The participants (N=130) comprised 57 (43.8%) male and 73 (56.2%) female students. The mean age of the sample was 16.64 years, and most participants (113/130, 86.9%) were under 17 years of age. Over half (102/130, 78.5%) lived with both parents. Approximately 20.8% (27/130) of the students had experience of smoking; this included any tobacco product or e-cigarette. Over 30% had family members (45/130, 34.6%) and close friends (41/130, 31.5%) who were smokers (Table 2).

Table 2. Participants' characteristics (N=130).

Characteristic	Value
Sex, n (%)	
Male	57 (43.8)
Female	73 (56.2)
Age (years), mean (SD)	16.64 (0.73)
Age group (years), n (%)	
≤17	113 (86.9)
≥18	17 (13.1)
Household status, n (%)	
Live with both parents	102 (78.5)
Other	28 (21.5)
Have you ever smoked? (any tobacco product or e-cigarette), n (%)	
Yes	27 (20.8)
No	103 (79.2)
Do any of your family members smoke?, n (%)	
Yes	45 (34.6)
No	85 (65.4)
Do any of your close friends smoke?, n (%)	
Yes	41 (31.5)
No	89 (68.5)

Game-Playing and Content-Learning Experiences

We applied the following two measures to examine the acceptability of the games: game-playing and content-learning experiences. Table 3 shows the distribution of ARCS elements (representing game-playing experiences), knowledge improvement and perceived persuasiveness (representing content-learning experiences), and intention to abstain from smoking (outcome). The item average scores for these variables (defined as the total score divided by the number of items) revealed that the participants provided positive responses. The ARCS-related responses indicated that most students agreed or strongly agreed that the educational games were motivational. The item average scores for attention, relevance, confidence, and satisfaction were all approximately 4 (measured using a Likert-type scale ranging from 1 to 5; scores for the four variables ranged from 3.95 to 4.19). There was a significant improvement in knowledge, with a mean difference of 2.97 between pretest and posttest (t_{129}=25.67, *P*<.001). Most students indicated that they were persuaded, with an item average score of 4.28 points (determined using a Likert-type scale ranging from 1 to 5).

Table 3. Descriptive results for the acceptability evaluation and intention to abstain from smoking.

Game-playing experiences	Item average scores	Sum of mean scores	SD
ARCS			
Attention (four items)	4.19	16.76	2.75
Relevance (four items)	3.95	15.78	2.70
Confidence (three items)	4.03	12.08	1.84
Satisfaction (four items)	4.10	16.38	2.52
Content-learning experiences			
Knowledge improvement (postscore−prescore)	N/A[a]	2.97[b]	1.39
Perceived persuasiveness (four items)	4.25	17.00	2.48
Outcome measure			
Behavioral intention (two items)	4.18	8.36	1.85

[a]N/A: not applicable.

[b]Mean score for the difference between pretest and posttest.

Measurement Model Assessment

We established the convergent validity of the latent variables through consideration of CR and AVE. All variables in the model displayed acceptable internal consistency, as evidenced by the fact that their CR scores were greater than 0.7 (ranging from 0.80 to 0.96), and all AVE values were higher than 0.5 (ranging from 0.57 to 0.92). Thus, it was concluded that the model had satisfactory convergent validity (Table 1). The values of these indices satisfied the recommended criteria and suggested that the proposed measurement model was reliable and valid.

As shown in Tables 4 and 5, we established the discriminative validity using the Fornell-Larcker criterion and HTMT. The Fornell-Larcker criterion was satisfied, as the square root of AVE for each variable exceeded the correlation of the latent variables. Almost all of the HTMT values were <1.00 [32], with one of the HTMT values being 1.06, indicating that this criterion was acceptable.

Table 4. Results for the Fornell-Larcker criterion.

Variable	Attention	Relevance	Confidence	Satisfaction	Knowledge	Perceived persuasiveness	Behavior intention
Attention							
Latent variable correlation	0.88[a,b]	0.61	0.59	0.65	0.05	0.66	0.42
Relevance							
Latent variable correlation	0.61	0.79	0.60	0.62	−0.03	0.70	0.49
Confidence							
Latent variable correlation	0.59	0.60	0.76	0.76	0.05	0.62	0.41
Satisfaction							
Latent variable correlation	0.65	0.62	0.76	0.78	0.01	0.70	0.51
Knowledge							
Latent variable correlation	0.05	−0.03	0.05	0.01	1.00	−0.01	0.03
Perceived persuasiveness							
Latent variable correlation	0.66	0.70	0.62	0.70	−0.01	0.84	0.60
Behavior intention							
Latent variable correlation	0.42	0.49	0.41	0.51	0.03	0.60	0.95

Table 5. Results for the heterotrait-monotrait ratio of correlations.

Variable	Attention	Relevance	Confidence	Satisfaction	Knowledge	Perceived persuasiveness	Behavior intention
Attention							
Value	N/A[a,b,c]	0.70	0.77	0.76	0.06	0.75	0.46
Relevance							
Value	0.70	N/A	0.82	0.74	0.07	0.83	0.56
Confidence							
Value	0.77	0.82	N/A	1.06	0.06	0.83	0.52
Satisfaction							
Value	0.76	0.74	1.06	N/A	0.03	0.84	0.59
Knowledge							
Value	0.06	0.07	0.06	0.03	N/A	0.04	0.03
Perceived persuasiveness							
Value	0.75	0.83	0.83	0.84	0.04	N/A	0.67
Behavior intention							
Value	0.46	0.56	0.52	0.59	0.03	0.67	N/A

[a]N/A: not applicable.

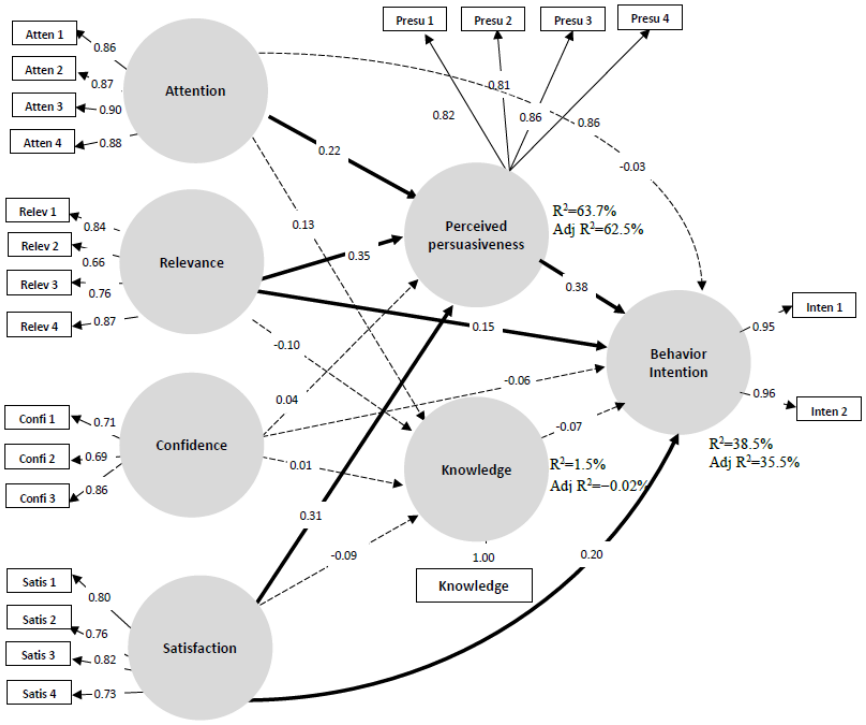
[b]The heterotrait-monotrait ratio is the geometric mean of the heterotrait-heteromethod correlations (ie, the correlations of indicators across constructs) divided by the average of the monotrait-heteromethod correlations (ie, the correlations of indicators within the same construct).

[c]There are no *P* values to provide.

Structural Model Assessment

The model exhibited adequate correspondence with the data (SRMR=0.075). To assess the structural model, we used the R^2 values and the path coefficients as the essential measures. As shown in Figure 2, the four latent variables of ARCS (attention, relevance, confidence, and satisfaction) accounted for 63.7% of the variance in perceived persuasiveness. However, these four latent variables accounted for only 1.1% of the variance in knowledge improvement. Overall, the four latent variables of ARCS, perceived persuasiveness, and knowledge improvement accounted for 38.2% of the variance in the intention to abstain from smoking.

Figure 2. Model for acceptability evaluation of educational virtual reality games.



Regarding the path analysis, Table 6 lists the path coefficients and *P* values for each hypothesis. The results of the hypothesis test showed that six of the 14 hypotheses were supported. These six supported hypotheses postulated that the three latent variables of attention, relevance, and satisfaction significantly influenced perceived persuasiveness (H1-2: path coefficient=0.23, *t*=3.19, *P*<.001; H2-2: path coefficient=0.35, *t*=4.28, *P*<.001; H4-2: path coefficient=0.31, *t*=3.49, *P*<.001). Only confidence did not influence perceived persuasiveness (H3-2: path coefficient=0.04, *t*=0.42, *P*=.67). In addition, relevance, satisfaction, and perceived persuasiveness significantly influenced the intention to abstain from smoking (H2: path coefficient=0.26, *t*=2.39, *P*=.02; H4: path coefficient=0.34, *t*=3.07, *P*=.002; H6: path coefficient=0.45, *t*=3.57, *P*<.001). In contrast, intention was not significantly influenced by knowledge improvement (H5: path coefficient=−0.06, *t*=1.31, *P*=.19).

In addition to the direct effect on the intention to abstain from smoking, an indirect effect was observed from relevance to intention via perceived persuasiveness (indirect effect, *t*=2.87, *P*=.004). Further, another indirect effect was observed from satisfaction to intention via perceived persuasiveness (indirect effect, *t*=2.11, *P*=.04). Finally, although not directly affecting the intention to abstain from smoking, attention showed an indirect effect on intention via perceived persuasiveness (indirect effect, *t*=2.16, *P*=.03).

Table 6. Results of hypothesis tests.

Hypothesis	Hypothesized paths	Original coefficient	Bootstrapped coefficient	*t*	*P* value	Path support
H1	Attention → behavioral intention	0.06	0.06	0.51	.61	No
H2[a]	Relevance → behavioral intention	0.27	0.26	2.39	.02	Yes
H3	Confidence → behavioral intention	−0.05	−0.04	0.42	.68	No
H4[a]	Satisfaction → behavioral intention	0.34	0.34	3.07	.002	Yes
H5	Knowledge → behavioral intention	−0.07	−0.06	1.31	.19	No
H6[a]	Perceived persuasiveness → behavioral intention	0.44	0.45	3.57	<.001	Yes
H1-1	Attention → knowledge	0.13	0.12	0.78	.44	No
H1-2[a]	Attention → perceived persuasiveness	0.22	0.23	3.19	<.001	Yes
H2-1	Relevance → knowledge	−0.11	−0.10	0.92	.36	No
H2-2[a]	Relevance → perceived persuasiveness	0.35	0.35	4.28	<.001	Yes
H3-1	Confidence → knowledge	0.01	0.01	0.06	.95	No
H3-2	Confidence → perceived persuasiveness	0.04	0.04	0.42	.67	No
H4-1	Satisfaction → knowledge	−0.09	−0.09	0.50	.62	No
H4-2[a]	Satisfaction → perceived persuasiveness	0.31	0.31	3.49	<.001	Yes

[a]Paths with significant coefficients.

Discussion

Acceptability Evaluation

In this study, we aimed to evaluate the acceptability of smoking-prevention–focused educational VR games among high school students. We measured acceptability based on the following two aspects: game-playing and content-learning experiences. As motivation is essential for effective learning [33], we adopted the ARCS motivation model as a framework for examining the students' game-playing experiences. Our findings indicated that the educational games invoked a noticeable degree of learning motivation. Based on the responses of the students to the ARCS-related items, most students agreed or strongly agreed that the educational games were motivational. Many researchers have applied the ARCS model as a framework for instructional design, and the efficacy of the ARCS framework for enhancing students' motivation has been validated [34,35]. Further, a previous study supported the effectiveness of applying the ARCS framework in the context of learning activities by successfully using it in a randomized controlled trial [36]; the applicability of the ARCS framework for new digital technology, such as mobile augmented reality, has also been proven [37]. Our findings are consistent with those of previous studies and revealed that the educational games could function as supplementary material that engages students and motivates them to learn. The content-learning experiences included in the games comprised knowledge improvement and perceived persuasiveness. We found that the students' knowledge had significantly improved as a result of playing the VR games. Further, similar to the item average scores for ARCS, most students agreed or strongly agreed that the games had persuaded them to improve their attitudes regarding smoking prevention.

We used persuasive strategies in the design of the human-computer interactions in the games. Several persuasive strategies have been suggested across previous studies [38,39];

however, our findings indicate that strategies concerning competition, self-awareness, feedback, social comparison, and reinforcement are effective in the context of smoking prevention among high school students. Our findings also revealed that the games' content-learning experiences were influenced by the game-playing experiences. Researchers have emphasized that, to achieve favorable learning outcomes, effective engagement should be pursued over mere passive engagement [40]; theoretically, the students who played our games were motivated to learn through ARCS experiences [41]. The ARCS framework comprises not only instructional approaches to motivate students, but also preliminary elements of effective content learning. We expected that motivated students would show better results in terms of content learning (ie, knowledge improvement and perceived persuasiveness). The study findings consequently showed that attention, relevance, and satisfaction had notable effects on content learning, but confidence did not. Specifically, for the educational games, students who reported high levels of attention, relevance, and satisfaction perceived themselves as being persuaded. Persuasion is a process that concerns changing or reinforcing attitudes or behaviors [24]. Our educational games were designed to discourage students from smoking by reinforcing nonsmoking attitudes and behaviors. In other words, we tried to influence students' behaviors through messages conveyed in the games. After playing the games, the students reported increased awareness of and concern regarding smoking prevention. In addition, their understanding and self-efficacy in relation to practicing preventive skills were enhanced.

Our findings revealed that only some of the four aspects of motivation (ARCS) contribute to perceived persuasiveness, namely, attention, relevance, and satisfaction. Similar to our findings, attention and relevance have previously been found to be associated with overall persuasiveness [21]. Thus, the present and existing findings imply that, in order to effectively persuade learners, the inclusion of attention and relevance in game design should be prioritized. Further, we found that students who were satisfied with the educational games tended to be persuaded, indicating that satisfaction should also be included in future game design. In contrast, confidence was not an influencing factor; a possible reason for this is that students felt the game tasks were not very challenging and were easy to complete. Some students suggested speeding up the games or increasing the difficulty or number of levels.

The ARCS experiences did not have significant effects on knowledge improvement. In other words, students' levels of knowledge were not influenced by the game-playing experiences. A possible reason the games nevertheless induced significant knowledge improvement is that the students received written materials while they were waiting in line to play the educational games. Our findings indicate the necessity of integrating other learning strategies into educational games in order to obtain knowledge improvement. As the games function as supplementary material for smoking-prevention education, game playing alone may not be sufficient to influence knowledge. Further, there are conflicting findings in the literature regarding the association among knowledge, positive attitudes, and intent to take action [42,43]. The structural model revealed that knowledge improvement does not influence the intention to abstain from smoking. Consequently, in addition to knowledge of the hazards of smoking, we recommend, for future game development, the inclusion of an emphasis on changing attitudes regarding smoking [44]. However, the gap between knowledge and behavior intention requires further study. Knowledge improvement was viewed as a mediator in the proposed model. Considering knowledge improvement as parallel to behavioral intention rather than a mediator is an idea for further studies.

Once a student's learning motivation is aroused, how does the level of motivation affect subsequent attitude changes or the achievement of learning objects? We examined this mechanism by analyzing the path from ARCS elements to intention to abstain from smoking. The results revealed that the four aspects of motivation (ARCS) had different influencing paths to intention. In addition to directly influencing students' intention to abstain from smoking, relevance and satisfaction had indirect effects on intention via perceived persuasiveness. Although the level of attention did not directly influence intention, it had an indirect effect on intention via perceived persuasiveness. These findings indicate that perceived persuasiveness has mediating effects on motivation's influence on intention. To discourage students from smoking, along with fostering their motivation to learn, perceived persuasiveness should be taken into consideration.

Implementation

Future efforts to design educational games should incorporate theoretical frameworks that can advance the understanding of the influencing mechanisms for motivation. In this research, we proposed the integration of the ARCS framework and persuasive strategies, and the PLS-SEM results consequently revealed that game-playing experiences that are based on the ARCS framework have direct effects on persuasiveness. Future educational game–focused research could adopt this integrative approach. Second, teaching staff who provide smoking-prevention education in schools could seek to make these VR games as accessible for students as possible, such as through holding activities in fair stalls on school days or during orientation for first-year students. Interesting games can be used to increase students' awareness of smoke-free campus policies and strengthen students' commitment to abstain from smoking. Finally, knowledge alone is unlikely to generate behavioral intention; thus, designers of smoking-prevention activities should seek to expand their focus beyond the improvement of knowledge. In addition, a possible problem with true/false questions is that respondents can easily guess the correct answer [45]. Multiple choice questions should be adopted in the future to measure knowledge.

Limitations

There are several limitations in this study. First, our investigation of the influencing paths for behavior intention was performed in the context of smoking prevention (an unhealthy behavior). While we were certain of the applicability of the ARCS framework and persuasive strategies to educational games that focused on such behaviors, the findings may not be fully generalizable to contexts concerning healthy behaviors. Thus,

they should be applied with caution. Second, we could not determine the separate effects of each educational game on behavioral intention, as the participants' game-playing experiences were obtained as a whole, rather than in terms of each type of game. Third, we could not validate the intervention effects of the educational games, as no comparison group was involved. Finally, one of the HTMT values was larger than 1.00. This implies that two latent constructs may be conceptually similar. Despite these limitations, this study, which was intended as an acceptability evaluation, elaborated on the mechanisms of game-playing and content-learning experiences in the context of behavior intention. We recommend that this experiment design be adopted in future endeavors.

Conclusion

In this study, we evaluated the acceptability of educational VR games for use in smoking-prevention education for high school students. Our findings revealed that the educational games were positively accepted by the participating students, and that the integration of the ARCS framework and persuasive strategies is an applicable approach for smoking-prevention education. The ARCS framework was significantly associated with perceived persuasiveness, and perceived persuasiveness has direct effects on the intention to abstain from smoking. We recommend that the games be included as teaching material in smoking-prevention education.

Abstract

Background: Early warning tools identify patients at risk of deterioration in hospitals. Electronic medical records in hospitals offer real-time data and the opportunity to automate early warning tools and provide real-time, dynamic risk estimates.

Objective: This review describes published studies on the development, validation, and implementation of tools for predicting patient deterioration in general wards in hospitals.

Methods: An electronic database search of peer reviewed journal papers from 2008-2020 identified studies reporting the use of tools and algorithms for predicting patient deterioration, defined by unplanned transfer to the intensive care unit, cardiac arrest, or death. Studies conducted solely in intensive care units, emergency departments, or single diagnosis patient groups were excluded.

Results: A total of 46 publications were eligible for inclusion. These publications were heterogeneous in design, setting, and outcome measures. Most studies were retrospective studies using cohort data to develop, validate, or statistically evaluate prediction tools. The tools consisted of early warning, screening, or scoring systems based on physiologic data, as well as more complex algorithms developed to better represent real-time data, deal with complexities of longitudinal data, and warn of deterioration risk earlier. Only a few studies detailed the results of the implementation of deterioration warning tools.

Conclusions: Despite relative progress in the development of algorithms to predict patient deterioration, the literature has not shown that the deployment or implementation of such algorithms is reproducibly associated with improvements in patient outcomes. Further work is needed to realize the potential of automated predictions and update dynamic risk estimates as part of an operational early warning system for inpatient deterioration.

patient deterioration; early warning scores; digital tools; vital signs; electronic medical record

Introduction

Background

In recent years, proactive clinical processes have been developed to target timely and appropriate care for deteriorating or high-risk patients. Emergency responses such as *Rapid Response Systems* have been implemented with the aim to intervene and avoid preventable death, cardiac arrest, or transfer to an intensive care unit (ICU) in adult [1-3] and pediatric [4,5] patients. These systems have evolved to consist of a recognition (afferent) limb, commonly known as early warning scores (EWSs), and a response (efferent) limb (escalation and intervention). The responders rely on an accurate recognition limb, which in turn relies on a combination of empirical rules, statistical models, and clinical judgment to recognize deterioration. Initial EWSs were limited to vital signs, as these were the only routinely collected physiological data available for analysis in real time. The EWSs are currently available as paper or digital tools and vary significantly in their modeling, design, and escalation guidance [3,6-10].

The growth of rich, detailed, and dynamic clinical digital documentation in electronic medical records (EMRs) raises the possibility of using a broader range of clinical data, including pathology and diagnoses. An EMR collects the detailed phenotype of the patient in real time. Data collected, such as previous history, comorbidities, and demographic descriptors, are static during an admission. Observations of dynamic processes such vital signs, clinical measurements, imaging, and laboratory results that document biological and pathological processes are also recorded and continuously updated. Further evolving diagnoses, events, and interventions (eg, operations and drugs that are administered) capture the changing status of a patient. Finally, a rich source of dynamic information lies in the metadata: the timing, frequency, and location of actions and observations that occur to the patient and patient movements in the system. These data enable refined predictive models and more effective, patient-specific treatments. To create clinical decision support, these data must be analyzed and risk interpreted, and then critically, the clinical decision support communicating this real-time risk needs to be engineered back into the routine clinical workflows of the clinicians caring for the patient.

There is a diversity of models for predicting patient deterioration. Some risk estimates are static systems that identify high-risk patients at the time of diagnosis and allow triage of patients to a higher intensity care destination. Other approaches use vital sign observations to maintain an up-to-date risk evaluation. Typically, these dynamic systems either identify an extreme singular derangement or use weighted sums of a few vital signs and their variation from normal values. In both situations, the likelihood of deterioration and poor outcome anticipated with worsening values is increased. In some cases, these models have been developed and validated only for specific and narrow patient groups [11-13], whereas other general models are applicable to wider adult or pediatric ward patients [3-5,10,14].

Objectives

The aim of this review is to identify studies conducted within a general hospital setting that have attempted to develop prediction algorithms for detecting a deteriorating ward patient in real time, based primarily on routinely collected EMR data. This review includes model statistical validation and, where available, the results of digital hospital implementation of new or existing prediction models or rule-based systems for predicting patient deterioration. A secondary aim is to review those successful examples for common data elements, approaches, and statistical or machine learning techniques that were associated with successful clinical use.

Methods

This review followed the recommendations of the Center for Reviews and Dissemination [15] and PRISMA (Preferred Reporting in Systematic Reviews and Meta-Analyses) [16].

Data Sources and Search Strategy

A systematic search of PubMed, Scopus, Web of Science, IEEE Xplore, and ACM Digital Library using a combination of controlled vocabulary (eg, MeSH [Medical Subject Headings] terms) and free text keywords was conducted. The search strategy was first developed for PubMed, guided by the recommendations of Hausner et al [17] and Fatehi et al [18], and transposed to other databases. Across databases, free text keywords remained the same, but controlled vocabulary was mapped where possible (eg, from MeSH to Index Terms). The search was limited by language (English), date of publication (January 1, 2008, to June 30, 2020) and type of publication (original papers).

Screening and Study Selection

Reports that have developed prediction algorithms for detection of clinical patient deterioration in real time, primarily based on routinely collected patient data, were identified. The included studies had to (1) use any kind of (electronic) patient record, (2) use an early warning tool for patient deterioration, (3) use of a system that was dynamic, or observations of a patient over time, and (4) document the model statistical accuracy and performance. The studies were peer reviewed and published in journals or conference proceedings. The focus of this review was on tools in a general hospital ward and in a real time setting. Excluded studies were those conducted solely in a critical care or an emergency department setting, those limited to a single diagnosis or organ dysfunction patient cohort, those that used a static time point or an observation to assess risk of deterioration, and those that were qualitative with no quantitative assessments.

The results of electronic database searches were exported into an EndNote [19] library, and duplicates were removed. Title and abstract screening was coordinated on Rayyan web application (Qatar Computing Research Institute) [20]. Two independent reviewers screened titles and abstracts for relevance, and unresolved differences were adjudicated by a third reviewer. Full texts of remaining papers were assessed by 2 independent reviewers against the inclusion and exclusion criteria. Unresolved differences were adjudicated by a third reviewer. Where more than one publication was found for the same project, the papers were grouped, and the publication with the most comprehensive findings was included.

Data Extraction and Synthesis

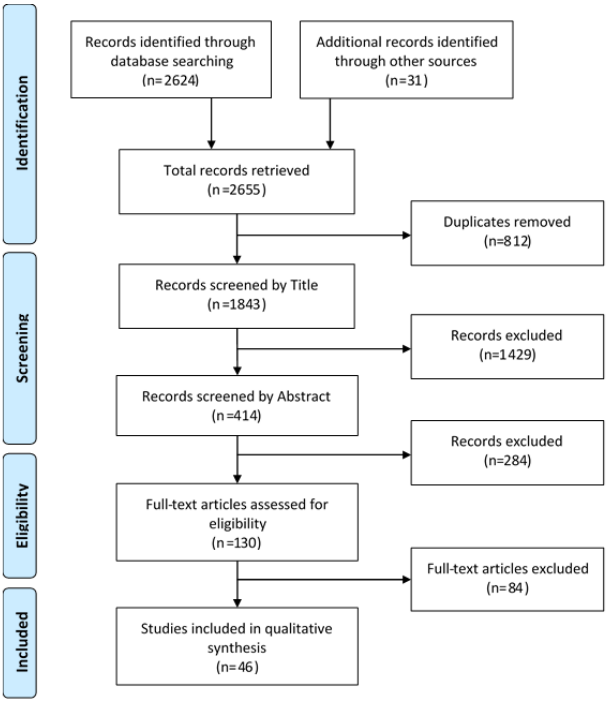
An electronic web form was developed according to the aims of this review and was used for data extraction from full-text papers. Data extraction was conducted by one reviewer and checked by a second reviewer. Owing to the heterogeneity of the included studies in terms of study designs, aims, and outcome measures, it was not possible to conduct a meta-analysis. Thus, a narrative approach was adopted for data synthesis. An assessment of study quality, including risks of bias, was conducted using PROBAST (Prediction Model Risk of Bias Assessment Tool; UMC Utrecht) [21] and ROBINS-I (Risk of Bias in Non-Randomised Intervention Studies; Cochrane) tool [22].

Results

Overview

The initial electronic search of five databases yielded 2624 records, and an additional 31 records were identified from other sources (Figure 1). After removing duplicates, 1843 unique records remained for eligibility assessment. Following the screening of titles and abstracts, 130 papers were deemed relevant, and their full texts were obtained. After a full-text inspection, 46 papers met the eligibility criteria and were included in this review.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of study selection.



Characteristics of the Studies

Of the 46 papers in this review, the majority (37/46, 80%) were retrospective studies that attempted to develop and/or evaluate the performance of a prediction model or compare the performance of a number of predictive models using historical patient data [23-59]. One study reported both the retrospective development of a prediction model and a prospective observational study of the developed model [60]. The remaining studies included one randomized controlled trial [61], 4 before-after (implementation) studies [62-65], and 3 prospective observational studies [66-68].

Overview of Studies

Studies from the same setting and institution were grouped and ordered according to the chronological model development, evaluation, and implementation, if available.

Of the identified studies, 6 described a body of research undertaken by researchers from Kaiser Permanente in California, as well as the University of Chicago [34,35,40,44,62,63] (Table 1). Kaiser Permanente is a large integrated managed care organization in the United States and began the deployment of EMRs in its hospitals in 2006. Escobar et al [35] reported the development of the early detection of impending physiological deterioration algorithm, which was further developed and subsequently named the Advanced Alert Monitor [44] and the early detection of impending physiological deterioration version 2 algorithm [40]. These models were developed to predict the

risk of unplanned ICU transfer or mortality, using historical data of hundreds of thousands of patients retrieved from the Epic system, have also been retrospectively tested in a simulation study for feasibility [40], piloted in 2 hospitals [62], and more recently implemented as the Advanced Alert Monitor program and evaluated across the remaining Kaiser Permanente Hospitals [63,69,70].

Table 1. Studies undertaken on Kaiser Permanente Hospitals.

Author and year	Study design	Settings	Study aim	Model type or used	Outcome measure	Key findings
Escobar et al, 2012 [35]	RS[a]: tool development	102,422 hospitalizations; 14 KP[b] hospitals; 2006-2009	To develop a model for the prediction of unplanned ICU[c] transfer using EMR[d] data	Pooled logistic regression models	Transfer to ICU or death	EMR-based detection of impending deterioration outside the ICU is feasible. The overall performance of the model incorporating physiology, diagnosis, and longitudinal data was superior to MEWS[e]. Model *c* statistic 0.85, validation model 0.78
Escobar et al, 2013 [34]	RS: tool development	391,584 hospitalizations; 248,383 patients; 21 KP hospitals; 2008-2011	To develop a risk adjustment methodology applicable to all hospitalized patients	Pooled logistic regression models	Death	Risk adjustment of hospital mortality using EMR is feasible. Incorporation of physiological data increased model discrimination and explanatory power. Model *c* statistic 0.80, validation model 0.88
Kipnis et al, 2016 [44]	RS: tool development and evaluation	649,418 hospitalizations; 374,838 patients; 21 KP hospitals; 2010-2013	To describe the development and performance of an automated EWS[f] based on EMR data: The AAM[g]	Discrete time logistic regression	Transfer to ICU or death	The AAM had better performance compared with NEWS[h] and eCART[i] in all metrics and prediction intervals (AUC[j] 0.82). Around half the alerts triggered occurred within 12 hours of the event and almost two-thirds within 24 hours.
Escobar et al, 2016 [62]	Prospective study: tool implementation	2 KP hospitals	To detail technical and operational challenges of deploying an EWS	AAM	Pre- and postimplementation metrics	The pilot implementation in 2 hospitals was successful and further deployment to other hospitals will go ahead.
Hu et al, 2018 [40]	RS: tool simulation and feasibility	174,632 hospitalizations; 21 KP hospitals	To evaluate the impact of proactive transfer to ICU based on EDIP2[k] score, on mortality rate and LOS[l]	EDIP2	Transfer to ICU or death	Proactively transferring of the most severe patients could reduce mortality rates without sacrificing other patient outcomes.
Escobar et al, 2020 [63]	RS: tool implementation and evaluation	548,838 hospitalizations; 326,816 patients; 21 KP hospitals	To evaluate a staggered deployment of an automated predictive model; identifying patients at high risk for clinical deterioration.	AAM	Pre- and postimplementation outcomes: transfer to ICU, 30-day mortality, LOS, favorable status	30-day mortality after an alert was lower in the intervention compared with control (three deaths avoided per 1000 eligible patients). The intervention was also associated with lower incidence of ICU admission, higher percentage of patients with favorable status 30 days after alert, shorter LOS, and longer survival.

