions for mental disorders have often been introduced as potential cost-saving alternatives to face-to-face individual or group therapy [71,72]. Findings from our study add to the evidence base that delivering cognitive-behavioral therapy over the internet has a high probability of being cost-effective in reducing insomnia symptoms among employees. In view of scarce resources and rising costs in health care systems, evidence-based guidance regarding cost-effectiveness of iCBT-I can potentially help to inform decision-makers to the choice of first-line treatments of insomnia. However, future studies should directly compare iCBT-I with face-to-face–delivered CBT-I.

Considering the shortage of therapists and available resources [13], a rather low uptake of professional help [3], and the potential to scale up iCBT-I interventions to efficiently alleviate the health and economic burden caused by insomnia, it would be worthwhile to integrate this type of intervention into routine practice. However, some risks need to be taken into account when scaling up this intervention. Involving individual eCoaches may hamper scaling up the intervention. The support offered by an eCoach may not only affect clinical effectiveness and cost-effectiveness of the intervention but also the target group's willingness to participate in this intervention, thereby influencing intervention effects at the population level. Thus, future studies should compare the acceptability, effectiveness, and cost-effectiveness of guided and unguided iCBT-I interventions. In addition, there are no guarantees that adherence and (by proxy) effectiveness will be maintained if this sort of unsupported iCBT-I intervention is scaled up in the population. Finally, the same technical resources available in the research setting (eg, stable and secure internet connections) may not be available when the intervention is scaled up.

Conclusions

Findings from our trial indicate that iCBT could be considered as good value for money in insomnia therapy. Given the evidence for the effectiveness of iCBT-I interventions to reduce insomnia symptoms, the potential scalability and cost-effectiveness of these interventions might strategically pave the way to alleviate the health and economic burden related to insomnia disorder (and its sequelae) in an affordable way. However, before a nationwide dissemination can be considered, future studies need to evaluate the comparative clinical and economic outcomes of guided and unguided iCBT-I interventions, and to determine what works best for whom such that the deployment of the intervention can optimally target the right population segments. Moreover, implementation studies are needed to clarify the real-world effects of these interventions and to gain insights into the willingness of specific population segments to fully engage in them (eg, individuals with a low education level or those of low-income status).

Acknowledgments

DDE, DL, and MB obtained the funding for this study. DDE, DL, HR, MB, and HH contributed to the design of the clinical study. HH and DDE analyzed the clinical data. CB designed and performed the health-economic evaluation with support from FS. CB had full access to the clinical and economic data and takes full responsibility for the integrity of the data and the accuracy of the health-economic data analyses. CB drafted the manuscript; FS, KS, DL, and DDE supervised the writing process. All authors contributed to the further writing of the manuscript and approved the final manuscript.

This was not an industry-supported study. The European Union funded this study (European Regional Development Fund: ZW6-80119999 and CCI 2007DE161PR001). The funder did not have a role in study design; data collection, analysis, and interpretation of results; or the decision to publish the study results.

Conflicts of Interest

DDE, DL, and MB are stakeholders of the GET.ON Institute, which aims to implement scientific findings related to digital health interventions into routine care. HH serves as business developer at the GET.ON Institute. DDE has served as a consultant on the scientific advisory boards of Sanofi, Novartis, Minddistrict, Lantern, Schoen Kliniken, Ideamed, as well as German health insurance companies (BARMER and Techniker Krankenkasse) and a number of federal chambers for psychotherapy. The other authors have no conflicts of interest to declare.

Abstract

Background: The COVID-19 pandemic has limited daily activities and even contact between patients and primary care providers. This makes it more difficult to provide adequate primary care services, which include connecting patients to an appropriate medical specialist. A smartphone-compatible artificial intelligence (AI) chatbot that classifies patients' symptoms and recommends the appropriate medical specialty could provide a valuable solution.

Objective: In order to establish a contactless method of recommending the appropriate medical specialty, this study aimed to construct a deep learning–based natural language processing (NLP) pipeline and to develop an AI chatbot that can be used on a smartphone.

Methods: We collected 118,008 sentences containing information on symptoms with labels (medical specialty), conducted data cleansing, and finally constructed a pipeline of 51,134 sentences for this study. Several deep learning models, including 4 different long short-term memory (LSTM) models with or without attention and with or without a pretrained FastText embedding layer, as well as bidirectional encoder representations from transformers for NLP, were trained and validated using a randomly selected test data set. The performance of the models was evaluated on the basis of the precision, recall, F_1-score, and area under the receiver operating characteristic curve (AUC). An AI chatbot was also designed to make it easy for patients to use this specialty recommendation system. We used an open-source framework called "Alpha" to develop our AI chatbot. This takes the form of a web-based app with a frontend chat interface capable of conversing in text and a backend cloud-based server application to handle data collection, process the data with a deep learning model, and offer the medical specialty recommendation in a responsive web that is compatible with both desktops and smartphones.

Results: The bidirectional encoder representations from transformers model yielded the best performance, with an AUC of 0.964 and F_1-score of 0.768, followed by LSTM model with embedding vectors, with an AUC of 0.965 and F_1-score of 0.739. Considering the limitations of computing resources and the wide availability of smartphones, the LSTM model with embedding vectors trained on our data set was adopted for our AI chatbot service. We also deployed an Alpha version of the AI chatbot to be executed on both desktops and smartphones.

Conclusions: With the increasing need for telemedicine during the current COVID-19 pandemic, an AI chatbot with a deep learning–based NLP model that can recommend a medical specialty to patients through their smartphones would be exceedingly useful. This chatbot allows patients to identify the proper medical specialist in a rapid and contactless manner, based on their symptoms, thus potentially supporting both patients and primary care providers.

Introduction

The COVID-19 pandemic has encouraged the development of telemedicine and the use of digital platforms [1]. In the field of remote medical support, various digital tools help minimize the number of face-to-face interactions between patients and health care providers (HCPs) [2]. Artificial intelligence (AI) chatbots, also called conversational agents, have recently been designed to support HCPs [3]. Most AI chatbots utilize deep learning–based natural language processing (NLP), which can analyze natural human language input and respond appropriately in a conversational manner [4]. The advantages of an AI chatbot over human HCPs include the absence of face-to-face interaction; minimization of bias based on certain patient demographic characteristics such as age, gender, and race; greater cost-effectiveness; and 24/7 availability since the chatbot does not get fatigued or sick [5]. In a recent systematic review on the effectiveness of AI chatbots in health care, the bots performed well in terms of both usability and satisfaction, and overall positive or mixed effectiveness was reported in most studies [6].

In primary care, it may be important for HCPs to determine which medical specialty is most appropriate for their patients. Since patients generally have no professional medical knowledge, they have to rely on the decisions made by the primary care provider. It cannot be overemphasized that high-quality primary care systems ensure favorable health outcomes and decrease the economic burden [7]. Currently, however, the COVID-19 pandemic limits the amount of physical contact between patients and primary care providers. This state of affairs hinders communication between patients and primary care providers, which prevents timely provision of appropriate treatment by a medical specialist and worsens health outcomes. Therefore, the need for digital tools including AI chatbots to complement the care provided by HCPs and support the decision-making capacity of primary care providers (for example, by connecting patients to medical specialists) is greater.

To develop AI chatbots, electronic medical records (EMRs) have generally been used as input data pipelines for NLP-related medical studies. Using EMRs for NLP facilitates the identification of patients with digestive disorders [8,9] and the prediction of the risk of psychiatric problems, such as actual self-harm, harm to others or victimization, and the risk of health care–associated infections such as surgical site infections [10,11]. Furthermore, EMRs have been used to develop an excellent medical specialty classifier built using deep learning–based NLP, which reportedly had area under receiver operating characteristic curve (AUC) scores of 0.975 and 0.991 and F_1-scores of 0.845 and 0.870 in 2 different EMR data sets [12]. However, the text-formatted EMR data generated by HCPs are mainly composed of medical terminology, which differs from the expressions used by patients to describe their symptoms. Therefore, a new data set consisting of sentences that are commonly used by patients to ask their HCPs about their symptoms was required to fulfill the purpose of our chatbot. This study aims to collect data that accurately describes patients' symptoms in a real-world setting (much more friendly to patients than HCPs) and to develop a deep learning–based NLP model for medical specialty classification. Specifically, we constructed various deep learning–based NLP models, compared their performances, and then selected the best model for our AI chatbot. Finally, the developed AI chatbot was deployed in Google Cloud, which can be used on both desktops and smartphones.

Methods

Data Collection and Cleansing

For supervised learning of the deep learning–based model for NLP, both a single-sentence symptom description and its corresponding medical specialty were required. A Korean website called HiDoc [13]—a web-based health care platform—provides a medical consultation service for anonymous users (patients) by linking them to more than 4000 medical specialists. All medical specialists submitted their professional licenses for approval to provide medical consultation to HiDoc users. HiDoc posts, in which users describe their symptoms, have two parts: title and content. The titles of the posts, in a single-sentence format, were collected for our data set. The medical specialty corresponding to each title sentence was obtained from the profile of the medical specialist who responded to the post.

In the first step of the data cleansing process, duplicate and missing data were eliminated. Second, ambiguous sentences that were not sufficient for accurate classification of the medical specialty, including sentences with ≤2 words or those not related to medical consultations, were manually excluded. Third, very few instances of mislabeled data were appropriately relabeled by a well-trained physician.

Exploratory Data Analysis

Exploratory data analysis (EDA) was performed to extract the interpretable features of the data before development of the deep learning–based NLP models. First, we enumerated the sentences related to symptoms in each class to assess the data distribution. We also visualized the most frequently used words to create lists of words, such as stop words (not useful for classification) and keywords (useful for classification) for word representation. The sentence lengths were determined (in terms of both word count and character count) to ascertain the maximum length of the input sequence for each model.

Development of Deep Learning Models

Long Short-Term Memory Models

Clinical word representation has proven to be an important factor in the performance of NLP models [14]. To extract the

XSL•FO
RenderX

appropriate word representation, each sentence was mined for nouns excluding the words in the list of stop words, and each noun was converted to an index if included in the list of keywords. Using a tokenizer in the Keras library, 15,000 high-frequency nouns were replaced with the corresponding numbers. Thereafter, padding tokens were added to the sentence to ensure consistency in sentence length. As the input of the long short-term memory (LSTM) models, we used either word embedding vectors trained on our data set or word embedding vectors pretrained with the Korean corpus from FastText. The number of embedding dimensions was set to 2048. As the fundamental LSTM architecture, a 256-cell bidirectional LSTM served as the backbone of the model with or without an added attention layer [15,16]. Further, 2 fully connected layers with a rectified linear unit function were applied, followed by a dense layer with the softmax function for classification.

We built 4 different LSTM models. The first is the LSTM model with embedding vectors trained on our data set. Second is the LSTM model with Bahdanau attention. Most settings are the same in the first and second models, but the second model includes an attention layer with 256 cells after the bidirectional LSTM layer. The third model is the LSTM model with FastText pretrained vectors. We loaded FastText's pretrained vector data set and reorganized it to create the embedding matrix. This matrix was used as the embedding layer's weight. The unmentioned hyperparameters are the same as those in the first LSTM model. The last variation is the LSTM model with both FastText vectors and Bahdanau attention. It has an embedding layer based on FastText pretrained vectors and a Bahdanau attention layer.

When compiling all 4 models, categorical cross-entropy and Adam were applied as the loss function and training optimizer, respectively. For the training process, 10-fold cross-validation was conducted to ensure evaluation accuracy. Furthermore, early stopping callback monitoring validation loss was used to prevent overfitting. The batch size and number of epochs were set to 1000 and 30, respectively.

Bidirectional Encoder Representations From Transformers Model

The bidirectional encoder representations from transformers (BERT) model, proposed by Google, has achieved state-of-the-art performance on biomedical and clinical entity normalization with EMRs as well as other NLP tasks such as question answering and natural language inference [17]. Therefore, we used the BERT model for sentence classification through fine-tuning. For preprocessing of the sentences, we applied an open-source tokenizer from Huggingface [18]. This tokenizer encoded each sentence to be used as input of the BERT model by, for example, adding special tokens ([CLS] for beginning and [SEP] for end of sentence), padding to the maximum sequence length, and generating an attention mask. The BERT classification model was built from the pretrained BERT model with a fully connected layer and the softmax function on top. Categorical cross-entropy and Adam optimizer were used for compilation. As in the LSTM models, 10-fold cross-validation was used to increase the reliability of the statistical findings, and early stopping callback observing "validation loss" with patience 2 was set to avoid overfitting. Training was carried out for 30 epochs per fold, with a batch size of 100.

Evaluation

We performed 10-fold cross-validation for the entire data set for each model, and then we calculated the mean score of the 10 different folds to evaluate the general performance of the models. Model performance was evaluated on the basis of precision, recall, F_1-score, and AUC. These indexes are calculated from the rates of true positive, false positive, and false negative results, as follows:

AUC = area under the curve of the false positive rate (x-axis) vs the true positive rate (y-axis).

The Wilcoxon signed rank test was used to test the significance of between-group differences.

Development of the AI Chatbot

We next developed a user-friendly application that allows patients to interact with our chatbot model. As we aimed to make our chatbot usable for all, without creating any digital health disparities on the basis of factors including age, and ensure that it provided accurate medical information, we adopted the formal tone of the Korean language. A well-designed chatbot provides agility for developers and is able to run continuously in any environment. We constructed a chatbot architecture considering those factors.

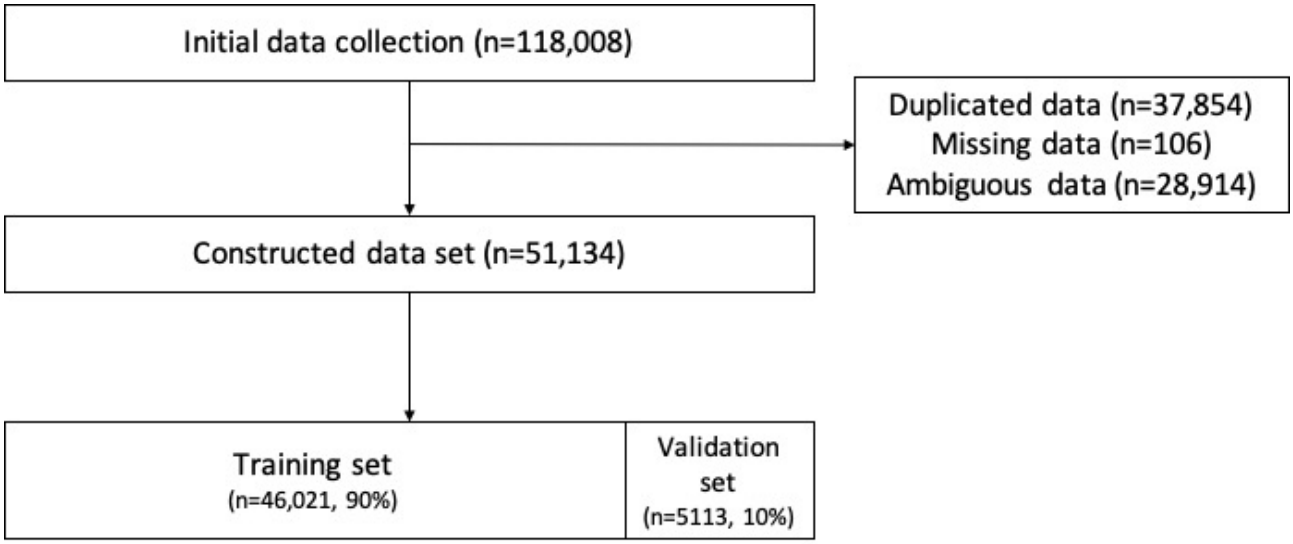
A typical chatbot architecture can be simplified into 2 parts. The first part is the client-side showing the main user interface. The other part is the server-side that includes the dialog processing logic and an NLP model.

We developed a prototype chatbot client using an open-source chatbot framework Alpha [19]. There are various chatbot user interface alternatives to Alpha, including "chat-bubble," but Alpha is superior for several reasons. In general, open-source chatbot user interface frameworks only have features for sending and receiving messages. They are difficult to test or execute in a developer environment. The Alpha chatbot framework is a highly customizable, fully complete chatbot framework. Alpha is predockerized and built with a WebKit, which may help developers quickly run and test the continuously changing codebase. Furthermore, Alpha includes a cross-platform feature that allows it to be used on both desktops and smartphones. For rapid development, we modified Alpha's client-side dialog logic to fit with the targeted user base.

Tools

Frequently used words were visualized in a word cloud using a Python package called "WordCloud." The Python package for Korean NLP "KoNLPy" was used for word representation.

XSL•FO
RenderX



The Huggingface “Transformers” package was used to encode sentences and load a pretrained model for BERT. The “Tensorflow” framework was adopted for building and evaluating the deep learning models. Google Colab, a cloud service for machine learning research, was used in this study. It provides various libraries and frameworks for deep learning and a robust graphics processing unit. Statistical analysis was conducted using R (version 4.0.3, The R Foundation).