[a]RS: retrospective study.

[b]KP: Kaiser Permanente.

[c]ICU: intensive care unit.

[d]EMR: electronic medical record.

[e]MEWS: Modified Early Warning Score.

[f]EWS: early warning score.

[g]AAM: Advanced Alert Monitor.

[h]NEWS: National Early Warning Score.

[i]eCART: electronic Cardiac Arrest Risk Triage.

[j]AUC: area under the receiver operating characteristic curve.

[k]EDIP2: early detection of impending deterioration version 2.

[l]LOS: length of stay.

Another group of papers from the University of Chicago program was based on experiments using the electronic patient records from a number of hospitals in the Chicago area [29-33,37,66] (Table 2). Churpek et al [29] in several papers reported the development and validation of the electronic Cardiac Arrest Risk Triage score and other tools for predicting cardiac arrest and ICU transfer in Chicago (Table 2). They also showed that mortality and cardiac arrest were easier to predict than ICU transfer [29], and machine learning methods were more accurate than logistic regression for predicting patient deterioration [32].

Table 2. Studies conducted in Chicago hospitals.

Author and year	Study design	Setting	Study aim	Model type or used	Prediction event	Key findings
Churpek et al, 2012 [31]	RS[a]: tool development and evaluation	47,427 patients, 1 hospital, 2008-2011	To develop a CART[b] score and compare with the MEWS[c]	Logistic regression	CA[d] or transfer to ICU[e]	The CART score more accurately predicted cardiac arrest than the MEWS. Model AUC[f] 0.84
Churpek et al, 2013 [29]	RS: tool development	59,643 patients, 1 hospital, 2008-2011	To assess the impact of outcome selection on the performance of prediction algorithms	Logistic regression (4 models)	CA, transfer to ICU, death, all combined	Mortality is the easiest outcome to predict (AUC range 0.73-0.82), and ICU transfer is the most difficult.
Churpek et al, 2014 [30]	RS: tool development	59,301 patients, 1 hospital, 2008-2011	To derive and validate a prediction model for CA	Logistic regression	CA and transfer to ICU	The model can simultaneously predict the risk of CA and ICU transfer and was more accurate than ViEWS[g]. Model AUC 0.88 for CA, 0.77 for ICU
Churpek et al, 2014 [33]	RS: tool development	269,999 admissions, 5 hospitals, 2008-2011	To develop and validate eCART[h] score using commonly collected EMR[i] data	Survival analysis	CA, transfer to ICU, or death	eCART score was more accurate than MEWS for detecting CA, ICU transfer, or death. Model AUC 0.83 for CA, 0.75 for ICU transfer, 0.93 for death and 0.77 all combined
Somanchi et al, 2015 [56]	RS: tool development	133,000 patients, 4 hospitals, 2006-2011	To develop a prediction model for Code Blue, using EMR data, and compare with MEWS	SVM[j] and logistic regression	Code blue event in the next x hours	The model was able to predict Code Blue with ~80% recall and 20% false positive rate 4 hours ahead of the event. It out-performed MEWS.
Churpek et al, 2016 [32]	RS: tool development and evaluation	269,999 patients, 5 hospitals, 2008-2013	To compare the accuracy of different techniques for detecting clinical deterioration on the wards	Logistic, decision trees, SVM, K-NN[k], neural net, MEWS	CA, transfer to ICU, or death	This multicenter study showed that several machine learning methods can more accurately predict clinical deterioration than logistic regression.
Kang et al, 2016 [66]	Prospective study: feasibility study	3889 admissions, 3 wards, 2013-2014	To assess the feasibility of a real-time risk stratification tool	eCART	CA, transfer to ICU, or death	eCART score identified more CA and ICU transfers, many hours in advance, compared with standard RRT[l] activation.
Green et al, 2018 [37]	RS: tool evaluation	107,868 admissions, 5 hospitals, 2008-2013	To compare the BTF[m] calling criteria to MEWS, NEWS[n] and eCART score	BTF, NEWS, MEWS, eCART	CA, transfer to ICU, or death (24 hours)	eCART was more accurate than BTF, MEWS, NEWS for predicting the composite outcome of CA, ICU transfer and death. eCART AUC 0.80 (0.79-0.80)
Bartkowiak et al, 2019 [25]	RS: tool evaluation	32,537 admissions, 1 hospital, 2008-2016	To assess the accuracy of three EWS[o] postoperatively	NEWS, MEWS, eCART	CA, ICU transfer or ward, or death	The eCART score was the most accurate followed by MEWS. Maximum respiratory rate was the most predictive vital sign.
Mayampurath et al, 2019 [48]	RS: tool development	115,825 admissions, 1 hospital, 2008-2016	To develop a model from visual timelines to predict mortality	Convolutional neural network	Death	The model was more accurate than MEWS and SOFA[p], validation model AUC 0.91, and visual timelines enabled interpretation of a deep neural network.

[a]RS: retrospective study.

[l]RRT: rapid response team.

[m]BTF: Between the Flags.

[n]NEWS: National Early Warning Score.

[o]EWS: early warning score.

[p]SOFA: Sequential Organ Failure Assessment.

Several other studies have evaluated screening tools such as the National Early Warning Score, Modified Early Warning Score, Rothman Index, and Sequential Organ Failure Assessment, for the early warning and detection of patient deterioration in hospital settings across different countries [26,39,41,50,52,54,57,59,64,65,67] (Table 3). The evaluation included applying tools retrospectively on historical clinical data to assess the feasibility of future use as well as assessing tools prospectively alongside the standard clinical systems. The studies of screening tools reported differing results of both good and poor predictive accuracy and usefulness for escalation of care through medical emergency team (MET) or rapid response team (Table 3).

Of the studies detailing the implementation of scoring tools across institutions [50-52,61,62,64,65], high-risk patients were appropriately identified as aiding in clinical response (Table 4). However, when comparing intervention and control patient cohorts, differing results were seen with either significant reductions or no impact on the assessed deterioration events.

Within the reviewed papers, deterioration prediction methodologies included single and multiparameter scoring tools, such as the National Early Warning Score and Modified Early Warning Score, as well as statistical and machine learning methods. Single and multiparameter scores were derived from a set of vital sign threshold derangements (Tables 3 and 4). The statistical and machine learning methods included logistic regression, survival models, Cox regression, Gaussian process regression, Markov models, decision trees (random forest and gradient boosted trees), K-nearest neighbor, support vector machine, and neural networks (Tables 1 and 2, and Multimedia Appendix 1 [23,24,27,28,36,38,42,43,45-47,49,51,53,55,58,60,68]). Most of these models attempted to account for changes in physiologic measures over time using novel model frameworks, for example, taking a sliding time window looking forward or backward in time to predict outcomes.

Across all the studies, models of greater complexity and statistical and machine learning methods were shown to have superior performance in predicting deterioration than scoring tools (Multimedia Appendix 1). For example, there was timelier detection and earlier warning of high deterioration risk in more complex models. Furthermore, the discrimination of patient deterioration using statistical and machine learning methods (as assessed with the area under the receiver operating characteristic curve or *c* statistic) outperformed conventional tools.

All patient deterioration prediction tools used vital sign measures, most commonly blood pressure, heart rate, respiratory rate, temperature, oxygen saturation, and a level of consciousness measure (Multimedia Appendix 2, Tables S2 and S3 [23-39,41-45,47-61,63-65,67,68]). In addition, most of the models included basic patient demographic data, such as age and gender, as well as administrative measures, such as admission status, time since admission, length of stay, and patient location. Many of the models attempted to incorporate various pathology or laboratory test results where available, noting that they would experience some level of time delay. Composite indices or scores for severity of illness, longitudinal comorbidities, and combined laboratory results were often included in models where available. The more complex models considered higher-level features of their data such as the frequency, change, minimum, maximum, moving average, and patterns of physiological measures over time [23,24,38,42,45,56,58].

Of the studies that reported missing data, the majority were filled by propagating a previous value carried forward if a current value within a set time window was not measured. If no prior value was available, values were imputed with a representative value such as a population-based estimate or normal value. In models that consider dynamic irregularly sampled physiologic time series data, Gaussian process models were used to deal with sparsity in the data [23,24,55].

Overall, the quality of the studies included in this review was high, with low and unclear risks of bias and concern for the applicability of prediction models in addressing our review questions (Multimedia Appendix 2, Table S2). The majority of prediction model studies appropriately selected model data for inclusion, assessed model predictors and outcomes, approached model development, and adequately tested models. Studies assessed as unclear were because of ambiguous details in reporting the number of participants or samples per derivation and validation data sets, handling of missing data, and lack of detail in model validation. The study quality of the implementation studies we identified was also high, with low to moderate risk of bias identified (Multimedia Appendix 2, Table S4). Moderate concerns were because of the lack of adjustment for potential confounding, participant selection, and lack of detail for handling of missing data.

Table 3. Retrospective studies evaluating scoring tools.

Author, year, and country	Settings	Study aim	Scoring tools	Prediction event	Key findings
Lighthall et al, 2009 [67], United States	1089 patients, 1 hospital, 2006	To evaluate vital signs and association with critical events	MET[a] call criteria	CA[b], ICU[c] transfer or death	Even a single recording of an abnormal vital sign increases the risk of critical events in hospitalized patients.
Huh et al 2014, [41], Korea	3030 events, 1 hospital, 2008-2010	To evaluate the efficacy of screening triggered alerts for MET management	Medical alert system criteria	MET activation	The automatic alert system triggers, along with a skilled intervention team, were successful in managing the MET
Romeo-Brufau et al, 2014 [54], United States	34,898 patients, 2 hospitals, 2011	Comparative analysis of the performance of common EWS[d] methods and how they would function if automated	MEWS[e], SEWS[f], GMEWS[g], Worthing, ViEWS[h], NEWS[i]	Resuscitation call, RRS[j] activation or ICU transfer	The evaluated scores did not offer good predictive capabilities for an automated alarm system. Positive predictive values ranged from <0.01-0.21, and sensitivity ranged from 0.07-0.75.
Yu et al, 2014 [59], United States	328 cases, 328 controls, 1 hospital, 2009-2010	To compare the ability of 9 risk prediction scores in detecting clinical deterioration among non-ICU ward patients	SOFA[k], PIRO[l], ViEWS, SCS[m], MEDS[n], MEWS, SAPS II[o], REMS[p], APACHE II[q]	Critical care consult, ICU transfer or death	Prediction scores can be used to estimate a ward patient's risk of clinical deterioration, with good discriminatory ability comparable with that of existing track-and-trigger systems. 0-12 hours before clinical deterioration, 7 of 9 scores performed with acceptable discrimination (AUC[r]>0.70).
Wengerter et al, 2018 [57], United States	217 cases, 868 controls, 1 hospital, 2013-2015	To evaluate whether Rothman Index variability can predict RRT[s] activation in surgical patients	Rothman Index	RRT activation, mortality	Rothman Index variability predicted likelihood of RRT activation.
Bedoya et al, 2019 [26], United States	85,322 patients, 2 hospitals, 2014-2016	To determine the effectiveness of NEWS implementation on predicting and preventing patient deterioration	NEWS	ICU transfer or death	No change after implementing NEWS. At both academic and community hospitals, NEWS had poor performance characteristics and was generally ignored by nursing staff.
Heller et al [39], 2020, Germany	3827 patients, 2 wards, 2016-2017	To develop a prediction model for Code Blue, using EMR[t] data, and compare with MEWS	MEWS with paging functionality	CA or ICU transfer	The rate of CA and ICU transfers significantly decreased after implementing MEWS with paging functionality.

Table 4. Studies of scoring tool implementation.

Author, year, and country	Study design	Setting	Study aim	Scoring tool	Intervention assessment	Implementation outcome	Key findings or conclusions
Bailey et al, 2013 [61], United States	PS[a]: RCT[b]	19,116 patients, 1 hospital, 2007-2011	To validate the EWS[c] in general medical wards and trial real time alerting.	Two-tiered EWS [38]	Comparison of alerts between intervention and control patients.	Among patients identified by EWS, there were no differences in proportion transferred to ICU[d] or died in the intervention group compared with control.	Alerts generated for patients meeting the threshold were highly specific for ICU transfer and death. However, sending real time alerts to the nurse manager did not improve event outcomes.
Evans et al, 2015 [64], United States	PS: observational study	6289 patients, 1 hospital, 2012-2013	To develop and evaluate a detection and alert system for monitoring patients every 5 min	MEWS[e] with pager alerts	Comparison of events from patients in 2 wards pre and post intervention	Ward A patients had more ICU transfers, MET[f] calls and greater LOS[g] but fewer deaths during intervention compared with preintervention. No differences were seen in ward B.	Implementation of the predictive model increased appropriate MET calls. Mortality decreased in the ward with older patients and multiple comorbidities, but not in the other ward.
Subbe et al, 2017, [65], United Kingdom	PS: before and after study	4402 patients, 1 hospital, 2014-2015	To assess the effect of a vital sign monitoring and alert system on outcomes	Vital sign monitoring system	Comparison of serious events between control and intervention periods	Deaths, CAs[h] and, for patients transferred to ICU, severity of illness scores were lower in the intervention compared with control.	Deploying an EWS based on vital signs increased RRT[i] calls and decreased mortality and CAs.
Oh et al, 2018 [52], Korea	RS[j]: before and after study	207,054 surgeries, 1 hospital, 2008-2016	To evaluate whether a RRS[k] reduces incidence of postoperative CA	RRS with thresholds and calling criteria	Change in cardiopulmonary arrest rate in patients before and after intervention	Cardiopulmonary arrest relative risk (pre vs post intervention) was 0.56 during RRS operational hours but was unchanged during nonoperational hours. These associations remained after comorbidity adjustment.	Implementation of the RRS reduced postoperative cardiopulmonary arrest incidence but only during RRS operational hours.
Morgan et al, 2020 [50], United States	PS: quality improvement study	30,292 patients, 1 hospital, 2017-2018	To evaluate the implementation of a continuous cloud-based EWS to activate an RRT.	Cloud-based modified NEWS[l] with RRT call threshold	Comparison of intervention with control patients for time to first lactate order, ICU[d] transfer and mortality.	The intervention group had improved the time to the first lactate order within 24 hours of modified NEWS ≥7. There was no significant improvement in time to ICU transfer, ICU length of stay, or hospital mortality.	The study provides preliminary evidence for a pragmatic integration of cloud-based, automated monitoring with standardized and timely RRT intervention.

Discussion

Principal Findings

This review examines the use of data sets collected in EMRs to develop and implement decision support for clinicians to predict and prevent inpatient deterioration. The current literature confirms that it is possible for routinely collected EMR data to be used to anticipate patient deterioration. However, there are few reports on the performance and efficacy of these systems when used in clinical settings. Despite the wide and increasing adoption of EMRs, the successful implementation of EMR-based early warning systems or their impact on patient-centered outcomes is not commonly reported.

The studies that met the eligibility criteria and the variability in methods created a narrative review rather than a quantitative review. There was considerable variation in the models developed, methodological approach, and data collected. The common study designs (retrospective, small cohorts, and before and after studies) pose a risk of bias. The institutions where models were developed and implemented predominately from the United States, which may pose additional risks of bias because of the nature of the health care system and environment. The heterogeneity in the methodology of the developed models makes comparison of their statistical accuracy and performance difficult. The area under the receiver operating characteristic curve statistic has been used as a comparison metric, but it is important to note the differences in model specification, complexity, and outcome when interpreting model output (eg, scores) and their usefulness for implementation in a real-time clinical setting. In addition, the reporting of superior performance in statistics from models of greater complexity may be the result of model overfitting if this has not been appropriately addressed in model development. Consideration should be made such that data used to develop early warning tools reflect previous cohorts of patients and may not be relevant for future cohorts. It is reasonable that retrospective patterns of deterioration will repeat themselves in the future; however, with advances in health care technology and the potential for new and emerging health disease trends, adapting or updating tools will be required to maintain relevance. We conclude that the effectiveness of current EMR-based digital early warning tools remains promising but has not been reproducibly demonstrated.

We propose that there are multiple factors that make a patient-centered outcome evaluation of EMR-based deterioration prediction difficult. Demonstration of improved patient outcomes following early warning tool implementation relies on the successful performance of all four components of implementation, recognition, escalation, and response. Where there has been successful statistical validation for the EWSs, validation of the escalation and response (ie, implementation) has been elusive. Several factors may contribute, which are not unique to digital warning implementation. The current metrics for outcome measures are problematic. Death, an outcome that is easy to count, does not always account for treatment limitations. Cardiac arrest events are rare; therefore, they are insensitive measures. ICU transfer can reflect MET resourcing deficiencies, ICU bed availability, and local admission practices or end-of-life planning rather than preventable deterioration. Emergency callout rates may reflect individual clinician sentiment rather than true risk or deterioration, or alternatively, not be called when they should be. There is inconsistency in efferent limb performance (assessment, intervention, transfer, monitoring, and follow-up). The time required for implementation and translation into improved outcomes will frequently be confounded by other system improvements, changes within an individual health service, or the maturity of the rapid response system itself. Therefore, the relationship between implementation and patient outcomes remains unstudied, rather than unproven by the current studies.

These issues will continue to challenge the empirical validation of a complete rapid response system. The lifecycle of these technologies has yet to mature to the point where evaluation and assessment of a possible effective intervention can be performed. One example of practical limitations is to recognize which data are contemporaneously available. Data can only inform a ward-based, real-time prediction model once the information is available in the EMR for analysis. This is relevant to model development and evaluation. For a pathology result, for example, there are times of sample collection, arrival at the laboratory or analysis, and the time the result is available for integration into the clinical picture. The results of the test are only available for integration once they are available in the clinical space. However, the metadata confirming that the sample was actually ordered or collected, where it was done, and the number of samples, is immediately available. The result of a positive blood culture can take hours to days, and a definitive negative result can only be finalized 2-5 days after collection. Providing actionable decision support with such dynamic data sets is a challenge, and it could be argued that the performance of the model on an experimental data set is irrelevant unless, once deployed to the EMR, the relevant decision support is actionable by clinicians in time to avoid an adverse outcome.

As maturity grows in the development cycle within EMRs, there will be potential opportunities to improve EMR-based deterioration tools and assess their impact on patient care. The development of algorithms can help monitor in real time rich clinical data from our patients, including vital signs, investigation results, drug prescription, and provide useful decision support to improve care trajectories. These clinical data can then be used at the patient level to provide visibility of deteriorating or at-risk patients to individual clinicians, wards, clinical teams, and the MET responders, and place decision support back into the EMR to support clinicians in accurately predicting and preventing inpatient deterioration. At the system level, the data could provide feedback to guide the optimization of the digital or clinician interaction and maximize response efficiency. Successful implementation should improve

patient-centered outcomes, reduce suffering, incapacity, and mortality, as well as reduce length of stay, increase hospital capacity, improve efficiency, and increase care delivery to meet ever-increasing demands.

One final, but highly important, factor for consideration in the future implementation of EMR-based deterioration tools is the aspect of medical device regulation. For example, with the recent introduction of regulations for software based medical devices in Australia by the Therapeutic Goods Administration, clinical decision support software such as algorithms to predict patient deterioration that meet the definition of a medical device would be subject to regulation and possibly inclusion in the Australian Register of Therapeutic Goods. The legislation also allows for clinical decision support software to be considered as an exempt medical device subject to how it is intended to be used. Either way, it is expected that regulation will lead to increased clinical acceptance and uptake of such algorithms.

Conclusions

The development and accuracy of digital EWSs is increasing, facilitated by the growing availability of digital data sets. However, despite the relative performance of algorithms that can predict patient deterioration, the current literature shows that limited deployment of such algorithms into clinical practice is associated with improvement in patient outcomes. There is a paucity of quality studies in this area, and further work is needed to explore potential clinical benefits, including optimizing of the digital or clinician interaction, consideration of limitations in implementation, such as the requirement for real-time data availability, and use of standardized measures.

Acknowledgments

The work presented in this manuscript was supported by Clinical Excellence Queensland, Queensland Health, and by the National Health and Medical Research Council Centre for Research Excellence in Digital Health (1134919). However, these sponsors had no influence on the study design; on the collection, analysis, and interpretation of data, on the writing of the manuscript; or decision to submit the manuscript for publication.

Abstract

Background: Medically unexplained physical symptoms are physical symptoms, such as pain, fatigue, and dizziness, that persist for more than a few weeks and cannot be explained after adequate medical examination. Treatment for preventing the chronicity of symptoms is recommended. A promising approach is identifying patients who are at risk and subsequently offering a blended care intervention that focuses on promoting self-management while using eHealth as a supportive tool. When these interventions match with a patient's expectations, their effectiveness grows.

Objective: This study aimed to obtain more insights into usability from the patient perspective to improve future interventions.

Methods: A mixed methods design (ie, the use of qualitative and quantitative data) was used. Through semistructured interviews, in-depth insights were gained into patients' perspectives on usability. The analysis process was continuous and iterative. Data were synthesized and categorized into different themes. The System Usability Scale, which measures the usability of a system, was used to compare participants that found usability to be low, medium, or high. This study was approved by the Medical Ethical Committee Utrecht (approval number: 17-391/C).

Results: Saturation was reached after interviewing 13 participants. The following four themes emerged from the interviews: motivations and expectations prior to participating in the program, the applicability of e-coaching, the role of health care professionals, and the integrated design of the blended approach.

Conclusions: The successful implementation of integrated blended care interventions based on patients' perspectives requires matching treatments to patients' individual situations and motivations. Furthermore, personalizing the relative frequency of face-to-face appointments and e-coaching can improve usability.

KEYWORDS

usability; medically unexplained physical symptoms; blended care

Introduction

Medically unexplained physical symptoms (MUPS) are physical symptoms that persist for more than a few weeks and cannot be explained after adequate medical examination [1]. MUPS are a serious concern, since approximately 25% to 50% of symptoms remain unexplained in primary care [2,3]. Patients with MUPS experience symptoms such as pain, fatigue, and dizziness [4]. These symptoms often have a major impact on daily life and result in a high burden for patients with MUPS [5]. MUPS can be divided into the following three stages: mild, moderate, and chronic [6]. These stages are based on the frequency of consulting a general practitioner, the duration of symptoms, and the physical and psychological dysfunctions experienced [6]. Existing research on treatment for the chronic stages of MUPS has provided valuable insights, and recommended interventions have included cognitive behavioral therapy, exercise therapy, and neuroscience education [7]. Treatment for preventing the chronicity of symptoms has been recommended in order to reduce the severity of symptoms and the direct and indirect costs of care [8,9]. This is in line with the general trend in health care policy; policies nationwide aim to strengthen health programs to prevent diseases and address risk factors [10]. Health care is thereby changing its focus from cures and care to behavior and health [11].

In order for programs to succeed in shifting their focus to behavior and health, these programs must include proactive and indicated prevention [12]. A first step is identifying patients who are at risk for developing chronicity [13,14]. Moreover, literature has shown that programs and interventions should focus on promoting patients' self-management [15,16]. eHealth can serve as a supportive tool for both personalization and the promotion of self-management [17,18]. eHealth is not only supportive of usual therapeutic guidance but is also a substantial element of interventions as a whole [19]. This is referred to as *blended care*—the combination of face-to-face contact with integrated web-based applications [20]—or as *e-coaching*, which is defined as "the use of technology during coaching to motivate and stimulate (groups of) people to change attitudes, behaviors, and rituals" [21,22].

When these interventions match patients' expectations, sustainable changes in patients are achieved more effectively [23]. More insights into usability from the patient perspective can further improve these interventions [24,25]. For example, from the patient perspective, interventions should be easy to use and acceptable. This usability, which is defined as "the quality of a system with respect to ease of learning, ease of use and user satisfaction" [26], can be measured.

The objective of this study was to gain more understanding into patients' perspectives on the usability of integrated blended care interventions. In order to do so, this study analyzed a recent proactive, multidisciplinary, and integrated blended care intervention that was developed to prevent chronicity in patients with MUPS in primary care [27,28]. At-risk patients were identified by using electronic medical records [29]. e-Coaching was used to integrate technology into the intervention. The main goals were to (1) promote self-management among patients and (2) provide patients with insights into dealing with their complaints.

Methods

Study Design and Setting

A mixed methods design (ie, the use of qualitative and quantitative data) was used. Through semistructured interviews, qualitative data were gathered in order to gain an in-depth understanding of usability from patients' perspectives. System Usability Scale (SUS) scores (low, medium, and high) were compared to responses in the interviews, which allowed us to gain better insight into the relationship between identified themes from interviews and experienced usability. This study was approved by the Medical Ethical Committee of University Medical Center Utrecht (approval number: 17-391/C).

Participants

Patients who participated in the PARASOL intervention were eligible for inclusion. To be included in the intervention, all patients (aged ≥18 years) must have had ≥5 consultations with their general practitioner in the past 12 months. Of these consultations, ≥3 had to be classified as "suggestive of MUPS" based on 1 of the 104 International Classification of Primary Care codes. Patients with medical and psychiatric diagnoses were excluded [28]. Only participants in the PARASOL intervention who provided informed consent for this follow-up study were invited. In order to obtain rich data, stratified purposeful sampling was conducted based on the outcomes of the SUS. Patients with validated SUS scores of <70, between 70 and 80, and >80 were included; these represent low, medium, and high scores for usability, respectively [30].

Measurements

Qualitative data were collected in one-to-one semistructured interviews, which were conducted at an agreed-upon location. A second researcher was available to play the role of observer. The topic list for the interviews was based on the theoretical construct of De Bleser et al [26] and supplemented with the determinants of health care innovation that were selected and developed by the Netherlands Organization for Applied Scientific Research [31] (Textbox 1). The quantitative data consisted of the outcomes of the SUS. The SUS has high reliability [30] and contains 10 questions on the usability of a system [32]. Questions were answered on a numeric rating scale with scores that range from 1 to 5 ("strongly agree" to "strongly disagree"). The SUS was administered at the end of the intervention. The demographic data consisted of age, gender, and educational level (basic, intermediate, and high). Educational levels were derived from the Standard Classification of Education used by Statistics Netherlands [33].

Textbox 1. Outline of the interview guide [26]. The key areas are shown.

Performance

- Impact of use environment
- Impact of user characteristics
- Ease of the manipulation of the device

Satisfaction

- Physical dimension
- Privacy dimension
- Human interaction
- Self-concept
- Routine
- Sustainability

Acceptability

- Acceptance for daily life use
- Willingness to pay for device

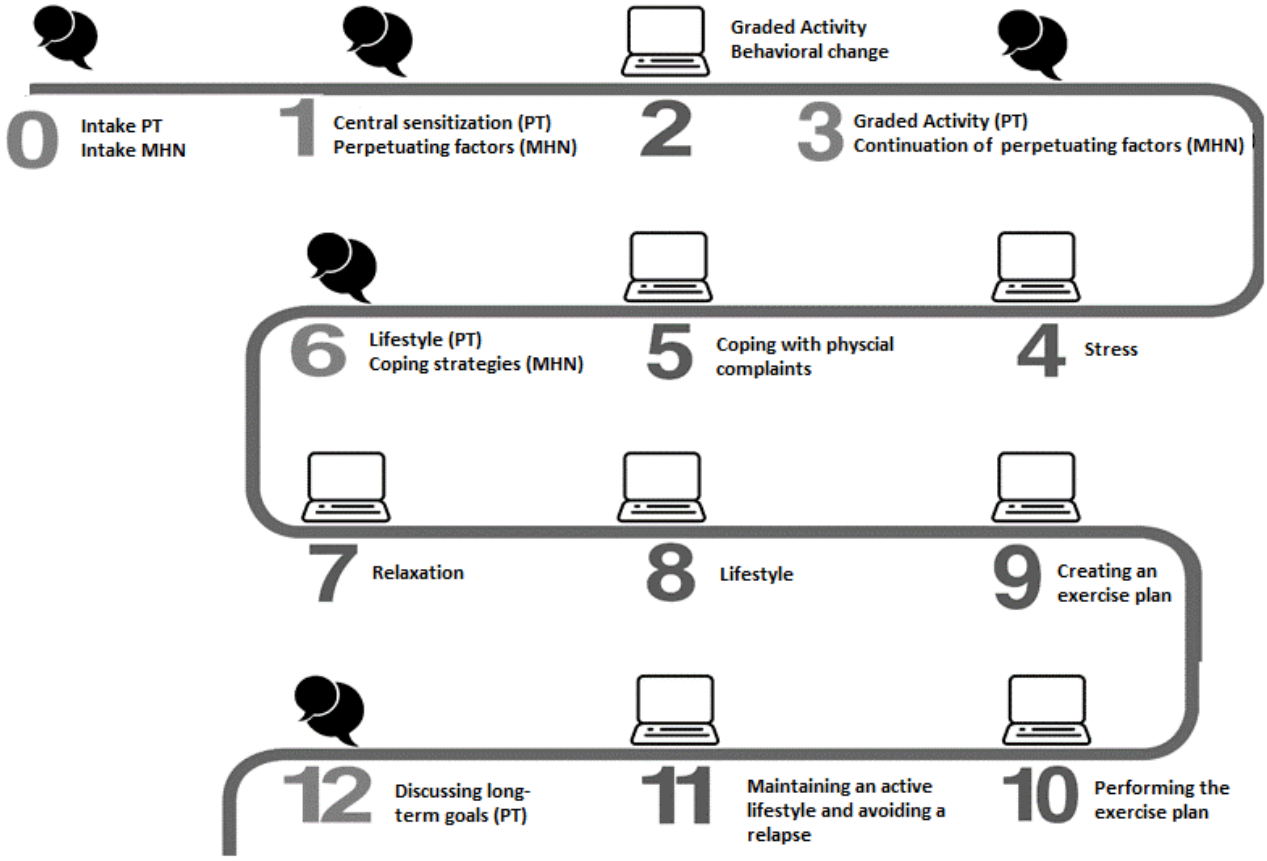
Procedure

Qualitative data were collected from semistructured interviews within 4 weeks after participants completed the PARASOL intervention to avoid recall bias. Interviews took place in patients' homes or in one of the participating health care centers, depending on the preferences of the patients. Before the interview started, procedures regarding sound recording and the coding of data were explained, after which permission was requested from the participants. Quantitative data were collected for the randomized controlled trial PARASOL (Evaluation of a Proactive Preventive Program in Patients With MUPS; trial registration number: NL57931.041.16) [28]. Demographic data were retrieved from baseline measurements. After 3 months, upon the completion of the PARASOL intervention, SUS scores were gathered.

PARASOL Intervention

The PARASOL intervention was a 12-week integrated blended care intervention that consisted of 4 face-to-face consultations with a mental health nurse and 5 physical therapy sessions and was supplemented with e-coaching (Figure 1). e-Coaching consisted of information modules and videos on self-management and educative themes, videos and instructions on prescribed home exercises, and assignments for gradually increasing physical activity. The intervention aimed to improve patients' perceptions of symptoms and identify modifiable risk factors of chronicity by providing therapeutic neuroscience education and promoting self-management. The intervention also aimed to promote an active lifestyle by using a cognitive behavioral approach and graded activities. Health care professionals were instructed on how to treat patients with moderate MUPS during a 2-day training session. Beyond the program itself, instructions included presentations on the study population, central sensitization, therapeutic neuroscience education, graded activities, and perpetuating factors. Furthermore, health care professionals were instructed on how to integrate e-coaching during the intervention. They were, for instance, guided on how to personalize general themes and instructed to ask patients about whether they understood information that is given on web-based platforms. All health care professionals received a guideline after finishing the training.

Figure 1. Overview of the PARASOL intervention. The text cloud images indicate face-to-face contact with a PT and MHN. The computer images indicate modules of e-coaching. MHN: mental health nurse; PT: physical therapist.



Data Analysis

Interviews were recorded and transcribed verbatim, and transcriptions were checked by 2 researchers. Within 1 week after completing the interviews, a summary was sent to all participants. This member check verified whether interpretations were correct. After the initial interviews were conducted, the interviewer added other questions based on the themes that emerged from these interviews. Both researchers encoded meaningful text fragments independently, and a set of preliminary concepts and codes was generated. The analysis process was continuous and iterative. Data were synthesized and categorized into 4 different themes. In the last stage of the analysis, for each theme, interview responses were compared on the basis of participants' SUS ratings. This allowed us to gain better insight into the relationship between identified themes from interviews and experienced usability.

Results

Interview Results

Saturation was reached after 13 interviews. Interviews lasted for approximately 20 to 50 minutes and had a mean duration of 33 minutes. Participants' mean age was 42 years. A majority of participants were female (10/13, 77%). Further, 5 participants had an SUS score of <70, 5 participants had a score of between 70 and 80, and 3 participants had a score of >80. The demographic characteristics of the study population can be found in Table 1.

Table 1. Demographic characteristics.

Participant number	Age (years)	Sex	Educational level	Previous experience in blended care	Interest in technology in the field of health care	System Usability Scale score
1	35	Female	Intermediate	No	Yes	67.5
2	48	Female	Intermediate	No	No	60.0
3	38	Female	Intermediate	No	Neutral	77.5
4	23	Female	Intermediate	No	Neutral	57.5
5	42	Female	Basic	No	Neutral	55.0
6	42	Male	Intermediate	No	Yes	50.0
7	48	Female	High	Yes	Yes	77.5
8	43	Female	Intermediate	No	Yes	85.0
9	47	Female	High	Yes	Yes	80.0
10	38	Male	High	No	No	72.5
11	31	Female	High	No	Yes	72.5
12	52	Male	High	No	Yes	87.5
13	57	Female	High	No	No	95.0

The 13 interviewees formed a subset of participants from the PARASOL intervention arm (n=80; age: mean 47 years; female: 57/80, 71%). The overall averages of the PARASOL intervention participants were hence comparable to those who were selected for interviews on the basis of purposeful sampling. The overall mean SUS score in the PARASOL intervention arm (n=55) was 74.6. A total of 19 participants had an SUS score of <70, 15 participants had an SUS score of between 70 and 80, and 21 participants had an SUS score of >80. Further, 20 participants in the PARASOL intervention did not complete the intervention, and 5 questionnaires were not submitted.

As the use of e-coaching integrated in treatment is relatively new, participants were asked about their general experience with and interest in technology in health care. Every participant had used some form of technology (in the broadest sense of the word). The use of a PC, smartphone, and tablet were mentioned. The integration of technology in health care was only previously experienced by 2 of the participants. When asked about technology in health care, participants mentioned the use of pedometers, health apps, and websites. Participants' interest in technology differed, as can be seen in Table 1.

A total of 4 themes emerged from the interviews. These themes provided insight into the usability of a blended approach to an integrated intervention from patients' perspectives.

Theme 1: Motivations and Expectations Prior to Participation in the Intervention

There was no consensus on participants' expectations prior to the intervention. Some participants stated that they had no expectations or that they had no expectations that their complaints would disappear by participating in the intervention. Others expected fewer complaints and more physical activity, and some expected that their pain would go away. A recurring statement reflected the hope that someone would seriously consider their complaints:

> *That someone finally thinks about the fact that these complaints are really there, and that a program is being made.* [Participant #3]

In terms of motivation, some participants participated mainly for personal interest. Other participants were just curious and saw no disadvantages, and some started the intervention because of a referral from their general practitioner. Experiencing intense pain was a motivation for participating in the intervention, and some participants mentioned that there were no other options for treatment with regard to their complaints. One participant stated:

> *I take this, because elsewhere a program is never really offered.* [Participant #8]

When the results were analyzed based on SUS score groups, they showed that higher overall SUS scores were related to quotes regarding autonomy and intrinsic motivation (Textbox 2). In terms of expectations related to the intervention program, there was no difference among SUS groups (Textbox 3).

Textbox 2. Quotes related to motivation. The quotes are stratified by System Usability Scale (SUS) score groups.

SUS score group: <70

- "I participate to stay active"
- "Advice from GP"

SUS score group: 70-80

- "Interesting to see whether the mental and physical aspects come together"
- "I don't understand my complaints and want to know what they are, and how I can deal with them"

SUS score group: >80

- "I have to make use of this opportunity, as I have been looking for ways to deal with my complaints for two years"
- "I had no way to resolve my complaints, and perhaps this will help me"

Textbox 3. Quotes related to expectations. The quotes are stratified by System Usability Scale (SUS) score groups.

SUS score group: <70

- "I don't know if it will work"
- "I have no idea what to expect"

SUS score group: 70-80

- "I'm curious, rather than have any expectations"
- "I thought, this must really work"

SUS score group: >80

- "I was open to something new"

Theme 2: Applicability of e-Coaching

References were made to e-coaching during interviews twice. The first reference concerned the look and feel of the application, and the second concerned the application's acceptability. Some participants mentioned that they spent a long time searching within the application and found the web-based portion to be confusing. For example:

> *I had to watch instruction videos but I could not find them.* [Participant #3]

Other participants however found the site to be well structured. There was no consensus on the ease with which documents or instruction videos could be found. Many participants had problems with logging in. In addition, the application often had bugs. This did not promote the use of e-coaching. One participant said:

> *I did my exercises every day but the program did not work so I just did not fill it in.* [Participant #13]

Another participant missed an evaluation that would have given insight into their progress. The ability to ask questions on web-based platforms and the fact that people can use the intervention anywhere were mentioned as facilitators. Participants stated that the planning assignments and exercises were clear every week. One participant said:

> *What I found very clear was that you could just click and do your exercises and activities on a weekly and daily basis.* [Participant #8]

Participants appreciated the ability to tick off the followed modules so that it was immediately clear which modules had been completed and which were still open. There was no consensus on whether obtaining information through text or film was preferred. Participants gave the following tips for the use of e-coaching:

> *Add forms on the site to leave notes on progress, e.g. how many minutes one walked.* [Participant #9 and Participant #11]
>
> *Make assignments more accessible by using visual support (colors, shapes).* [Participant #7]

The higher the satisfaction (as measured by the SUS), the more participants understood and used the web-based environment (Textbox 4).

Textbox 4. Quotes related to the applicability of e-coaching. The quotes are stratified by System Usability Scale (SUS) score groups.

SUS score group: <70

- "It is unclear for me how to use the website"
- "I can't enter the system, I never accessed the online part"
- "I often did not fill out the online sections, I prefer face-to-face treatments"

SUS score group: 70-80

- "I could not find the video, so I used text"
- "Clear and easy to use"

SUS score group: >80

- "The videos are clear and easy to use in daily life"
- "The site was clear"
- "It was easy to get the hang of the application"

Theme 3: The Role of Health Care Professionals

An often-mentioned facilitator of the treatment was agreement among health care professionals. Participants felt that they were receiving the same information from different angles. In face-to-face treatments, which participants felt to be useful, health care professionals provided psychoeducation, in which reminders and repetition were introduced to patients. A participant stated:

> *Because both the mental health nurse and the physical therapist spoke about interpreting pain, for example, and the physical therapist explains it more anatomically.* [Participant #11]

The important roles of health care professionals were found to be discussing exercises, providing information, setting goals, and helping patients reach these goals. Participants also appreciated the fact that health care professionals supported reflections on behaviors and thoughts via confrontation, convincement, and motivation. For example:

> *Holding up a mirror to me, that there was a confrontation, it was very helpful that the physical therapist was confrontational.* [Participant #12]

Another facilitator was the approachability of the mental health nurse. Participants recommended increasing the involvement of the general practitioner to increase the amount of feedback and encouragement that they receive. One participant stated:

> *I can imagine that people with these complaints do not always immediately think the mental health nurse and the physical therapist are going to solve the problem, so I think that the GP is still important for encouragement.* [Participant #3]

Participants also did not expect physical therapists to engage in conversations as much as they did:

> *I think physical therapy is important only when giving exercises and not for conversations.* [Participant #10]

The higher the SUS score, the more patients understood that health care professionals acted as coaches rather than as therapists (Textbox 5). There was no difference among subgroups with regard to interprofessional collaboration (Textbox 6).

Textbox 5. Quotes related to the role of professionals. The quotes are stratified by System Usability Scale (SUS) score groups.

SUS score group: <70

- "I feel the need to have my own say more"
- "Sometimes I feel I have the same conversation twice, the physical therapist and I were a better match and we could converse more easily"

SUS score group: 70-80

- "The physical therapist remember me and my story, and that made me feel good"
- "I expected more from the physical therapist, just conversing and no exercises"

SUS score group: >80

- "The professionals were very involved"
- "It's good that the professionals held up a mirror to me"

Textbox 6. Quotes related to interprofessional collaboration. The quotes are stratified by System Usability Scale (SUS) score groups.

SUS score group: <70

- "Good cooperation, same advice"
- "The same advices, did not notice cooperation, I did know they coordinated amongst the two of them"

SUS score group: 70-80

- "The combination of the mental health nurse and the physical therapist was good"
- "There was an overlap, but that did not bother me, it was complementary"

SUS score group: >80

- "I know they coordinated, they did not enter each other's domains"
- "One was more physical, the other was more psychological"

Theme 4: Integrated Design of the Blended Approach

Given that only 2 participants had previous experience with blended care, interview questions about this new method of delivering health care were asked. Some participants were satisfied with the higher frequency of face-to-face appointments at the start of the intervention, while others were not. The time between appointments increases the chance of forgetting parts of the treatments. The face-to-face sessions served as a reminder:

> *Because I forget a lot, so it's nice that I can have feedback reminder.* [Participant #5]

Participants suggested making the number of face-to-face sessions dependent on individual preferences. One participant said:

> *I think you should personally consult with each individual on the number of appointments.* [Participant #13]

Others indicated that the number of face-to-face appointments should be made dependent on one's experience with web-based applications. For example:

> *I think for me personally I could have done with fewer appointments, as I am used to work online.* [Participant #8]

Participants also mentioned that it was important for face-to face sessions and e-coaching to be coordinated. One participant stated:

> *You are encouraged to do the online program and then you come to practice and can get the information again, it connects.* [Participant #7]

Another stated that face-to-face sessions filled the gap that was left on web-based platforms:

> *In fact, I first had to read the explanation on the website and then my questions were discussed.* [Participant #10]

The possibility to schedule therapy based on personal preferences however was seen as an advantage. For example:

> *I liked the times. It was possible for me to make an appointment at the end of the day.* [Participant #7]

The advantage of e-coaching was that participants could prepare specific questions that could be asked during the face-to-face sessions (eg, "I could ask specific questions I prepared myself" [Participant #10]). Further, participants generally perceived blended care as positive (eg, "But that you can check it yourself at home. I think this is very good" [Participant #7]).

Participants appreciated the integrated design of the intervention across all of the different SUS score groups (Textbox 7).

Textbox 7. Quotes related to the integrated design of the blended approach. The quotes are stratified by System Usability Scale (SUS) score groups.

SUS score group: < 70

- "Because feedback is more specific for my own situation"
- "Face-to-face was a reminder...I find personal contact to be very important"

SUS score group: 70-80

- "The proportion [face-to-face and online] and frequency was good"
- "Face-to-face and online matched"
- "Repetition made it easier to remember"

SUS score group: >80

- "I find it easy to combine with other activities, I could do with less appointments"
- "The number of appointments should be based on personal preferences"

Overall, the results of this study show that participants experienced the intervention positively. This integrated blended care intervention aimed to promote self-management among patients and provide patients with insights into dealing with their complaints. Participants stated that they learned about self-management:

> *Now, I can estimate what I can do and cannot do.* [Participant #9]
>
> *I can actually do it all by myself.* [Participant #8]

Participants also gained more insights into dealing with their complaints:

> *Knowing nothing is broken, that idea has reassured me.* [Participant #4]
>
> *Because of graded activity, pain turns into pride; I am happier, undertake more, sing more; I'm enjoying more.* [Participant #11]

Textbox 8 includes all of the core themes that emerged from the semistructured interviews and hence summarizes usability from patients' perspectives. It shows the factors that were appreciated and lessons learned for improving usability.

Textbox 8. Summary of findings.

Factors that patients appreciated

- Information being recognizable
- The intervention as an incentive
- The personal approach
- The holistic approach
- Interprofessional collaboration

Lessons learned for improving usability

- Connect the intervention to the individual's situation and motivation
- Improve the accessibility of and technology support in e-coaching
- Introduce the possibility of asking questions on web-based platforms
- Personalize the intervention with respect to the amount of personal guidance alongside e-coaching

Discussion

Principal Findings

In this study, we evaluated patients' perspectives on the usability of an integrated blended care intervention. All included patients participated in a 12-week proactive blended care intervention in primary care with the aim of preventing the chronicity of MUPS. Participants were all generally positive about the received care. Various aspects of usability were highlighted, and responses were categorized into 4 themes.

The first theme that arose from interviews was the motivations and expectations of patients prior to the intervention. Existing literature shows that interventions that match patients' expectations are more effective in achieving sustainable changes in patients [23]. This especially holds true for intrinsic motivation rather than extrinsic motivation, which increases one's willingness to spend more time on assignments [34] and results in better health care outcomes [35]. Motivation also seems to be a factor of patients' adherence to eHealth [36]. In this study, we found differences in motivation related to satisfaction. When the overall results of the interviews were compared based on SUS scores, intrinsic motivation seemed to be an important factor related to experienced usability. Another factor that may influence a patient's motivation is patient selection. In this study, an electronic screening method involving the use of data from the electronic medical records of general practitioners' patients was used [29]. All eligible patients who were at risk for the chronicity of complaints were proactively approached by their general practitioners via an invitation letter. The selection of patients via this approach also has implications for patients' motivation, as the chance of approaching patients who may be less motivated may increase. To achieve adherence in patients, one should therefore take motivation into account in future interventions.

Many participants were not satisfied with the technical support provided in e-coaching, as technical functions did not work and logging in was a problem. The degree of satisfaction, which was measured with the SUS, increases when the web-based environment is understood and can be used. When patients were uncertain about the usefulness of e-coaching, the e-coaching modules were not used. This phenomenon has also been found in literature. Adapting eHealth to users' understanding and capabilities leads to a more usable and useful system [23]. When comparing the ages and educational levels of the participants in the low and high SUS score groups, a finding that stood out was that those with lower satisfaction were substantially younger and had lower educational levels. Existing literature shows that individuals with less education have worse actual and self-rated skills for evaluating the quality of web-based health information and lower trust in web-based health information compared to those with more education [37]. Studies however have found no consensus regarding the relationship between satisfaction and age [37].

Irrespective of the differences in satisfaction with e-coaching, participants were satisfied with the interprofessional collaboration. The holistic approach, through which physical therapists and mental health nurses provided information from different angles, was positively received by the participants. The expectations of participants regarding the role of health care professionals however differed among the SUS score groups. The higher the SUS score, the more patients understood that health care professionals acted as coaches rather than as therapists. Participants in the lower SUS score group, for instance, felt that they had to explain their complaints twice and expected that the roles of physical therapists would include more than just engaging in conversations and providing exercises. As the organization of health care has changed (ie, focusing more on prevention) [38], the role of health care professionals will also change; health care professionals will shift their focus from being a therapist to being more of a coach [39]. It seems important to explain this new role at the start of integrated blended care interventions in order to better shape the expectations of patients. Aside from interprofessional collaboration, attention should also be given to the collaboration between professionals and patients. Shared decision-making can support this process [40].

Participants appreciated the integrated design of the intervention across all of the different SUS score groups. They positively evaluated the possibility of saving texts and videos for future reference and the repetition of information in e-coaching combined with face-to-face sessions. The ability to personalize face-to-face sessions by allowing patients to prepare specific questions after studying the general information in the e-coaching modules was appreciated. Earlier studies have underlined the importance of face-to-face treatment combined with web-based care, as this has been found to improve and preserve outcomes [35,36,41]. The extent to which the intervention was tailored to participants made interventions and information recognizable. Participants also mentioned that an important yet missing part of the intervention was a diary or a free space for taking notes on exercises. The option to tick off exercises and modules and the explanation of exercises were considered to be helpful. These findings are supported by literature stating that the key components of the positive effect that eHealth has on health outcomes are personalization, stimulation, goal setting, and the integration of e-coaching [21]. All of these elements were available in the integrated blended care intervention.

The results of this study demonstrate the usability of an integrated blended care program for patients with MUPS. More research is needed to investigate whether these results are patient specific or whether the results of this patient population are unique. What remains important is ensuring that the use of technology in treatment fits the participants [42]. A checklist can help health care professionals, together with patients, to decide whether a patient is eligible for this program and whether the program matches a patient's characteristics (eg, abilities, needs, and preferences) and prior experiences with blended care [41].

Strengths and Limitations

A limitation of this qualitative study is that all information is based on a specific integrated blended care intervention—the PARASOL intervention. Therefore, some items of the core themes are directly linked to this specific intervention. However, recommendations are insightful in general when starting an integrated intervention with a blended approach.

The theoretical construct of Bleser et al [26] was chosen. This construct contains the performance, satisfaction, and acceptability features. Other theoretical constructs for gathering insights into usability also exist, such as the Unified Theory of Acceptance and Use of Technology and the Technology Acceptance Model. These other constructs however largely overlap [43,44]. The Unified Theory of Acceptance and Use of Technology focuses more on social influences related to behavioral intention, whereas the Technology Acceptance Model focuses on perceived usefulness and ease of use. Given the findings of this study, including other measuring instruments, such as the Intrinsic Motivation Inventory and the Rotter locus of control scale, could be an interesting addition in future research. These could shed more light on patients' motivations at the start of the program. The strengths of this study are the use of an iterative process during the analysis of the results and the use of triangulation methods during the whole research process. Furthermore, patient involvement was sought in all research phases.

Conclusions

The successful implementation of integrated blended care interventions based on patients' perspectives requires matching treatments to patients' individual situations and motivations. In addition, personalizing the relative frequency of face-to-face appointments and e-coaching is of importance.

Acknowledgments

This work was supported by SIA-RAAK-public (grant 2015-02-24P).

Authors' Contributions

SAJT, PEVW, MFP, and CV initiated this study and contributed to the concept and design of this study. SAJT organized the interviews and participated as an interviewer, and PEVW and SK participated as observers. SAJT and SK analyzed and interpreted the data. MEN was the qualitative interview expert. All authors revised the manuscript and approved the final version for submission.

Conflicts of Interest

Abstract

Background: Diabetes has become one of the most prevalent chronic diseases, and many people living with diabetes use social media to seek health information. Recently, an emerging social media app, TikTok, has received much interest owing to its popularity among general health consumers. We notice that there are many videos about diabetes on TikTok. However, it remains unclear whether the information in these videos is of satisfactory quality.

Objective: This study aimed to assess the quality of the information in diabetes-related videos on TikTok.

Methods: We collected a sample of 199 diabetes-related videos in Chinese. The basic information presented in the videos was coded and analyzed. First, we identified the source of each video. Next, 2 independent raters assessed each video in terms of the completeness of six types of content (the definition of the disease, symptoms, risk factors, evaluation, management, and outcomes). Then, the 2 raters independently assessed the quality of information in the videos, using the DISCERN instrument.

Results: In regard to the sources of the videos, we found 6 distinct types of uploaders; these included 3 kinds of individual users (ie, health professionals, general users, and science communicators) and 3 types of organizational users (ie, news agencies, nonprofit organizations, and for-profit organizations). Regarding content, our results show that the videos were primarily about diabetes management and contained limited information on the definition of the disease, symptoms, risk factors, evaluation, and outcomes. The overall quality of the videos was acceptable, on average, although the quality of the information varied, depending on the sources. The videos created by nonprofit organizations had the highest information quality, while the videos contributed by for-profit organizations had the lowest information quality.

Conclusions: Although the overall quality of the information in the diabetes videos on TikTok is acceptable, TikTok might not fully meet the health information needs of patients with diabetes, and they should exercise caution when using TikTok as a source of diabetes-related information.

Introduction

Diabetes has become one of the most prevalent chronic diseases throughout the world. According to a recent report by the International Diabetes Federation, the estimated global prevalence of diabetes in people aged 20-79 years reached 493 million in 2019, accounting for 9.3% of the total world population [1]. Crude estimates of diabetes prevalence are 13.0%

for US adults [2] and 12.8% for Chinese adults [3]. This high prevalence of diabetes results in huge financial burdens and losses for societies. In 2019, diabetes and related complications led to approximately 4.2 million deaths globally and resulted in US $760 billion of health expenditures [1]. Therefore, there is a pressing need to take action in managing diabetes.

Individuals living with diabetes can actively manage their chronic condition. Early studies suggest that intensive blood glucose control can greatly reduce the risk of complications from the disease [4-6]. However, effective blood glucose control is not an easy task among people living with diabetes. Adequate glycemic controls require a constellation of actions, such as a customized diet, exercise plans, regular self-assessments of blood glucose levels, and optimized medication [7]. According to one study, in 2013, only 25.8% of patients with diabetes had received treatment in China, and only 39.7% of those treated had adequate blood glucose control [8]; such low treatment and adherence rates may be associated with people's limited knowledge of the disease [9]. People living with diabetes often have diverse needs for information regarding their chronic condition, such as basic information on diabetes and the effectiveness of treatment options, on the sequelae of diabetes, blood glucose control, etc [10]. Nevertheless, they usually encounter many difficulties finding relevant and easy-to-understand information on their conditions [11].

Emerging internet technologies provide opportunities for better health communication and patient education. The internet has shifted the role of patients from passive information recipients to active information seekers [12]. General health information consumers use social media platforms (eg, discussion forums, microblogs, and group chatting) to seek both instrumental advice and emotional support [13-15]. Patients with diabetes who actively use social media for information, according to recent evidence, are associated with having lower glycated hemoglobin values [16]. A possible explanation for this is that social media provides patients with many opportunities to gain health knowledge, thereby increasing patient activation (ie, the ability and willingness that equip patients to take active action in managing their health care) [17]. Therefore, it is essential to utilize social media for better health communication for managing diabetes conditions.

Despite the considerable benefits of social media, its use for health communication has some limitations. In the literature, the quality of the information is the most extensively mentioned concern [18]. The possibility of encountering faulty health information on social media increases risks for patients, who may make health decisions on the basis of inaccurate information [19]. The quality of unmoderated information poses challenges for both patients and health care providers. On one hand, patients need to be able to distinguish high-quality information sources from low-quality ones [20,21]; one the other, health professionals and institutions are expected to respond to and combat health misinformation to protect the public [22]. Therefore, it is important to examine the quality of health information on social media.

Recently, an emerging short video app, TikTok, has attracted the interest of health care researchers [23]. During the COVID-19 pandemic, health-related videos on TikTok were widely viewed and shared. For example, COVID-19–related videos on the app have been watched approximately 93.1 billion times [24]. TikTok contains many videos about diabetes; however, their quality remains unstudied. To address this gap, this study aimed to systematically assess the quality of the information in diabetes-related videos on TikTok.

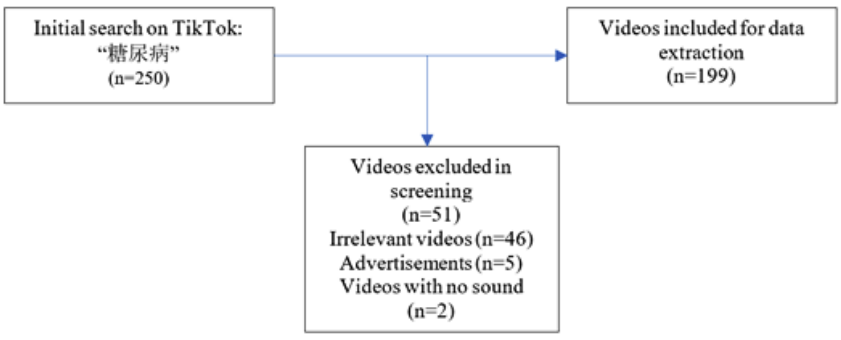
Methods

Search Strategy and Data Extraction

Using the keyword "糖尿病" ("diabetes" in Chinese), we searched TikTok during the period from January 20-25, 2021, and we retrieved the first 250 videos delivered by TikTok's recommended sorting process. We included the videos directly related to diabetes and excluded videos on other topics, commercial advertisements, and videos with no sound. After the screening, we obtained 199 videos for further data extraction and analysis (Figure 1).

We retrieved and extracted the basic information for each video, including the URL, publication date, name of the uploader, type of uploader (individual vs organization), uploaders' verification status, length of the video, number of times it was shared, and number of "likes" and comments it received. The extracted data were recorded in Excel (Microsoft Inc).

Figure 1. Video screening procedure.



Measures

We measured 2 aspects of diabetes-related videos on TikTok: their content and the quality of their information. First, we adopted the coding schema proposed by Goobie et al [25] to rate the quality of six types of content: the definition of the disease, signs/symptoms, risk factors, evaluation, management, and outcomes. Two raters assessed each video independently

and scored how sufficiently the video addressed each of the content types on a 3-item scale: 0 points (no content), 1 point (some content), 2 points (extensive content).

To rate the quality of the information, we adopted the DISCERN instrument. According to a systematic review [26], since its publication in 1998, DISCERN has been one of the most widely adopted instruments for assessing the quality of health information. It is a brief questionnaire that enables its users to assess the quality of health information concerning treatment choices [27]. The instrument consists of 16 questions, with response choices based on a 5-point scale, ranging from 1=poor to 5=good. These 16 questions are divided into 3 sections. The first 8 concern the reliability of the publication, such as whether its aims are clear and whether it is relevant, balanced, and unbiased. The scores for this section indicate whether the publication can be trusted as a source of information for choosing a treatment for a particular disease. The 7 questions in the second section focus on the details of treatment choices, such as whether the publication describes how each treatment works and explains its risks and benefits. The scores for this section reflect the quality of the publication's information about treatment choices (including self-care). The third section consists of 1 final question, based on all the previous ones; it asks users to rate the overall quality of the publication as a source of information about treatment choices. Of note is the fact that, although the original DISCERN instrument was designed for evaluating written publications, it has been widely used for assessing health-related videos. For example, researchers have used it to evaluate YouTube videos informing patients about treatments for cancer [28,29] and diabetes [30].

Rating process

Two authors (WK and LS) worked on the rating tasks; both are certified physicians who work at endocrinology departments at 2 local hospitals. The raters independently scored each video for its coverage of the 6 types of content and applied the 16 questions of the DISCERN instrument. Interrater reliability was assessed with SPSS (version 22, IBM Corp). The interrater reliability for each of the 6 items relating to video content ranged from 0.813 to 0.981, and all of the reliability coefficients are highly significant at an error margin of 0.1%. The interrater reliability for each of the 16 items of the DISCERN instrument ranges from 0.898 to 0.991, and all of the reliability coefficients are highly significant at an error margin of 0.1%. These results indicate satisfactory interrater reliability.

Results

Video Sources

We identified 2 primary sources of the videos: individual and organizational users. We further identified 3 types of video creators among individual users: health professionals, science communicators, and general users. Among organizational users, we identified three types of sources: news agencies, nonprofit organizations, and for-profit organizations.

The results suggest that individual users published most of the videos (n=156, 78.4%). Among individual users, health professionals contributed the most videos (n=138, 69.3%), followed by general users (n=12, 6.0%), and science communicators (n=6, 3.0%). We noted that only 43 videos were uploaded by organizational users, and these accounted for 21.6% of the videos in our sample. Among organizational users, news agencies contributed the most videos (n=31, 15.6%), followed by nonprofit organizations (n=7, 3.5%) and for-profit organizations (n=5, 2.5%) (Table 1).