Results

Data Set Construction

We initially collected 118,008 sentences that discussed patients’ symptoms, which fit into the 26 classes of medical specialty in HiDoc, and eliminated duplicate data (n=37,854) and missing data (n=106). After excluding ambiguous sentences (n=28,914), the final data set including 51,134 sentences in 26 medical specialty classes was constructed. The data set was randomly split into a training set (n=66,021, 90%) and validation set (n=5,113, 10%) during 10-fold cross-validation. The flow diagram of the entire data set construction process is shown in Figure 1.

Figure 1. Flow diagram for data set construction.

EDA

By specialty, the number of sentences was the highest in dermatology (19.87%), followed by psychology (12.04%), neurology (9.93%), and orthopedic surgery (7.10%) (Table 1).

As the word cloud showed that some frequent words including daily expressions were predominant in the data set, we investigated the list of frequent words. Furthermore, some useful statistical information could be identified at the word and character levels (Table 2).

The EDA results provided 3 crucial ideas to help identify the best NLP model for the AI chatbot. First, owing to the class imbalance of the data, the F_1-score should be considered the most important measure to accurately evaluate and compare the models. Second, to improve the performance of the models through data preprocessing and tokenizing, we decided to compile a list of stop words, such as “hello,” “question,” and “ask,” which might not be helpful for classification, and a list of keywords, which are frequently found in medical expressions (n=15,000), such as “pain,” “head,” and “sudden.” Third, considering the sentence length at both levels, the maximum length of the input sequences for each deep learning model (10 for the LSTM models and 30 for the BERT model) was determined to fix the shape of the input layer in each model.

Statistic	Word level, n	Character level, n
Maximum	52	156
Minimum	1	1
Mean	4.68	20.14
Median	4	18
SD	2.78	11.03
First quartile	3	12
Third quartile	6	27

Comparison of Deep Learning Models

The performance outcomes after 10-fold cross-validation in the 5 different deep learning models for NLP are summarized in Table 3. The BERT model showed the best performance, followed by the LSTM model, with embedding vectors trained on our data set.

After saving all trained models in the server, we determined that the BERT model was too heavy to be run on our GCP computation engine with limited performance because the server should be able to handle requests on both desktops and smartphones. Therefore, we had to utilize the lighter LSTM model with embedding vectors trained on our data set, which showed the second-best classification performance.

[a]Comparison of F_1-scores of the models with the reference, which showed the lowest F_1-score.

Deployed AI Chatbot

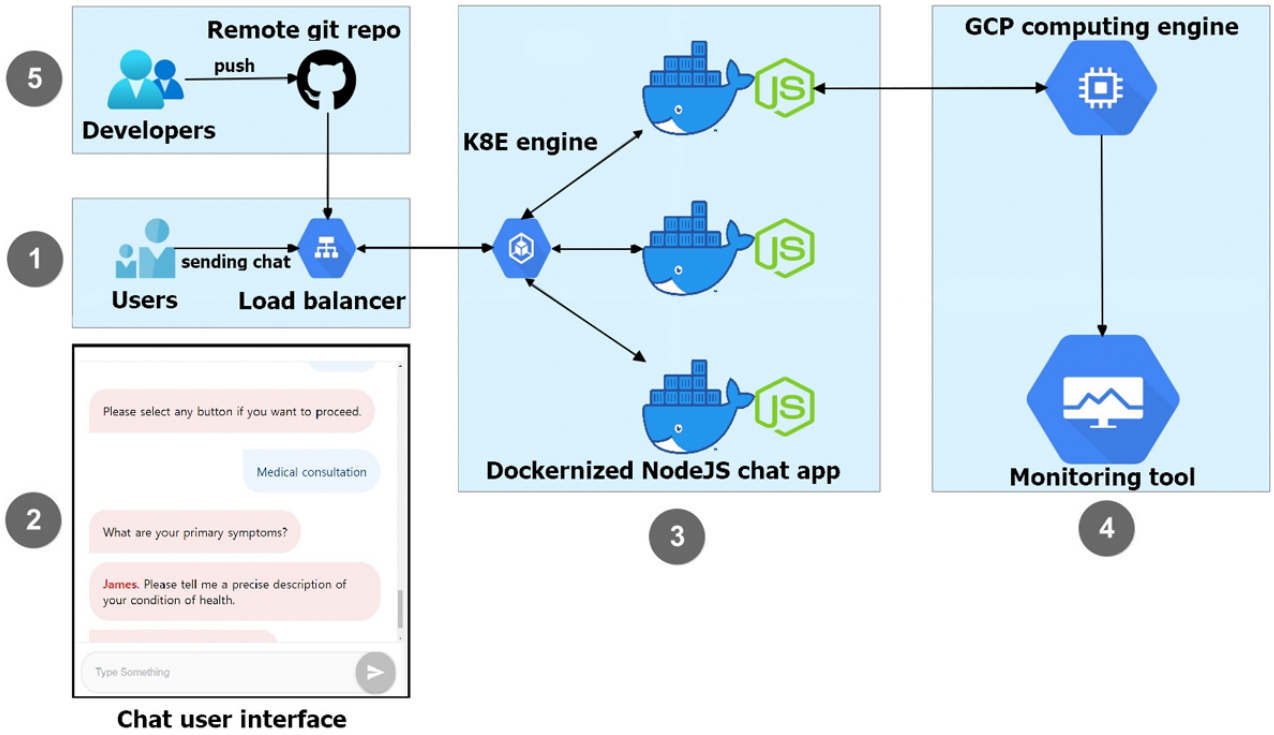

Figure 2 presents the overall architecture of our chatbot. On top of the complete chatbot features, we added basic bubble-like buttons that classify medical departments using our deep learning model, link to an online appointment system, list medical doctors, and provide a simple introduction of the chatbot. When a user selects “medical consultation,” the chatbot asks to send a natural Korean language sentence that describes the user's health state. The sentence is sent to a deployed server and the NLP model classifies medical specialties using the given information. The server responds to the client with the classified medical specialty. The user's device shows the complete sentence generated on the client-side. Based on the medical specialty outcome, the chatbot asks the user if it should provide some services, such as presenting the schedule of physicians in the medical specialty and helping to make an appointment with a physician.

Our NLP model was deployed to a server-side e2-medium (2 vCPU, 4 GB memory) GCP computation engine. We deployed this chatbot framework on Google Cloud Platform Kubernetes Engine (GKE), which is conveniently coupled with containerized by docker, for rapid development. GKE's Kubernetes has a load-balancer feature that distributes application traffic to prevent sudden chatbot outages. Applying Kubernetes at an early stage of development helps developers optimize the uptime, performance, and cost of the application.

We also applied automated git automation with Kubernetes to accelerate the speed of delivery. When a developer pushes modified code from a local computer to a remote GitHub repository, GitHub triggers the containerized chat app cloned in GKE. This continuous deployment method eases the burden on developers by eliminating the need for complex configured scripts on a deployment server. In the cloud-native environment, this chatbot framework laid the groundwork to easily extend further features.

XSL•FO

Figure 2. Architecture of the chatbot. This figure illustrates the workflow of the developed prototype chatbot. (1) Users send a sentence through the chatbot's input box. (2) A simple example of our chatbot's user interface. (3) The Containerized Node js chat application includes responding logic without classifying a medical department. (4) The GCP computing engine, which has a natural language processing model, which classifies the medical department from the sentence input in (3). (5) This dockerized NodeJS-based chat app is deployed by continuous git push steps.

Discussion

Principal Findings

In this study, the BERT model was the best classifier of medical specialty, followed by the LSTM model with embedding vectors trained on our data set. These 2 models had an AUC of 0.964 and 0.965 and F_1-score of 0.768 and 0.739, respectively; however, these values were lesser than those reported previously (AUC of 0.975-0.991 and F_1-score of 0.845-0.870) [12]. Nonetheless, the main findings of this study include the following: (1) we developed not only a deep learning classification model for medical sentences but also a prototype AI chatbot to be executed on a smartphone; (2) to our knowledge, this study is the first to use real patients' actual descriptions of their symptoms to develop a deep learning–based NLP model for medical specialty classification; and (3) we constructed Korean language data sets, which can be used in further studies.

This AI chatbot may help patients understand which medical specialty is appropriate for the treatment of their present symptoms and then make an appointment with the corresponding medical specialist, without any face-to-face contact throughout the process. Previous deep learning–based studies on medical sentences developed and suggested optimized deep learning models for several purposes [12,20-23]. However, even with these deep learning models, it takes a great deal of time, effort, and trial and error to deploy a web-based service for practical use. We also made the final choice of deep learning model considering performance and size before deployment. Similar to various recently developed web-based medical tools that offer assessment, communication, management, and other features [24-28], we also focused on the accessibility of our AI chatbot among users with smartphones. As the use of AI techniques in medical services such as telemedicine is growing owing to the COVID-19 pandemic, we believe that this type of research (from the development of a deep learning model to deployment of an AI chatbot) has become extremely important as it can be rapidly applied in practical medical settings.

Most NLP-related medical studies have used EMRs such as clinical notes and discharge notes [21,29,30]. These types of medical texts consist of "physician-friendly" words; that is, medical terminology. Therefore, in those studies, patients' expressions of their own complaints must be transformed in an appropriate manner before being used as input for the model. It was also not suitable for the input of the AI chatbot. However, the data set constructed and used for the development of the deep learning–based NLP model in this study consists of "patient-friendly" words taken from a currently operating web-based health care platform. The use of this data set helped develop an AI chatbot with which patients can interact easily and conveniently. Furthermore, this data set of Korean medical language may be useful for further NLP-based medical studies, including those on diagnosis, treatment, and prediction [31-33] because different languages have different features that can greatly influence the study of NLP.

Limitations

One limitation of this study is that the corpus of the data set that was used for the development of the NLP models was obtained

XSL•FO
RenderX

from one specific website. Demographically, most HiDoc users who accessed the website were less than 65 years of age (Multimedia Appendix 1). They also have nonemergent symptoms that are not complex enough to be differentially diagnosed and not too sensitive to readily share with others. This may explain why the largest proportion of symptom-related sentences were associated with dermatology, followed by psychology (Table 1). Second, the present chatbot, which uses text messaging for remote communication, might be uncomfortable for older adults. To not ignore the needs of this vulnerable and continuously increasing population, an additional communication strategy, such as voice-based communication, is required. A recent study reported that a smart speaker was an effective solution for bringing an AI-based digital health system for older Korean adults [34]. Therefore, other AI-based technologies including smart speakers should be considered for further studies. Third, our model provides classification into 26 medical specialties based on the system of a single general hospital. This may affect the generalizability of our model; a few medical specialties that exist in other medical facilities may be missing. Fourth, some aspects of the study may have been restricted, such as the amount or quality of the data and computing resources. To improve the performance of the deep learning model for classification, additional large collections of high-quality data as well as a costly, latest-generation high-performance computation engine could be used for a large model such as BERT. Fifth, concerning the interpretability of deep learning models, the use of shallow learning models such as support vector machines and naïve Bayes classifiers might be suggested for further studies. Sixth, a clinical trial is required to evaluate how well our AI chatbot service chooses the correct medical specialty in a real-world setting.

Conclusions

In this study, we illustrate the potential of a smartphone-compatible AI chatbot service to recommend a suitable medical specialty to patients. We developed a deep learning–based NLP model and deployed the novel AI chatbot. This type of non–face-to-face medical service is a promising strategy to overcome the current difficulties associated with the COVID-19 pandemic.

Authors' Contributions

HL designed the study. HL, JK, and JY implemented the study. HL drafted the manuscript. JK and JY provided critical revisions to the manuscript. All authors approved the final manuscript.

Abstract

Background: With advances in science and technology, biotechnology is becoming more accessible to people of all demographics. These advances inevitably hold the promise to improve personal and population well-being and welfare substantially. It is paradoxical that while greater access to biotechnology on a population level has many advantages, it may also increase the likelihood and frequency of biodisasters due to accidental or malicious use. Similar to “Disease X” (describing unknown naturally emerging pathogenic diseases with a pandemic potential), we term this unknown risk from biotechnologies “Biodisaster X.” To date, no studies have examined the potential role of information technologies in preventing and mitigating Biodisaster X.

Objective: This study aimed to explore (1) what Biodisaster X might entail and (2) solutions that use artificial intelligence (AI) and emerging 6G technologies to help monitor and manage Biodisaster X threats.

Methods: A review of the literature on applying AI and 6G technologies for monitoring and managing biodisasters was conducted on PubMed, using articles published from database inception through to November 16, 2020.

Results: Our findings show that Biodisaster X has the potential to upend lives and livelihoods and destroy economies, essentially posing a looming risk for civilizations worldwide. To shed light on Biodisaster X threats, we detailed effective AI and 6G-enabled strategies, ranging from natural language processing to deep learning–based image analysis to address issues ranging from early Biodisaster X detection (eg, identification of suspicious behaviors), remote design and development of pharmaceuticals (eg, treatment development), and public health interventions (eg, reactive shelter-at-home mandate enforcement), as well as disaster recovery (eg, sentiment analysis of social media posts to shed light on the public’s feelings and readiness for recovery building).

Conclusions: Biodisaster X is a looming but avoidable catastrophe. Considering the potential human and economic consequences Biodisaster X could cause, actions that can effectively monitor and manage Biodisaster X threats must be taken promptly and proactively. Rather than solely depending on overstretched professional attention of health experts and government officials, it is perhaps more cost-effective and practical to deploy technology-based solutions to prevent and control Biodisaster X threats.

XSL•FO
RenderX

This study discusses what Biodisaster X could entail and emphasizes the importance of monitoring and managing Biodisaster X threats by AI techniques and 6G technologies. Future studies could explore how the convergence of AI and 6G systems may further advance the preparedness for high-impact, less likely events beyond Biodisaster X.

6G; artificial intelligence; biodisaster X; biodisasters; biosafety; biosurveillance; biotechnology; bioterrorism; COVID-19; disease X; sixth-generation technologies

Introduction

Humans have been living with disasters for thousands of years. Records from ancient civilizations, albeit difficult to come across and piecemeal, document the undeniable presence and the lingering impacts of disasters throughout human history [1-8]. Evidence from recent decades alone, for instance, shows that the world witnesses approximately 400 natural disasters and 30-40 armed conflicts annually [9]. Although already daunting, these numbers likely underrepresent the accurate scale and severity of these disasters in society; many often occur in remote places that draw little to no attention of the media or the research community. While humanity is no stranger to various disaster-led debates and discussions focused on the risks posed by natural and anthropogenic disasters [10-12], collectively, research still indicates that societies at large perform poorly when it comes to disaster preparedness [13-19].

As apparent from the COVID-19 pandemic, from the measures assembled during the first outbreaks in 2020 to the faltering waves of public health policies established throughout the first months of 2021, the lack of disaster preparedness and readiness in the wake of global health crises resulted in drastic consequences to the economy and to society [20-25]. Even though the World Health Organization made Disease X (a placeholder term for any unknown pathogenic disease with a pandemic potential) a global priority in 2018 [26], and warned of the potential for a COVID-19–like pandemic to cause disorder in society, unfortunately, few measures were taken to prepare for it [27]. As of May 6, 2021, approximately 155 million COVID-19 cases and over 3.24 million mortalities have been reported worldwide [28]. Parallel with the growth of scientific research in the biological sciences, warnings of the importance of pandemic preparation have been issued throughout the twentieth century [26,29-33] across multiple disciplines. The possibility of bioterrorism and a pathogen's potential to be unleashed without countermeasures is an increasing concern [34-36]. The use of bioweapons by state actors has long been a risk [37-45]; however, with rapid developments in biotechnology, it becomes increasingly feasible for nonstate actors to develop powerful bioweapons in low-barrier contexts, such as home environments, thus increasing the likelihood of biodisasters [46].

Overall, following the pattern of "Disease X," here we introduce the term "Biodisaster X" to refer to disasters caused by the accidental or intentional misuse of biotechnologies by state or nonstate actors. In general, there are no practical insights on approaches to monitor and manage Biodisaster X preemptively. Considering the potential risks Biodisaster X could pose to society's safety and security, research is urgently needed to bridge the knowledge gap. Advances in information and communication technologies have revealed several opportunities to harness digital tools in this effort, particularly with the latest generation of artificial intelligence (AI) techniques and the development of 6G wireless communication technologies, which arguably includes the most promising advanced technological platforms for addressing Biodisaster X threats. Therefore, to this end, this study aimed to identify (1) the potential dangers Biodisaster X poses to society at large and (2) solutions that use emerging 6G and AI technologies to help monitor and manage Biodisaster X threats.

Methods

Methods Overview

A review of the literature on the application of AI and 6G technologies for monitoring and managing biodisasters was conducted via PubMed, using articles published from database inception through to November 16, 2020. The literature search focused on three themes: AI techniques, 6G technologies, and biodisasters. The search terms we utilized are listed in Table 1. To ensure that up-to-date evidence was included, validated news reports, articles identified by examining the reference lists of eligible articles, and records found through an updated literature search in January 2021 were also included.