In our sample, the shortest video lasts only 13 seconds, while the longest lasts 407 seconds. On average, the videos are approximately 1 minute long. All videos were published after 2019. The earliest video had been on TikTok for 589 days, while the latest one was published 3 days prior to the day we collected the data. The videos in the sample received 2.75 million "likes" and 157,700 comments and were shared 305,200 times. Table 2 shows the characteristics of the videos, described by the median numbers across different sources.

Table 1. Descriptions of video sources.

Source type	Source description	Videos, n (%)
Individual users (n=156)		
Health professionals	Individuals who identify themselves as health professionals (eg, doctors and nurses)	138 (69.3)
General users	General users (eg, general health consumers)	12 (6.0)
Science communicators	Individuals who are engaged in scientific communication (eg, popular science writers)	6 (3.0)
Organizational users (n=43)		
News agencies	News agencies and the press	31 (15.6)
Nonprofit organizations	Organizations operated for collective, public, or social benefit and public hospitals	7 (3.5)
For-profit organizations	Organizations that pursue commercial interests	5 (2.5)

Table 2. Characteristics of the videos across sources (median numbers).

Source type	Length of video (seconds), median	Days on TikTok, median	"Likes," median	Comments, median	Times shared, median
Health professionals (n=138)	50.5	131	4191	164	802.5
General users (n=12)	135.5	161	3089.5	78.5	891
Science communicators (n=6)	43	135	24,000	593	4966
News agencies (n=31)	43	90	9917	167	3505
Nonprofit organizations (n=7)	52	200	23,000	194	3023
For-profit organizations (n=5)	63	317	33,000	405	6759

Video Content

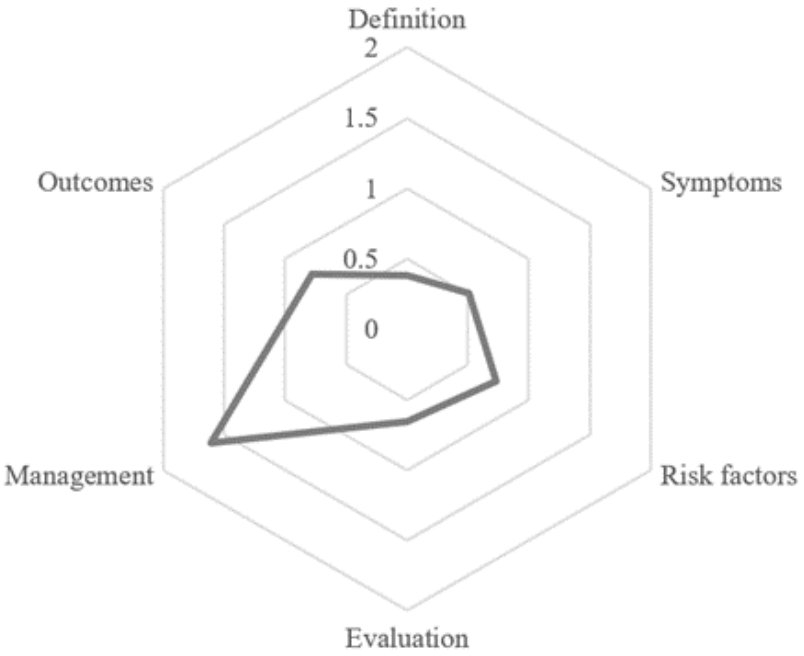
It was not our intention to exclude any type of diabetes during searching and screening. However, we found that most of the videos were about type 2 diabetes mellitus (n=193, 97%). We identified only 4 (2%) videos about gestational diabetes mellitus and 2 (1%) videos about type 1 diabetes mellitus.

Moreover, we averaged the scores of the 2 raters for each aspect of the video content and obtained scores that ranged over the full 5-point scale, from "no content" to "extensive content." The results show that more than half of the videos contain little or no content on the definition of the disease, symptoms, or evaluations of diabetes. Overall, 46.2% of the videos contain little or no content on diabetes-related risk, and 66.8% have some or more information on outcomes. Management of diabetes was the most frequent topic in the sample. Overall, 67.8% of the videos sufficiently introduced diabetes management (Table 3). The overall scores for all the videos are given in Figure 2.

Table 3. Completeness of video content.

Content	Definition, n (%)	Symptoms, n (%)	Risk factors, n (%)	Evaluation, n (%)	Management, n (%)	Outcomes, n (%)
No content (0 points)	113 (56.8)	115 (57.8)	79 (39.7)	100 (50.3)	14 (7.0)	54 (27.1)
Little content (0.5 points)	27 (13.6)	9 (4.5)	13 (6.5)	8 (4.0)	3 (1.5)	12 (6.0)
Some content (1 point)	52 (26.1)	47 (23.6)	66 (33.2)	54 (27.1)	44 (22.1)	115 (57.8)
Most content (1.5 points)	7 (3.5)	14 (7.0)	17 (8.5)	4 (2.0)	3 (1.5)	5 (2.5)
Extensive content (2 points)	0 (0)	14 (7.0)	24 (12.1)	33 (16.6)	135 (67.8)	13 (6.5)

Figure 2. Completeness of video content.



Information Quality

Our results suggest that the general quality of the diabetes information videos on TikTok is acceptable. Overall, the videos published by the nonprofit organizations had the highest DISCERN scores, followed by those published by the health professionals and news agencies. The videos published by the for-profit organizations had the lowest total DISCERN scores, followed by those of the science communicators and general TikTok users. The mean numbers for the whole instrument indicate significant differences across the video sources, at α=.01 (Table 4).

Regarding reliability, videos published by the nonprofit organizations had the highest scores, while those from the for-profit organizations had the lowest scores. Our results suggest that nonprofit organizations, news agencies, and individual health professionals also contributed videos with relatively high reliability. The differences in reliability across the different video sources are significant, at α=.01.

In regard to treatment choices, diabetes-related videos on TikTok were of medium to low quality. Nonprofit organizations and health professionals contributed higher-quality videos on treatment choices than other sources; however, the differences are not significant.

Table 4. DISCERN scores of diabetes-related TikTok videos by source.

Video source	Reliability of the videos (items 1-8)[a], mean (SD)	Quality of treatment choices (items 9-15)[b], mean (SD)	Overall information quality (item 16)[c], mean (SD)	Total DISCERN scores[d], mean (SD)
Health professionals (n=138)	28.10 (3.59)	16.37 (5.00)	3.26 (0.67)	47.74 (7.71)
General users (n=12)	25.38 (3.19)	13.42 (3.63)	2.58 (0.51)	41.38 (6.14)
Science communicators (n=6)	25.00 (3.21)	15.25 (5.29)	3.08 (0.20)	43.33 (8.23)
News agencies (n=31)	28.48 (3.76)	16.02 (5.14)	3.23 (0.71)	47.73 (7.39)
Nonprofit organizations (n=7)	29.14 (2.25)	18.00 (3.40)	3.50 (0.50)	50.64 (4.61)
For-profit organizations (n=5)	24.20 (30.50)	13.20 (5.03)	2.60 (0.55)	40.00 (7.11)

[a]*P*=.005 (1-way analysis of variance).

[b]*P*=.23 (1-way analysis of variance).

[c]*P*=.004 (1-way analysis of variance).

[d]*P*=.009 (1-way analysis of variance).

Discussion

Principal Findings

This study systematically evaluated the information quality of diabetes-related videos on TikTok. According to a recent systematic review [13], the use of social media as a source of information is gaining in popularity among patients with diabetes. The various social media channels provide patients with a convenient means to seek medical knowledge and get social support [31]. While traditional social platforms (eg, Facebook, Twitter, and Instagram) have been widely investigated as channels of diabetes-related health communication [32], the role of emerging, mobile-based apps in disseminating diabetes knowledge is not yet fully understood. Our results reveal that TikTok is a powerful platform for disseminating diabetes-related information. The 199 diabetes videos examined in our study received 2.75 million “likes” and were commented on and shared thousands of times, which indicates that TikTok is a promising channel for health communication.

We identified 2 main categories of video uploaders (ie, individual and organizational users), each containing several more specific types of users. Individual users included health professionals, science communicators, general TikTok users; organizational users comprised news agencies, nonprofit organizations, and for-profit organizations. Health professionals contributed the most videos, while the for-profit organizations contributed the least. Many prior studies have suggested that health professionals and organizations can utilize social media for effective health communication and public health promotion [33,34]. Our study revealed that health professionals in China have been actively engaged in promoting diabetes knowledge via TikTok; however, nonprofit health organizations use this emerging video-based channel less frequently.

In terms of video content, the study found 3 types of imbalances. First, most of the videos were about type 2 diabetes mellitus, while very few videos discussed gestational diabetes mellitus and type 1 diabetes mellitus. Second, most of the videos were about disease management, but few fully addressed other aspects of content, such as the definition and symptoms of the disease, risk factors, evaluation, and outcomes. Third, when many videos are generally reliable, these videos were of average to fair quality concerning treatment choices. Prior studies suggest that patients with diabetes have various health information needs, including a need for information about treatment, course of the disease, abnormalities in glucose metabolism, progression of diabetes through their life cycle, coping techniques, and prevention [35,36]. Moreover, these information needs vary, depending on the type of diabetes mellitus. For example, young people with type 1 diabetes mellitus may be particularly interested in “diabetes through the life circle” [35]. Given the observed imbalances in video content, we suspect that current diabetes-related videos on TikTok cannot fully meet patients’ information needs. Therefore, we call for more pertinent videos to address patients’ comprehensive information needs.

Our study found that the quality of information in the videos differed with the type of source. Videos published by nonprofit organizations had the highest quality, while those from the for-profit organizations had the lowest quality. This finding is consistent with those of prior studies, which suggest that government-sponsored platforms are more likely to publish high-quality information than for-profit organizations [25]. Unfortunately, the videos contributed by the nonprofit organizations account for a mere portion of the total corpus of diabetes-related videos on TikTok. We suggest that government departments and public hospitals contribute more high-quality material and leverage the power of this social media channel to promote public health. Given the large variations in information quality from the different sources, we also suggest that patients exercise caution when using TikTok to obtain diabetes-related information.

Limitations and Future Directions

The findings of this study should be viewed in light of several limitations. First, the study looked only at the quality of diabetes information, not the quality of communication. For example, we observed that the communication modalities varied largely in the TikTok videos. Some videos used rich materials (eg, illustrative images or cases and visual data) to communicate the information, while some were based on plain narratives. Unfortunately, the instruments employed in this paper targeted information quality and overlooked the quality of communication. We call for more empirical studies in the future to investigate the communication quality of diabetes-related videos on TikTok. Second, the videos included in our study were in Chinese; therefore, the findings cannot be applied to diabetes-related videos on TikTok in other languages (eg, English). We encourage future researchers to assess the information quality of diabetes-related videos in other languages to obtain deeper insight into quality issues with diabetes-related videos on TikTok. Third, there are many instruments for assessing the quality of health-related information, such as DISCERN, JAMA benchmarks, and the HONcode principles. This study employed the DISCERN instrument because it has proved effective for assessing the quality of videos on other platforms and apps (eg, YouTube). However, we encourage more studies using a variety of instruments to triangulate the validity of these findings in the future.

Conclusions

This study assessed the information quality of 199 diabetes-related videos on the short video mobile app TikTok. The results show that the videos primarily addressed diabetes management but contained limited information on other types of content, such as the definition and symptoms of the disease, risk factors, evaluation, and outcomes. The overall quality of the diabetes videos was found to be acceptable on average, although it varied significantly, depending on the type of source. We conclude that the health information needs of patients with diabetes might not be fully met by watching TikTok videos, and patients should exercise caution when using TikTok for diabetes-related information.

Acknowledgments

We thank the anonymous reviewers and editors for their helpful comments on the manuscript. The study was supported by the National Science Foundation of China (72074112, 72174083) and the Key Projects of Philosophy and Social Sciences Research of Chinese Ministry of Education (19JZD021).

Abstract

Background: Along with the proliferation of health information technologies (HITs), there is a growing need to understand the potential privacy risks associated with using such tools. Although privacy policies are designed to inform consumers, such policies have consistently been found to be confusing and lack transparency.

Objective: This study aims to present consumer preferences for accessing privacy information; develop and apply a privacy policy risk assessment tool to assess whether existing HITs meet the recommended privacy policy standards; and propose guidelines to assist health professionals and service providers with understanding the privacy risks associated with HITs, so that they can confidently promote their safe use as a part of care.

Methods: In phase 1, participatory design workshops were conducted with young people who were attending a participating *headspace* center, their supportive others, and health professionals and service providers from the centers. The findings were knowledge translated to determine participant preferences for the presentation and availability of privacy information and the functionality required to support its delivery. Phase 2 included the development of the 23-item privacy policy risk assessment tool, which incorporated material from international privacy literature and standards. This tool was then used to assess the privacy policies of 34 apps and e-tools. In phase 3, privacy guidelines, which were derived from learnings from a collaborative consultation process with key stakeholders, were developed to assist health professionals and service providers with understanding the privacy risks associated with incorporating HITs as a part of clinical care.

Results: When considering the use of HITs, the participatory design workshop participants indicated that they wanted privacy information to be easily accessible, transparent, and user-friendly to enable them to clearly understand what personal and health information will be collected and how these data will be shared and stored. The privacy policy review revealed consistently poor readability and transparency, which limited the utility of these documents as a source of information. Therefore, to enable informed consent, the privacy guidelines provided ensure that health professionals and consumers are fully aware of the potential for privacy risks in using HITs to support health and well-being.

Conclusions: A lack of transparency in privacy policies has the potential to undermine consumers' ability to trust that the necessary measures are in place to secure and protect the privacy of their personal and health information, thus precluding their willingness to engage with HITs. The application of the privacy guidelines will improve the confidence of health professionals and service providers in the privacy of consumer data, thus enabling them to recommend HITs to provide or support care.

Introduction

Health Information Technologies

Digital health has quickly become an integral component of best practice health care, transforming the way care is delivered. By capitalizing on digital infrastructure, it is widely recognized that digital health solutions improve access to care, particularly for individuals with mobility or transport restrictions, or for those who live remotely where health care resources may be limited [1,2]. The availability of health information technologies (HITs) is proving invaluable during the COVID-19 pandemic, where face-to-face mental health care is often delivered digitally (eg, videoconferencing) [3]. Beyond access issues, however, digital health also has the potential to optimize or eliminate waitlists and facilitate routine outcome monitoring to strengthen and maintain patient-health professional relationships [4], allowing for shared, data-driven decision-making on appropriate treatment plans [5]. With a greater need for and reliance on digital health solutions for screening, treatment, and ongoing maintenance of health, there is now an increased focus on the privacy and security of personal and health information collected via HITs, such as health-related apps and e-tools (eg, websites and web-based courses).

Legal and Ethics Rights of Individuals

It is crucial to consider the legal and ethical rights of individuals who choose to both explicitly and passively share their web-based health information. This is essential, particularly in the area of mental health care, where data often contain highly personal information that could cause significant harm and distress if not handled appropriately. There is increasing documentation and guidance in this area, such as the recent release of the National Safety and Quality Digital Mental Health Standards (consultative draft) by the Australian Commission on Safety and Quality in Health Care [6], which includes educational brochures that provide tips to consumers, caregivers [7], and clinicians [8] on choosing a digital mental health service. Specific to privacy, the Australian Privacy Principles require that all organizations have a clearly expressed and current privacy policy detailing how personal information is managed [9]. As personal and health information is deemed particularly sensitive, extra protection concerning its handling was established under the Privacy Act 1988 [10]. The World Economic Forum also has highlighted *trust* as one of the primary issues that needs to be addressed on a global scale to ensure consumers' and health professionals' trust in the privacy and security standards of new digital tools and technology-based therapies [11].

Privacy Practices of HITs

The use of health-related apps has rapidly increased in recent years, with 47% of Australian consumers using apps in 2018 [12]. Health professionals are also increasingly recommending HITs as part of clinical practice. For example, approximately half of Australian general practitioners responding to an annual technology survey indicated that they recommend HITs for at least monthly use by patients, with mindfulness and mental health apps recommended most often [13]. Although HITs, including apps and e-tools, have gained considerable favor with consumers and health professionals for promoting self-management of health and well-being, the privacy of personal and health information remains a notable area of concern. A systematic review of 79 health and wellness apps certified as clinically safe and trustworthy by the United Kingdom National Health Service Health Apps Library found that 66% of apps transmitting personal information on the internet did so without encryption, and 20% did not have any form of privacy policy [14]. Furthermore, although no app collected or shared information in a manner that was not explicitly stated in the privacy policy, the nature of the personal information included in such transmission was not described in 78% of policies [14]. A recent cross-sectional assessment of 36 top-ranked apps found that 92% of them transmitted data to a third party; however, only 64% of privacy policies made this explicit. In addition, only 43% and 50% of privacy policies disclosed that apps were transmitting data to Google and Facebook, respectively [15]. This begs the question, can users trust that personal and health information collected via HITs will be kept private and secure?

Objectives

This study aims to use co-design methodologies to better understand young people's preferences for learning about how their personal and health information will be handled by HITs and create prototypes for the InnoWell Platform. The InnoWell Platform was developed by InnoWell, a joint venture between the University of Sydney and PricewaterhouseCoopers (PwC; Australia) through Project Synergy, an Aus $30 million (US $22.1 million) Australian government–funded initiative [16]. As described previously [5,17], the InnoWell Platform is a co-designed digital tool embedded within traditional in-clinic and web-based mental health services to support person-centered, measurement-based care. This study also seeks to develop and apply a privacy policy risk assessment tool to assess whether existing HITs meet the recommended privacy policy standards and present guidelines to assist health professionals and service providers to ask the appropriate questions for themselves and HIT manufacturers to ensure that they can confidently promote the safe use of HITs as part of care.

Methods

Phase 1

Participatory Design Workshops

Participatory design (ie, co-design) methodologies are routinely used to ensure that digital tools are designed to meet the needs of the intended user base, thus increasing uptake and engagement [18,19]. Our research team has extensive experience in the use of participatory design, including workshop design and facilitation as well as knowledge translation [19-23].

Our research team conducted a series of 10 participatory design workshops from July to September 2018 in 9 urban and rural *headspace* centers across Australia (Ashfield, Bathurst, Broken Hill, Dubbo, Orange, Wagga Wagga, and Wollongong, New South Wales [NSW]; Townsville, Queensland; Edinburgh North, South Australia). *headspace* centers are primary mental health

services providing support to young Australians and their families to promote mental health and engagement with the community. The methods and results of these workshops were previously reported in detail by Cheng et al [24]. In summary, the workshops brought together key stakeholders from the participating *headspace* communities, including help-seeking young people, supportive others, health professionals, and service providers, to collaboratively discuss technology designs, ideas, and principles to support mental health and well-being. In these workshops, technology designs, ideas, and principles, including the concepts of data privacy and security, were evaluated by the participants. Due to varying numbers of participants and other contextual factors, workshops ranged from 2.5 to 4 hours in duration and consisted of the following stages: discovery, evaluation, and prototype. The discovery stage focused on current ways in which technology is used by participants, including for the purposes of supporting mental health, internet access issues in regional communities, and concerns about sharing personal and health information via web-based programs or tools. During the evaluation stage, participants were presented with images of components of the InnoWell Platform and asked to document their feedback. Finally, in the prototype stage, participants were given the opportunity to brainstorm new items, functionalities, and wireframes using sketchbooks for the components or functionalities of the InnoWell Platform. In this paper, we present findings related to the development and inclusion of privacy information in HITs as co-designed by the participants. Importantly, these results were not included in the original publication [24].

Participants

Participants included individuals from the participating *headspace* communities, including young people attending a participating *headspace* center, a supportive other of a young person attending a participating *headspace* center (eg, family member, caregiver, or friend), or a health professional or service provider working at a participating *headspace* center. The inclusion criteria for participation in the study required participants to be aged ≥12 years, proficient in reading and speaking English, and having completed the participant consent process. Details of recruitment, screening, and informed consent processes have been previously documented by Cheng et al [24].

Knowledge Translation

The InnoWell Platform consists of a multidimensional assessment evaluating a range of biopsychosocial domains (eg, psychological distress, sleep, alcohol use, and physical health) to provide a holistic view of the consumer. The assessment results are available in real time and designed to be reviewed collaboratively by the consumer and their health professional to promote shared decision-making about care options, accounting for consumer preferences. A consumer's progress can then be routinely tracked and monitored over time using assessment tools to inform treatment planning, clinical review, and coordinated care within and between services.

As previously described [24], workshop notes and descriptive artifacts were reviewed by an independent knowledge translation team with 2 young researchers without previous knowledge of the InnoWell Platform or the fundamental principles underpinning its design. Each team member, taking note of their general observations, reviewed all data independently and subsequently identified the key concepts noted by workshop participants to then produce prototype designs of the components of the InnoWell Platform.

Ethics

This study was approved by the University of Sydney's Human Research Ethics Committee (protocol number: 2018/130).

Phase 2

Development of the Privacy Policy Risk Assessment Tool

Drawing from digital health privacy and security criteria published by existing research and professional associations, our research team developed a privacy policy risk assessment tool (Multimedia Appendix 1) to evaluate privacy policies for HITs, including apps and e-tools. Developed in 2018 by a multidisciplinary expert panel of health professionals, informaticists, medical students, and consumers with lived experience of mental illness, the American Psychiatric Association app evaluation model includes risk, privacy and safety questions as part of their simple four-stage hierarchal app review process [25]. Although the American Psychiatric Association model served as the primary reference, to ensure an all-encompassing assessment tool, we also incorporated details from the National and Safety Quality Digital Mental Health Standards developed by the Australian Commission on Safety and Quality in Health Care to improve the quality of digital mental health care and protect the privacy of service users [6]. The final privacy policy risk assessment tool consists of 23 items covering (1) privacy policy (6 items), (2) personal health information (PHI; 4 items), (3) data security and storage (9 items), and (4) other aspects of privacy (4 items). As the questions and concepts included in the privacy policy risk assessment tool were drawn from previously published privacy and security standards, we were confident that the measure has face and construct validity; however, a specific validity analysis was not conducted.

Review of Digital Health Tool Privacy Policies

Importantly, the privacy policy risk assessment tool is broadly applicable to HITs. To demonstrate its utility, in this study, we evaluated the privacy policies of the apps and e-tools in the *youth* configuration of the InnoWell Platform [16]. Within the InnoWell Platform, there are two types of care options: clinical and nonclinical. Clinical care options require health professionals' involvement, such as individual therapy and group therapy, whereas a consumer can immediately access and begin using nonclinical care options, such as apps and e-tools, without the support of a health professional [26]. During the co-design process, care options are tailored to the consumer population; in this case, young people receiving care through primary youth mental health services (eg, *headspace* centers).

Aligned with established evaluation processes [15], privacy policies and any related material that may contain privacy-related content, such as terms and conditions, were

sourced from associated websites and app store links. A nonrestrictive process was used, allowing all hyperlinks from the app store or within the privacy policy to be considered. All available information was collated and reviewed in accordance with the privacy policy risk assessment tool developed primarily by a member of the research team (AER), with support from a research intern (Toby Wong).

Assessing Readability

The readability levels of each privacy policy were assessed as part of the evaluation process. There are multiple readability formulas available; however, for the purpose of this study, we used the Flesh-Kincaid readability tests because of their acceptance in the health care literature [27]. The readability tests were designed to indicate how difficult an English passage of writing is to understand using a formula calculated from the average number of syllables per word and the average number of words per sentence [28]. Both the Flesch reading ease and the Flesch-Kincaid reading grade level were calculated using the web-based readability tools [29]. The scores indicate the readability of a passage of text on a scale from “very easy to read" to "very difficult to read” and “fifth grade reading level” to “professional reading level,” respectively. Scores were calculated using the first two paragraphs of the privacy policies. The paragraphs (at least 100 words) were copied into a readability formula calculator, and a score was given.

Data Analysis

Descriptive statistics were used to analyze all aspects of the assessment data. SPSS version 25 (IBM Corp) was used for all analyses.

Phase 3

Development of Privacy Guidelines: Consultations

As a result of Project Synergy and the development of the InnoWell Platform, a set of core principles and privacy guidelines were used as the starting point to formalize a more encompassing set of privacy guidelines. A series of consultations were held between 2014 and 2016 (phase 1) and then again between 2017 and 2018 (phase 2) to develop a set of privacy guidelines for Project Synergy. Initial consultations were conducted by Orygen (the National Centre of Excellence in Youth Mental Health) [30]. The subsequent consultations were conducted by the Project Synergy research and development team (led by the authors TAD and IBH). These consultations were held at the University of Sydney’s Brain and Mind Centre, either in-person or via teleconference, and brought together key stakeholders across relevant organizations.

Participants

Participants included key stakeholder groups, including Orygen (the National Centre of Excellence in Youth Mental Health), the Young and Well Cooperative Research Centre, Mental Health Commission of NSW (Pacific Privacy Consulting Pty Ltd), the Project Synergy research and development team (the University of Sydney’s Brain and Mind Centre), InnoWell, and PwC (Australia). Select individuals were nominated by each organization, with participants contributing diverse expertise and experience, such as the involvement of 2 ex-serving privacy commissioners for NSW and Victoria (Australia).

Preliminary Development of Privacy Guidelines for Phase 1 Project Synergy (2014-2016)

From the outset of the development cycle of the prototype and as part of phase 1 of Project Synergy (2014-2016) [16], this ongoing series of consultations were envisaged to inform the development of the privacy guidelines. Therefore, an initial set of guidelines was developed; these guidelines were produced by Orygen and supported by the Young and Well Cooperative Research Centre and the Mental Health Commission of NSW [30]. They were also reviewed by the Project Synergy research and development team at the University of Sydney’s Brain and Mind Centre (the authors) and Pacific Privacy Consulting.

Ongoing Development of Privacy Guidelines for Phase 2 of Project Synergy (2017-2020)

As a result of the review of the initial guidelines developed in phase 1 of Project Synergy, a narrower focus was decided upon and used as the starting point for the development of more encompassing privacy guidelines for phase 2 of Project Synergy (2017-20). Specifically, upon review of the initial guidelines whereby the University of Sydney and Pacific Privacy Consulting determined that privacy concerns were the most important priority, a narrower focus was given to 8 core foundation principles to be followed by organizations using the prototype in phase 1 of Project Synergy (2014-2016) [16]. The core foundation principles included responsibility for legal compliance, anonymous or pseudonymous services wherever practicable, individual control, transparency, interaction with individuals, encryption, deidentification, and cross-border processing risk. Development of the broad structure and content of the guidelines was guided by the Project Synergy research and development team, with review and input by Pacific Privacy Consulting and InnoWell.

This paper presents privacy guidelines to assist health service providers in considering the privacy of their consumers when using HITs as part of care. The guidelines were first drafted by the Project Synergy research and development team based on the information gathered through the initial collaborative consultation process. The checklist was then reviewed, discussed, and evaluated by the research team, ultimately resulting in agreement by consensus.

Results

Knowledge Translation Findings

The results of the knowledge translation process highlighted that participants wanted privacy information to be presented before being required to create an account. Specifically, they emphasized the need for privacy information to be readily available, allowing a user to be completely comfortable when entering more sensitive information into a HIT, such as the InnoWell Platform (eg, “Always ask could this site be more secure with my information” [Wollongong workshop]). This included the ability to change permissions concerning data sharing at their discretion (eg, “[I] would want privacy settings

in place so that not everyone that shares the system can see" [Broken Hill workshop]). Participants noted that privacy information is frequently confusing and difficult to understand, leaving them unsure whether they should trust the HIT to protect their personal and health information. Thus, multiple participants suggested a pin code or password (eg, "Consider password security like in bank apps." [Townsville workshop]) to access certain data so the consumer controls who has access to their information in the InnoWell Platform. Importantly, the idea of consumer control extended beyond HIT manufacturers such as InnoWell and included health professionals and supportive others (ie, family members and carers) accessing personal and health information (eg, "Need privacy setting like Facebook...can filter who can see the information" [Bathurst workshop]).

App and e-Tool Privacy Policy Assessment

We evaluated 34 privacy policies using the privacy policy risk assessment tool. Most of these apps and e-tools were designed for both youth and adult users (28/34, 82%), whereas the remaining 18% (6/34) were specifically designed for youth audiences (aged ≤25 years). Most apps and e-tools (20/34, 59%) were self-help or self-management tools supporting mental health and well-being, including three specifically using cognitive behavioral therapy techniques. There were also 12% (4/34) symptom trackers, 6% (2/34) web-based counseling services, 6% (2/34) planning and time management tools, 6% (2/34) psychoeducational websites, and 2% (1/34) mindfulness and meditation app. The remaining apps and e-tools supported fitness (2/34, 6%) and relationships (1/34, 2%).

Summary of Privacy Policy Information

Overview

The summary results from the review of privacy policies are presented in Table 1. All apps and e-tools had privacy policies. Some of the policies were not readily accessible directly from the app or e-tool but rather were hosted on an external website that the app or e-tool privacy policy fell under (ie, a privacy policy for a hospital or government department). Importantly, most of the policies (26/34, 76%) explicitly stated that they met the standards of the Privacy Act 1988 (Australia) or international equivalent (ie, Health Insurance Portability and Accountability Act). In addition, most manufacturers (31/34, 91%) introduced the purpose of the privacy policy, stating that the policy explained the manufacturers' approach to privacy, protection, and management of personal information. Similarly, 97% (33/34) of privacy policies were noted to provide adequate information for all potential users. In contrast, manufacturers (26/34, 76%) frequently did not provide adequate information about their organization and how or why they operated.

Table 1. Summary results of the privacy policy assessment results (N=34).