Inclusion and Exclusion Criteria

The literature inclusion criteria for studies in this literature review are listed in Table 2. Overall, articles were excluded if they (1) were not published in English, (2) did not focus on biodisasters, (3) did not focus on either AI techniques or 6G technologies, or (4) did not provide detailed information on the utilization of AI techniques or 6G technologies for monitoring or managing biodisaster threats.

Table 2. Study inclusion criteria.

Data type	Inclusion criteria
Language	English
Study context	Centered on discussions about biodisasters (disasters that occur as a result of infectious pathogens with bioweapon potentials unleashed by state or nonstate actors)
Technology type	Artificial intelligence and 6G
Study design	Focus on utilizing artificial intelligence techniques or 6G technologies to address issues associated with biodisasters

Results

Drawing insights from the review of the literature, the broader literature, as well as the structure of our research objectives and overall study foundation, a clear and comprehensive comparison of the similarities and differences between Disease X and Biodisaster X was developed, details of which are provided in Table 3. As our research objectives were focused on the real-world impact and implications of Disease X and Biodisaster X, rooted in, yet above and beyond what has been discussed and debated in the current literature, our results have been arranged as such. Additionally, to provide a structured and systematic understanding of the findings, we further modeled the study results using the following frames: type of disaster, origin, antecedent, pathogen, transmissibility, transmission predictability, controllability and treatability, nonpharmaceutical mitigation effort, pharmaceutical solution, primary goal, as well as positive unanticipated outcome and negative unintended consequence. A detailed comparison of Disease X and Biodisaster X has been made in Table 3.

XSL•FO
RenderX

Table 3. Similarities and differences between Disease X and Biodisaster X.

Parameter	Disease X	Biodisaster X
Type of Disaster	• Infectious diseases • Natural disasters: epidemics or pandemics	• Infectious diseases • Anthropogenic biodisasters: initially inaccurately identified as a naturally occurring epidemic or pandemic; later identified as anthropogenic
Origin	• None initially, but can be exacerbated by human action or inaction; for example, through livestock mismanagement or failure to contain early infections	• Humans: state or nonstate actors
Antecedent	• None	• Advances in and accessibility of biotechnology; inadequacy of biosecurity measures; intent or malice of nonstate actors
Pathogen	• Originated in nature, with no human engineering • Unfamiliar or unknown to humans	• Originated in a laboratory, mainly as a result of human engineering • Unfamiliar or unknown to humans
Transmissibility	• Highly transmissible, mainly as a result of naturally occurring human interconnectivity	• Highly transmissible, mainly as a result of calculated dissemination and distribution of the pathogen, capitalized on naturally occurring human interconnectivity
Transmission Predictability	• Initially unpredictable; predictability increases over time	• Initially predictable (in principle); extremely low to extremely high predictability over time (depending on the ability of society at large to identify the risk)
Controllability and Treatability	• Low	• Extremely low to extremely high (based on the intent of the actor)
Nonpharmaceutical Mitigation Effort	• Have an agile, evidence-based, and flexible disaster response plan • Equip high-population-density areas with sufficient resources • Limit social interactions; replace physical human interconnectivity with web-based social interactions when possible • Integrate cost-effective technology-based surveillance systems into the emergency management systems • Prepare for a secondary Disease X (potential for mutations or gene transfer, in turn leading to a new Disease X)	• Have an agile, evidence-based, and flexible disaster response plan • Equip high-population density areas with sufficient resources • Limit social interactions; replace physical human interconnectivity with web-based social interactions when possible • Integrate cost-effective technology-based surveillance systems into the emergency management systems • Prepare for a secondary Biodisaster X (actors might further escalate the situation by generating a new Biodisaster X). Once accurately identified as anthropogenic in nature, there will be an urgent need prioritize the identification of the actor
Pharmaceutical Solution	• Difficult and time-consuming to develop vaccines • Extensive and exhaustive efforts needed to identify treatment plans	• Have the potential to be developed fairly easily and time-efficiently once the nonstate actors and the pathogen manufacture process have been identified: vaccine and treatment plans
Primary Goal	• Stop the spread of the pathogen; identify and deploy suitable treatments	• Stop the spread of the pathogen; identify and deploy suitable treatments; locate the source of the pathogen and prevent further action
Positive Unanticipated Outcome and Negative Unintended Consequence	• Physical and psychological health issues associated with the pharmaceutical and nonpharmaceutical solutions • Posttraumatic stress • Increased resource allocation for medicine and public health • Possible economic consequences including a global recession	• Physical and psychological health issues associated with the pharmaceutical and nonpharmaceutical solutions • Posttraumatic stress • Increased resource allocation for medicine, public health, and law enforcement • Possible economic consequences including a global recession

Discussion

Biodisaster X could result in catastrophic human and economic consequences. Yet to date, no studies have examined the potential role of information technologies in preventing and mitigating Biodisaster X, especially in the context of advanced and emerging technologies such as AI and 6G. To bridge the research gap, in this study, we sought to explore 2 fundamental research questions that could considerably enrich the literature: (1) what Biodisaster X might entail and (2) solutions that use AI and emerging 6G technologies to help monitor and manage Biodisaster X threats. In the following sections, we will detail our findings pivoting on these 2 research objectives, as well as practical and powerful strategies that have the potential to effectively control and contain Biodisaster X threats.

Biodisaster X: What is in a Name?

A disaster can be defined as "a serious disruption of the functioning of a community or society involving widespread human, material, economic, or environmental losses and impacts, which exceeds the ability of the affected community or society to cope using its own resources" [47]. Based on the contributing causes, disasters are usually categorized as natural (eg, earthquakes, infectious disease-inducing epidemics, or pandemics of natural origin) and anthropogenic (eg, armed conflicts, nuclear accidents, or the release of pathogenic genetically modified organisms from laboratory settings). In the context of this study, biodisasters are defined as disasters that occur as a result of infectious pathogens with bioweapon potential, which are unleashed by state or nonstate actors accidentally and intentionally (eg, the Japanese government's controversial decision to dump Fukushima's contaminated water into the boundless and borderless ocean shared by all life forms on earth, including humans and sharks [48]). In the context of biodisasters, a state actor often takes the form of a nation that deliberately and systematically designs and develops infectious pathogens with its national interest in mind. In contrast, a nonstate actor is an individual or group acting independently to obtain or manufacture a pathogen either owing to misguidance or malice. Of note, although existing multilateral agreements prohibit the production and use of bioweapons by state actors (termed biowarfare) [49], the presence of signed agreements does not imply that accidental or intentional development and release of pathogens by state actors will not occur.

The concept of "bioterrorism," defined as the deliberate release of pathogens that could cause illnesses and deaths in society, is not the focus of this study because "bioterrorism" entails both deliberation and malice (eg, to elicit terror to the public) [50]; antecedents may not necessarily apply to Biodisaster X threats. Insights from behavioral science [51-53] and evidence regarding individual-caused mass casualty events (eg, indiscriminate mass shootings) [54-56] suggest that individual actors' behaviors, potentially leading to the onset of Biodisaster X, may or may not include conscious deliberation to harm. In other words, while it is possible that individual actors' malicious actions might cause some biodisasters, it is also possible that some individual-caused biodisasters are accidental.

Furthermore, the term bioterrorism is limited, in that "terror" is the main outcome. We believe that for Biodisaster X, which could upend lives, livelihoods, and economies, "disaster" is a more appropriate description that sheds light on the scale and severity of its consequences and is more diverse than "terror." Drawing insight from real-world examples, similar to the prevalent ransomware hacks, it is possible that state or individual actors could develop and utilize infectious pathogens as "ransomgens" for financial gain rather than merely aiming to generate terror in society. Therefore, under the current research context, we adopted the term "biodisaster" instead of "bioterrorism." Furthermore, considering that various studies have discussed approaches to address state actor–initiated biodisasters [57-61], this study focuses on biodisasters that are infectious in nature, caused by individual actors, and can result in catastrophic human and economic consequences.

Biodisaster X vs Disease X

The risk of biodisasters, such as Biodisaster X, is increasing in likelihood: advances in technology, particularly the availability and maturity of biotechnology, have grown considerably in recent years. Inadvertently, these advances may resemble those of Oppenheimer [62] in facilitating the release of destructive factors. One example of the misuse of biotechnology is a microbiologist, vaccinologist, and senior biodefense researcher who worked at the United States Army Medical Research Institute of Infectious Diseases, who allegedly engineered the 2001 anthrax attacks [63-65]. While the scale of the 2001 anthrax attacks was minor, it demonstrated how easily biodisasters can occur and how unprepared society was for these events. As seen in the lack of adequate preparation and coherent responses to infectious disease–induced pandemics, including COVID-19 [66-69], Biodisaster X's effects may be compounded to the same, if not greater, degree by incompetence across international, national, and regional agencies and organizations.

The concept of Biodisaster X can be best understood in contrast with Disease X. In terms of similarities, both Biodisaster X and Disease X are driven by pathogens unknown to humans and have the potential to cause crippling effects on society. Furthermore, based on previous inadequacies in response to emergency events including pandemics [66-74], the world at large may be ill-prepared for both Biodisaster X and Disease X. In terms of unique attributes, compared to Disease X, Biodisaster X is more likely to have the following characteristics: (1) having a pathogen directly affiliated to a laboratory; (2) having distinctive and engineered attributes tailored by the capabilities and intentions of the developer; and (3) the origin, development, and history can be definitively ascertained upon identification of the developer, which is not possible for naturally occurring pathogens (eg, the 1918 influenza pandemic), where there is always uncertainty regarding the origin and evolutionary history of the disaster [75-77].

The Imperative of Preparing for Biodisaster X

Some of the deadliest pandemics—the most recent ones ranging from AIDS, severe acute respiratory syndrome, Middle East respiratory syndrome, Ebola, and COVID-19—all have zoonotic origins [78]. Studies have further shown that for viruses that

XSL•FO
RenderX

can transmit from animals to humans, especially those that can infect a diverse range of host species, the transmission speeds are substantially amplified once human-to-human transmission is established, and the diseases can quickly evolve into global pandemics [79]. Consequently, once a pathogen is transmissible within a population, there is a low access threshold: an individual actor can "obtain" these deadly pathogens without the need for advanced laboratory skills or extensive financial resources. However, costs to physical and mental health may reveal a counternarrative.

Based on available evidence, it is difficult to determine whether an individual can be a malicious "patient zero"; an individual who intentionally contracts a novel virus intending to cause infectious disease outbreaks in a society [80]. It is not impossible to purposely study and capture known or unknown deadly pathogens that can trigger infectious diseases; microbial surveys are commonly conducted to identify novel pathogens before they pose a threat to public health [81-84]. In theory, there could be individual actors, with adequate knowledge or experience (similar to the microbiologist allegedly behind the 2011 anthrax attacks [63-65]), who may take the same actions but with different motives, ranging from scientific curiosity to ill-guided intentions. Considering the rich biodiversity of wildlife, along with the large number of "missing viruses" and "missing zoonoses" that remain unidentified [85], close contacts with latent deadly pathogens are nearly impossible to control, which in turn, renders it challenging to locate or identify individual actors who might utilize them. Advances in synthetic biology may further compound the situation, especially considering the scholarly endeavors using pathogens in laboratory settings, which could amount to the level of real-world pandemics (eg, laboratory-cultured viruses such as smallpox [86-88]). The likelihood of Biodisaster X increases in proportion to these factors.

Overall, considering the species diversity of wildlife, the unknown factors related to the scale and severity of viruses in animals, which have the latent potential to infect humans, and the varying degrees of competency of community health centers in detecting infectious disease outbreaks in a bottom-up manner, it could be tremendously difficult for health experts and government officials to monitor potentially emerging Biodisaster X threats. However, not all hope is lost. Technology-based solutions, especially those utilizing AI and 6G technologies, can help address these issues.

The Need for Advanced Technology Solutions for Monitoring and Managing Biodisaster X

The Need for Technology-Based Solutions

Once Biodisaster X becomes a reality, human contact will drive transmission and become the primary fuel for exacerbating infections and deaths caused by the disaster. As seen during the COVID-19 pandemic, owing to virus spread and subsequent public health policies (eg, lockdowns), many critical societal functions could be substantially disrupted. The potential to control and contain human and economic consequences of Biodisaster X, such as the functionality of the health care systems (eg, infected health care professionals) [89-91], may also become critically undermined. In these circumstances, technology-based solutions could be the key to addressing these crises, as they are different from conventional solutions; they are not highly dependent on physical interactions and transportation. Overall, technology-based solutions require limited human resources (eg, with the ability to operate without human input), can be delivered independent of physical human contact (eg, web-based and remote deployment), and are immune to infectious diseases (eg, can function in contaminated environments). Furthermore, technology-based solutions are less vulnerable to issues ranging from physical fatigue to mental health burdens, which are health challenges that frontline workers often face amid emergency events.

The Need for Advanced Technologies

To effectively predict, control, and manage Biodisaster X, which is an event with a low probability (ie, difficult to detect preemptively) and a high impact (ie, difficult to control and contain), advanced technologies are needed. While many emerging technologies can address the dangers and damages associated with Biodisaster X [92,93], 2 families of advanced technology-based solutions show particular promise, namely AI techniques and 6G technologies.

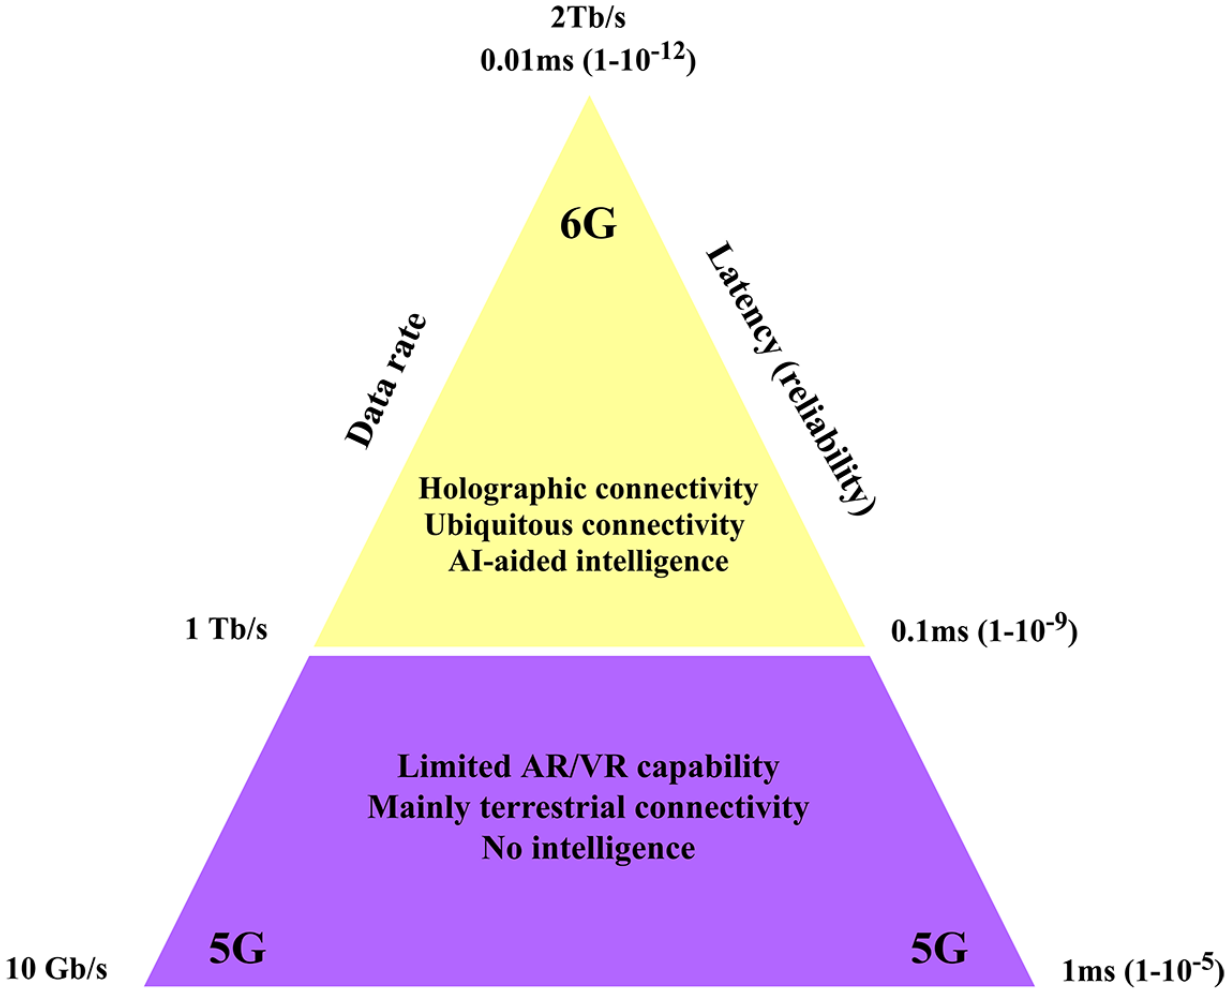
Unique Capabilities of AI

AI is generally considered synonymous with "thinking machines" [94], or techniques that can facilitate "a computer to do things which, when done by people, are said to involve intelligence" [95]. With AI technologies, machines can identify patterns too intricate for humans to identify and process quickly. AI techniques are widely used in areas such as natural language processing, speech recognition, machine vision, targeted marketing, and health care, including efforts to combat COVID-19 [96-99]. While technologies such as virtual reality, smart sensors, drones, and robotics could play a positive role in supporting health care professionals to cope with the pandemic [100-102], AI technologies are arguably most instrumental in addressing some of the most prominent issues health experts and government officials are faced with, ranging from pandemic surveillance to COVID-19 drug and vaccine development [103-106].