Privacy policy questions and responses	Value, n (%)
Is there a privacy policy?	
No	0 (0)
Yes	34 (100)
Does the app or e-tool claim to meet the standards of the Privacy Act 1988 (Australia), HIPAA[a] (United States), or another international equivalent?	
No	8 (24)
Yes	26 (76)
Did the manufacturer introduce the purpose of the privacy policy?	
No	3 (9)
Yes	31 (91)
Does the privacy policy provide an introduction to the organization, including its vision and purpose?	
No	26 (76)
Some information	3 (9)
Yes	5 (15)
Does the privacy policy provide adequate information (both targeted and general) relevant for all users, including consumers seeking care and health professionals?	
No	0 (0)
Some information	1 (3)
Yes	33 (97)

[a]HIPAA: Health Insurance Portability and Accountability Act.

Readability of Privacy Policies

In relation to the Flesch reading ease, the privacy policies were all found to fall into the top three of the seven available score categories, with 9% (3/34) rated as *fairly difficult to read*, an additional 53% (18/34) rated as *difficult to read*, and the remaining 38% (13/34) rated as *very difficult to read*. The

Flesh-Kincaid grade-level test illustrated similar results with only the top two levels represented out of eight possible levels. All but three policies fell into the *college graduate* grade level (31/34, 91%), with the remaining considered *professional-level* reading difficulty (3/34, 9%).

Collection of PHI

Table 2 presents results from the PHI assessment. Most apps and e-tools (32/34, 94%) collected some form of PHI, ranging from simple demographic information to more sensitive information such as information related to mental health. The remaining 6% (2/34) of apps and e-tools were considered informational tools and collected data such as email addresses. Of the 32 apps and e-tools that collected PHI, most (28/32, 87%) shared this information in some manner (data sharing is reviewed in greater detail below). This use was disclosed in most privacy policies (27/32, 85%), explicitly stating that reasonable steps were taken to ensure the security of the PHI; however, for 6% (2/32) and 9% (3/32) of privacy policies how PHI was shared was *somewhat clear* or *not clear*, respectively. Although more than half of the privacy policies (17/32, 53%) clearly stated how and when PHI was deleted, this information was either *somewhat clear* or *not clear* in the remaining 3% (1/32) or 44% (14/32) privacy policies, respectively.

Table 2. PHI[a] assessment results (N=34).

PHI questions and responses	Value, n (%)
Does the app or e-tool collect PHI (ie, demographic information, medical histories, test and laboratory results, mental health conditions, or insurance information)?	
No	2 (6)
Yes	32 (94)
Is PHI (ie, demographic information, medical histories, test and laboratory results, mental health conditions, or insurance information) shared?	
No	4 (13)
Yes	28 (87)

[a]PHI: personal health information.

Data Sharing and Use of Information

Results of the assessment questions related to data sharing, data preferences, and data storage are presented in Table 3. Most privacy policies (32/34, 94%) declared how data were used and for what purposes, with approximately two-thirds (22/34, 65%) stating that users were allowed to delete data. Notably, only 3% (1/34) of apps allowed data sharing preferences to be changed, although this required the user to contact the manufacturer via email; 9% (3/34) of apps and e-tools enabled users with some permissions specific to data sharing, such as receiving push notifications or allowing the user to choose whether to share data such as location with the mobile app.

Table 3. Data sharing and data use assessment results (N=34).

Data sharing and data use questions and responses	Value, n (%)
Does the privacy policy declare data use and purpose?	
No	2 (6)
Yes	32 (94)
Is shared data deidentified? (ie, is data anonymous—is personal information masked or severed from the identity of the contributor)	
No	11 (33)
Yes	23 (67)
Can the user change their preferences regarding data sharing (ie, switch it on or off)?	
No	30 (88)
Yes	1 (3)
Some permissions	3 (9)
Can the user delete their data from the app or e-tool?	
No	10 (29)
Yes	22 (65)
Informational webpage only	2 (6)
Is user data stored on the device?	
No	27 (79)
Yes	4 (12)
Unspecified	3 (9)
Is user data stored on a server?	
Yes	32 (94)
Unspecified	2 (6)
For how long is user data stored?	
Unspecified or unclear	12 (35)
Until no longer needed	12 (35)
1 year or less	2 (6)
1-3 years	3 (9)
More than 3 years	3 (9)
At user discretion	2 (6)
What type of server is used to store user data? (eg, Amazon Web Services, within Australian borders)	
Secure Australian server	6 (19)
Secure overseas server	11 (34)
Unspecified server	7 (22)
University server	2 (6)
Hospital or PHN[a]	2 (6)
Unclear	4 (13)
In what country is the server located ?	
Australia	13 (38)
United States	9 (26)
Canada	3 (9)
Europe	1 (3)
Multiple countries	2 (6)
Unclear or unspecified	6 (18)

[a]PHN: Primary Health Network.

Most apps and e-tools (32/34, 94%) stored data on a server, with a small number (4/34, 12%) storing data on both the device (ie, PHI) and a server (ie, email address and website activity). In addition, 6% (2/34) of apps and e-tools did not specify where the data were stored. Data storage duration ranged from up to 1 year (2/34, 6%), 1 to 3 years (3/34, 9%), and more than 3 years (3/34, 9%). Although more than one-third of the apps and e-tools were unclear or did not specify for how long data were stored (12/34, 35%), approximately one-third (12/34, 35%) stored the data until no longer needed by the organization. The remaining 6% (2/34) of privacy policies stated that the data would be deleted at the user's discretion.

Of the 32 apps and e-tools that stored data on a server, 11 (34%) stored data on a secure overseas server, 6 (19%) stored data on a secure Australian server, 7 (22%) stored data on an unnamed or unspecified server. In addition, 6% (2/32) of apps and e-tools stored data on a university server, 6% (2/32) stored data on a hospital or primary health network server system, and 13% (4/32) were unclear on the type of server used. The location of data storage was mixed between Australia (13/34, 38%), the United States (9/34, 26%), Canada (3/34, 9%), Europe (1/34, 3%), and multiple locations (2/34, 6%), with the remainder unclear as to where data were stored (6/34, 18%).

Review of How Data Are Shared

Most apps and e-tools (27/34, 79%) shared data with relevant third parties, including but not limited to partners, suppliers, collaborators, advisers, and business associates. The types of data shared varied from PHI to aggregated user data, such as location. A small number of apps and e-tools (4/34, 12%) shared information with irrelevant third parties, including social media platforms such as Facebook. In addition, 38% (13/34) of apps and e-tools shared data with a research partner or university, 15% (5/34) shared information with government departments, and 38% (13/34) shared data with a health-related group or person (eg, a support person or health professional).

Additional Information

All privacy policies were assessed for their inclusion of various other details, which are summarized in Table 4. More than half of the apps and e-tools (20/34, 59%) used third-party vendors, such as Google Analytics, to evaluate and track consumer use of websites, collect demographic data, and evaluate other information related to the apps or e-tool website and the user's device. Less than one-quarter of privacy policies (8/34, 24%) adequately explained how the manufacturer would respond to a data breach, although most policies (31/34, 91%) provided some details as to how to provide feedback or lodge a complaint either with the manufacturer or through an expert third party (ie, Office of the Australian Information Commissioner). Finally, only 24% (8/34) of privacy policies explicitly warned individuals about privacy risks involved in accessing services that are outside the control of the service provider, such as third-party advertisements, with an additional 9% (3/34) of policies providing some detail in this regard.

Table 4. Overview of additional details provided by privacy policies (N=34).

Additional questions and responses	Value, n (%)
Does the app or e-tool use third-party vendors (eg, Google Analytics)?	
No	11 (32)
Yes	20 (59)
Unspecified	3 (9)
Is the manner in which the organization will respond to a data breach adequately explained?	
No	26 (76)
Yes	8 (24)
Does the privacy policy inform users how they can make inquiries and provide feedback and lodge complaints, including both contact details for the relevant party within the organization and a third-party expert (eg, Office of the Australian Information Commissioner)?	
No—does not provide either	3 (9)
Some—provides information for internal or third party only	16 (47)
Yes—provides both internal and third-party expert	15 (44)
Does the privacy policy explicitly warn users about privacy risks involved in accessing services offered that are outside the control of the organization ?	
No	23 (67)
Somewhat	3 (9)
Yes	8 (24)

Privacy Considerations for Health Services

As generated through the collaborative consultation process described previously, Textbox 1 presents privacy guidelines to assist health professionals and service providers to ask the appropriate questions—of themselves and to HIT manufacturers—before confidently promoting the safe use of HITs as part of mental health care.

Textbox 1. Privacy guidelines—health professional and service provider considerations regarding the use of health information technologies (HITs) for care.

Privacy guidelines

- The HIT manufacturer has clearly introduced the purpose of its privacy policy.
- The privacy policy includes an introduction to the HIT manufacturer and how and why their organization operates.
- The privacy policy provides adequate information and addresses my concerns.
  - If no, I am aware who I need to contact to seek clarification...
- The privacy policy is written clearly.
  - If no, I am aware who I need to contact to seek clarification...
- The privacy policy adequately explains how the HIT manufacturer will collect and use personal data.
- The privacy policy adequately explains how and when the HIT manufacturer will disclose personal data to third parties.
  - If the HIT manufacturer shares data with third parties, I am confident that the third-party partners are reputable and will comply with all legislative requirements when collecting, storing, and sharing data.
  - If no, I am aware who I need to contact to seek clarification...
- I am confident the HIT manufacturer has taken the appropriate steps to protect everyone's data, adopting the strongest security measures.
- I have been made aware of how end users can access and correct their personal information on the HIT.
  - If no, I am aware who I need to contact to seek clarification...
- The privacy policy outlines how and when the HIT manufacturer will delete personal data.
- The privacy policy outlines how the HIT manufacturer will respond to any data breaches.
- The privacy policy includes information on how I can inquire, provide feedback, or make complaints.
- There is the opportunity for me to contact a third-party expert to inquire about the privacy policy (such as the Office of the Australian Information Commissioner).
  - If yes, they are...
- From what I read, I feel comfortable using the proposed HIT as part of my clinical care and/or practice.

Discussion

Listening to Consumers

With their increased experience and exposure, consumers are becoming more sophisticated users of HITs. They can offer valuable insights into how privacy information should be presented to ensure that it is clear, informative, and transparent. Participants of our co-design workshops highlighted the need for all HITs to have a privacy policy that provides relevant data security information before collecting information from an individual, preceding the account creation process. In addition, participants stated that privacy policies should be accessible, transparent, and user-friendly, ensuring that consumers understand what personal and health data will be collected, stored, and shared and, in turn, enabling them to trust the HIT to protect their data. These findings align with those reported by Schueller et al [31], which indicated that 70% of mental health app users rate the inclusion of a privacy policy and data encryption as important. Of note, when a mental health app was deemed to be from a *trusted source* (no shared definition of what constituted a trusted source), users assumed that the app adequately protected their data [31], potentially leaving their data vulnerable to unrecognized data sharing pathways.

Privacy Policy Risk Assessment

As evidenced by our co-design results, consumers are calling for greater clarity and transparency in the privacy policies of HITs so that they can be confident that they understand how their personal and health information may be used. Importantly, all apps and e-tools included in this study had a privacy policy. All but 1 of those policies provided explicit details explaining the manufacturer's approach to privacy and how personal information is managed and protected. However, approximately one-quarter of the privacy policies did not meet the standards of the Australian Privacy Act 1988 or other international equivalents, raising concerns regarding undisclosed data sharing and poorly secured data storage. Even when the use of data adheres to privacy standards, issues of transparency often arise. For example, a recent review of the data sharing practices of 24 health-related apps found that data were shared with 55 unique entities, including app developers, their parent companies, and third parties (ie, service providers). Subsequently, third parties shared user data with an additional 216 integrated fourth parties (eg, Facebook sharing data with data brokers to enable targeted advertising) [32].

In addition to poor overall transparency, our results also confirm that privacy policies, when present, are fairly difficult to read

and require a college or professional reading level, essentially rendering them useless for a large portion of potential users (eg, children and young people or individuals with cognitive impairments or intellectual disabilities). This aligns with previous research by Robillard et al [33], which highlighted that the readability of privacy policies of mental health apps is typically written at too high a level for the general population. Strikingly, a longitudinal review of privacy policies found both a decline in readability and a marked increase in length [34]. To improve the readability of privacy policies, it is suggested that HIT manufacturers either compare different versions of their policy to determine which one has the best readability score or that the policy be rewritten until it meets a predetermined grade level. Researchers have suggested that a grade 9-10 reading level is likely to be appropriate for the general population [35].

Most apps and e-tools included in this study collected some form of PHI (32/34, 94%), including, in some cases, information related to mental health, with 87% (28/34) of those apps and e-tools then sharing these data in some manner. Although data sharing was disclosed in most privacy policies (27/32, 84%), how PHI was shared was not transparent in 15% (5/32) of the policies. Most apps and e-tools shared data with relevant third parties (27/34, 79%); however, 12% (4/34) also shared information with third parties deemed to be irrelevant, such as social media platforms (ie, Facebook). Of note, few apps and e-tools (4/31, 13%) allowed users to update their permissions concerning data sharing.

Although it is unlawful in Australia, for example, to share PHI for purposes other than those stated in a privacy policy, the complexities of the web-based environment frequently preclude a full understanding of how data are shared and for what purpose [36]. Users must recognize that shared data enters into a *supply chain*, being passed from apps and e-tools to parent companies and then on to third parties such as data trackers, aggregators, and brokers [37]. Subsequently, data may be sold to researchers and government agencies for advertising purposes. In addition to driving targeted advertising campaigns, this aggregated data may also be used to influence employment and financial and insurance decisions, with potentially marked consequences at the individual level [37], potentially leading to incarceration or human rights abuses in some countries [11]. Given the risks described above, explicit and transparent documentation of how data are shared is critical to ensure that users are able to provide informed consent. Furthermore, it is critical that governance structures and regulatory standards are established globally to ensure ethical practice in digital mental health care, including the handling of PHI. As advised by the World Economic Forum, regulations should not be designed exclusively by governments but rather in collaboration with consumers with lived experience, mental health professionals, technology manufacturers, and policy makers, with the aim of facilitating efficient access to effective and safe digital tools to address growing mental health needs [11].

Most apps and e-tools in our sample stored data on a server (32/34, 94%), with more than half (21/32, 66%) storing data on an unnamed or unspecified server. Although other server types included university servers (2/32, 6%) and a hospital or primary health network server system (2/32, 6%), the type of server used to store data for an additional 22% (7/32) of apps and e-tools was unclear. Once data are transmitted to a third-party server, it is often difficult to determine the robustness of the privacy and confidentiality standards in place to protect the PHI. For example, Cultura Colectiva, a digital media company with access to user information from Facebook, stored data on a publicly accessible server, resulting in the exposure of 540 million individual records, including user IDs and names [38]. In addition, although it is ideal that all information being transmitted is encrypted, personal and health information may still be visible in server logs with few restrictions in terms of access [39]. Notably, when different apps and e-tools use the same server, it may be possible to link different PHIs together to create digital profiles of users [40] with potentially negative repercussions such as impacts on employment and insurance. Despite the frequency of data breaches [41], 76% (26/34) of the privacy policies reviewed in this study failed to document how the organization would respond to data breaches, leaving the user to wonder what steps might be taken to protect their data from exposure and misuse (ie, identify theft).

Privacy Guidelines for Health Professionals and Service Providers

Given the concerns regarding accessibility, transparency, and readability outlined above, through a consultative process with key stakeholders, our team developed privacy guidelines (Textbox 1) to prompt health professionals and service providers to ask informed questions when reviewing an HIT privacy policy to ensure adequate data privacy and security measures are in place. The guidelines aim to support health professionals and service providers to confidently promote the safe use of HITs as part of care and within the broader service. The privacy guidelines have considered the privacy policy of HIT manufacturers to emphasize the importance of building trust between users and HIT manufacturers through transparency [42]. Thus, it is the responsibility of the HIT manufacturer to be aware of all (both current and emerging) regulatory requirements and best practice principles [42] to ensure that the privacy policy is communicated to all users. This not only minimizes potential harm but also allows users to be well informed and to have more control when consenting to use HITs.

As few consumers will review academic literature before accessing HITs, they are more likely to learn about available apps and e-tools via the internet, app stores, social media, word of mouth, or health professionals. In relation to the latter, it is recommended that health professionals and service providers conduct their own risk assessment before implementing HITs into their service to ensure appropriate risk strategies are in place [3]. Not only should providers have an understanding of privacy risks but it is also important that they work with consumers to ensure they are aware of the potential for privacy breaches to ensure they are providing informed consent before engaging with an HIT [37].

Limitations

This study has some limitations that are important to note. Although we engaged in a thorough collaborative consultation

process to develop the broad structure and content of the privacy guidelines for Project Synergy, the development of the privacy policy risk assessment tool and the guidelines for health professionals and service providers was conducted by the research team, independent of this broader stakeholder group. Therefore, we acknowledge that both the assessment tool and the guidelines may benefit from further input or revision by individuals with expertise in data privacy and security, both from a legal perspective and regarding manufacturers of digital tools. As highlighted by the co-design work presented in phase 1, our group recognizes the importance of including the voice of those with lived experience in our work to reform mental health services and systems of care, including the ethical development and application of digital tools. With that being said, we acknowledge that the privacy policy risk assessment tool and guidelines were developed without contributions from consumers with lived experience of mental ill health.

Conclusions

Given the increasing uptake of HITs, both by individuals for the purposes of self-management and by health professionals as a means to complement clinical services, it is essential that all users have a clear understanding of what personal and health information will be collected, how these data will be shared and stored, and what privacy and security measures are in place to ensure it is protected. Our findings highlight the ubiquitous poor readability and lack of transparency in existing privacy policies, a stark contrast to what consumers emphasized as essential factors in the presentation of privacy information. Although consumers, health professionals, and services are becoming increasingly reliant on HITs to deliver, support, or enhance care, concerns regarding the privacy of health and personal information are likely to undermine user confidence and willingness to engage with HITs. Therefore, we provide suggested guidelines that can be easily adopted by health professionals and service providers when considering the implementation of HITs, including apps and e-tools, into their service. We recommend that these guidelines be adopted to ensure that HITs are used to their full potential to maximize patient health outcomes while minimizing risk and that users are informed of privacy and security considerations to make educated decisions as to whether they would like to share their personal and health information.

Acknowledgments

The authors IBH and TAD were integral in securing funding to support this study. This study was designed by HML, AER, TAD, and GL. All data analyses were conducted by HML and AER. All authors have contributed to and approved the final manuscript. This research was conducted on behalf of the Australian Government Department of Health as part of Project Synergy (2017-20). InnoWell was formed by the University of Sydney and PricewaterhouseCoopers (Australia) to deliver the Aus $30 million (US $22.1 million) Australian government-funded Project Synergy. The authors would also like to acknowledge Future Generation Global for funding the Youth Mental Health & Technology Program, which aims to improve young people's access to quality mental health care, including through the use of co-design methodologies. The authors would like to acknowledge and thank Hannah Yee for her contributions to the knowledge translation and Toby Wong for his assistance with data collection. The authors would also like to thank the participants in the co-design workshops for their insights on how to best present privacy information to users.

Conflicts of Interest

IBH is the codirector of health and policy at the Brain and Mind Centre, University of Sydney. The Brain and Mind Centre operates an early-intervention youth service at Camperdown under contract to headspace. He is the chief scientific advisor to and a 5%-equity shareholder in InnoWell Pty Ltd. InnoWell was formed by the University of Sydney (45% equity) and PricewaterhouseCoopers (Australia; 45% equity) to deliver the Aus $30 million (US $22.1 million) Australian government-funded Project Synergy (2017-2020; a 3-year program for the transformation of mental health services) and to lead the transformation of mental health services internationally through the use of innovative technologies. TAD is now the director of research and evaluation at the Design and Strategy Division of the Australian Digital Health Agency. The funding source does not entail any potential conflicts of interest for the other members of the Project Synergy research and development team.

Abstract

Background: The use of the internet and web-based platforms to obtain public health information and manage health-related issues has become widespread in this digital age. The practice is so pervasive that the first reaction to obtaining health information is to “Google it.” As SARS-CoV-2 broke out in Wuhan, China, in December 2019 and quickly spread worldwide, people flocked to the internet to learn about the novel coronavirus and the disease, COVID-19. Lagging responses by governments and public health agencies to prioritize the dissemination of information about the coronavirus outbreak through the internet and the World Wide Web and to build trust gave room for others to quickly populate social media, online blogs, news outlets, and websites with misinformation and conspiracy theories about the COVID-19 pandemic, resulting in people’s deviant behaviors toward public health safety measures.

Objective: The goals of this study were to determine what people learned about the COVID-19 pandemic through web searches, examine any association between what people learned about COVID-19 and behavior toward public health guidelines, and analyze the impact of misinformation and conspiracy theories about the COVID-19 pandemic on people’s behavior toward public health measures.

Methods: This infodemiology study used Google Trends’ worldwide search index, covering the first 6 months after the SARS-CoV-2 outbreak (January 1 to June 30, 2020) when the public scrambled for information about the pandemic. Data analysis employed statistical trends, correlation and regression, principal component analysis (PCA), and predictive models.

Results: The PCA identified two latent variables comprising past coronavirus epidemics (pastCoVepidemics: keywords that address previous epidemics) and the ongoing COVID-19 pandemic (presCoVpandemic: keywords that explain the ongoing pandemic). Both principal components were used significantly to learn about SARS-CoV-2 and COVID-19 and explained 88.78% of the variability. Three principal components fuelled misinformation about COVID-19: misinformation (keywords “biological weapon,” “virus hoax,” “common cold,” “COVID-19 hoax,” and “China virus”), conspiracy theory 1 (ConspTheory1; keyword “5G” or “@5G”), and conspiracy theory 2 (ConspTheory2; keyword “ingest bleach”). These principal components explained 84.85% of the variability. The principal components represent two measurements of public health safety guidelines—public health measures 1 (PubHealthMes1; keywords “social distancing,” “wash hands,” “isolation,” and “quarantine”) and public health measures 2 (PubHealthMes2; keyword “wear mask”)—which explained 84.7% of the variability. Based on the PCA results and

the log-linear and predictive models, ConspTheory1 (keyword "@5G") was identified as a predictor of people's behavior toward public health measures (PubHealthMes2). Although correlations of misinformation (keywords "COVID-19," "hoax," "virus hoax," "common cold," and more) and ConspTheory2 (keyword "ingest bleach") with PubHealthMes1 (keywords "social distancing," "hand wash," "isolation," and more) were r=0.83 and r=–0.11, respectively, neither was statistically significant (P=.27 and P=.13, respectively).

Conclusions: Several studies focused on the impacts of social media and related platforms on the spreading of misinformation and conspiracy theories. This study provides the first empirical evidence to the mainly anecdotal discourse on the use of web searches to learn about SARS-CoV-2 and COVID-19.

KEYWORDS

internet; novel coronavirus; SARS-CoV-2; COVID-19; infodemiology; misinformation; conspiracy theories; public health

Introduction

Overview

A novel coronavirus initially named 2019-nCoV emerged in Wuhan, China, and was formally reported to the World Health Organization (WHO) on December 31, 2019 [1-3]. Further scientific evidence soon unveiled the semblance of the 2019-nCoV's genome sequence to a previous epidemic, the severe acute respiratory syndrome (SARS), a disease epidemic caused by SARS-CoV, which broke out in Foshan, China, in 2002 [4,5]. Some initial studies also identified similar features that were related to the Middle East respiratory syndrome (MERS) epidemic caused by MERS-CoV as the causative agent [6].

The outbreak was originally named 2019-nCoV on January 13, 2020, the same day that the first imported case outside China occurred in the Philippines and other countries [7]. The spread of 2019-nCoV continued across many countries, causing the WHO to declare the outbreak a pandemic [6]. The 2019-nCoV was later renamed SARS-CoV-2 and identified as the causative agent of COVID-19 in February 2020 [8,9]. The highly contagious COVID-19 spread rapidly globally and caught the world unprepared. With no adequately planned health communication strategies, panic ensued, while confirmed cases of infections and deaths from COVID-19 increased rapidly worldwide [3]. The public rushed to internet platforms to learn about the outbreak through Google searches, online news outlets, and social media platforms [10-15].

In March 2020, the WHO launched a free online introductory training course in different languages, including English, French, Spanish, and Chinese, to make the public aware of the contagious COVID-19 [6]. However, it is unclear how many people knew about or used the free training lessons about COVID-19 that the WHO had made available via its website [6]. Instead, several studies suggest that the public flocked to the internet to learn about SARS-CoV-2 and COVID-19 through web searches, online news outlets, and social media [16,17]. Analyzing how people search and navigate the World Wide Web and other internet platforms for health-related information can provide valuable insights into the health-related behavior of populations [18-20]. The public's preference for online health information closely matches the field of infodemiology, a term that is a portmanteau of information and epidemiology. According to Eysenbach [18], the term is defined as the science of distribution and determinants of information in an electronic medium—specifically the internet—or in a population, with the aim to inform public health and public policy. Considering the global spread of COVID-19, using the internet to learn or gain information about the pandemic in this digital age is not surprising, as internet use has become pervasive worldwide [21,22]. Several studies have examined social media's influence on what people learned and the appropriate behaviors toward misinformation and conspiracy theories [14,15]. Similarly, Sulyok et al [12] examined the impact of web searches on the confirmed cases of COVID-19 in Europe, while Neely et al [23] investigated information-seeking behaviors on social media regarding the pandemic.

Miller [14,15] identified political leaders' failure in sensitizing the public as a motivating factor that pushed people to the internet as an alternative information source to learn about the COVID-19 pandemic. Misinformation had started flooding the web right from the initial stage of the emergence of the novel coronavirus, mainly from user-created content on social media [24]. Thus, as people turned to the web to search for information, there was limited nontechnical information for the nonexpert public about the coronavirus. Rather, people either got exposed to learning incorrect information about SARS-CoV-2 and COVID-19 or embraced fake news, misinformation, and conspiracy theories, with grave consequences [16]. Some of the unfounded misinformation included misconstruing COVID-19 as a "common cold" or as a hoax, which made people have a false sense of immunity, while others ignored any public health safety measures [11]. Similarly, the conspiracy theories propagated online included that COVID-19 was a bioweapon, that China intentionally released the virus to reduce the world population, and that 5G technology contributed to the fast spread of the pandemic. These beliefs initially led to the hoarding of essential goods as well as racial attacks against Chinese and other Asian people [14,15,25,26].

Other studies examined the role of social media and internet news outlets in generating misinformation, disinformation, fake news, and conspiracy theories about COVID-19 [25,27-29]. These studies tend to leave out the aspect of web searching, such as the use of Google searches, which constitutes a major channel through which the public obtain health-related information [30,31].

Research Objectives

This paper undertakes the first empirical investigation using a web search to learn about SARS-CoV-2 and COVID-19 and people's attitudes toward public health guidelines as expressed in the following research objectives:

1. Determine what people learned about the COVID-19 pandemic through web searching.
2. Examine any association between what people learned about COVID-19 and behavior toward public health guidelines.
3. Analyze the impact of misinformation and conspiracy theories about the COVID-19 pandemic on people's behavior toward public health measures.

These objectives are developed into research hypotheses in the sections that follow.

Theoretical Background

The Connectivism Learning Theory

This section examines the connectivism learning theory, which explains the use of digital platforms to enable learning [32,33]. This study employs this approach to explore how people learned about SARS-CoV-2 and COVID-19 through web searching and the potential behavioral implications toward public health guidelines, which scientists and medical experts recommend as ways to check the spread of COVID-19. For example, the study investigates if learning through web searching helped people acquire accurate knowledge or misinformation and conspiracy theories about the COVID-19 pandemic and its implications. Also, recent studies show that many people have yet to understand the science and the concept of SARS-CoV-2 and the disease, COVID-19, which increases the danger of embracing misinformation [14,28]. Several web platforms, including social media, online news, and other internet channels, contribute significantly to misinformation and conspiracy theories [14,34].

According to Dunaway [33], the connectivism theory developed by George Siemens analyzes the use of digital devices, computer networks, and electronic platforms to learn. The view is considered a pedagogical strategy for the digital age, emphasizing knowledge sharing across an interconnected web and internet network [32,33]. The approach focuses on knowledge acquisition using information technology platforms and learning from multiple sources, developing skills, and disseminating information [32]. The platforms incorporate information on social media, internet websites or blogs, and search engines that users can employ to learn and exchange knowledge, skills, and expertise [28,33].

Implications of the Connectivism Learning Theory

One of the implications of the connectivism learning theory is that learning can occur outside the traditional classroom by using networked systems that enhance connections, interactions, and collaborations among learners [29]. However, some learning theory experts criticize the connectivism theory for not offering any improvement to the actual learning method other than using Web 2.0 and related platforms [32,33]. Hence, it cannot be deemed a substantive learning theory. Instead, it provides a bridge to other pedagogical methods: behaviorism, cognitivism, and constructivism. The core of the Siemens and Downes connectivism idea aims to move away from the traditional classroom learning techniques to a new theory of learning that embraces technology as the learning tool, which can inspire the new generation of learners and educators [32,33]. Thus, the theory draws its strength from web-based activities [29].

The key benefit of the method is its intuitiveness and its ability to captivate learners due to the ubiquitous use of the internet in today's world. The following principles contribute to the popularity of connectivism as a learning theory [33]:

1. Learning and knowledge rest in diversity of opinions, as experienced today.
2. Learning is a process of connecting specialized nodes or information sources.
3. Learning may reside in nonhuman appliances.
4. The capacity to know more is more critical than what is currently known.
5. Nurturing and maintaining connections help to facilitate continual learning.
6. Ability to see connections between fields, ideas, and concepts is a core skill.
7. Currency (accurate, up-to-date knowledge) is the intent of all connectivism learning activities.
8. Decision making is itself a learning process. Choosing what to learn and the meaning of incoming information is seen through a shifting reality.

The connectivism learning theory, as explained above, closely mirrors the use of Google Trends and other internet platforms to learn about the outbreak of SARS-CoV-2 and COVID-19, especially where the masses did not get adequate, timely information about the coronavirus from the public agencies [35,36].

The connectivism learning theory is well suited to personal study and self-regulated learning [37,38]; in this case, how individual members of the public learned about SARS-CoV-2 and COVID-19 using web searches in the first 6 months of the COVID-19 pandemic.

An Overview of the SARS-CoV-2 Outbreak and the COVID-19 Pandemic

The Global Impacts of the SARS-CoV-2 Outbreak

The COVID-19 pandemic has caused severe problems ranging from health crises to psychological, social, business, and economic consequences all over the world [16,18,39]. Meanwhile, there is currently no specific cure for COVID-19. However, there has been significant progress in technological advances leading to substantial breakthroughs in vaccine discovery and development through the pioneering efforts of Pfizer, Moderna, and other companies from the United Kingdom, India, China, and other countries [40]. Administering the COVID-19 vaccines is ongoing worldwide, while several other vaccine discoveries and developments are in progress [41]. In the meantime, ongoing prevention, monitoring, and public health awareness are essential to mitigate the public health and economic burdens. The most important prevention strategy is to understand the disease and how it spreads.

Transmission

Coronavirus transmission primarily occurs through respiratory droplets released from infected persons during coughing, sneezing, or speech. One can also become infected with the virus via contact with contaminated surfaces. The virus can remain infectious in the air for 3 hours and on inanimate surfaces for up to 9 days or longer. This has implications for nosocomial spread and superspreading events [42]. The virus has also been isolated from blood, urine, and stool specimens. It is important to note that asymptomatic infected people may not be aware that they are infected because they do not have the symptoms or may not recognize the symptoms. Infected individuals can be contagious for up to 4 weeks and can unknowingly be spreading the infection during this time [42].

Clinical Presentation and Diagnosis

Symptoms usually appear 2 to 14 days after exposure. Most confirmed cases of SARS-CoV-2 infection are asymptomatic, and they recover without treatment. Common symptoms include fever, cough, shortness of breath, chills, myalgia, headache, sore throat, anosmia, and dysgeusia. Severe cases present with dyspnea, tachypnea, hypoxia (blood oxygen saturation ≤93%), a ratio of the arterial partial pressure of oxygen to the fraction of inspired oxygen of less than 300 mm Hg, and lung infiltration [43]. Some patients present with gastrointestinal symptoms, such as vomiting, diarrhea, and abdominal pain, as well as cardiovascular features, such as arrhythmia, shock, and acute cardiac injury [44]. There have been reports of asymptomatic carriers presenting with symptoms such as loss of smell and taste. In children, the majority present with mild (ie, fever, cough, fatigue, and congestion) or moderate (ie, pneumonia) symptoms [44]. Some may be asymptomatic. Children under 5 years old may present with respiratory organ failure.

Chest computed tomography scans shows a distinct appearance of ground-glass lung opacity, often bilateral, in patients who develop pneumonia [43]. Other radiographic features, such as "crazy-paving sign, multifocal organizing pneumonia, and architectural distortion in a peripheral distribution," may appear with disease progression. Diagnostic testing is performed from respiratory (ie, nose, throat, and saliva) and serum samples, using a real-time reverse transcription–polymerase chain reaction panel or antibody test. Viral RNA has also been detected in stool and blood [5].

Complications

Some hospitalized patients develop thromboembolism, especially deep venous thrombosis, and pulmonary embolism. Other complications include microvascular thrombosis of the toes, clotting of catheters, myocardial injury with ST-segment elevation, and large vessel strokes. This complication may be associated with the release of high levels of inflammatory cytokines and activation of the coagulation pathway caused by hypoxia and systemic inflammation secondary to COVID-19 [45].

Prevention and Control

People must be well-informed. Infected persons must practice respiratory etiquette to avoid infecting others, including covering coughs and sneezes with a tissue and discarding it properly, coughing into the inside of the elbow, and covering the nose and mouth properly with a surgical face mask. Best practices include proper handwashing with soap and water for at least 20 seconds or at least 60% alcohol–based hand rub. Touched surfaces must be cleaned frequently with disinfectants. People must avoid touching the eyes, nose, and mouth with unwashed hands and they must avoid close contact with people who are ill [46]. The US Centers for Disease Control and Prevention (CDC) recommends that infected and exposed individuals must isolate or quarantine themselves, respectively, for at least 14 days. The CDC also recommends social distancing, including avoiding mass gatherings or large community events, shaking hands, or giving "high fives" [41]. In health care settings, standard contact and airborne precautions, as well as eye protection, should be used to mitigate the spread of SARS-CoV-2 [46]. There is no specific cure for COVID-19. Management is mainly supportive care and treatment of secondary infections. Severely ill patients may need advanced organ support.

Methods

Google Trends and Search Keywords About SARS-CoV-2 and COVID-19

This study used an infodemiology approach to evaluate the use of web searching to learn about SARS-CoV-2 and COVID-19. As an area of scientific research, infodemiology is a method or technique designed to measure and track health information "demand" automatically (eg, by analyzing search queries) as well as "supply" on the internet [18,20,47]. The goal is to inform public health policy and practice. This study uses data from Google Trends, a freely available online resource that provides information on what was and is trending based on actual users' Google queries [11,48,49].

Google Trends offers various search options, such as "Trending Searches" (ie, trending queries for daily search trends and real-time searches in a selected region) or "Year in Search" (ie, what was trending in a specific area in a particular year). Another option is to "Explore," which allows an investigation of an area of interest based on keywords over the selected periods and regions. This study uses the "Explore" option, which allowed data to be retrieved directly from the Google Trends "Explore" page in comma-separated values format. It is also important to note that Google Trends data points are normalized to have a maximum value of 100 and a minimum value of 0. We normalized the data set by dividing each data point by total searches of the geography and the time range it represents to compare relative popularity. Note that the value 0 does not necessarily indicate no searches but represents a significantly low search volume that does not warrant inclusion in the results [47].

In this study, we captured the worldwide Google Trends data covering the initial months of the SARS-CoV-2 outbreak from January 1 to June 30, 2020 (ie, 182 daily data points for each search term). Regarding the search terms, this paper employed 25 keywords and phrases used by the public to learn about the COVID-19 pandemic through web searches. We identified the search keywords (Table 1) through a literature survey of

published documents indexed on the Web of Science. Six search terms were related directly to the ongoing pandemic: "nCoV," "2019-nCoV," "SARS-CoV-2," "COVID-19," "pandemic," and "coronavirus." Another six keywords addressed previous viral or coronavirus epidemics: "SARS-CoV," "SARS," "MERS-CoV," "MERS," "virus," and "influenza." The third category of search terms represented public health safety measures that experts recommended as guidelines to limit the spread of COVID-19: "social distancing," "wear a facial mask," and "wash hands." The final category of keywords represented misinformation and conspiracy theories, such as "China virus," "common cold," and "bioweapon" (Table 1 [2,3,6,7,9,11,14,15,25-27,42,46,50-60]).

Table 1. Web search terms used to learn about SARS-CoV-2 and the COVID-19 pandemic, misinformation and conspiracy theories, and public health safety guidelines, based on a literature review.

Category	Search terms
COVID-19 and related epidemics	"2019-nCoV" [3], "nCoV" [3,9], "SARS-CoV-2" [42], "COVID-19" [9,25,50], "pandemic" [6,7], "MERS-CoV" [51,52,60], "MERS[a]" [51,53], "SARS-CoV" [42,52], "SARS[b]" [52,53], "virus" [54], "coronavirus" [2,53,55], "influenza" [46], and "flu" [59]
Misinformation and conspiracy theories	"virus hoax" [14,15], "injecting or ingesting bleach" [56], "5G" or "@5G" technology enhancing the spread of the virus [25,27], "COVID-19 hoax" [14,15,26], "common cold" ("commoncold2020") [11], "China virus" [50], and "bioweapons" created by China [14,25,60]
Public health measures	"social distancing" [57], "wash hands" or "hands wash" [57], "wear a facial mask" [58], "isolation" [57], and "quarantine" [57]

[a]MERS: Middle East respiratory syndrome.

[b]SARS: severe acute respiratory syndrome.

Research Hypotheses

Hypothesis 1

For the purpose of determining what people learned about the COVID-19 pandemic through web searching, we defined the null and alternative hypotheses as follows:

- Hypothesis 1_0: People did not learn about COVID-19 through web searching using the identified keywords.
- Hypothesis 1_1: People learned about COVID-19 through web searching using the identified keywords.

Hypothesis 2

Based on the literature, using a web search to learn about a subject of interest can influence the learner's decision making and actions [61]. On this premise, this study examined any association between what people learned about COVID-19 and people's behavior toward the public health guidelines. We developed two separate hypotheses (Hypotheses 2 and 3). The first aspect related to web searching to learn about COVID-19 (ie, concept, science, and structure of SARS-CoV-2 and COVID-19), while the second aspect evaluated learning about misinformation and conspiracy theories as well as the behavioral response to the public health measures. The null and alternative hypotheses regarding the first aspect are as follows:

- Hypothesis 2_0: There is no association between what people learned about COVID-19 through web searching and behavior toward public health measures.
- Hypothesis 2_1: There is an association between what people learned about COVID-19 through web searching and behavior toward public health measures.

Hypothesis 3

There is a widely held assertion that misinformation and conspiracy theories about the COVID-19 pandemic have had a significant impact on people's behavior toward public health measures. We defined the null and alternative hypotheses for learning about misinformation as follows:

- Hypothesis $3A_0$: There is no association between misinformation learned about COVID-19 and people's behavior toward public health measures.
- Hypothesis $3A_1$: There is an association between misinformation learned about COVID-19 and people's behavior toward public health measures.

Similarly, we defined the null and alternative hypotheses for learning about conspiracy theories as follows:

- Hypothesis $3B_0$: There is no association between conspiracy theories learned about COVID-19 and people's behavior toward public health measures.
- Hypothesis $3B_0$: There is an association between conspiracy theories learned about COVID-19 and people's behavior toward public health measures.

Data Analysis

Data analysis employed statistical trends and graphical visualization, correlation and regression, principal component analysis (PCA), and predictive models [12,56,62-64]. The statistical trends and analyses involved evaluating relationships among the listed variables using the statistical trends, including graphical display, correlation, and PCA, which helped determine the predictiveness of the learning attributes and learners' actions toward public health guidelines. We used the JMP 15 package from SAS software (SAS Institute Inc) [65] for statistical analysis and Microsoft Excel 2019 to create the charts and graphs. We also used SPSS software (version 27; IBM Corp) to compute the correlation matrix and the PCA as well as statistical packages in R (version 4.0.5; The R Foundation) for the linear modeling. The evaluation helped establish the correlation between the study attributes.

Results

Overview

The data analyzed in this study came from the Google Trends worldwide index covering the period from the initial outbreak of COVID-19 on January 1, 2020, up to June 30, 2020, when the pandemic became widely known [2]. The outbreak had been reported to the WHO's office in China on December 31, 2019 [6]. The reason for focusing on the first 6 months of the pandemic was to capture what people learned during the early days of the outbreak as well as the possible impacts of what people learned through web searching on individuals' attitudes toward public health safety measures.

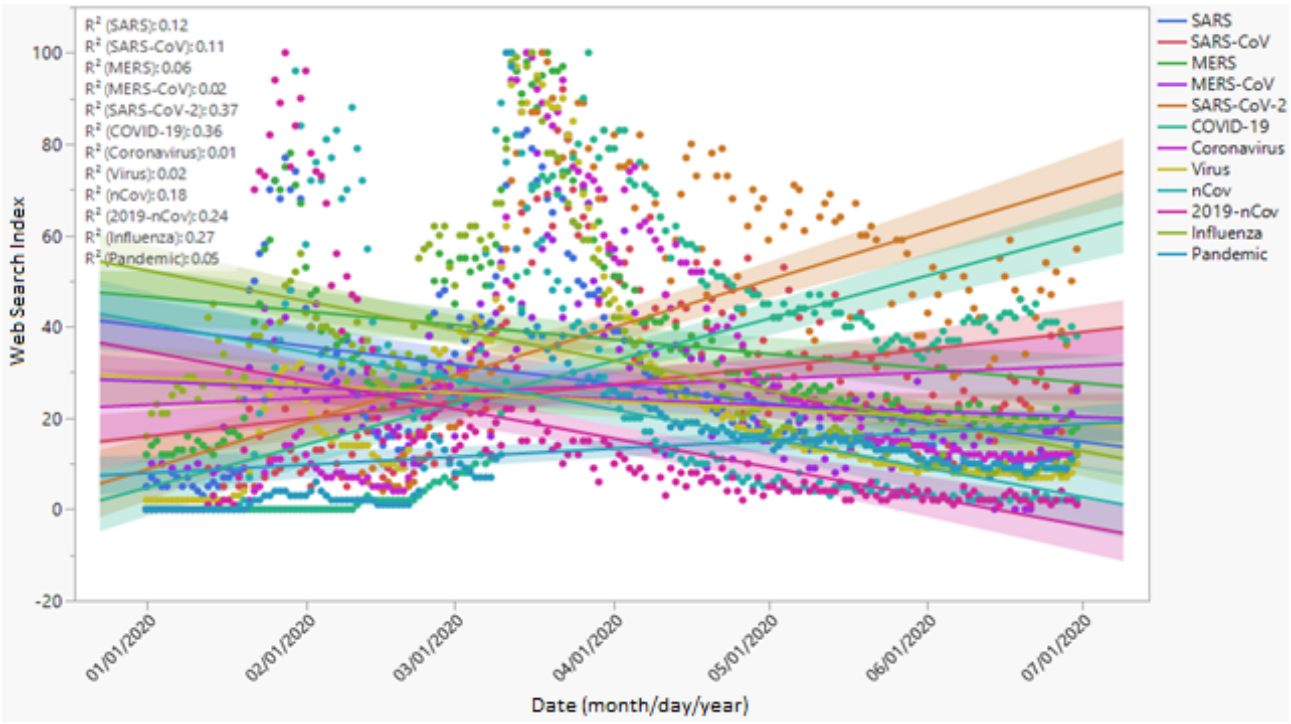
To better understand the characteristics of Google Trends data, we have presented the summary statistics of the daily search index for each of the 25 keywords or search terms and phrases (Table S1 in Multimedia Appendix 1). The average normalized scores for the terms varied from 2.65 ("ingesting bleach") to 39.75 ("SARS-CoV-2"), as shown in Table S1 in Multimedia Appendix 1.

Temporal Trends: Using Web Searches to Learn About SARS-CoV-2

The keywords employed to conduct web searches indicate what people learned about the COVID-19 pandemic [66]. As presented in Table 1, some of the search keywords addressed the novel coronavirus directly, while others examined misinformation and conspiracy theories.

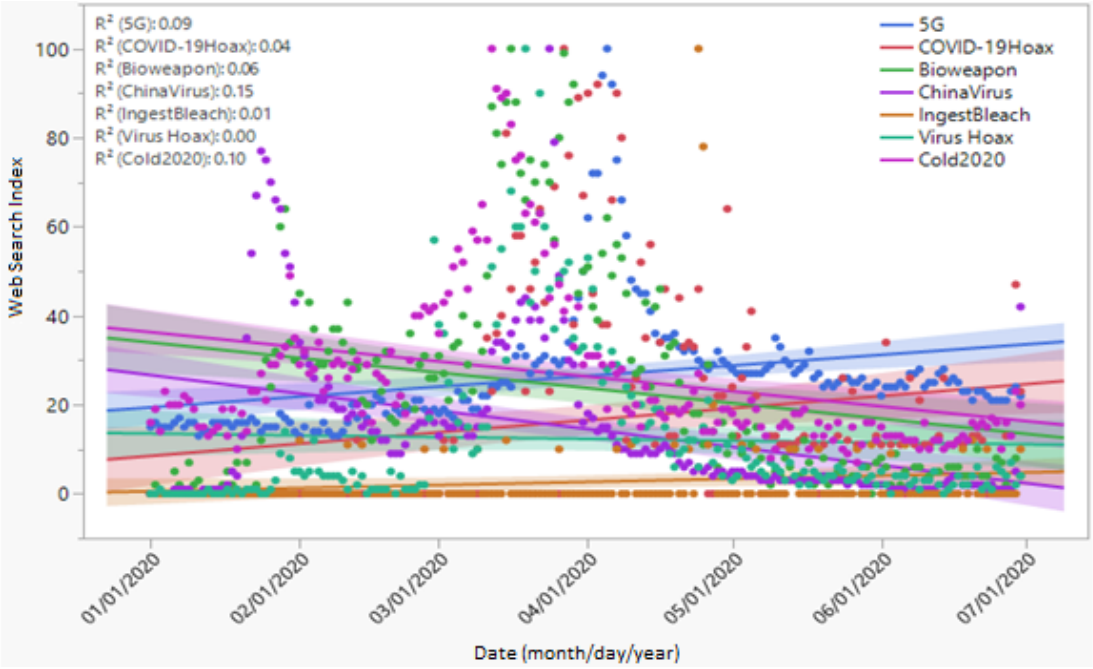
Figure 1 presents the first category of web search terms that people used to learn about the COVID-19 pandemic. In the early period, most people used keywords and phrases that explain previous coronavirus epidemics, including "influenza," "MERS," "MERS-CoV," "SARS," and "virus." Although scientists ruled out the past epidemics, the WHO officials highlighted those terms as examples of past coronavirus outbreaks during press briefings [6]. The use of those keywords in the web searches nosedived after the WHO formally named the novel coronavirus and the disease (ie, "nCoV," "2019-nCoV," "SARS-CoV-2," and "COVID-19"). The coefficients of determination (R^2) of the keywords are 0.37 for "SARS-CoV-2," 0.36 for "COVID-19," 0.27 for "influenza," 0.24 for "2019-nCoV," 0.18 for "nCoV," 0.12 for "SARS," and 0.11 for "SARS-CoV," indicating the proportion of the variation in the search index over the period for the listed keywords. Similarly, the search terms "MERS," "MERS-CoV," "pandemic," "virus," "coronavirus," "nCoV," and "2019-nCoV" had R^2 values of less than 0.1.

Figure 1. The keywords used by people to learn about SARS-CoV-2 and COVID-19 through web searches. MERS: Middle East respiratory syndrome; SARS: severe acute respiratory syndrome.



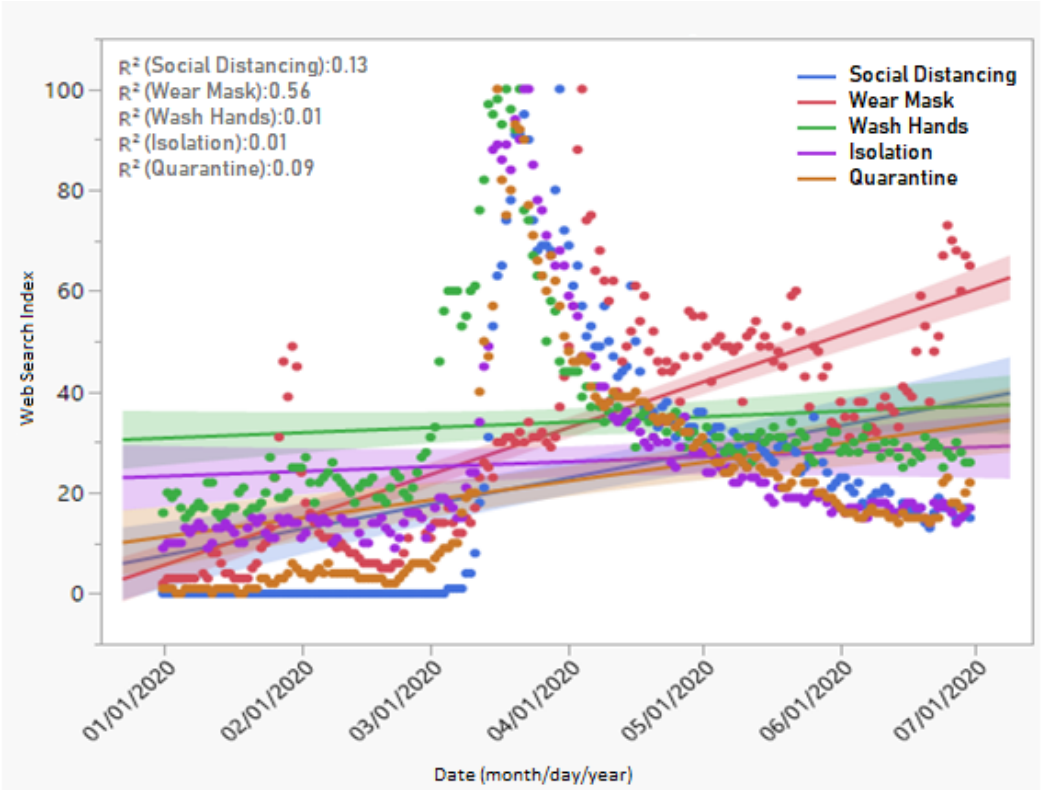
The second category of keywords involved misinformation and conspiracy theories (Figure 2). The variation in the use of the terms was measured using coefficients of determination (R^2), which were 0.15 for "China virus," 0.10 for "common cold," and 0.09 for "5G" or "@5G." Most searches in the initial months of the outbreak used the keywords "common cold" ("cold2020"), "biological weapon," and "China virus," thus encouraging the misconception about SARS-CoV-2 as a "common cold," a "biological weapon," or a "China virus" [50]. Some studies explain that the purpose of releasing the coronavirus was to reduce the world population [14,25]. However, web searches using these terms fell continuously over time to a near-zero search index, while new words ("5G" and "COVID-19 hoax") surfaced and increased significantly (Figure 2).

Figure 2. Worldwide search index showing the learning terms that represent misinformation and conspiracy theories about COVID-19.



The third segment of the trend analysis involved web searches to learn about public health measures (Figure 3). The results show that there was little or no interest in learning about wearing a facial mask ("wear mask") and maintaining social distancing ("social distancing") at the start of the pandemic. But the trends changed quite quickly, recording a dramatic increase from a search index of 0 at the beginning of the outbreak to achieving a maximum search index of 100 in March and April 2020, as the pandemic spread worldwide. The coefficients of determination were as follows: "wear mask" (R^2=0.56), "social distancing" (R^2=0.13), and "quarantine" (R^2=0.09). The increases, especially regarding "wear mask" and "social distancing," were sustained for a long time.

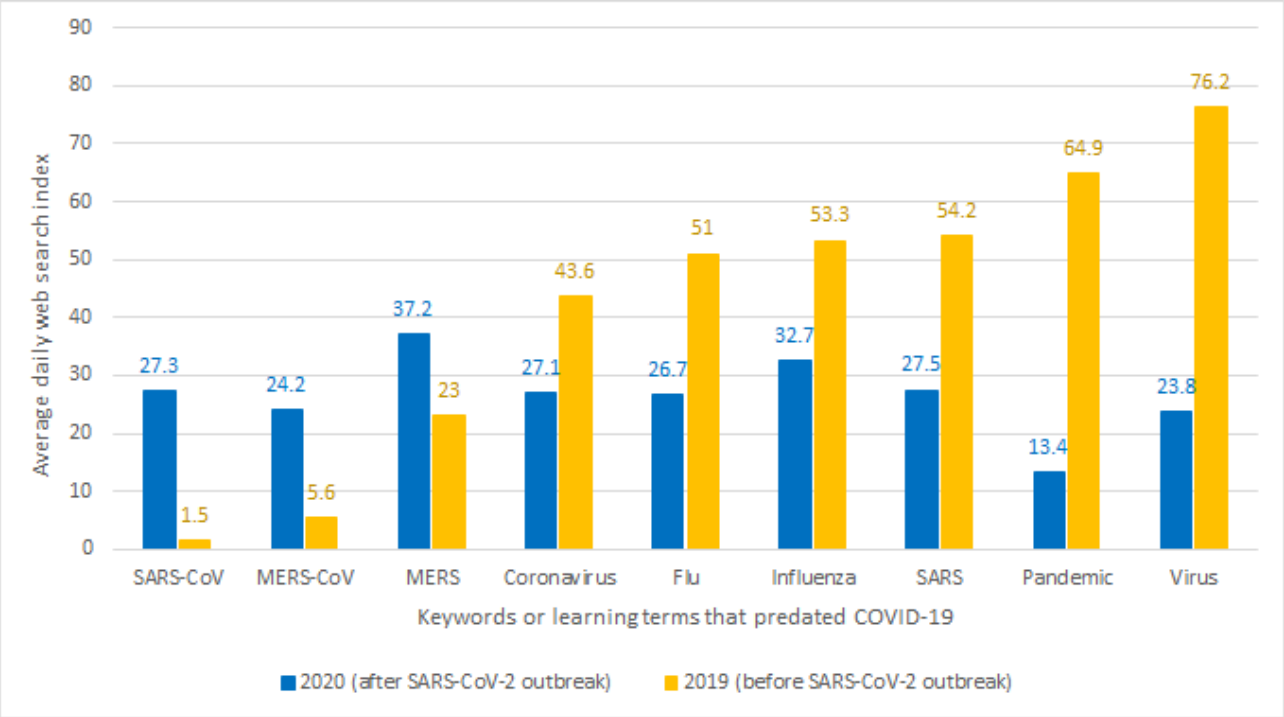
Figure 3. Trend analysis showing the web search index for learning about public health safety measures.



What Did People Learn About COVID-19 Through Web Searches?

The keywords identified above approximate what people learned about SARS-CoV-2 and COVID-19 through web searches. However, some of the search keywords existed before the ongoing pandemic, while some terms referred to previous coronavirus epidemics (eg, “SARS,” “SARS-CoV,” “MERS,” “MERS-CoV,” “influenza,” “virus,” “pandemic,” and “coronavirus”). It is plausible to argue that the search index for the pre-existing keywords listed represent purposes other than learning about COVID-19. Based on this assumption, we conducted a dependent two-sample *t* test to examine the difference in the mean search index of the pre-existing keywords in the previous years before the COVID-19 outbreak and during the ongoing pandemic. Figure 4 compares the mean search index before and after the outbreak for each keyword.

Figure 4. The average search index for pre-existing keywords before and during the COVID-19 pandemic. MERS: Middle East respiratory syndrome; SARS: severe acute respiratory syndrome.

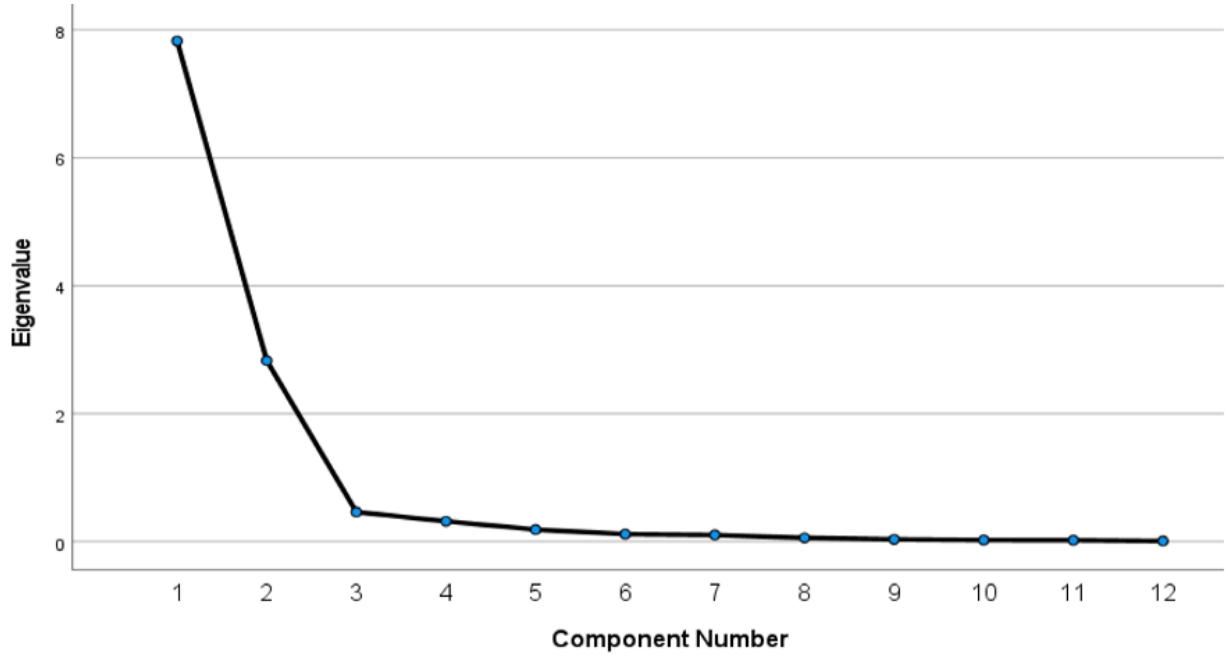


The null hypothesis was that the search indexes of each learning term—“SARS,” “SARS-CoV,” “MERS,” “MERS-CoV,” “influenza,” “virus,” “pandemic,” and “coronavirus”—before and after the outbreak of COVID-19 would be equal, and the alternative hypothesis was that they would be unequal. The results, as seen in Figure 4, show that the differences in the mean search indexes before and during the ongoing pandemic were more than 60% in all cases. Also, the P values were close to zero for all the variables. We rejected the null hypothesis and concluded that the significant differences in the mean search indexes of the variables were due to the ongoing COVID-19 pandemic. Unexpectedly, the mean search index for some pre-existing keywords (eg, “flu,” “influenza,” “SARS,” “pandemic,” and “virus”) declined during the pandemic.

What Search Terms Contributed to Learning About SARS-CoV-2 and COVID-19?

PCA was employed to evaluate the underlying latent variable of the search terms that contributed to learning about COVID-19. Based on the scree plot and the elbow rule, we can limit the factors extracted to the first two principal components (Figure 5): the keywords that address previous epidemics (pastCoVepidemics) and the keywords that explain the ongoing pandemic (presCoVpandemic). A scree plot is a graphical representation of the percentage variability explained by each principal component.

Figure 5. Scree plot of COVID-19 learning terms; two principal components extracted 88.78% of the total variation.