AI and machine learning techniques are particularly valuable in their ability to identify trends and patterns across large amounts of data promptly and cost-effectively; for example, in identifying or searching for specific patterns. With natural language processing, for instance, data can be extracted retrospectively from clinical records or prospectively in real time and statistically processed for insights, which, in turn, can supplement existing structured data to enrich actionable information [86]. During the COVID-19 pandemic, natural language processing models have been used to analyze publicly available information such as tweets, tweet timestamps, and geolocation data, to identify and map potential COVID-19 cases cost-effectively, without utilizing testing devices or other medical resources that involve health care professional [107].

Overall, most, if not all, AI techniques are irreplaceable in regard to administering complex tasks such as extracting useful information from large data sets. Moreover, with the

XSL•FO
RenderX



continuously increasing speed of its technological advancements and applications, AI technologies are often utilized as core components in other emerging technologies [108]. Smart sensors that perform advanced tasks, such as effectively identifying and recognizing captured motions and images, often need to integrate deep learning technologies (a subgroup of AI) [109-111]. These combined insights suggest that AI techniques have great potential in monitoring and managing Biodisaster X threats.

Unique Capabilities of 6G Networks

6G technologies are the next generation of wireless communication systems following 5G networks [112]. While 6G is still under development, it is envisioned as the most capable communication network currently available [112-119]. The advantages of 6G networks derive from their high data transmission speed (up to 1 terabyte per second), wireless hyper-connectivity (100 million connections per km^2), low end-to-end latency (< 1 ms), reliability ($1\text{-}10^{-9}$) (reliability in terms of the frame error rate, which is defined as the ratio of the number of incorrectly decoded frames to that of total transmitted frames), and high-accuracy positioning capabilities (indoor: <10 cm in 3D; outdoor: <1 m in 3D) [112-119]. Adding the fact that 6G networks also excel in their energy efficiency and spectrum efficiency, these networks can provide fast and efficient wireless reporting and access to remote computational facilities, facilitating mobile biomonitoring and disaster management.

For instance, the high reliability and data transmission speed of 6G technologies will be of critical importance amid global emergency events with the scale of Biodisaster X. At the onset of the COVID-19 pandemic, many internet companies and service providers experienced outrage and were forced to reduce the amount of data individuals and organizations could utilize to ensure continuous communication for all [120]. This limitation of existing communication networks could compromise the ability of health experts and government officials to monitor and manage COVID-19–related threats and other disasters promptly and properly. Of note, in the face of an extremely deadly, contagious, and fast-developing Biodisaster X, information will be predominantly updated and exchanged remotely and over the internet. The speed and success of updating and exchanging information are highly dependent on the reliability of communication networks, in which 6G technologies excel, especially when spatial big data have been introduced for disease control and prevention since the COVID-19 pandemic [27,108,121]. Figure 1 lists visual comparisons in communication capabilities between 6G and 5G networks.

Figure 1. A schematic representation of the unique advantages of 6G compared to 5G technologies. AI: artificial intelligence, AR: augmented reality, VR: virtual reality.

AI and 6G Technologies for Biodisaster X Control and Management

Drawing insights from the COVID-19 pandemic [103-106], AI techniques, especially when coupled with advanced communication capabilities enabled by 6G technologies, can elevate biodisaster control and management. In other words, 6G-based AI technologies can be applied to address issues ranging from early Biodisaster X detection (eg, identification of suspicious behaviors) to remote design and development of pharmaceuticals (eg, treatment development) and public health interventions (eg, reactive shelter-at-home mandate enforcement), and disaster recovery (eg, sentiment analysis of social media posts to shed light on the public sentiments and readiness for recovery building). While there are research issues worth exploring, in this study, we specifically (1) focus on early detection of Biodisaster X, a disaster management stage that could yield maximum benefit in personal and public health protection, and (2) discuss critical aspects of the utilization and application of 6G-based AI technologies in monitoring and managing Biodisaster X threats. Further information on these AI techniques is available in Figure 2.

Figure 2. Artificial Intelligence techniques discussed in detail in the study. Statistical machine learning refers to techniques that do not involve natural language processing or deep learning processes. AI: artificial intelligence.

Natural Language Processing Analysis

With the benefit of high reliability and high data transmission speed, rather than depending on 1 source of data, 6G-based AI surveillance systems could synthesize various data sources to identify suspicious behaviors for epidemiologists, public health experts, and government officials for further analysis; this may also enable the National Intelligent Syndromic Surveillance System (an AI-based disease surveillance system) [108,122]. As available literature suggests [123-126], for instance, with the help of 6G technologies, natural language processing could be applied to analyze search queries (eg, searches such as “How to build an influenza virus weapon”), credit card transaction data (eg, receipts for equipment that are indispensable to develop a deadly virus), medical records (eg, whether the individual actor has a recent or frequent infectious disease diagnosis), public health records (eg, infectious disease cases coinciding with an actor’s activities), and social media activities (eg, reports of infectious disease symptoms and suspicious behaviors) interactively and in real time. While the analysis of isolated individual data sources may yield more noise than useful information, when the analyses are synthesized with corresponding data from diverse and complementary data sources, actionable information could become more readily available.

It is important to note that natural language processing can also help shed light on people’s mental health, such as identifying at-risk populations with severe mental health disorders including schizophrenia and suicide attempts [127-129]. In an analysis of 826,961 unique Reddit users from 2018 to 2020, with the help of natural language processing techniques, researchers have been able to determine how specific mental health disorders (eg, schizophrenia) manifest in textual language, and, in turn, cost-effectively and unobtrusively identified at-risk mental health in social media users [130]. In the same study, natural language processing also offered researchers the opportunity to

XSL•FO
RenderX

compare pre– and mid–COVID-19 posts to identify people whose mental health disorders had become more pronounced during the pandemic [130].

Statistical Machine Learning Solutions

To increase the usefulness of information, 6G-based AI systems can also capitalize on previously tested infectious disease control and management techniques, such as sewage-based epidemiology. Sewage-based epidemiology, or waste-based epidemiology, has helped scientists detect early warnings of pathogenic virus outbreaks, ranging from hepatitis A and norovirus to COVID-19 [131-135]. Different from conventional sewage monitoring, which incorporates little to no innovative technologies, the utilization and application of cost-effective and data-driven technologies in the field have significantly upscaled the information that researchers can gather from wastewater, thus reducing monitoring and reporting times, and, in turn, elevating societies' ability to better monitor and manage infectious diseases [132-135]. The United Kingdom, for instance, has been rapidly developing its sewage monitoring systems to track COVID-19 outbreaks to understand pandemic transmission patterns more swiftly and accurately [136]. By analyzing human waste, researchers in the United Kingdom and worldwide were able to detect RNA from SARS-CoV-2 and better identify the location, scale, and possible trajectory of COVID-19 transmission [136-138].

However, current sewage monitoring technologies often face challenges such as delays in generating insights and inaccurate results owing to limitations caused by poor data processing speed [115,116], which could be overcome by 6G-based AI systems. The use of machine learning techniques has improved the ability to monitor events, such as poliovirus and enterovirus outbreaks with greater precision, as machine learning models could substantially improve surveillance sensitivity and the quantity and quality of actionable information garnered from wastewater [139]. Overall, with the high reliability and high data transmission speed provided by 6G networks, AI systems could advance sewage epidemiology (eg, through widespread remote analysis and evaluation) and facilitate real-time analyses of potential anomalies such as high volume or density of pathogenic viruses in waste and early infectious disease cases, before these threats progress to outbreaks. Insights gained from natural language processing can be further synthesized with information gained through other control measures, such as systematic and comprehensive sewage monitoring (eg, whether there is a suspicious presence of known or suspected pathogens in certain neighborhoods).

Deep Learning–Based Image Analysis

In addition to using natural language processing and statistical machine learning techniques, deep learning–based image analysis can also help with the early detection of Biodisaster X, particularly with the assistance of advanced networks enabled by 6G technologies. One application of deep learning in Biodisaster X monitoring and management would be gauging whether there are patterned disease outbreak signs, on the basis of insights gained from analyzing nontextual health records, such as medical images and real-time surveillance footage. While unstable and low-speed communication networks could affect AI-based disease surveillance architectures that use both regular reporting and remote computation systems, the influences of low-speed networks will be more pronounced for remote systems that use server-side analysis of high-resolution images to generate actionable information. This high network demand may create issues, such as requiring down-sampling of data, in turn compromising discrimination power and accuracy and the ability of the system to yield useful insights [140].

Machine vision enables machines to recognize visuals with the support of cameras, images, and learning models [141]. These processes can be fine-tuned to recognize and identify objects, such as patients' medical images, and help health care professionals better gather information from imaging data and yield diagnoses and treatment plans [142-144]. Combined with the high speed of 6G networks, remote machine vision could be made more effective by allowing the transmission of high-quality images (eg, high resolution) and video-based surveillance (eg, no lag, high frame rate) in real time, facilitating more remote processing than would be possible otherwise.

With 6G technologies, deep learning–based machine vision could have "superhuman" capabilities in monitoring and managing Biodisaster X threats (eg, tracking multiple objects simultaneously and providing real-time analysis of potential threats with high accuracy), helping health officials track and monitor individual actors once identified. With advancements in 6G and deep learning techniques, machine vision may eventually have the potential to identify individual actors, even when they wear face masks. Scientists have proposed the use of machine vision to help health experts and government officials monitor and reinforce COVID-19 safety rules, such as face-making and social distancing (eg, masked face recognition) [145-147].

Limitations

While this study addresses important knowledge gaps in the literature, there are some limitations to consider. First, owing to the scarcity of literature on the subject, we were unable to adopt a systematic review approach to investigate the research question. While our scoping search is justified for the scale of the current studies in this area, it nonetheless limits our findings. Second, while preparation plans for biodiaster X should involve multiple elements, ranging from surveillance, biosecurity mandates, and communication guidelines, to personnel training, we only discussed 1 aspect of Biodisaster X control and prevention. To address these limitations, assuming an increasing number of studies in this field, future studies should adopt a systematic or more comprehensive approach to examine this topic for further understanding ways to better prepare for Biodisaster X threats. Of note, although many AI techniques are now well-established, 6G technologies are still in their infancy. With the many unknown factors associated with AI and 6G development, it is possible that in the future, 6G and AI technologies may underperform in their ability to assist biodisaster monitoring and management, compared to our expectations and discussion in this study. However, this limitation may only be adequately addressed once empirical evidence on real-world 6G-based AI applications becomes more available and accessible.

XSL•FO
RenderX

Conclusions

Biodisaster X is a looming but avoidable catastrophe. Considering the potential human and economic consequences Biodisaster X could have, actions that can effectively monitor and manage Biodisaster X threats must be taken promptly and adequately. Rather than solely depending on overstretched professional attention of health experts and government officials, it is perhaps more cost-effective and practical to deploy technology-based solutions to prevent and control Biodisaster X threats. This study discusses what Biodisaster X could entail and emphasizes the importance of monitoring and management of Biodisaster X threats through AI techniques and 6G technologies. Future studies could investigate how the convergence of AI and 6G systems may further advance the preparedness for high-impact, less likely events beyond Biodisaster X, including the facilitation of the development of the national intelligent syndromic surveillance system.

Acknowledgments

We thank the International Institute of Spatial Lifecourse Epidemiology and the Hong Kong Polytechnic University (1-BE58) for research support, and we wish to express our gratitude to the editors and reviewers for their constructive input.

Authors' Contributions

ZS conceived the study, reviewed the literature, and drafted and edited the manuscript. DMD, BLB, JH, FS, AC, JA, and PJ reviewed the literature and edited the manuscript. All authors approved the final manuscript for submission.

Abstract

Background: Conversational agents (CAs) for chronic disease management are receiving increasing attention in academia and the industry. However, long-term adherence to CAs is still a challenge and needs to be explored. Personalization of CAs has the potential to improve long-term adherence and, with it, user satisfaction, task efficiency, perceived benefits, and intended behavior change. Research on personalized CAs has already addressed different aspects, such as personalized recommendations and anthropomorphic cues. However, detailed information on interaction styles between patients and CAs in the role of medical health care professionals is scant. Such interaction styles play essential roles for patient satisfaction, treatment adherence, and outcome, as has been shown for physician-patient interactions. Currently, it is not clear (1) whether chronically ill patients prefer a CA with a paternalistic, informative, interpretive, or deliberative interaction style, and (2) which factors influence these preferences.

Objective: We aimed to investigate the preferences of chronically ill patients for CA-delivered interaction styles.

Methods: We conducted two studies. The first study included a paper-based approach and explored the preferences of chronic obstructive pulmonary disease (COPD) patients for paternalistic, informative, interpretive, and deliberative CA-delivered interaction styles. Based on these results, a second study assessed the effects of the paternalistic and deliberative interaction styles on the relationship quality between the CA and patients via hierarchical multiple linear regression analyses in an online experiment with COPD patients. Patients' sociodemographic and disease-specific characteristics served as moderator variables.

Results: Study 1 with 117 COPD patients revealed a preference for the deliberative (50/117) and informative (34/117) interaction styles across demographic characteristics. All patients who preferred the paternalistic style over the other interaction styles had more severe COPD (three patients, Global Initiative for Chronic Obstructive Lung Disease class 3 or 4). In Study 2 with 123 newly recruited COPD patients, younger participants and participants with a less recent COPD diagnosis scored higher on interaction-related outcomes when interacting with a CA that delivered the deliberative interaction style (interaction between age and CA type: *relationship quality: b*=−0.77, 95% CI −1.37 to −0.18; *intention to continue interaction: b*=−0.49, 95% CI −0.97

XSL•FO
RenderX

to −0.01; *working alliance attachment bond: b*=−0.65, 95% CI −1.26 to −0.04; *working alliance goal agreement: b*=−0.59, 95% CI −1.18 to −0.01; interaction between recency of COPD diagnosis and CA type: *working alliance goal agreement: b*=0.57, 95% CI 0.01 to 1.13).

Conclusions: Our results indicate that age and a patient's personal disease experience inform which CA interaction style the patient should be paired with to achieve increased interaction-related outcomes with the CA. These results allow the design of personalized health care CAs with the goal to increase long-term adherence to health-promoting behavior.

conversational agents; chatbots; human-computer interaction; physician-patient interaction styles; deliberative interaction; paternalistic interaction; digital health; chronic conditions; disease management; COPD; chronic obstructive pulmonary disease

Introduction

The occurrence of chronic diseases is on the rise owing to greater longevity of the population, increasing exposure to environmental pollution, and unhealthy lifestyles [1]. As chronic diseases are not curable, related care is directed toward improving the functional status, reducing distressing symptoms, extending life duration through secondary prevention, and improving health-related quality of life [2,3]. This requires comprehensive and personalized disease management based on active long-term collaboration between health care practitioners and chronically ill patients [1].

However, disease management is time-consuming and staff-intensive and is thus often not sufficiently provided [1]. Conversational agents (CAs) (ie, computer programs that imitate interactions with humans) have the potential to improve the status quo as they allow for cheaper and scalable patient support outside the clinical setting [4,5]. When deployed on a smartphone, CAs remain easily accessible and can accompany patients in their daily lives [6,7]. However, long-term adherence to interventions delivered by health care CAs and the effectiveness of interventions with regard to health-related outcomes remain challenging [8,9].

To increase adherence and user value with respect to satisfaction, task efficiency, or the likelihood of sustained outcomes, personalization of CAs is viewed as promising [10]. Despite numerous design considerations [9] for health care CAs, such as personalized recommendations [10] and anthropomorphic cues [11], it is still unclear which CA-delivered interaction styles chronically ill patients prefer and whether the preference has an impact on CA-related perceptions (eg, working alliance) and health outcomes (eg, change in health-promoting behaviors). Research has singled out the importance of the interaction style for treatment satisfaction, adherence, and subsequent outcome [12-14] in face-to-face encounters between physicians and patients and in distance therapy via the phone, internet, or other means [15]. As people apply social behavior and expectations to computers or other media in the presence of anthropomorphic cues ("computers are social actors" paradigm) [16], CA-delivered interaction styles are expected to be of high relevance.

This paper applies and investigates the following four interaction styles of health care CAs [17]: (1) paternalistic (the physician, as a guardian [17], decides alone about the most appropriate treatment based on the assumption of shared values); (2) informative (the physician, as an expert [17], neutrally provides the patient with all treatment-related facts, so that the patient can choose); (3) interpretive (the physician, as a counsellor [17], helps the patient to elucidate the preferences and then leaves it to the patient to make a decision); and (4) deliberative (the physician, as a teacher or friend [17], conjointly discusses with the patient the best way forward).

Contemporary medical research advocates the deliberative style [18,19], which can also be referred to as shared decision making [20], as it is thought to consider patients' values and autonomy and the physician's caring role better than other interaction styles [17,20]. It was also the preferred interaction style by the majority of patients in preference studies [21,22]. However, there is evidence in the literature that sociodemographic and disease-related variables have an impact on the preferred interaction style. Older patients, for instance, tend to prefer a paternalistic interaction style [23,24], based on the assumption that they are accustomed to physicians being traditionally seen as an authority figure [25]. Among men, there is also a preference for the paternalistic interaction style [23,24]. Fatigue, lacking expertise or knowledge about the condition, and the fear of making a wrong decision are additional reasons mentioned in the literature that explain patients' preferences for a paternalistic interaction style in case of a severe condition, a newly diagnosed disease, or minor health literacy [26]. No influence of socioeconomic variables has been found [27] that could explain a preference for the informative style over the deliberative style. There seems to be no further evidence in the current literature base that talks about preferences for the interpretive interaction style.

To address these issues, we conducted two studies. The first study aimed to explore if there exist patient preferences for a paternalistic, informative, interpretive, or deliberative interaction style when a CA takes the role of a caregiver. The results of this study informed the second study that explored in more detail (1) which variables moderate preferences for the CA interaction style and (2) whether preferences have an impact on CA-related perceptions (eg, working alliance) and health outcomes (eg, change in health-promoting behaviors). Both studies involved patients diagnosed with chronic obstructive pulmonary disease (COPD), one of the global top four leading causes of premature death from chronic diseases [28].

Methods

Study Design

First, we conducted Study 1, a paper-pencil survey with COPD patients treated at a leading Swiss Hospital in the German-speaking part of Switzerland. Besides covering sociodemographic and health-related questions, the survey explored baseline differences in patient preferences for a deliberative, informative, interpretive, or paternalistic interaction style with a hypothetical health care CA.

The outcomes informed Study 2, an online experiment. For this study, we recruited COPD patients from four hospitals in the German-speaking part of Switzerland, from the Swiss Lung Association, and from an honorary led self-help association for COPD patients in the German-speaking part of Switzerland. We designed a between-subject online experiment where patients were randomly assigned to interact with a CA that followed either a deliberative or paternalistic interaction style. We chose these two styles since (1) we have already developed and experimentally tested the implementation of deliberative and paternalistic CA interactions in a recent study [29]; (2) there is the most information in the literature for these two styles regarding the moderating influences of sociodemographic and health-related variables; and (3) we expected to find significant effects when choosing the most and least preferred interaction styles as determined in Study 1. Both studies did not fall within the scope of Human Research Law, according to the local Swiss ethics authority, and thus did not require any formal authorization.

Sample Size Considerations

The primary objective of Study 1 was to explore whether general differences exist between interaction style preferences of COPD patients for their interaction with a CA. Thus, this part of the study was exploratory by nature and did not contain a detailed power analysis.

We conducted an a priori power analysis for Study 2 using R software (version 3.5.2) and the R package WebPower [30]. To identify a medium effect (f^2=0.15) [31] in a hierarchical multiple regression with an alpha level of .05, a statistical power of 0.80, a reduced model with one predictor, and a full model with 13 predictors, a total of 127 participants was required.

Inclusion Criteria

For Study 1, we defined the following inclusion criteria: (1) COPD diagnosis, (2) age of 18 years or older, and (3) ability to speak German.

We defined the same inclusion criteria for Study 2. Here, the first inclusion criterion was checked before distributing the link to the online experiment. The link was only sent out to patients who were registered as COPD patients at any of the participating hospitals, the lung association, or the self-help association. In addition, patients also had to confirm that they have COPD during the online experiment. The second and third inclusion criteria were checked at the beginning of the online experiment. If patients did not confirm either being of age or being able to speak German, the experiment was automatically completed. There were no exclusion criteria.

Procedure of Study 1 and Study 2

Study 1 was administered as a paper-and-pencil survey and divided into four parts. Before starting with the actual questions, we provided general information about the survey (ie, we clarified the objective and structure, and provided an illustrative explanation of a CA-based intervention). After querying sociodemographic and health-related questions, the survey explored patients' preferences regarding their interaction style with a hypothetical CA. Patients could choose from snippets portraying exemplary interactions with a CA, and each snippet depicted a different interaction style (see Figure 1 for an overview).

The procedure of Study 2 was as follows. Participants agreed to the study conditions and confirmed the study inclusion criteria (ie, being of age and being able to speak German). After querying standard demographic data (age, gender, mother tongue, and education), patients answered questions about their general health status and COPD. Patients were then randomly assigned to interact with a CA presenting a deliberative or paternalistic interaction style. The interactions were text-based and followed by a prescripted dialogue based on two predeveloped scripts. These scripts were developed and assessed in a recent study, where they were verified to be perceived as eliciting a deliberative or paternalistic interaction style between a CA and users [29]. During the conversation with the CA, patients could choose between one to three predefined answer options, which were identical in both conditions (ie, deliberative and paternalistic interaction styles). Deviations between the answer options only occurred when needed to keep the conversational flow realistic. Both interactions with the CA (ie, paternalistic and deliberative) were approximately of the same length and duration (38 conversational turns in the deliberative version and 32 in the paternalistic version with a reading duration of roughly over 12 minutes). After the interaction with the CA, participants were asked to evaluate the interaction with the CA on several dimensions. Details about the measures can be found in the measures section below.

To conclude the experiment, participants had to answer a short COPD health literacy quiz. The questions were based on the standardized Bristol COPD Knowledge Questionnaire (BCKQ), a multiple-choice questionnaire developed to measure the disease-specific knowledge of COPD patients [32]. Finally, patients reported on their perception of the length of the study and could leave some free-text feedback. All questions of Study 2 can be found in Multimedia Appendix 1.

RenderX

Figure 1. Illustrations outlining the four physician-patient interaction styles.

Technical Implementation of CAs for Study 2

We used Qualtrics, a software-based online survey and data collection platform, for the online experiment and for randomly assigning patients to one of the two experimental settings (ie, interaction with a CA using a deliberative interaction style and interaction with a CA using a paternalistic interaction style). We further used Collect.chat, a commercially available chatbot software, to develop the CA dialogues, and iframe to embed the CA into the Qualtrics HTML.

Recruitment and Management of Study Participants

We recruited the participants for Study 1 from the pulmonology department of a leading Swiss hospital. The patient database included around 1300 patients, and we contacted all by mail. Eligible patients received the printed survey and a letter containing information about the survey and participation conditions. We also provided a prefranked return envelope to reduce the necessary effort to reply to the survey and to minimize financial expenses for the participants. The postal send out took place on April 9 and 10, 2019, and we started to receive responses 1 week later. We received replies for 2 months in total, and the majority of replies reached us in the first 3 weeks.

The patients of Study 2 were recruited during a 3-month period from February to April 2020 at six study sites in Switzerland. The study sites were the pulmonology departments of four hospitals in the German-speaking part of Switzerland, the Swiss Lung Association, and an honorary-led self-help association for COPD patients. Participants were recruited via email or postal mail or in-person by participating health care professionals on-site. When they were recruited in-person, participating health care professionals handed out a flyer to potential participants. This flyer contained some information on the study and a link to the online experiment (see Multimedia Appendix 2 for the flyer). Participating health care professionals had previously received study instructions from the study authors. When patients were recruited via email, they received an email from the participating hospital, the Swiss Lung Association, or the self-help association. In this email, the participating contact person explained the study and asked for voluntary participation. The email further contained the same flyer as used for the on-site recruitment. When participants were recruited via postal mail, they received a letter from the participating hospital with study information and a link to the online experiment, which they had to type into a web browser. The postal letter is presented in Multimedia Appendix 3. We followed a multichannel and multisite recruiting process. More precisely, we contacted 903 patients at three study sites via email and postal mail. Additionally, 110 flyers were printed and displayed at two further study sites. Here, the flyers were displayed in the study sites' waiting rooms and were free to pick up for the patients. There were no additional prompts by medical personnel to participate in the study. The email and

XSL•FO
RenderX

postal mail had the same design and included exactly the same content as the flyer. At the sixth study site, 27 local COPD patient groups were contacted via email. Importantly, the resulting response rate has to be interpreted as a lower bound estimate since patients might have received an invitation more than once. For example, they could have been regular patients in hospital X and, at the same time, also a member of a COPD patient organization that distributed study invitations.

To start the online experiment, participants had to either click on the study link in the email or type the URL in their browser in case they received a postal letter. A simplified URL (ie, only portraying a shorter number of signs) was created with Bitly [33] to access the online experiment and to reduce barriers to participate. The experiment was available online from April to August 2020.

Measures of Study 1: Paper-and-Pencil Survey

For Study 1, we gathered basic sociodemographic (age, gender, and education) and health-related data (GOLD COPD level) [34]. GOLD stands for Global Initiative for Chronic Obstructive Lung Disease and is an internationally used scale for classifying the severity of COPD [34]. Patients reported sociodemographic and health-related data before being presented with the four main physician-patient interaction styles.

Sociodemographic Data

For the item *age*, patients reported their birth year. To derive patients' actual age, their birth year was subtracted from 2020 in the descriptive analyses. For the item *gender*, patients could choose their gender from a tick box with answer options "female," "male," and "no answer." For the item *education*, patients could choose one of the following four different options: *no formal education*, *secondary 1 education*, *secondary 2 education*, and *tertiary education*. Drawing on the 2011 International Standard Classification of Education (ISCED) Scheme [35], a comprehensive framework for comparing and organizing education programs and qualification across countries, these options translate to other global educational systems, such as the US system as follows. *Secondary 1 education* in Switzerland corresponds to level 2 of the ISCED scheme (ISCED 2, lower secondary education) and 9 years of education completed. ISCED 2 translates to completing junior high school in the United States. *Secondary 2 education* corresponds to level 3 of the ISCED scheme (ISCED 3, upper secondary education) and 13 years of education completed. ISCED 3 translates to completing a senior high school degree in the United States. *Tertiary education* in Switzerland (ISCED 6-8) encompasses bachelor's, master's, and PhD degrees, corresponding to a total of 16, 18, and 21 years needed to complete these educational levels (equivalent to the degrees in the United States) [36,37].

Health-Related Data

We queried the *GOLD COPD level* for each patient with the item "What is your GOLD rating?" (translation by the authors) on a 5-point scale ranging from 1 (GOLD 1) to 5 (I do not know). The highest and most severe GOLD level is GOLD 4.

Next, we introduced the four main physician-patient interaction styles as per a previous report [17], and patients were asked which of the four they would prefer for their interaction with a CA. We provided a definition of the respective role of the physician in the interaction style.

Measures of Study 2: Online Experiment

Study 2 was pretested with two pulmonologists of a leading Swiss hospital (both specialized in COPD), one advanced practitioner nurse in lung disease, and 10 PhD students of the Swiss Federal Institute of Technology in Zurich. We aimed to identify possible problems in terms of clarity, accuracy, and relevance for assessing health-related measures that are specific for COPD. Based on the feedback, a few changes were made to improve the wording of the questions and the order of the items.

For the main analyses and for assessing the various aspects of the two interaction styles, we gathered basic sociodemographic data (age, gender, and education), health-related data (GOLD COPD level, years since COPD diagnosis, and disease literacy), and interaction-related data (willingness to change, relationship quality, intention to continue interacting, and working alliance).

Sociodemographic and Health-Related Data

Sociodemographic data were gathered before the interaction with the CA. For the item *age*, patients could choose their birth year from a dropdown menu, ranging from 1900 to 2020. To derive patients' age, their birth year was subtracted from 2020 in the analyses. For the item *gender*, patients could choose their gender from a tick box with answer options "female," "male," and "no answer." For the item *education*, patients could choose from 12 different options from a dropdown menu (eg, "apprenticeship" [translated by the authors]; all original German measures can be found in Multimedia Appendix 4). For the analyses, educational attainment was recoded as years of education based on the 2011 ISCED scheme [35].

Health-related data were gathered before the interaction with the CA. Just as in Study 1, we first queried the *GOLD COPD level* for each patient with the item "What is your GOLD rating?" (translation by the authors) on a 5-point scale ranging from 1 (GOLD 1) to 5 (I do not know). The highest and most severe GOLD level is GOLD 4. Second, we measured *years since COPD diagnosis* with the item "Have you been diagnosed with COPD?" (translation by the authors), with answer options "yes" and "no" to ensure that patients confirm their COPD disease, and the item "If so, in which year?" (translation by the authors), with a dropdown menu to select a year between 1900 and 2020. To derive patients' years of experience with the disease, the diagnosis year was subtracted from 2020 in the analyses. Third, we measured *disease literacy*. Disease literacy was assessed using the BCKQ [32]. To keep the handling time for patients as short as possible, we selected 10 items of the BCKQ after consultation with two nurses who frequently use the questionnaire themselves with their patients. For example, patients had to mark the statement "COPD is commonly an inherited disease" (translation by the authors) as "true," "false," or "I do not know." If they evaluated the statement correctly, they were given 1 point, and in case of a false or "I do not know"

XSL•FO
RenderX

answer, they were given 0 points. We built a sum score over the 10 items, with higher values indicating higher disease literacy. The complete BCKQ (68 items) was reported to have reasonable internal consistency with a Cronbach alpha of .73 in previous studies [32]. The 10-item subset used in our study had a Cronbach alpha of .62, which, though not ideal, can still be considered acceptable [38], especially given the drastically reduced number of items.

Interaction-Related Data

Interaction-related data were gathered after the interaction with the CA Robo. We first measured *willingness to change* with the item "Was Robo able to motivate you for the proposed exercise?" (translation by the authors), with answer options "yes" and "no." This item was adapted from a previous report [39]. We further measured *relationship quality* with the German adapted item [40] "How would you characterize your relationship with Robo?" (translation by the authors), with answers on a scale ranging from 1 ("complete stranger") to 5 ("close friend"), and the German adapted item [41] "I think Robo liked me" (translation by the authors), with answers fixed on a 5-point Likert scale ranging from 1 ("not at all") to 5 ("very much"). Next, we measured *intention to continue interacting* with the German adapted item [42] "I would like to continue using Robo" (translation by the authors), with answers fixed on a 6-point Likert scale ranging from 1 ("strongly disagree") to 6 ("strongly agree"). Finally, we measured *working alliance* between the patients and the CA Robo with a German-adapted version of the Working Alliance Inventory-Short Revised (WAI-SR) [43]. Here, we measured the two subscales *attachment bond* and *goal agreement* (eg, "Robo and I respect each other," translation by the authors), with answers fixed on a 5-point Likert scale ranging from 1 ("rarely") to 5 ("always") (Multimedia Appendix 4). We decided to omit measuring the third subscale *task agreement* as it does not directly relate to our research questions. For secondary analyses (Multimedia Appendix 5), we measured additional interaction-related data (eg, satisfaction with the interaction and recommendation to a friend).

Results

Results of Study 1: Paper-and-Pencil Survey

Preferences for the paternalistic, informative, deliberative, or interpretive style are depicted by gender, age, educational levels, and disease severity. Out of 181 participants who started the survey, only 139 participants who completed the CA preference task were included in the final sample of Study 1. Moreover, 22 additional participants were excluded because they reported not having COPD. The final sample consisted of 117 participants with a mean age of 65.7 years and a mean GOLD classification value of 2.87. Of the 117 participants, 66 were male. Descriptive statistics can be found in Table 1. R scripts for all tables can be found in Multimedia Appendix 6. Missing data were dealt with by list-wise deletion because of the small number of participants having missing values for a variable of interest.

Table 1. Descriptive statistics of the participants in Study 1 (N=117).

Characteristic	Value
Gender, n (%)	
Male	66 (56%)
Female	51 (44%)
Age (years), mean (SD)	65.67 (10.92)
Education, n (%)	
None	7 (6%)
Secondary I	15 (13%)
Secondary II	56 (48%)
Tertiary	36 (31%)
COPD[a] severity value, mean (SD)	2.87 (0.98)
COPD severity, n (%)

XSL•FO
RenderX

Gender

Across CA categories, women most often chose the deliberative CA type, whereas men preferred the informative and deliberative CA types (26 vs 24; Table 2). Within each category of the deliberative, paternalistic, or interpretive CA type, men and women were fairly equally represented. Men constituted 77% (26/34 persons) of persons who preferred the informative CA type.

Table 2. Conversational agent preferences by gender.

Variable (gender)	Value, n[a] (%[b] by conversational agent category)				Sum (N=117), n
	Paternalistic (n=7)	Informative (n=34)	Interpretive (n=26)	Deliberative (n=50)	
Male	4 (57%)	26 (77%)	12 (46%)	24 (48%)	66
Female	3 (43%)	8 (24%)	14 (54%)	26 (52%)	51

[a]Numbers represent the absolute numbers of participants.

[b]Percentages of male/female participants present in each conversational agent category are given in parentheses.