The first two underlying components explained a total of 88.78% of the variation in learning terms, with the first (pastCoVepidemics) and second (presCoVpandemic) components determining about 65.2% and 23.58%, respectively, of the information about COVID-19 from the 12 search keywords (Table 2).

Table 2. Total explained variance for search keywords used to learn about COVID-19.

Measure	PC[a] 1	PC 2	PC 3	PC 4	PC 5	PC 6	PC 7	PC 8	PC 9	PC 10	PC 11	PC 12
Total initial eigenvalue	7.82	2.83	0.46	0.32	0.19	0.12	0.11	0.06	0.04	0.03	0.02	0.01
Variance, %	65.20	23.58	3.86	2.65	1.57	0.98	0.88	0.49	0.29	0.21	0.19	0.09
Cumulative variance, %	65.20	88.78	92.64	95.30	96.87	97.84	98.72	99.21	99.51	99.72	99.91	100

[a]PC: principal component.

Linear combinations of the two components (pastCoVepidemics and presCoVpandemic) are as follows:

- PastCoVepidemics = 0.98 “virus” + 0.934 “coronavirus” + 0.929 “MERS” + 0.923 “flu” + 0.858 “MERS-CoV” + 0.858 “SARS” + 0.791 “SARS-CoV” + 0.799 “pandemic” + 0.814 “influenza”
- PresCoVpandemic = –765 “nCoV” + 0.784 “COVID-19” + 0.766 “SARS-CoV-2.”

Table 3 shows the weights (loadings) of the terms for the two components. Note that we record loadings greater than 0.6 to combine only search keywords that have a high correlation with the component in the linear combinations.

Table 3. Component matrix and weight loadings for search keywords used to learn about COVID-19.

Component[a]	Weight loading for each keyword											
	Virus 2020	Coronavirus 2020	MERS[b] 2020	Flu 2020	MERS-CoV 2020	SARS[c] 2020	Influenza 2020	Pandemic 2020	SARS-CoV 2020	COVID-19	SARS-CoV-2	2019-nCoV
1	0.98	0.934	0.929	0.923	0.858	0.858	0.814	0.799	0.791	0.562	0.601	0.45
2	–0.059	0.278	–0.305	–0.278	–0.121	–0.443	–0.477	0.315	0.505	0.784	0.766	–0.765

[a]Component 1 is pastCoVepidemics (keywords that address previous epidemics) and component 2 is presCoVpandemic (keywords that explain the ongoing pandemic).

[b]MERS: Middle East respiratory syndrome.

[c]SARS: severe acute respiratory syndrome.

What Terms Fueled Misinformation and Conspiracy Theories About COVID-19?

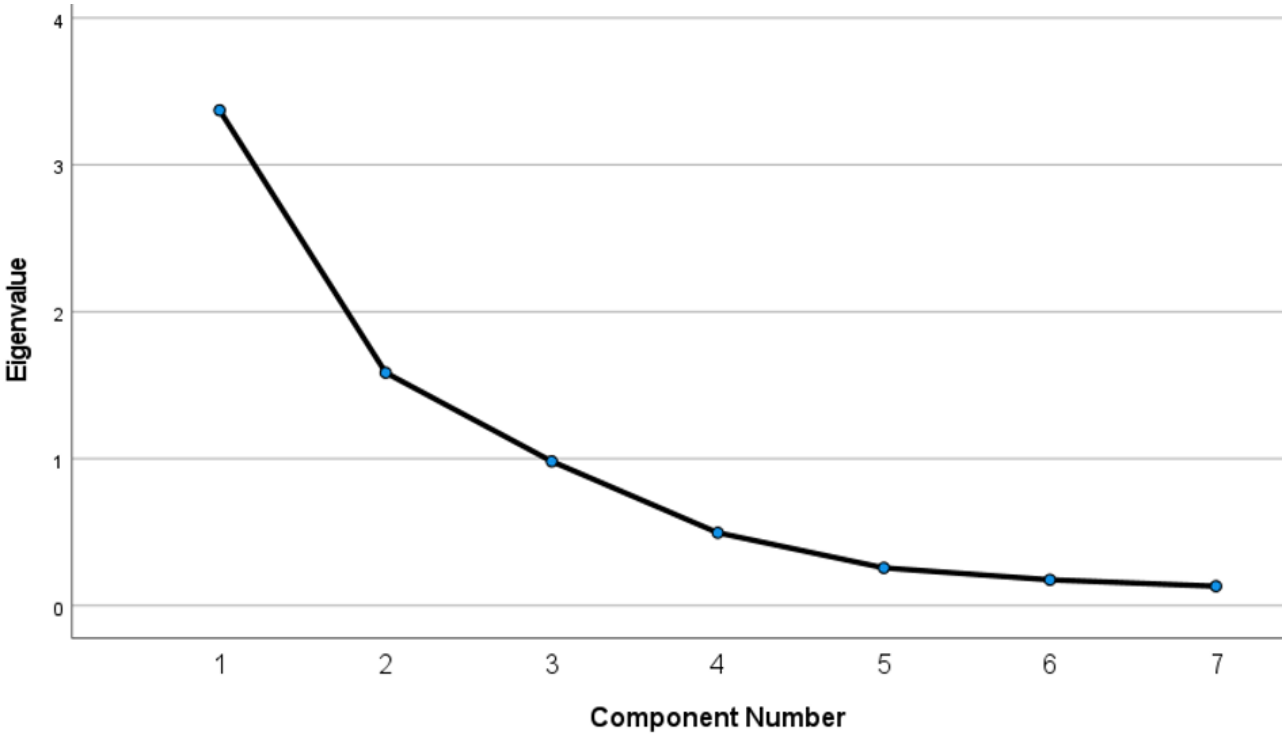
We identified eight search keywords from the literature that denote misinformation and conspiracy theories (Table 1). We also performed a PCA to evaluate the search terms that fueled misinformation and conspiracy theories. The results, as seen in Table 4 and Figure 6, identified three principal components and their variabilities based on the elbow rule: principal component 1 (48.17%), principal component 2 (22.65%), and principal component 3 (14.03%).

Table 4. Total variance explained involving terms that fueled misinformation and conspiracy theories.

Measure	PC[a] 1	PC 2	PC 3	PC 4	PC 5	PC 6	PC 7
Total initial eigenvalue	3.372	1.586	0.982	0.496	0.257	0.176	0.132
Variance, %	48.171	22.652	14.026	7.085	3.669	2.509	1.888
Cumulative variance, %	48.171	70.823	84.849	91.934	95.603	98.112	100

[a]PC: principal component.

Figure 6. Scree plot of misinformation and conspiracy theory terms.



The three components explained 84.85% of the variation in the search keywords under misinformation and conspiracy theories. The first component represented misinformation. We quantified the daily number of misinformation terms searched using the linear combination as follows:

- Misinformation = 0.789 “common cold” + 0.928 “bioweapon” + 0.908 “virus hoax” + 0.875 “cold 2020” + 0.692 “COVID-19 hoax” + 0.60 “China virus.”

The second and third components addressed two conspiracy theories (ConspTheory1 and ConspTheory2), which speculated that 5G technology contributes to the spreading of COVID-19, that COVID-19 is a “China virus” that was intentionally created and released, and that ingesting or injecting bleach can cure COVID-19 infection or kill the virus. The results present these variables in the separate components (Table 5) as follows:

- ConspTheory1 = 0.786 “@5G”
- ConspTheory2 = 0.97 “ingest bleach.”

Table 5. Component matrix and weight loading for terms that fueled misinformation and conspiracy theories.

Component[a]	Weight loading for each keyword						
	Bioweapon 2020	Virus hoax	Common cold 2020	COVID-19 hoax	China virus	@5G	Ingest bleach
1	0.928	0.908	0.789	0.692	0.601	0.471	–0.045
2	–0.152	0.033	–0.438	0.624	–0.558	0.786	0.226
3	0.03	0.005	0.093	–0.044	0.059	–0.145	0.973

[a]Component 1 is misinformation and is not included, component 2 is the conspiracy theory that 5G technology contributes to the spreading of COVID-19, and component 3 is the conspiracy theory that ingesting or injecting bleach can cure COVID-19 infection or kill the virus.

Public Health Safety Measures

This section investigates the impacts of what people learned through web searches on behaviors toward public health safety measures against COVID-19. Based on the elbow rule, the PCA identified two public health measure components, which we labeled as PubHealthMes1 and PubHealthMes2. The two components accounted for the variability in the search index of keywords used to learn about the public health measures against the spread of COVID-19 (Figure 7). The first and second components explained more than 75.4% and 18.7% of the variability, respectively; that is, the first two components explained about 94% of the variability (Table 6).

Figure 7. Scree plot of public health measures against COVID-19; two components extracted 93.99% of the variability in the search index.

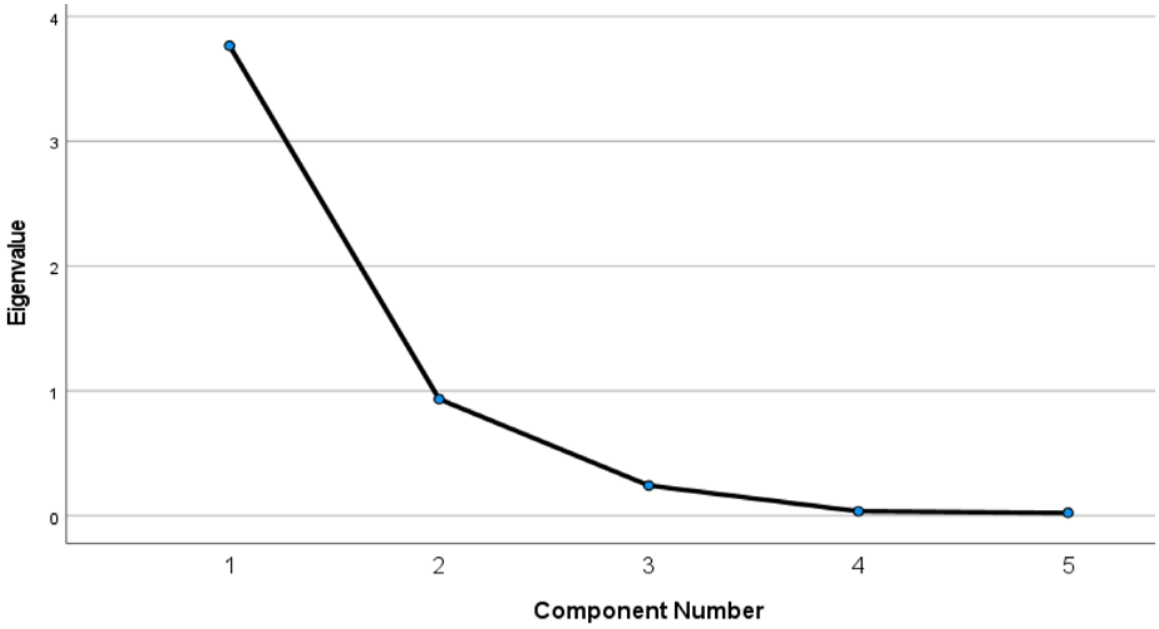


Table 6. Total explained variance for terms that explained the public health measures against COVID-19.

Measure	PC[a] 1	PC 2	PC 3	PC 4	PC 5
Total initial eigenvalue	3.768	0.933	0.24	0.035	0.023
Variance, %	75.359	18.665	4.799	0.71	0.466
Cumulative variance, %	75.359	94.025	98.824	99.534	100

[a]PC: principal component.

The first component, PubHealthMes1, includes the keywords "social distancing," "wash hands," "isolation," and "quarantine." In the second component, PubHealthMes2, the keyword "wear mask" explained 84.7% of the variability (Table 7):

- PubHealthMes1 = 0.953 "social distancing" + 0.847 "wash hands" + 0.953 "isolation" + 0.99 "quarantine"
- PubHealthMes2 = 0.847 "wear mask."

Table 7. Component matrix and weight loading for terms that explained the public health measures.

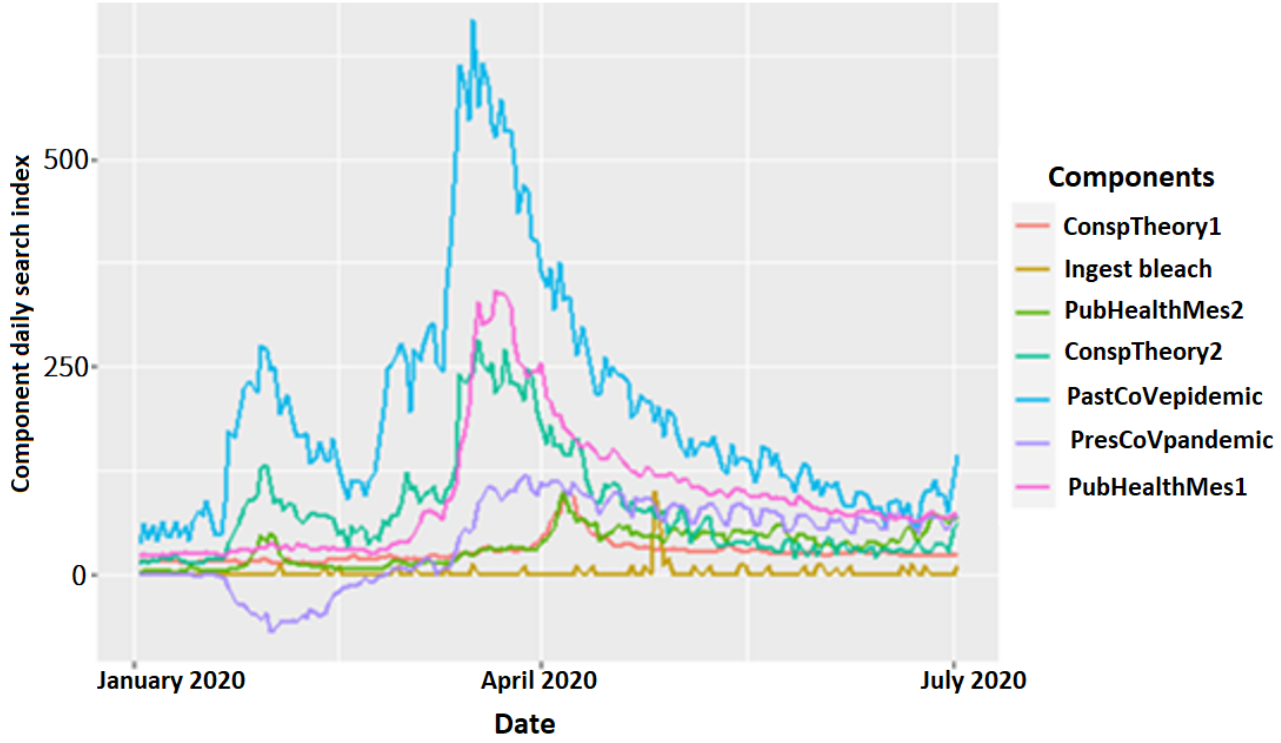
Component[a]	Weight loading for each keyword				
	Quarantine	Social distancing	Isolation	Wash hands	Wear mask
1	0.99	0.953	0.953	0.847	0.503
2	–0.028	0.143	–0.223	–0.38	0.847

[a]Component 1 is public health measures represented by the keywords "social distancing," "wash hands," "isolation," and "quarantine," and component 2 is the public health measure represented the keyword "wear mask."

Analysis of the Relationships Among the Principal Components

This section presents further analysis that tested the hypothesis raised in the earlier section using built predictive models. The variables identified the linear combination of search keywords significantly correlated (loading >0.6) to the principal components discussed in the Results subsections above. Also, Tables 2 to 7 present the underlying latent variables of the 25 search terms used to learn about COVID-19, the misinformation and conspiracy theories, and the public health measures. As stated, Figure 8 shows the underlying variables.

Figure 8. Daily search index of the principal components. ConspTheory1: conspiracy theory 1; ConspTheory2: conspiracy theory 2; pastCoVepidemics: keywords that address previous epidemics; presCoVpandemic: keywords that explain the ongoing pandemic; PubHealthMes1: public health measures 1; PubHealthMes2: public health measures 2.



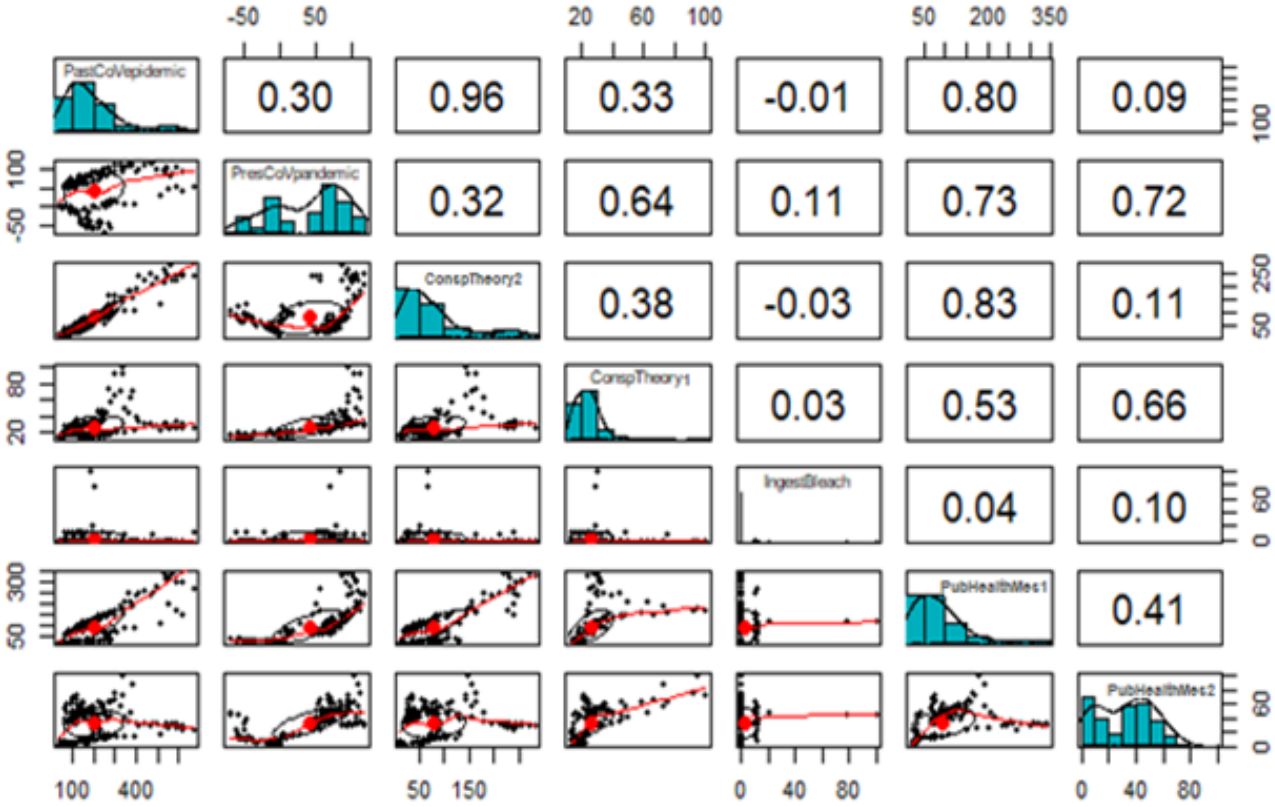
Here, we examine how the underlying variables and the search terms impacted learning and behavior toward the public health measures: learning about COVID-19 (pastCoVepidemics and presCoVpandemic), misinformation and unproven or misleading assertions (misinformation), conspiracy theories (ConspTheory1 and ConspTheory2), and public health safety measures (PubHealthMes1 and PubHealthMes2).

The results show three essential highlights from the daily search index. First, the most popular search terms used at the initial outbreak of the pandemic in early January 2020 were terms representing misinformation and past epidemics. The search keywords that represented conspiracy theories were not used until May 2020. Also, the use of learning terms that directly explained COVID-19 (ie, presCoVpandemic) corresponded with the WHO's naming and renaming of the coronavirus and the disease (ie, "2019-nCoV," "SARS-CoV-2," and "COVID-19") in January, February, and March 2020.

Information Learned Versus Behavior Toward Public Health Measures

We employed correlation analysis among the variables, scatterplots, and their histograms to examine the relationship between what people learned and their attitudes toward public health measures (Figure 9).

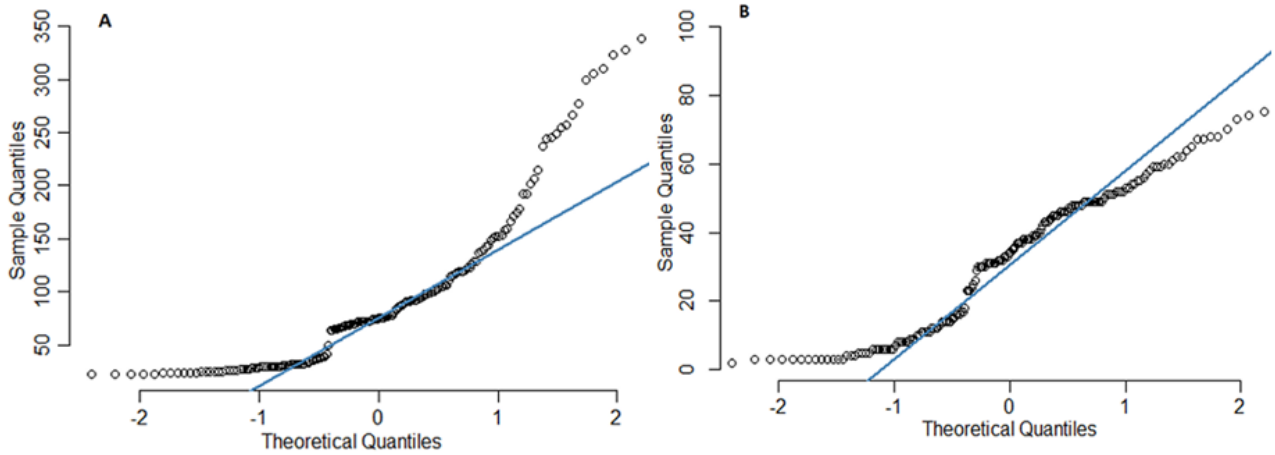
Figure 9. Panel pair plots of linear correlations between misinformation and conspiracy theory keywords. pastCoVepidemics: keywords that address previous epidemics; presCoVpandemic: keywords that explain the ongoing pandemic; PubHealthMes1: public health measure 1; PubHealthMes2: public health measure 2.



PubHealthMes1 has a robust positive relationship with pastCoVepidemics (r=0.80) and a moderate positive relationship with presCoVpandemic (r=0.73), which implies the effectiveness of learning keywords associated with past coronavirus epidemics (eg, "SARS," "SARS-CoV," "MERS," "MERS-CoV," and more) and the ongoing pandemic (eg, "2019-nCoV," "SARS-CoV-2," and "COVID-19"). Similarly, PubHealthMes2 (ie, wearing a facial mask) has a moderate positive relationship with presCoVpandemic (r=0.71). There is a strong association between actions taken and the information learned. Figure 9 shows a correlation matrix.

Given such a strong linear relationship between the search terms and people's behaviors and actions, a multiple linear regression model seems acceptable as a predictive model. But the data failed the assumption of normality, as shown by the quantile-quantile (Q-Q) plots in Figure 10, A and B. A normal Q-Q plot helps to compare two probability distributions, by plotting the residuals against theoretical quantiles. Plots A and B in Figure 10 show that most residuals are not lying on the diagonal line; hence, the data are not normally distributed.

Figure 10. Quantile-quantile (Q-Q) plots of (A) PubHealthMes1 (public health measures 1, represented by the keywords "social distancing," wash hands," "isolation," and "quarantine") and (B) PubHealthMes2 (public health measures 2, represented the keyword "wear mask").



From Figure 9, we can observe that the PubHealthMes1 histogram suggests a right-skewed distribution, while the PubHealthMes2 histogram suggests a bimodal distribution. To describe and explain the relationship between the public health measures and the terms that contributed to learning about COVID-19, misinformation, and conspiracy theories, we used the log-linear predictive model, since the data are based on a number of occurrences or frequency and not normally distributed. Also, the log-linear model does not need to satisfy any assumptions, which we represent as follows:

where x_i is the covariate and β_i is the parameter to be estimated.

The data obtained through the PCA have been fitted to a log-linear regression model using RStudio tools from R (version 4.0.5; The R Foundation). The regression model obtained becomes the following:

$$\text{Log(PubHealthMes1)} = 3.33 + 0.0024\ \text{pastCoVepidemics} + 0.011\ \text{presCoVpandemic}$$

The R^2 of the model is 0.93 and the P value is <.001. All the coefficients in this model are significant at an α level of 0. From the model, we see that there is a 1.10 percentage ($100 \times [\exp^{0.011} - 1]\%$) increase in the public health measure for every 1% increase in presCoVpandemic (ie, "2019-nCoV," "SARS-CoV-2," and "COVID-19"). This may be explained by links contained in recent COVID-19 pandemic articles on public health measures. For every 1% increase in past epidemic searches, there is a 0.25% increase in the searches of public health measures. Similarly, the regression model for PubHealthMes2 obtained becomes the following:

$$\text{Log(PubHealthMes2)} = 0.01 \times \text{presCoVpandemic} + 2.35$$

The R^2 of the new model is 0.50 and the P value is <.001. The two models show that both PubHealthMes1 and PubHealthMes2 are significantly predictive using the presCoVpandemic keywords. It shows that learning about the present pandemic creates an incentive for people to learn about public health measures, which we can approximate to a desired intention to comply with the measures.

Misinformation, Conspiracy Theories, and Public Health Measures

This section examines the relationship between conspiracy theories, misinformation, and public health measures using correlation and predictive analyses. As discussed earlier, we recategorized the search terms representing misinformation and conspiracy theories into two principal components. Hypothesis 3A, as defined in the Research Hypotheses section, focuses on misinformation and public health guidelines. At the same time, Hypothesis 3B addresses the impact of conspiracy theories on people's behavior toward the same safety measures.

Using correlation analysis to evaluate the association between conspiracy theories and public health measures, we observed a moderate positive linear association between ConspTheory2 and PubHealthMes2 (r=0.66) and a moderate linear relationship between ConspTheory1 and PubHealthMes1 (r=0.53). The log-linear analysis showed that conspiracy theories are not significant predictors of PubHealthMes1 (P=.62) but are for PubHealthMes2 (P=.008). Thus, the null hypothesis that there is no association between conspiracy theories (ie, ConspTheory1) and people's responses to public health (ie, wearing facial masks to limit the spread of COVID-19) is rejected. We can conclude that conspiracy theories are predictive of people's behaviors in wearing facial masks.

We also analyzed the relationship between misinformation and behavior toward public health measures. Although the correlation and the predictive analyses showed a moderate positive linear relationship between misinformation and PubHealthMes1 (r=0.83), it is not predictive. The relationship between the two variables is just mathematical but not causal. Despite a negligible negative linear relationship between misinformation and wearing a facial mask (r=0.11), the log-linear model shows that misinformation is not a significant predictor for both PubHealthMes1 (P=.27) and PubHealthMes2 (P=.13). Notwithstanding the strong linear relationship between web searches to learn about misinformation and public health measures, there is no sufficient evidence to reject the null hypothesis. We can conclude that there is no association between learning about COVID-19 misinformation and people's response to public health guidelines.

Discussion

Principal Findings

We found that people used search keywords related to past coronavirus epidemics (pastCoVepidemics) and the ongoing pandemic (presCoVpandemic) to learn about SARS-CoV-2 and COVID-19. However, the attention accorded to the pandemic led to less focus on terms relating to perennial illnesses (eg, "common cold," "flu," and more). These results corroborate studies reporting the unintended positive consequences of COVID-19 leading to declines in cases of influenza, flu, and similar infections (eg, Soo et al [46]). Other learning terms employed were keywords that addressed the pandemic directly. The average search indexes for those keywords were 19.01 for "nCoV" and "2019-nCoV," 39.75 for "SARS-CoV-2," and 32.40 for "COVID-19."

Studies examining learning by web searching emphasized the significance of the search terms or phrases on what the users intended to learn. A trending word on the web indicates what information people are interested in learning [11,61,66]. This study identified the 25 most-used keywords to learn about SARS-CoV-2 and COVID-19 through web searches.

Regarding the impacts of what people learned on their behavior toward public health measures, the PCA identified three latent variables, classified as misinformation, ConspTheory1, and ConspTheory2. Only ConspTheory1 ("@5G") directly and significantly influenced people's behavior toward public health measures (ie, PubHealthMes2 ["wear mask"]). The conspiracy that 5G technology enhances the easy spread of COVID-19 [14] highlights danger, which can cause people to take precautions. A different study [15] identified erroneous beliefs in the 5G

conspiracy theory as leading to the hoarding of essential goods during the initial period of the SAR-CoV-2 outbreak. Although there was a high correlation between misinformation (Tables 4 and 5) and behavior toward public health measures, this was not statistically significant based on the web search index. Also, as the pandemic lingers, thereby causing severe health and social crises, strains in family relations, and economic and business losses, many people are becoming increasingly aware of COVID-19 dangers [21,57,67-69]. Through direct impacts or by experience, this can cause changes in people's behavior irrespective of whether they believed the misinformation or not.

Strengths and Limitations

Internet platforms continue to play a significant role in health communication during the ongoing COVID-19 pandemic. Some studies attribute the increase in misinformation and conspiracy theories about COVID-19 in different countries to web searches, social media use, and online news media platforms that are used to learn about SARS-CoV-2 and COVID-19 [10,11,29]. However, most studies were anecdotal with no empirical evidence. Using Google Trends data, this study provides the first empirical evidence to this discourse. In the era of big data, the analysis of Google queries can be envisioned as a valuable tool for researchers to explore and predict human behavior, especially as studies suggest that online data can correlate with actual health data [70,71].