Age

Younger participants (40-50 years old) preferred the deliberative CA type over the paternalistic CA type. Participants in the age group 51-60 years preferred the informative type. Participants in the age groups 61-70 and 71-80 years most often chose the deliberative type, and the oldest participants (81-90 years old) were fairly equally distributed across the informative, interpretive, and deliberative CA types. Within categories, 57% (4/7) of participants who chose the paternalistic CA type were in the youngest age category (40-50 years old). On the other hand, in the interpretive and deliberative groups, 78% (20/26) and 70% (35/50) of participants, respectively, were older than 60 years (Table 3).

Table 3. Conversational agent preferences by age.

Variable (age)	Value, n[a] (%[b] by conversational agent category)				Sum (N=117), n
	Paternalistic (n=7)	Informative (n=34)	Interpretive (n=26)	Deliberative (n=50)	
40-50 years	4 (57%)	1 (3%)	1 (4%)	6 (12%)	12
51-60 years	2 (29%)	12 (35%)	5 (19%)	9 (18%)	28
61-70 years	0 (0%)	9 (27%)	9 (35%)	14 (28%)	32
71-80 years	1 (14%)	9 (27%)	9 (35%)	19 (38%)	38
81-90 years	0 (0%)	3 (9%)	2 (8%)	2 (4%)	7

[a]Numbers represent the absolute numbers of participants.

[b]Percentages of age category participants present in each conversational agent category are given in parentheses.

Educational Levels

Participants without any formal education preferred the informative CA type. Participants who finished secondary I were fairly equally distributed across categories. Participants with higher educational levels (secondary II and tertiary) preferred the deliberative CA type (Table 4). This pattern was more distinct for secondary II than tertiary, where participants also often chose the informative CA type. Within categories, participants who had secondary II and tertiary education constituted 85% (40/47) of those who chose the deliberative type. Similarly, participants who had secondary II and tertiary education constituted 87% (23/26) of those who preferred the interpretive type. In the paternalistic condition, only the first three educational levels were represented (no formal education, secondary I, and secondary II).

Table 4. Conversational agent preferences by educational level.

Variable (education)	Value, n[a] (%[b] by conversational agent category)				Sum (N=114), n
	Paternalistic (n=7)	Informative (n=34)	Interpretive (n=26)	Deliberative (n=47)	
Secondary I	3 (43%)	4 (12%)	3 (12%)	5 (11%)	15
Secondary II	3 (43%)	14 (41%)	14 (54%)	25 (53%)	56
Tertiary	0 (0%)	12 (35%)	9 (35%)	15 (32%)	36
No formal education	1 (14%)	4 (12%)	0 (0%)	2 (4%)	7

[a]Numbers represent the absolute numbers of participants.

[b]Percentages of educational level participants present in each conversational agent category are given in parentheses.

XSL•FO
RenderX

Severity of COPD

Across CA categories, participants with less severe disease (GOLD 1) preferred the informative and interpretive CA types. Participants with mid-severe disease (GOLD 2 and 3) preferred the deliberative CA type. Participants with severe disease (GOLD 4) preferred the deliberative and informative CA types. Within categories, participants with higher disease levels (GOLD 3+4) constituted 100% (3/3) of those who preferred the paternalistic CA type (Table 5).

Table 5. Conversational agent preferences by Global Initiative for Chronic Obstructive Lung Disease classification.

Variable (GOLD[a] classification)	Value, n[b] (%[c] by conversational agent category)[d]				Sum (N=75), n
	Paternalistic (n=3)	Informative (n=27)	Interpretive (n=12)	Deliberative (n=33)	
GOLD 1	0 (0%)	3 (11%)	3 (25%)	1 (3%)	7
GOLD 2	0 (0%)	7 (26%)	4 (33%)	9 (27%)	20
GOLD 3	2 (67%)	6 (22%)	3 (25%)	13 (39%)	24
GOLD 4	1 (33%)	11 (41%)	2 (17%)	10 (30%)	24

[b]Numbers represent absolute numbers of participants.

[c]Percentages of GOLD classification category participants present in each conversational agent category are given in parentheses.

[d]The data of a maximum of seven out of 117 participants were deleted for Table 5 because they did not report any information on their GOLD classification (neither "GOLD 1-4" nor "I do not know").

Results of Study 2: Online Experiment

We conducted hierarchical multiple regression modeling to predict participants' self-reported interaction quality with the CA, that is, *willingness to change*, *relationship quality*, *intention to continue interaction*, and *working alliance*, based on (1) the type of CA (paternalistic/deliberative), (2) patients' demographics (age, gender, and education), and (3) COPD-related measures (GOLD, COPD disease literacy, and experience with COPD). Each outcome was predicted in a three-step procedure. The first block added to the model was the CA type (labelled "model 1"). The second block contained the CA type and participants' demographics (labelled "model 2"), and the third block consisted of the CA type, participants' demographics, and COPD-related measures (labelled "model 3"). *Relationship quality*, *intention to continue interaction*, and *working alliance* were measured on a metric scale. We calculated hierarchical linear regressions for those outcomes and logistic regression for the binary outcome *willingness to change*. As in Study 1, missing data were dealt with by list-wise deletion.

Analysis of Sociodemographic and Health-Related Data

The descriptive statistics of the experiment are shown in Table 6. Out of 168 participants who started the survey, 124 completed the survey. One additional participant was excluded because of age (<18 years old), leading to a final sample of 123 participants. Of those 123 participants, 76 were male, with a mean age of 67.8 years and a mean duration of 8.4 years since their COPD diagnosis. The mean GOLD classification value was 2.70.

Table 6. Descriptive statistics of the participants in Study 2 (N=123).

Characteristic	Value
Gender, n (%)	
Male	76 (62%)
Female	47 (38%)

Analyses of Interaction-Related Data

For our analysis, we introduce interaction-related outcomes, defined in terms of the outcome variables *willingness to change*, *relationship quality*, *intention to continue interaction*, and two dimensions of *working alliance* (*attachment bond* and *goal agreement*). Better interaction-related outcomes indicate a higher willingness to change one's behavior after interaction with the CA, a higher perceived relationship quality, a higher motivation to continue interacting with the CA, and a higher-rated reported working alliance with the CA in terms of perceived close attachment bond and common goal agreement. Multimedia Appendix 5 presents the results of additional interaction-related data (eg, satisfaction with the interaction and recommendation to a friend). The R scripts for all analyses are presented in Multimedia Appendix 7.

Willingness to Change

Overall, participants who interacted with a paternalistic CA reported being more willing to change their behavior based on the CA intervention than those who worked with a deliberative CA (Table 7). There were no substantial interaction effects between CA type and participants' demographics or CA type and patients' COPD-related characteristics.

Table 7. Regression of conversational agent type, participants' demographics, and chronic obstructive pulmonary disease–related characteristics in terms of participants' willingness to change their behavior after conversational agent interaction.

Variable	Model 1[a], regression coefficient (95% CI)	Model 2[b], regression coefficient (95% CI)	Model 3[c], regression coefficient (95% CI)

[k]COPD: chronic obstructive pulmonary disease.

[l]Experience with COPD in years since COPD diagnosis.

Relationship Quality

On average, older participants reported better relationship quality with the CA than younger participants, irrespective of the CA type. Participants with more severe COPD reported better relationship quality with the CA than participants with less severe COPD, irrespective of the CA type. There was a negative interaction effect between CA type and age, implying that older participants preferred a paternalistic CA and younger participants preferred a deliberative CA with respect to relationship quality (Table 8).

Intention to Continue Interaction

Disease severity positively predicted participants' intention to continue interacting with the CA after the interaction ended. The higher a participant's GOLD classification, the higher was his or her intention to continue (Table 9). Participants with fewer years of experience with COPD reported a higher intention to continue the interaction, irrespective of the assigned CA type. Older participants reported being more likely to continue the CA interaction when working with a paternalistic CA, and younger participants reported that when working with a deliberative CA.

Working Alliance (Attachment Bond)

We found a substantial negative interaction effect among age, CA type, and reported attachment bond with the CA. This indicates that older participants had a higher attachment bond when working with the paternalistic CA type and younger participants had that when working with the deliberative CA type. Overall, participants who had a higher disease literacy of COPD also reported better attachment bond (Table 10), irrespective of the assigned CA type.

[l]Experience with COPD in years since COPD diagnosis.

Working Alliance (Goal Agreement)

Irrespective of the CA type participants were working with, those with a higher disease literacy reported higher perceived support to achieve their goals by the CA. Participants with fewer years of experience with COPD reported higher perceived support to achieve their goals by the CA. Older participants reported higher support by the CA when in the paternalistic condition, and younger participants reported that when in the deliberative condition. A positive interaction effect between CA type and experience with COPD implied that participants who were more experienced with COPD reported better perceived support in achieving their goals when interacting with a deliberative CA and participants who were less experienced with COPD reported that when interacting with a paternalistic CA (Table 11).

[l]Experience with COPD in years since COPD diagnosis.

Summary

In summary, we found evidence that age and experience with COPD inform participants' preferences for a deliberative or paternalistic interaction style of the CA. Older participants reported better interaction-related outcomes when interacting with a paternalistic CA, whereas younger participants reported that when interacting with a deliberative CA. Participants with fewer years of personal experience with COPD reported better interaction-related outcomes when interacting with a paternalistic CA, whereas those with more years of personal experience reported that when interacting with a deliberative CA. We did not find evidence for gender, disease level, and disease literacy. Irrespective of the CA type, disease literacy positively predicted both dimensions of working alliance, and participants with fewer years of experience with COPD reported higher perceived support in goal agreement by the CA and were more motivated to continue the interaction with the CA. A more severe disease level was associated with higher motivation to continue the interaction with the CA. Participants who worked with a paternalistic CA were more likely to change their behavior based on the intervention. Thus, our results indicate that knowing the age and years of experience of a patient with COPD can help to decide which interaction style to choose for the patient in order to increase interaction-related outcomes for the patient.

Discussion

Principal Findings

In this work, we investigated the preferences of patients with COPD for specific interaction styles of health care CAs. The interaction style between health care professionals and patients has long been recognized as a key success factor for chronic disease management and final treatment success [44,45]. Given the rising number of chronically diseased patients and the associated financial and personal burdens, CAs represent scalable and ubiquitous digital tools to support chronic patients and relieve human health care professionals. A systematic approach for inducing two specific interaction styles into CAs

XSL•FO
RenderX

in a health care setting has previously been developed and validated [29].

In our first study, we determined baseline differences for preferred interaction styles between 117 COPD patients and CAs. We showed that differences in preferences for specific interaction styles for the interaction between chronically diseased patients and CAs exist. In our second study, we explored the patterns of preferences for two specific interaction styles in 123 COPD patients. We found evidence that younger patients reported better interaction-related outcomes when interacting with a deliberative CA, while older COPD patients reported better interaction-related outcomes when interacting with a paternalistic CA. Additionally, COPD patients with longer personal experience with the disease reported better interaction-related outcomes when interacting with a deliberative CA. Moreover, COPD patients with lower COPD disease literacy reported better interaction-related outcomes when interacting with a paternalistic CA. Gender, disease severity, or disease literacy did not affect any preferences for specific interaction styles. Nevertheless, we found evidence that disease literacy, in general, positively predicted both dimensions of working alliance independent of the interaction style.

This paper is especially important for the development of personalized CAs in the context of digital health care, with a focus on chronic diseases. To our knowledge, this is the first investigation that systematically evaluated the preferences of chronic patients for their interaction style with CAs. While CAs have primarily been developed portraying a single interaction style for every human counterpart interacting with them, medical research has long stated the crucial importance of deploying personal interaction styles in order to improve patient satisfaction [40], treatment adherence, and final treatment outcome [46,47]. Addressing the gap in the literature regarding differentiated and personalized interaction styles for patient-CA interactions and adding to the growing body of literature on CA personalization [10,11], this paper now provides the first evidence that chronic patients report better interaction-related outcomes when interacting with CAs that display personalized interaction styles.

The findings of these two studies further inform the pairing of chronic patients to CAs that are personalized at the level of their interaction style. While medical research postulates the relevance of five factors (gender [23,24], age [23,24], disease level [26,48], personal experience with a disease [49], and disease literacy [50,51]) that influence the patient-physician interaction, we showed that not all of these aspects are similarly important when it comes to coupling chronic patients with CAs. Our first results indicate that knowing the age and personal disease experience of the patient is sufficient to decide which interaction style results in increased interaction-related outcomes for the patient at hand. While these are the first results from a restricted sample in an experimental setting, the implications for CA deployment could be significant. Especially from a privacy perspective, the findings would reduce the amount of personal patient data needed to achieve an advantageous CA-patient allocation, as only these two data points can be gathered instead of obtaining a whole plethora of personal data. In addition, these two data points can be easily collected at the start of the patient-CA interaction, without any specific (medical) knowledge needed for assessing them. This could reduce the work of health care professionals, whose time is limited and costly, as the best-fitting CA could be allocated based on responses to a simple digital questionnaire at the beginning of the patient-CA interaction. Notwithstanding these potential possibilities, more research needs to be done to be able to robustly understand patients' preferences in detail so that industry applications can be developed and reliably used.

Strengths and Limitations

This paper has several strengths. First, we followed a two-step approach by determining baseline differences of COPD patients' preferences for their interaction with a CA in Study 1 and subsequently expanding the findings to Study 2, a between-subject online experiment. Second, we deployed a systematic and validated approach for inducing two specific interaction styles into the patient-CA interaction [29]. Third, we continuously ensured an objective approach by integrating both theoretical knowledge and applied medical expertise into the development of the experiment. We did this by closely collaborating with medical professionals. Here, we worked together with not only medical experts on COPD (the chronic disease subject of this paper), but also health care professionals from other fields to reduce the risk of bias. In addition, we integrated the views of both senior and novice health care professionals to reflect traditional paternalistic-based training and current shared decision making–based training. Fourth, we focused on investigating the preferences of a specific target population, that is, patients with COPD. This focus on a relatively homogeneous patient group allowed us to delve into depth and gain a profound understanding of their preferences.

This work also has limitations. First, we tested baseline differences between all four major interaction styles in Study 1 (a paper-pencil study), but we only tested personal preferences for the deliberative and paternalistic interaction styles in Study 2 (online experiment). These are the two interaction styles where a systematic and validated approach for inducing the specific interaction style into the CA-patient interaction for a digital online setting exists. They further represent the start point and endpoint of a hypothetical ethical development process of a model patient-physician interaction [52]. Nevertheless, the results from Study 1 indicated that some patients might have personal preferences for other interaction styles than these two. The preferences for these interaction styles need to be investigated by future research. In addition, we could see differences in the preference allocation between the studies. While older participants in Study 2 preferred a paternalistic CA when evaluating relationship quality, 57% (4/7) of participants who chose the paternalistic style in Study 1 were in the youngest of the tested age ranges. This difference could be assumed to have originated in the respective study setup. Participants could choose from one single interaction snippet of the four main different interaction styles, and participants in Study 2 had a real interaction with a CA, but only the deliberative or paternalistic CA. As such, further research is needed to robustly understand patients' preferences, especially when it comes to a real interaction with a CA. Second, the study population only included German-speaking patients based in one country. It

XSL•FO
RenderX

could be that other languages or regions influence different interaction style preferences and personal requirements. Third, disease-related patient inputs (eg, GOLD status and years of diagnosis) were self-reported and hence not verifiable. Additionally, not all patients reported their GOLD status. Fourth, we only modeled the first part of an initial interaction between a patient and a CA. In reality, patients would need to interact over a prolonged period of time when a CA supports their chronic disease management. Fifth, we used a paper-based snippet of a hypothetical patient-CA interaction in Study 1 and a prescripted and rule-based CA in Study 2. While these two approaches were necessary because of the study condition in Study 1 (we sent a physical letter to the patients) and to control the experimental condition in Study 2, both approaches have their limitations when it comes to emulating a naturalistic patient-physician interaction. We are aware of the increasing number of artificial intelligence (AI)–based CAs [4] as well as voice-based CAs for health care purposes [53]. We believe this could be an interesting path for future research in this context of personalized patient-CA interaction styles. AI-based CAs could not only interact in a more naturalistic way by utilizing unconstrained written, spoken, or visual input [4], but also further adapt dynamically to personal developments, for example, the level of disease literacy of their human users.

Suggestions for Future Research

In general, we advise future research to put a stronger focus on the investigation of patients' personal preferences for specific interaction styles when interacting with CAs based on the long-known importance of this factor in the human patient-human physician context. In detail, we see specific possibilities for future research motivated by the limitations of this study and as an extension of it.

First, we advise future research to expand and test the used systematic approach for inducing two specific interaction styles to more interaction styles. As discussed above in the Strengths and Limitations subsection, we could see variations in preferences when patients could choose from four interaction styles (but only having one written interaction snippet to choose from) and a setting where they could interact for longer with either a deliberative or paternalistic CA. This could provide valuable insights into how many different interaction styles for patient-CA interactions are needed. In addition, we recommend future research to study the development of patients' preferences over time. It would be highly relevant to determine whether such preferences stay stable or dynamically evolve over time. Second, we suggest the development and evaluation of CAs in other languages besides German and in more diverse geographical settings to investigate the effects of language and regional specificities on patient-CA interaction styles. Third, we recommend focusing on the preferences of patients suffering from different diseases (both acute and chronic). We suggest focusing on differences within as well as between diseases to understand any influencing factors of the medical condition at hand in detail. Fourth, future research could expand our experiment and develop a more extended interaction between patients and interaction style–personalized CAs. This could bear interesting findings to further understand dynamic developments of personal preferences for interaction styles between patients and CAs. Fifth, we believe the development and implementation of AI-based CAs that are able to interact more naturally and adapt dynamically to the patient at hand could yield interesting results in the field of patients' personal preferences for their interaction with CAs.

Conclusions

The interaction style between patients and physicians is recognized as a critical parameter for patient satisfaction, treatment adherence, and subsequent treatment outcome and, as such, also plays a paramount role for chronic disease management. So far, CAs as ubiquitous and scalable digital tools have mainly utilized a single interaction style for every patient, thus ignoring the relevance of personalized interaction styles. In this paper, we showed that chronically diseased patients exhibit preferences for different interaction styles when conversing with a digital health CA. Our results provide evidence that patients' age and personal experiences with the disease inform their preferences for a specific interaction style. Hereby, this work provides insights into the rising trend of personalized CAs in health care. We envisage a future where every chronic patient gets paired with a CA exhibiting the right interaction style at the right moment and dynamically adapting to the needs of the patient, thereby allowing for a satisfying and fulfilling patient-CA interaction that supports the best possible treatment outcomes and disease management.

Acknowledgments

We want to express our deepest gratitude to the hospitals across Switzerland, the Swiss Lung Association, and the self-help association for COPD patients (www.copd-sauerstoffpatienten.ch) that allowed us to recruit study participants from their patient population member base. Without them, a study of this scale would not have been possible. We would also like to thank our fellow researchers at ETH Zurich, who helped us pretest the online experiment to guarantee a seamless experience for the study participants. We would also like to express our gratitude to Marcia Nießen of ETH Zurich for her considerations to the questionnaire of Study 1.

Conflicts of Interest

FW co-chairs the Center for Digital Health Interventions (CDHI), a joint initiative between the Department of Management, Technology and Economics at ETH Zurich and the Institute of Technology Management at the University of St. Gallen. The CDHI is funded in part by the Swiss health insurer CSS. TK is a scientific director at the CDHI and a co-founder of Pathmate Technologies, a university spin-off company that delivers digital clinical pathways with the help of conversational agents. Neither

Abstract

Background: The use of information and communication technologies (ICTs) to deliver mental health and addictions (MHA) services is a global priority, especially considering the urgent shift towards virtual delivery of care in response to the COVID-19 pandemic. It is important to monitor the evolving role of technology in MHA services. Given that MHA policy documents represent the highest level of priorities for a government's vision and strategy for mental health care, one starting point is to measure the frequency with which technology is mentioned and the terms used to describe its use in MHA policy documents (before, during, and after COVID-19). Yet, to our knowledge, no such review of the extent to which ICTs are referred to in Canadian MHA policy documents exists to date.

Objective: The objective of this systematic policy review was to examine the extent to which technology is addressed in Canadian government–based MHA policy documents prior to the COVID-19 pandemic to establish a baseline for documenting change.

Methods: We reviewed 22 government-based MHA policy documents, published between 2011 and 2019 by 13 Canadian provinces and territories. We conducted content analysis to synthesize the policy priorities addressed in these documents into key themes, and then systematically searched for and tabulated the use of 39 technology-related keywords (in English and French) to describe and compare jurisdictions.

Results: Technology was addressed in every document, however, to a varying degree. Of the 39 searched keywords, we identified 22 categories of keywords pertaining to the use of technology to deliver MHA services and information. The 6 most common categories were *tele* (n=16/22), *phone* (n=12/22), *tech* (n=11/22), *online* (n=10/22), *line* (n=10/22), and *web* (n=10/22), with n being the number of policy documents in which the category was mentioned out of 22 documents. The use of terms referring to advanced technologies, such as *virtual* (n=6/22) and *app* (n= 4/22), were less frequent. Additionally, policy documents from some provinces and territories (eg, Alberta and Newfoundland and Labrador) mentioned a diverse range of ICTs, whereas others described only 1 form of ICT.

Conclusions: This review indicates that technology has been given limited strategic attention in Canadian MHA policy. Policy makers may have limited knowledge on the evidence and potential of using technology in this field, highlighting the value for knowledge translation and collaborative initiatives among policy makers and researchers. The development of a pan-Canadian

XSL•FO
RenderX

framework for action addressing the integration and coordination of technology in mental health services can also guide initiatives in this field. Our findings provide a prepandemic baseline and replicable methods to monitor how the use of technology-supported services and innovations emerge relative to other priorities in MHA policy during and after the COVID-19 pandemic.

Introduction

According to a Canadian survey conducted in 2018 [1], approximately 5.3 million individuals aged 12 years and older reported a need for mental health care in the previous year, yet the mental health needs of almost half of these individuals were unmet. The need to improve access and quality of mental health and addictions (MHA) services is increasingly reflected in Canadian mental health policy and practice [2]. Moreover, consequences of COVID-19 have compounded the need for mental health services [3,4], with concurrent public health guidelines for social distancing creating additional challenges to the delivery of care. These challenges have driven rapid integration of technology into the MHA system [5-8].

The use of the internet and related information and communication technologies (ICTs) to deliver or enhance mental health services (also referred to as digital mental health/digital health, e-mental health/e-health, telehealth, or virtual care) is well recognized for its potential in helping to overcome some of the barriers that individuals face in accessing mental health care [9-12]. For example, compared to conventional approaches, the use of ICTs can provide more accessible, empowering, and sustainable care [11-14]; improve access to specialist mental health care; and reduce wait times [15]. This is particularly important for rural and remote areas that have inequitable access to mental health services due to geographic distance and scarcity of resources, and for populations that are less inclined to seek help in person due to stigma [11,12]. Moreover, opportunities to receive care via ICTs also have the potential to provide individuals choice and control over their care [16].

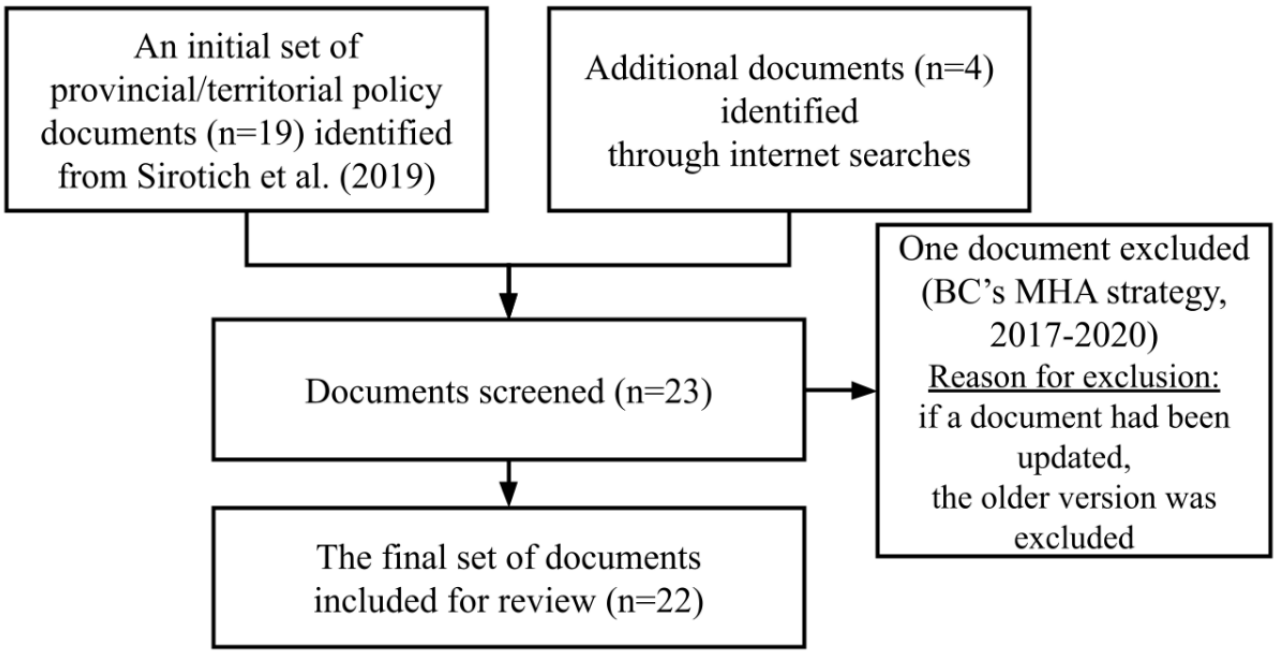
A wide range of ICTs (eg, telephone and videoconferencing services, websites, smartphone apps, social media) have been used to develop innovations that deliver mental health services [11,12]. In general, these innovations serve the purpose of providing information and self-management tools; conducting screening and assessment; facilitating monitoring of symptoms, activities, and behaviors; and delivering psychological and social interventions (eg, peer support, counseling, case management) [11,12]. Examples include telephone-based crisis interventions [17], psychiatric assessment and treatment via videoconferencing (also known as telepsychiatry) [18,19], web-based therapeutic interventions [20,21], behavioral and psychosocial treatments using smartphone software apps and secured websites [22,23], use of sensors for patient monitoring [24], online peer support through social media [25], and virtual reality therapies [26].

In terms of evidence, there is increasing research indicating the efficacy of using ICTs to deliver mental health services and its effectiveness [20,27,28]. For example, a recent review and meta-analysis demonstrated the efficacy of using ICT-based interventions to address eating disorders under controlled trials. Specifically, digital interventions were shown to be more effective than control conditions in reducing risk factors and symptoms in prevention-focused trials and treatment-focused trials [28]. However, other types of individual-level research, including economic analyses, are still needed, in addition to broader analyses, such as studying change at the policy level.

In Canada, innovation, research, and practice on the use of ICTs in mental health care has significantly advanced over the past decade. Several examples of such advancements are provided in the gray and peer-reviewed literature [10,11], including but not exclusive to evidence-based technology-supported initiatives from the Strongest Families Institute (a not-for-profit organization originating from clinical trials conducted at the IWK Health Centre (formerly Izaak Walton Killam Health Centre) in Nova Scotia and onlinetherapyuser.ca (based on clinical research conducted at the University of Regina with eventual sustained funding received from the Saskatchewan Ministry of Health). However, the use of ICTs in mental health care is still a relatively new paradigm [11,29,30], with implementation remaining limited and fragmented [11,29] even within the context of the COVID-19 pandemic. This indicates a systemic gap between evidence and its implementation, which may in part be due to limited guidance on how to translate evidence into policy and competing priorities in research and government contexts [31,32]. More research at the policy level can inform and bridge the evidence-policy-practice gap [33] and can inform effective collaboration on the development of policy among academics, researchers and developers, health care planners and policy makers, practitioners, and consumer representatives [11,29,32].

Mental health policy and action documents have a critical role and responsibility for optimizing technology integration within the mental health care system. The impact of such a role is well illustrated by the policy example of Australia, a country that is at the forefront of integrating technology in the delivery of mental health services. In 2012, the Australian government's Department of Health and Aging produced a policy document entitled, "E-Mental Health Strategy for Australia," which provided a vision for e-mental health services and key areas for action. The strategy also provided guidance on investment and development to advance the field and was created through input from expert advisors representing top researchers within the field, consumer representatives, and executive leads of organizations delivering mental health services using technology [34].

XSL•FO
RenderX



The role of technology in mental health policy is even more critical considering the COVID-19 pandemic. Given this, it is important to understand the priority given to technology in government policy and to monitor the advancement of this priority at the policy level before, during, and after the pandemic. In 2017, a systematic review was published with the aim of comparing areas of focus on the use of technology in pediatric mental health care by examining research studies, and government and organizational documents. It included 2 Canadian-based policy documents, 1 at the national level, and 1 from Ontario [32]. However, to our knowledge, no systematic review has focused on the extent to which technology is discussed in mental health policies from all Canadian provinces and territories to date. Thus, the objective of this systematic policy review is to determine the extent to which technology is considered in Canadian-based mental health policy documents. Specifically, we aimed to synthesize the policy priorities addressed in government-based MHA documents and to better understand the extent to which technology is described as having a role in achieving these policy priorities.

Methods

Collection and Selection of MHA Policy Documents

As illustrated in Figure 1, we started with an initial set of 19 provincial/territorial (P/T) policy documents published until June 2017 that were identified as part of a project led by CEA on the development of a pan-Canadian MHA performance measurement framework [2,35]. These initial documents were obtained from a systematic internet search of P/T government websites. They were then confirmed for completeness for each jurisdiction in consultation with researchers, data managers, and policy makers from the Mental Health Commission of Canada's (MHCC) Provincial and Territorial Advisory Group and through consensus by the research team based on inclusion criteria pertaining to policy timeframes, focus on special populations, and versions of documents [2,35]. Two additional team members from this current review (SL and LS) considered each of these 19 documents to determine if they met our inclusion criterion for the current review and to assess the need for additional searches. The inclusion criterion was a document that describes a P/T vision or strategy for mental health service delivery; we also endeavored to ensure that each P/T was represented by a mental health policy document. In the exceptional case of Nunavut, which became the newest Canadian territory in 1999 at which time a vision or strategy document did not exist, the next closest type of document was included [36]. The exclusion criterion was any older document for which an updated version of the same type of document from that P/T was available. This was to provide the most updated perspective of mental health policy across the P/T at the time of conducting the review.

Figure 1. Identification and selection of MHA policy documents. MHA: mental health and addictions.

To identify updated versions of the policy documents, during the summer of 2019, we conducted internet searches (on the P/T websites and using the Google search engine). Based on this search, we identified 4 additional documents: (1) a recent MHA policy document from British Columbia (2019-2029) [37], (2) Nova Scotia's progress update on the 5-year plan (2016) [38], (3) an action plan for suicide prevention in Nunavut (2016-2017) [39], and (4) the Final Report of Ontario's MHA Leadership Advisory Council (2017) [40]. Thus, we had a total set of 23 documents, from which we excluded 1, BC's MHA Strategy (2017-2020) [41] because a newer version was available; this resulted in a final set of 22 documents. Each of these documents is presented in Multimedia Appendix 1, including title, source in terms of P/T, URL links, and overview.

All documents described a vision or framework, strategy or action plan, or progress update related to MHA policy in that province/territory, 20 documents addressed MHA policies

XSL•FO
RenderX

pertaining to the P/T's population as a whole, while 2 documents were about MHA policy specific to a subpopulation in that P/T (ie, the 2013 BC First Nations and Aboriginal People's MHA 10 Year Plan and the 2014 Yukon's Child and Youth MHA Framework (2014) [42,43].

Data Extraction and Analysis

We first reviewed the documents using an initial list of 9 technology words (*e-mental health*, *tech*, *tele*, *net*, *internet*, *web*, *virtual*, *app*, and *digital*) to gain a preliminary impression of how technology was considered in the government documents. These 9 words were based on SL and CEA's previous review of the literature on technology in mental health care [12] and recent academic and gray literature (eg, e-mental health documentation from the MHCC [10]). We reviewed the documents systematically using the control-F function and recorded instances where the 9 words were mentioned in a Microsoft Word document table. We did not find many examples of policy documents mentioning the use of technology; however, we felt that perhaps this could have been due to the limited number of words we used to search the documents. The initial search process informed our understanding of the types of terms used in the policy documents and led to the development of a more detailed protocol to guide our review. Our protocol included data extraction tables for organizing the data (eg, name of policy document, year of publication, source, excerpts from the documents illustrating use of a technology term). As part of this protocol, we also created a process for validating the data extraction and analysis to enhance reliability of our results. Our final protocol included 39 technology-related keywords that would be used to examine the extent to which each policy document addressed the topic of technology in relation to the delivery of mental health services. This list was finalized through pilot testing in several of the documents before being implemented systematically across all the documents. We also translated this keywords list into French, first by a native French-speaking team member, with initial validation by a second native French-speaking team member (LS) and final validation by the project lead (SL) who is a native English-speaking team member. The keywords list in English and French is presented in Table 1.

Next, we reviewed each policy document to gain a better understanding of the type of document (ie, vision, strategy, and progress related to mental health policy). We determined the type of document mainly based on their titles, for example, documents that typically used the terms *vision*, *strategy*, or *update* in the titles. We also conducted a modified conventional content analysis [44] of the MHA policy priorities described in these documents to obtain a snapshot of the recurrent themes addressed across the set of 22 documents. This involved reviewing the content of each document with a focus on extracting the MHA priorities using a data extraction table in a Microsoft Excel file (LS). The priorities were then coded inductively (ie, staying close to the terms used) and then grouped to arrive at a list of 14 categories. These categories were then reviewed by 2 members of the team (SL and LS) to discuss overlaps, redundancies, and what each category represented in terms of content. This led to a final coding framework of 10 MHA priorities that were represented across the 22 documents. Finally, each of the documents was then re-examined by LS to tabulate which of the 10 MHA priorities was addressed by each of the P/Ts, and this tabulation was then validated by HL.

Next, using the control-F function, we searched each of the documents using the keyword terms listed in Table 1. All findings that represented the use of technology within the context of mental health care were charted in a Microsoft Excel file. The data in this Excel file were initially extracted by a member of our team (LS) and validated by another (HL).

After we completed the search for the keywords and all instances of the use of technology were extracted from the policy documents, we grouped the 39 keywords into 22 categories to facilitate the synthesis process. Specifically, we merged the synonyms and abbreviations of a keyword into the same category. For example, *electronic* and the abbreviation *EHR* (*electronic health record*) were grouped into the *electronic* category. We also removed keywords that had not been mentioned in any of the policy documents. For example, *EMR* (*electronic medical record*) was removed, since it was not mentioned in any document. This final set of 22 categories was arrived at through an iterative process involving discussion and consensus between SL and LS. We then organized our findings based on the number of policy documents (n) that mentioned each category out of the 22 policy documents (eg, the keyword category *Tele* was mentioned in 16 out of the 22 policy documents; n=16/22; Table 2); subsequently, we identified which P/Ts had documents mentioning each category (Table 2). We also counted the number of categories mentioned by each P/T out of the total 22 categories, as represented by n (eg, only 1 keyword category, *electronic*, was mentioned by the Northwest Territories; Multimedia Appendix 3). Note that we counted compound keywords twice to maintain a systematic approach to the keyword search of the policy documents. For example, *telephone* was counted once in *tele* and once in *phone*, and *text messages* was counted once in *text* and once in *messag**.

[g]iCBT: internet cognitive behavioural therapy.

Results

Description of the MHA Policy Documents

Most Canadian P/T governments (including Manitoba, New Brunswick, Northwest Territories, Prince Edward Island, Québec, and Saskatchewan) had 1 MHA policy document [45-50]. Alberta [51,52], British Columbia [37,42], Newfoundland and Labrador [53,54], Nova Scotia [38,55], Ontario [40,56-58], and Yukon [43,59] had two or more MHA policy documents. Nunavut did not have any MHA policy documents; instead, a statement of overall government directions and an action plan for suicide prevention in Nunavut were used in the analysis [36,39]. The types of policy documents we reviewed were visions or frameworks, strategies or action plans, and progress updates. The majority (n=17/22) of the policy documents were focused on MHA policy strategies and action plans. The remaining 5 documents were about visions or frameworks for an MHA system (n=2/22), progress updates on the MHA strategies or action plans (n=1/22), or combined MHA strategies or action plans and progress updates (n=2/22). We extracted data on the overview of each MHA policy document, particularly focusing on P/T policy priorities addressed in the documents (see Multimedia Appendix 1).

Our synthesis of P/T MHA policy priorities identified 10 themes, with 7 themes being found in the policies of all 13 P/Ts: wellness/recovery/MHA promotion, prevention, and early intervention (eg, promoting good mental health, reducing stigma); service integration (eg, integration of service delivery to improve the currently fragmented system); collaboration (eg, promoting a multidisciplinary and collaborative team approach); children, youth, and families (eg, youth suicide prevention, strongest families program); improving access (eg, better access to services for remote, rural, and underserved communities; decreasing wait times and travel times); cultural safety and indigenous communities (eg, culturally relevant treatments and services, health equity for diverse populations); and use of technology (eg, sharing of evidence-based MHA information or services online). The remaining 3 themes were support for seniors (n=12/13); innovation, improvement, and research (n=2/13); and reducing bullying (n=6/13). As depicted in Multimedia Appendix 2, we organized the policy priorities as themes related to a population or a service; 3 of the priorities related to specific populations (children, youth, and seniors; and diversity of communities, such as indigenous communities, racialized groups, new arrivals, and persons with disability), and the remaining 7 were related to a service priority.

XSL•FO
RenderX

Use of Technology in the MHA Policy Documents

Of the 39 keywords listed in Table 1, we identified 22 categories addressing the use of technology to deliver mental health services listed in Table 2. Table 2 also includes examples of keywords from each category that were used in the policy documents.

The 6 most common keyword categories were *tele* (n=16/22), *phone* (n=12/22), *tech* (n=11/22), *online* (n=10/22), *line* (n=10/22), and *web* (n=10/22). Among the 6 most common categories, 3 pertained to connecting people remotely in real-time: *tele* (eg, *telephone*, *telehealth*, *telepsychiatry*; n=16/22), *phone* (eg, *telephone counselling*, *crisis phone lines*, *phone-based coaching service;* n=12/22), and *line* (eg, *distress lines*, *mental health crisis line*, *helpline*; n=10/22). Policy documents also referred to *technology-based services* in general without detailing specific technologies. As such, *tech* (n=11/22) was the third most common category, followed by *online* (n=10/22), *line* (n=10/22), and *web* (n=10/22). Examples of words mentioned in this regard include *technology-based services*, *technology-based solutions*, and *technologies*; *online counselling*, *online information*, and *online cognitive behavioural therapy*; and *web-based*, *website*, and *mental health website*.

In this review, *high-tech* was used to describe technologies other than telephone-based services (eg, live chat on a website, the use of smartphone apps) and *low-tech* was used to describe telephone-based services (eg, crisis telephone help lines). High-tech categories were less common and included *virtual* (n=6/22), *electronic* (n=6/22), *social media* (n=5/22), *video* (n=4/22), *app* (n=4/22), and *link* (n=4/22). Examples of words mentioned in this regard include *virtual resources*, *virtual counselling*, and *virtual reality*; *electronic health record* and *electronically*; *social media* and *social media communications*; *video conference* and *videos*; *mobile applications*, *app*, and *online application*; and *Health Link*, *links*, and *electronic links*.

Other high-tech categories and broader approaches to the use of technology were mentioned at an even lower frequency: *text* (eg, *text*, *text messages*), *e-mental health* (eg, e-*mental health*, e-*mental health services*, e-*Mental Health and Addictions platform*), *platform* (eg, *platform*, *MyHealth platform*, *mental health and addictions platform*, *online platform*), *net* (eg, *internet*, *internet cognitive behavioural therapy*, [*iCBT*]), and *chat* (eg, *chat*, *online chat capabilities*, *web-based chat capabilities*) were each mentioned in 3 policy documents (n=3/22). *Digital* (eg, *digital therapy*, *digital view*) and *portal* (eg, *portal*, *web-based portal*) were each mentioned in 2 policy documents (n=2/22). *Mobile* (eg, *mobile applications*), *messag** (eg, *text messages*), and *e-referral* (eg, *e-referral tool*) were each mentioned in 1 policy document (n=1/22). Overall, there was a diverse range of high-tech categories mentioned in the P/T policy documents but these were mentioned at a much lower frequency compared to the low-tech categories.

Additionally, as shown in Multimedia Appendix 3, there was a high level of variation in the extent to which the policy documents referred to the 22 categories across the 13 P/Ts of Canada: Alberta (n=14/22), Newfoundland and Labrador (n=14/22), Yukon (n=11/22), British Columbia (n=10/22), Ontario (n=10/22), Saskatchewan (n=10/22), Nova Scotia (n=9/22), Nunavut (n=5/22), Manitoba (n=3/22), Prince Edward Island (n=3/22), Québec (n=3/22), New Brunswick (n=2/22), and Northwest Territories (n=1/22).

As noted above, more than half of the technology categories were mentioned in the policy documents of Alberta and Newfoundland and Labrador. Alberta's MHA action plans (2015, 2017-2020) emphasize developing and implementing a range of technology-based solutions (eg, websites, telehealth, mobile apps, virtual solutions) for MHA problems, and combining and enhancing resources that are already available (ie, telephone-based interventions such as Health Link and Kids Help Phone) [51,52]. For example, in its 2017-2020 MHA action plan, it states the following: "develop virtual, technology-based solutions to help people access tools, information and treatment to address addiction and mental health issues," and "share information on websites, telehealth, mobile, mobile applications, and other technologies" [51]. Similarly, Newfoundland and Labrador's vision for a renewed MHA system (2017) and MHA action plan (2017-2022) highlighted using a range of technologies (eg, including telehealth, videoconferencing, telephone crisis lines, online, text, virtual reality, social media, electronic health records, e-mental health) to achieve a full continuum of care and improve access to services [53,54].

Regarding the policy documents that mentioned only a few technology categories (eg, Québec, New Brunswick, and the Northwest Territories), Quebec's action plan (2015-2020) mentioned developing new technologies to offer a network of youth-friendly MHA services, reiterated the availability of 24-7 psychosocial telephone consultations, and mentioned 2 institutions that aimed to promote mental health and new technologies: the Centre national d'excellence en santé mentale (CNESM) and the Service d'accueil, d'analyse, d'orientation et de référence des services sociaux généraux (AAOR) offering services over the phone [49]. In the New Brunswick Family Plan (2017), the only reference to technology was "information related to MHA treatment options are available to the public through various means, including web-based and print materials" [46]. The only mention of technology in the Northwest Territories strategic framework (2016-2021) pertained to electronic health records to promote the integration of service delivery [47]. For more details, refer to Table 2.

Discussion

Our objective for this policy review was to determine the extent to which technology is prioritized in mental health and addictions (MHA) policy documentation. Given that policy is context-based, we focused on the Canadian context. The methods that we used in this review can help to inform future efforts to monitor the evolutionary role of technology in mental health policy in Canada and abroad. Our findings have implications for policy makers, health care leaders, and researchers working towards improving access and quality of mental health services.

XSL•FO
RenderX

Principal Findings

Our key findings are as follows. First, although all the documents referred to the use of technology for MHA care, there was a high level of variation in the extent to which technology was addressed across the P/T documents and how it was addressed. For example, Newfoundland and Labrador's MHA vision (2017) and action plan (2017-2022) described a variety of technology-based services (including telehealth, videoconferencing, telephone crisis lines, online, text, virtual reality, social media, electronic health records, e-mental health) to support access and continuum of care [53,54], whereas the strategic framework from the Northwest Territories (2016-2021) only mentioned electronic health records to promote the integration of service delivery [47], and Québec's action plan (2015-2020*)* only mentioned using technologies to offer MHA services to youth and providing psychosocial telephone consultations to the general population [49]. Second, only a few of the documents referred to the use of "high-tech" solutions, such as virtual reality and apps, with more than half mainly describing "low-tech" solutions, such as telephone-based helplines and telephone consultations for families. Considering the limitations of telephone-based interventions compared to other formats, such as video (eg, the latter resulting in fewer treatment errors and greater diagnostic and decision-making accuracy) [60] and considering mainstream society's increasing use of other formats of communication, such as texting, live chat, videoconferencing, and social media, addressing high-tech solutions in Canadian mental health policy is warranted. Third, there was inconsistency in the use of technology-related terminology across the documents, with the term *e-mental health* (the term used by the MHCC) [10,30] rarely mentioned. Fourth, there was limited strategic focus and guidance in the policy documents on how to move forward with the successful implementation of technology-enabled services within the public mental health care system.

It is important to note that the P/T policy documents reflect governmental priorities for MHA services and did not have the purpose of providing a complete perspective on the use of technology. Although it may not be the intention of the policy documents to provide an exhaustive list of initiatives, describing exemplary evidence-based initiatives (eg, onlinetherapyuser.ca) that have received government funding is warranted to provide guidance to local health authorities. Moreover, the variation that we identified across P/Ts on the degree of attention to technology in MHA care is noteworthy.

There are several implications of our findings. First, there is a need for strategic policy attention on the integration of technology in mental health; this requires addressing topics such as funding for implementation initiatives, infrastructure, regulation, capacity building, intersectoral collaboration, translation research, policy-research-practice partnerships, among others [11,12,29,32,33], as well as partnerships between researchers, practitioners, and policymakers. Advancement in these areas can be facilitated through interactions among policy makers and health services researchers specializing in the use of technology to deliver mental health care. Choi et al [61] provide several insights that can be helpful in this regard, including recommendations to incentivize collaboration among policy makers and scientists, use of knowledge brokers (to facilitate knowledge translation), and acknowledgment of the various issues affecting collaboration, including different languages and perspectives on evidence and different timeframes on achieving deliverables. Policy-making initiatives that facilitate the involvement of consumers, caregivers, and service is also important to consider.

Second, the inconsistency in the use of technology-related terms across the P/Ts is not surprising given the evolving nature of the field itself and inconsistencies in the research literature. Nonetheless, this poses challenges to conducting future policy reviews to monitor advancement in the field. To address this issue, a living document of terminology, that is updated yearly, could be made accessible to mental health policy makers to encourage a level of standardization in the language used to refer to the use of technology in mental health care.

Third, the inconsistency in the degree of attention on technology across the P/T documents may be a reflection that policy makers have limited knowledge on the evidence and potential of using technology in this field, highlighting the value for knowledge translation and collaborative initiatives among policy makers and researchers. It may also reflect the degree to which technology is prioritized at the front-line level of service delivery, raising the question of whether there is a lack of equity across the country in terms of the public's access to a wide range of services and interventions delivered through technology. This lack of attention in policy can contribute to a fragmented and unregulated approach to using technology to deliver mental health services in the country. Translational research for policy development and implementation planning is needed to better understand viewpoints from users, developers, providers, and policy makers on the implementation of technology-supported innovations, and to monitor the impact of implementation in terms of cost-effectiveness, access, and engagement, and the integration of models such as stepped care and clinical staging [11,30].

Fourth, it will be important to monitor the extent to which rapid responses to delivering mental health care in the context of the COVID-19 pandemic to address the increased need for mental health support among the general population [62] and those with existing MHA conditions [63-66] are reflected in mental health policy. Several of the P/Ts have responded to COVID-19 by providing information to the public about COVID-19 and maintaining mental health via social media [67]; delivering cognitive behaviour therapy through text messaging with mental health professionals (eg, Alberta's Text4Hope); expanding existing online mental health counseling programs (eg, British Columbia's MindHealthBC); and expanding use of existing mental health services for children and youth, such as text, live chat, mobile apps, and phone-based services [68]. At the same time, it is unclear whether the rapidly deployed initiatives are sufficient for responding to the mental health impacts of COVID-19 and to what extent will these initiatives address the already existing gaps in the continuum of mental health care for those with chronic mental health conditions. Given this, there is a continued need for comprehensive policy and research to support a coordinated and evidence-based integration of

XSL•FO
RenderX

technology in the Canadian mental health care system, during and after the COVID-19 pandemic.

Fifth, there is a further need for P/Ts and national collaboration to develop reliable and comprehensive environmental scans of the implementation of technology in Canadian mental health services, including analysis of failed attempts. Sixth, the development of a pan-Canadian framework for action that addresses the integration and coordination of technology in mental health service delivery can also help to guide P/T initiatives in this field.

Sixth, our findings provide a prepandemic baseline and replicable methods to inform a subsequent study of how the use of technology-supported services and innovations emerge as an important priority in mental health policy and practice, during and after the COVID-19 pandemic. Future research can also focus on examining how technology is considered in relation to the various mental health priorities addressed by policy documents (eg, use of technology in promoting wellness/recovery/MHA promotion, prevention, and early intervention; use of technology in promoting collaborative care; and use of technology in senior's mental health).

Limitations

We used an existing database (ie, the 19 P/T policy documents included in Sirotich et al [2]) as the main source of policy documents for our review. Therefore, it is possible that we might have missed some relevant documents. It is also acknowledged that there may be other documents potentially relevant to this review in these jurisdictions, but the documents we have identified outline government priorities for MHA care at the highest level and therefore are of primary importance for communicating a vision and strategy for mental health care services within a government's jurisdiction. It is also acknowledged that policies are frequently replaced; this review provides a report of relevant content available as of June 2019. In addition, we did not read through each page of each of the 22 documents to identify descriptions on the use of technology; although it was considered, it was deemed unfeasible by our team and also a potentially less reliable method of validation. We also believe that the final list of words we developed is quite comprehensive in its ability to capture the use of technology in mental health service delivery in these policy documents and that our methodology is both feasible and can be reliably replicated in future updated reviews.

Conclusions

This review on Canadian P/T mental health policy documents suggests that despite the potential for technology to improve access to and quality of MHA services, its implementation has been fragmented to date. Specifically, we identified large variations across Canadian P/T policy documents in terms of the types of technologies mentioned. Furthermore, many of the P/T policy documents mentioned only low-tech solutions, such as telephone-based interventions. The review also shows the limited attention given in the mental health policy documents to the evidence-based literature on the use of technology to deliver mental health services, suggesting a potential gap in knowledge on the part of policy makers regarding the evidence in this field. This gap can be reduced through collaborative interactions among academics, policy makers, and practitioners facilitated through sectors of P/T governments (eg, research and innovation, health services). It would be worth considering repeating this review at regular intervals, which would document the advancement of technology in care delivery, including related responses to the COVID-19 pandemic.

Acknowledgments

SL is funded by the Canada Research Chairs Program.

Authors' Contributions

Building on previous work conducted by CEA, SL conceived the plan and protocol for the study. Under the supervision of SL, LS extracted and analyzed data, and HL validated the data extraction and analyses. SL wrote the first draft of the manuscript. All authors contributed to revisions of this manuscript and approved the final draft.