Infodemiology studies have their limitations too. While Google search keywords are short and easy to classify automatically, interpreting the terms semantically can be challenging. It is not clear why people are searching for these keywords. Furthermore, when using Google Trends, the sample is unknown and may not be representative, and individuals using the internet are not representative of the entire population. They are more likely to be younger, more educated, earn higher incomes, and reside in urban areas [18]. Individuals who are more likely to be severely affected by COVID-19 are not usually represented by this population [72,73]. Despite the identified limitations, previous studies suggest that web-based data provide valuable and valid results in exploring and predicting behavior and highly correlate with actual data [70,71]. Further, there are reports of rapid penetration of internet access and usage in different parts of the world, except for in regions with low internet penetration or countries with low scores in freedom of speech [22,74,75].

Conclusions

The results of this empirical infodemiology study showed that a good portion of the global population learned about the outbreak of SARS-CoV-2 and COVID-19 through web searches, particularly in the early period of the pandemic. The period covers the initial days, weeks, and months from the emergence of the novel coronavirus in January 2020 up to June 30, 2020, when the public became more aware of the pandemic, especially after the first wave [1].

The PCA showed that people used the web to learn about the ongoing COVID-19 pandemic in two ways, namely, using pastCoVepidemics keywords and using presCoVpandemic keywords. The use of pastCoVepidemics keywords in web searches nosedived as the WHO formally named the novel coronavirus and the disease (ie, "nCoV," "2019-nCoV," "SARS-CoV-2," and "COVID-19") and, therefore, as these terms became available. The trends analysis showed that web searches used to learn about COVID-19 followed a similar trend as learning about public health measures, implying that the more that people focused their attention on learning about SARS-CoV-2 and COVID-19, the more they also learned about public health measures, and vice versa. Interestingly, learning about the conspiracy theory (ConspTheory1) that 5G technology contributes to the fast global spread of COVID-19 is a predictor of people's behavior toward public health measures (PubHealthMes2). This erroneous belief makes people take precautionary measures, such as wearing a facial mask, although borne out of fear [14,15]. The same studies using the survey method also identified the same 5G-related conspiracy theory as making people respond out of fear to take precautions. This factor contributed to stockpiling of goods in the early days of the pandemic [15]. This study is the first to examine what people learned through web searches and how these influence people's social behavior toward public health safety guidelines.

Conflicts of Interest

None declared.

Multimedia Appendix 1
Summary statistics of the normalized daily global Google Trends scores for different keywords used in this study. Data correspond to the time window between January 1, 2020, and June 30, 2020 (N=182 data points).

Abstract

Background: Digital health interventions (DHIs) have the potential to improve public health by combining effective interventions and population reach. However, what biomedical researchers and digital developers consider an effective intervention differs, thereby creating an ongoing challenge to integrating their respective approaches when evaluating DHIs.

Objective: This study aims to report on the Public Health England (PHE) initiative set out to operationalize an evaluation framework that combines biomedical and digital approaches and demonstrates the impact, cost-effectiveness, and benefit of DHIs on public health.

Methods: We comprised a multidisciplinary project team including service designers, academics, and public health professionals and used user-centered design methods, such as qualitative research, engagement with end users and stakeholders, and iterative learning. The iterative approach enabled the team to sequentially define the problem, understand user needs, identify opportunity areas, develop concepts, test prototypes, and plan service implementation. Stakeholders, senior leaders from PHE, and a working group critiqued the outputs.

Results: We identified 26 themes and 82 user needs from semistructured interviews (N=15), expressed as 46 Jobs To Be Done, which were then validated across the journey of evaluation design for a DHI. We identified seven essential concepts for evaluating DHIs: evaluation thinking, evaluation canvas, contract assistant, testing toolkit, development history, data hub, and publish health outcomes. Of these, three concepts were prioritized for further testing and development, and subsequently refined into the proposed PHE Evaluation Service for public health DHIs. Testing with PHE's Couch-to-5K app digital team confirmed the viability, desirability, and feasibility of both the evaluation approach and the Evaluation Service.

Conclusions: An iterative, user-centered design approach enabled PHE to combine the strengths of academic and biomedical disciplines with the expertise of nonacademic and digital developers for evaluating DHIs. Design-led methodologies can add value to public health settings. The subsequent service, now known as *Evaluating Digital Health Products*, is currently in use by health bodies in the United Kingdom and is available to others for tackling the problem of evaluating DHIs pragmatically and responsively.

Introduction

For public health interventions to significantly impact healthy life expectancy in a population, reach has to be combined with efficacy [1]. Reach is the proportion of the target population affected by an intervention, and efficacy is the effect of an intervention on the individuals it reaches. There is considerable interest in the potential of digital health interventions (DHIs) to improve public health. DHIs are delivered on digital platforms, such as the web or smartphone apps intended to deliver health care or health promotion [2]. Such DHIs are expected to combine the reach of large-scale population initiatives, such as media advertising, with the efficacy of individual treatments. Furthermore, DHIs are intended to increase both capacity and access to public health initiatives by providing services in areas where face-to-face options are unavailable or unable to meet demand.

Although there is evidence for the efficacy of many DHIs in public health [3-10], few studies indicate that their public health potential is being realized in practice. What constitutes success is viewed differently by biomedical researchers and digital product developers. Biomedical research on digital health is heavily influenced by the pharmaceutical model with a focus on trials and effectiveness, whereas digital developers often focus on usability and acceptability [11]. However, both perspectives are required [11]. A digital product cannot be successful at scale without satisfactory usability. However, user ratings can be insufficient, sometimes bearing either no relation or even an inverse relation to the effectiveness of DHIs [12-14].

As a public health body with a finite budget and responsibility for improving population health, Public Health England (PHE) was at the forefront of considering how best to use DHIs to improve health outcomes and evaluate their value (measured as an improvement to public health). Multiple biomedical and digital approaches to the evaluation of DHIs exist and are described and critiqued elsewhere [2,11,15-18]. This paper reports on a project by PHE to develop and operationalize an evaluation framework that combines these approaches with the goal of demonstrating the impact, cost-effectiveness, and benefit of DHIs on public health.

Methods

Design

User-centered design (UCD), applied by a multidisciplinary team, was used to synthesize the strengths of digital evaluation approaches with those of the biomedical approach. The project objectives were as follows:

1. Identify core audiences and stakeholders for evaluation of DHIs (user groups)
2. Identify the needs of users for evaluating DHIs, including barriers and facilitators
3. Identify the key performance indicators (KPIs) and outcomes that different audiences and stakeholders consider important in evaluating DHIs
4. Identify evaluation methods (ways of conducting an evaluation study), tools (resources that can aid in carrying out an evaluation), and metrics (standard quantitative measures that can be used in an evaluation) applicable to DHIs
5. Prototype and test an evaluation approach for DHIs used in a public health context

User-Centered Design

A modified UCD approach, known as service design, was adopted. The UCD approach bases the design, testing, and development of a product or service on the needs of the users affected by it [13]. This approach, which began as a focus on the end user's interaction with products, has evolved into designing both products and services. It considers the needs of a broad range of users, including organizational users providing the service, users responsible for the finances and direction of the service, and other users in the service ecosystem. This holistic evolution is reflected in service design [19,20], a choreography of the processes, technologies, and interactions needed to set up and drive a service through a UCD perspective [21].

Service design helps reduce risk by investing upfront in validating a service proposition with end users before physically building the product or service (desirability and usability), clarifying what is required of the organization to deliver the service (feasibility), clarifying the potential business impact of the service (viability), having a strong focus on outcomes, and embedding the host organization's team that will eventually run the service in research and design activities [22]. By designing to meet the needs of users, service design methods are intended to ensure that the resultant service is more likely to be desirable, usable, feasible, and viable. Throughout this study, the term UCD refers to the service design variation.

The project team followed the English Government Digital Service's agile approach, comprising discovery, alpha, beta, and live phases [23]. This approach has subsequently been adopted by governments worldwide. This paper reports the discovery and alpha phases.

Setting and Project Team

At the time of the project, PHE was the national public health agency in England responsible for protecting and improving the nation's health and well-being and reducing health inequalities. The discovery phase was delivered from May to June 2018 and the alpha phase was delivered from August 2018 to March 2019. The beta phase commenced in July 2019 and was completed in 2021.

The project team was established using a competitive tender [19], where applicants read a seminal paper [2] about evaluating DHIs and presented an example of how they would integrate

evaluation into the design and development of a DHI. The successful applicant, Livework Studio Ltd, a service design agency, worked alongside the internal PHE team to form the overall project team (the project team).

In response to this challenge, Livework created a visual model showing how different evaluation approaches and metrics could be integrated into the design and experience of a DHI. The model or design object (Figure S1 in Multimedia Appendix 1) tangibly represents the problem of evaluating DHIs for various stakeholders. The model was iterated as the project progressed.

PHE formed a working group with representatives across the English health system, including the Department of Health and Social Care, National Institute of Health and Care Excellence (NICE), University College London (UCL), and the World Health Organization. The working group provided knowledge on the wider digital health landscape and sense-checked research and deliverables.

The project team conducted 14 *show and tells* in the discovery and alpha phases, wherein the project's progress was shared with a wider group of stakeholders (*Show and tells* are opportunities for team members to showcase their work to their team and wider stakeholders; it is a project management and engagement technique commonly used by digital professionals). This included sharing project plans, early research findings, and design outputs from different research sessions. Stakeholder feedback helped validate or raise concerns with the findings and linked the project team to initiatives in the wider digital health ecosystem.

Ethics

This project complied with the code of conduct of the Market Research Society as required by PHE's Research Ethics and Governance Group, and informed consent was obtained from the interview participants. The project's methodology and results were presented at two government-mandated service assessments [23] at the end of the discovery and alpha phases to ensure adherence to the government Service Standard [24] for digital projects.

Recruitment

Three categories of professionals involved in the design, development, and commissioning of public health DHIs were identified: academics, digital product developers (hereafter referred to as *digital developers*), and public health professionals. Research participants (N=15) for the interviews were selected to reflect these user groups. Additional participants were recruited in the following stages.

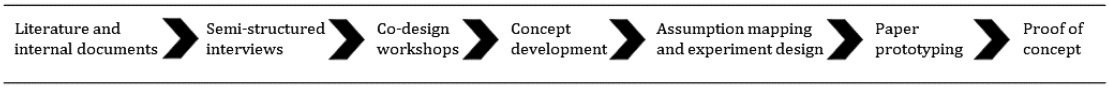
Academics were recruited for their expertise in developing and evaluating DHIs, as reflected in their publications and national reputation. Digital professionals with a track record of successful development and wide-scale deployment of DHIs were selected, including those working for PHE, National Health Service England and Improvement (NHSE/I), and the private sector. Public health professionals were selected for their experience of commissioning or delivering public health services via digital means and their strategic overview of the challenges involved. Within digital and public health professionals, those with and without experience of evaluating DHIs were sampled.

Results

Iterative Data Collection Methods Presented With Results

We used seven data collection methods: (1) review of the literature and internal documents, (2) semistructured interviews, (3) co-design workshops, (4) concept development, (5) assumption mapping and experiment design, (6) paper prototyping, and (7) proof of concept. The outputs of each stage were the inputs for the next stage (Figure 1). Through a series of iterative developments, the project team progressively evolved its understanding of the problem, user needs, and potential solutions. The seven data collection and analysis methods, along with the results of each stage are presented in the following sections.

Figure 1. The seven data collection methods with the output of each stage becoming the input for the next stage.



Review of the Literature and Internal Documents

Methodology

Internal PHE documents and sample publications on the evaluation of DHIs provided by PHE staff, including the paper by Murray et al [2] used in the supplier challenge, were reviewed. The aims of the review were to (1) develop an understanding of the problem space, (2) identify themes pertaining to evaluating DHIs—including barriers and facilitators—for exploration in semistructured interviews (project objective 2), and (3) identify evaluation methods, tools, and metrics applicable to DHIs (project objective 4). The evaluation methods identified were categorized into academic, health, economic, and digital methods. For each method, a simple description, scenarios of use, pros and cons, cost, time, and existing tools and guidance were captured.

The output of stage 1 formed the basis of a discussion guide (Multimedia Appendix 2) for the semistructured interviews (stage 2). Additional publications were collected and synthesized throughout the study.

Corresponding Results

The barriers identified were organizational and disciplinary silos associated with public health commissioning, design and development of digital services, and academic evaluation; unclear expectations and roles; different disciplinary expectations on what tools and methods to use for evaluation and how to measure success or failure; limited time, capacity, and funding; lack of evaluation experience; and rapidly evolving DHIs (inherent tension with resource- and time-intensive evaluations).

The facilitators identified were clear organizational goals (outcomes) and decision-making processes, prioritizing evaluation from the outset, ring-fenced funding, team capacity and resources, guidance and case studies, communities of practice, interdisciplinary collaboration, data standards, and constructive feedback.

The resultant discussion guide (Multimedia Appendix 2) was structured around the process of conducting an evaluation of a DHI, as identified from the review of the literature and internal PHE documents. Discussion guide sections included unawareness and initiation of an evaluation; setup, information, guidance, and tools; data, decisions, and outputs; and wrap up, outputs, and outcomes. Questions within each section were created to further explore themes pertaining to evaluating DHIs, including decision-making; intervention mechanisms of action; organizational obligations (to evaluate); metrics; success criteria; and feedback loops. For the different user groups, additional questions exploring the barriers to and facilitators of evaluating DHIs were added. In total, 46 evaluation methods were identified and categorized (Textbox 1; additional information captured is available upon request).

Semistructured Interviews

Methodology

Semistructured interviews were conducted to identify user needs (project objectives 1 and 2). Interviews explored participants' roles in relation to commissioning, designing, or developing DHIs; their understanding of evaluation; and their previous evaluation experience. Subsequent questions focused on the process of evaluation and its evolution as a DHI are developed, along with the key themes, barriers, and facilitators identified in stage 1.

Interviews were conducted by service designers with expertise in design research, lasted 60-90 minutes, and were audiorecorded. Detailed field notes were also provided. Both field notes and transcribed interviews formed a part of the data set.

An interview capture template was used to highlight and thematically organize the interview data. After each interview, the researcher reviewed their field notes and transcripts, highlighting the points of interest. These points were coded using a common set of themes based on the stages of the evaluation process (before, beginning, during, and after) and known areas of interest, such as collaboration, clinical risk, support and guidance, technology, and data, as identified in stage 1. If an observation did not obviously fit within an existing theme, a new theme was created to code it, or it was highlighted for further review by the wider project team.

Key user statements and interview observations generated the first iteration of user needs [18], including needs being met by current means of evaluating DHIs and needs that remained unmet or were causing difficulty and frustration in evaluation efforts. Identified user needs were articulated using an accepted UCD template called Jobs To Be Done (JTBD), which identifies the type of user, their need, when the need arises, and the outcome they are trying to achieve [25]. This structured articulation clearly communicates the user's needs to stakeholders and the project team.

After the initial round of analysis, the project team collectively reviewed all interviews; shared points of interest, observations, and user needs; and clustered them according to the common themes. User needs were mapped against a common user journey—a way of showing a user's journey through a service across time [26]. This produced an overview of where and when user needs occurred throughout the process of designing a DHI evaluation.

Corresponding Results

A total of 15 semistructured interviews were completed, five per target user group (Table 1). Some participants were invited to take part in multiple data collection stages, with 6 interviewees participating in the co-design workshops (stages 3 and 4), 4 co-design workshop attendees participating in paper prototyping (stage 7), and 1 interviewee participating in the proof of concept (stage 8).

In total, 26 themes about evaluating DHIs were identified and validated (Textbox S1, Multimedia Appendix 1). These themes were organized by a user group (academic, digital, and public health) and an evaluation stage (overview; unawareness and initiating an evaluation; setup, information, guidance, and tools; data, decisions, and outputs; outcomes, feedback, and decisions; and incidents and changes).

A total of 82 JTBD were generated (18/82, 21% academic; 37/82, 45% digital; and 27/82, 32% public health), derived from the outputs of stages 1 and 2. Table 2 shows an example of the semistructured interview analysis and the resulting JTBD.

The initial set of JTBDs was refined and augmented through feedback from stakeholders at the show and tells. The project team then reviewed the outputs and distilled the superset of research findings and user needs into a smaller subset of user needs or JTBD: (1) representing the essential stages of the journey, (2) most essential stages (ie, if the need was not met then subsequent needs could not be met), and (3) those stages most strongly indicated by research stages 1 and 2 (semistructured interviews and publications). The refined 46 JTBDs (13/46, 28% academic; 20/46, 43% digital; and 13/46, 28% public health) and the outputs of stage 1 formed the input for the first co-design workshop.

Table 2. For each user group, we provide an example aligned theme, illustrative quote, and Jobs To Be Done mapped to the relevant evaluation stage.

User group	Evaluation stage	Theme	Illustrative quote	Jobs To Be Done
Academic	Stage 2: setup, information, guidance, and tools	Evaluation methods	"You have a set of tools and paradigms that are going to be suitable for different types of problems. When you're investigating different types of problems, for particular types of stakeholders, which particular types of objectives, or even particular types of technology, or particular stages of innovation, you have to be careful about finding the right thing and not trying to squeeze a round peg into a square hole."	• As an evaluator • When I design/set up an evaluation • I need access to a range of evaluation tools and paradigms • So that I can choose the one fit for the problem
Digital	Stage 4: outcomes, feedback, and decisions	Design process	"It's fundamental to my role in a non-academic non-traditional sense, as far as a non-empirical sense, because I'm the one who manages [metric company name] and given what it takes to insure and also the research we conduct with users to define and validate services prior to committing resources developing them. But also to maximize them later, so we use informal or design led evaluation means to validate, to research, to prove assumptions prior to designing things."	• As a digital professional • When deciding what to design and how to design it • I need to validate service propositions by proving assumptions • So that I can be confident in committing resources developing them
Public health	Stage 0: overview	Funding and costs	"First, we're using it to channel shift. So, if we can get people to use digital interventions rather than face-to-face interventions which are much more expensive, then we're developing a range of products and services around that. On sexual health, we have a new program on contraceptive access for women to help them to make choices online and to get their contraceptive online rather than going in through GP[a] services."	• As a Director of Public Health and Well-being • When I am planning service changes • I need to know if people will use a digital approach • So that we can save money by shifting service from more expensive face-to face-services

[a]GP: general practitioner.

Co-design Workshop 1

Overview

Two co-design workshops were held to (1) validate the findings from semistructured interviews (project objectives 1 and 2), (2) help create a user journey that reflected the user requirements for all three user groups (project objective 2), (3) identify evaluation methods, tools, and metrics applicable to DHIs (project objectives 2, 3, and 4), and (4) consider the structure of DHIs (ie, intervention component and delivery component; project objectives 4 and 5).

Methodology

Findings from stages 1 and 2 were articulated as JTBDs or user needs for each of the three user groups. These were mapped onto a user journey reflecting all stages for meeting the goal of evaluating a DHI (Figure S2; Multimedia Appendix 1). This mapping was used to reflect the timings and interdependencies of each step and the user needs preceding the evaluation of a DHI.

Workshop participants were divided into groups of three: one person from each profession (digital, public health, and academic). These trios worked through the draft user journey from the perspective of a specified user group, discussing reactions, validating the user needs that they recognized, editing where necessary, and adding missing user needs. The exercise was repeated twice until each trio reviewed the draft journey from the perspective of all three user groups. Reviewing all three sets of user needs promoted the understanding of other perspectives among the workshop participants and the project team.

Participants then reviewed and edited a catalog of 46 evaluation methods and tools collated by the project team in stages 1 and 2. Participants considered different ways of categorizing them according to the timing in the journey of planning and conducting an evaluation.

Corresponding Results

Workshop participants validated, refined, or rearticulated the 46 JTBDs (13/46, 28% academic; 20/46, 43% digital; and 13/46, 28% public health) across the stages of the evaluation journey. A further 27 JTBDs (8/27, 29% academic; 1/27, 3% digital; and 18/27, 66% public health) were added by workshop participants. The project team had a total of 73 JTBDs (21/73, 28% academic; 21/73, 28% digital; and 31/73, 42% public health) at the end of the first workshop.

The first co-design workshop structure also exposed participants representing the three user groups to the aims, perspectives, and corresponding needs of the other user groups. Participants were observed sharing points of view, articulating their needs that were not self-evident to other user groups, and learning where their respective needs coincided. Furthermore, the different user groups learned about the scope and responsibilities of each other's roles and where interdependencies between their needs and evaluation activities were.

Workshop participants reviewed, validated, and differentiated the evaluation catalog into evaluation methods, tools, or metrics. Of the initial 46 evaluation methods, tools, and metrics, six were amended, and the participants added three methods, three tools, and 14 metrics.

Participants were observed learning about evaluation methods, tools, and metrics they had not previously used, including their benefits and potential scenarios of use. Participants from different user groups shared with each other how they used the evaluation methods, tools, and metrics in their own role and how they chose the appropriate one, for example, based on the potential health risk of a DHI.

After the first co-design workshop, the project team collectively reviewed the outputs and distilled the 73 JTBDs (21/73, 28% academic; 21/73, 28% digital; and 31/73, 42% public health) into a smaller subset to be used as design stimulus for the second co-design workshop. Following the same process for selecting a subset of user needs as performed in stage 2, the subset of JTBDs was selected by (1) representing the essential stages of the journey, (2) most essential need (ie, if the need was not met then subsequent needs could not be met), (3) those needs most strongly indicated by research stages 1-3, and (4) those needs that were actionable and useful as stimuli for a design workshop.

The project team prioritized 9 JTBDs (3/9, 33% academic; 3/9, 33% digital; and 3/9, 33% public health; Table 3) for input into the second co-design workshop. The resultant catalog of evaluation methods, tools, and metrics from the first co-design workshop formed the basis of an evaluation method catalog (project objective 4) used in stage 8 (proof of concept: prototype of full-service experience).

Table 3. The nine Jobs To Be Done prioritized for co-design workshop 2, with three prioritized per user group.

User group	JTBD[a] 1	JTBD 2	JTBD 3
Public health	• As a public health professional • When reviewing the outcomes of an evaluation • I need the flexibility within the project and team to make decisions that change the direction of the project • So that learnings can be used to change the service for the better	• As a public health professional • When evaluating a service • I need to know if the service is having an impact on key metrics • So that I can make an investment case for rolling the service out at scale	• As a commissioner • When writing a brief • I need to set expectations around metrics, methods, and implementation as well as provider skills and capabilities • So that providers can build these into their solution design and implementation plan
Academic	• As an evaluator • When evaluating a health product or service • I need access to clean, accessible and linked data from across the health system • So that I can do my evaluation	• As an evaluator • When designing or setting up an evaluation • I need access to a range of evaluation tools and paradigms • So that I can choose the one fit for the problem	• As an academic evaluator • When doing evaluation • I need an in-depth understanding of the intervention and the pathway of action • So that I can properly evaluate it
Digital	• As a digital professional • When evaluating a service qualitatively • I need to be able to observe users • So that I can understand why they are having difficulties	• As a digital professional • When planning a DHI[b] • I need to know what sort of evaluations might need to take place • So that I can be prepared to participate	• As a digital professional • When deciding what to design and how to design it • I need to validate service propositions by testing assumptions • So that I can be confident in committing resources to develop them

[a]JTBD: Jobs To Be Done.

[b]DHI: digital health intervention.

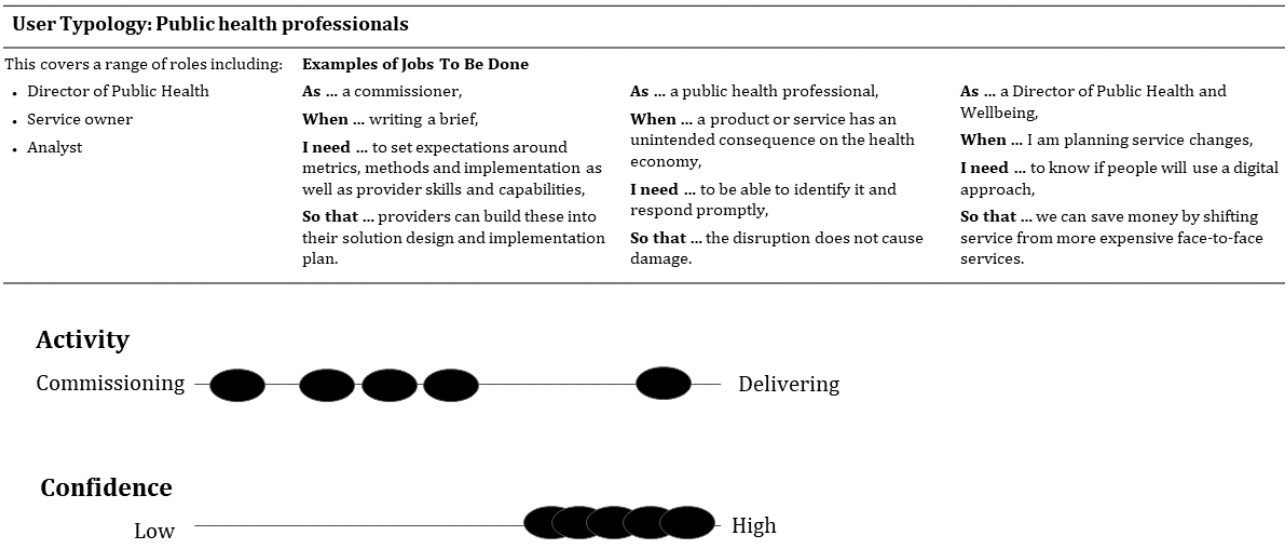
Co-design Workshop 2

Methodology

The second co-design workshop was built on the first and aimed at designing concepts for an evaluation framework for DHIs in a public health context (project objective 5). Attendees worked in groups of three, as before. Using a DHI case study, the attendees created a concept for an Evaluation Service by imagining how a user would conduct an evaluation in each case. Stimulus materials, comprising interactive design artifacts and JTBD from stages 1 to 3 and those specifically created for the workshop (Figure S3 in Multimedia Appendix 1), provided some structure for creating the concept. Attendees synthesized these inputs into a service concept that they named, described, and visualized using a concept template (Figure S3 in Multimedia Appendix 1). Each concept was shared with all workshop attendees for feedback.

Workshop outputs included a series of eight conceptual drawings and descriptions. Using the outputs from stages 1 to 4, the project team further articulated the different user groups as user typologies [27] based on key dimensions of difference (Figure 2).

Figure 2. User typology for public health professionals evaluating a digital health intervention (black circles indicate the distribution of participants in stage 2 semistructured interviews).



Corresponding Results

The workshop produced eight raw concepts considered essential by the participants for the DHI evaluation framework:

1. Integrated evaluation: builds in evaluation thinking, skills, and tools at the beginning of the DHI development process.
2. Parallel playbook: a series of experiments to validate DHI propositions and iterate these to validate the impact.
3. Contract guidance: a person to help write contract terms, thereby ensuring providers build evaluation into the design and agree to cease or change course if the desired outcomes are not indicated.
4. Measurements aggregator: a way to discover and integrate health outcome measures into one place. This would enable digital teams to explore health outcome data and make informed decisions when developing their DHI.
5. Standardized way of collecting or structuring data: a visible, accessible history of the development process for a DHI and how it was evaluated.
6. Conventional medical model: linking user data from a DHI to how it affects end users' health outcomes.
7. Access shortcuts: an NHS data owner who has an agreement with the local authority and clinical commissioning group for sharing and accessing data to inform DHI development and evaluation.
8. Innovation framework: a PHE open-source innovation framework for understanding the DHI context and sharing data.

Figure 2 shows the user group typologies designed using the dimensions of activity in evaluation (commissioning or delivering) and confidence in evaluation (low or high).

Concept Development and Prioritization

Methodology

Stages 1 to 4 outputs formed the basis of the concepts the project team further developed, prioritized, and carried forward. We synthesized seven distinct concepts for evaluating DHIs with clear propositions to support prioritization by the project team and working group (Table 4; Multimedia Appendix 3, containing the image of project team member synthesizing stages 1-4 outputs into the seven distinct concepts for evaluating DHIs). How each concept was linked to meet user needs via three key interconnected *scenarios of use* was visualized (Figure 3).

The concepts were scored and prioritized according to the following criteria: meeting user needs, delivering on project objectives, and feasibility for implementation within the PHE. The highest scoring concepts were taken forward into the alpha phase of the project.

Table 4. Final seven concepts for evaluating digital health interventions and underlying Jobs To Be Done.

Concept	Concept proposition	Example underlying JTBD[a]	Sample user quote[b]
Evaluation thinking	• When doing a digital health project at PHE[c], evaluation thinking, skills, and tools should be integrated into the project from the start. • Evaluation needs to be a central part of the design process and iterative delivery of any PHE service or product.	• As a Director of Public Health • When commissioning services • I need evaluation to be aligned closely with service delivery • So that it is formative and not a separate piece of work	"You have to get them at the beginning. And it's really hard when you don't get them at the beginning, 'cause then you've got to try and do a retrospective evaluation. You never have the right data. It's never as good of quality."
Evaluation canvas	• The evaluation canvas is PHE's validated and accepted portfolio of metrics, tools, and methods for evaluating DHIs[d]. • This canvas is the first step to creating a knowledge base on the effectiveness of digital health in meeting health outcomes and will support decisions on policy, practice, and research.	• As an evaluator • When designing or setting up an evaluation • I need access to a range of evaluation tools and paradigms • So that I can choose the one fit for the problem	"You have a set of tools and paradigms that are going to be suitable for different types of problems. When you're investigating different types of problems, for particular types of stakeholders, which particular types of objectives, or even particular types of technology, or particular stages of innovation, you have to be careful about finding the right thing and not trying to squeeze a round peg into a square hole."
Contract assistant	• A way for PHE teams to create strategic relationships with suppliers, supported by forward-thinking contracts. • A core requirement when working for PHE will be embedding evaluation into the design and development of the DHI and allowing for flexibility in contracted deliverables as the DHI progresses.	• As a public health professional • When setting up evaluations • I need to get the data-sharing agreements in place as simply as possible • So that I can collect, collate, and evaluate the data	"It's setting a level of expectation...as part of their bids, they need to articulate how they're going to capture data and how they're going to evaluate. And we needed some commonality so that if we have three sites, we can compare across the three sites... aggregate all our data together."
Testing toolkit	• Simple tools and methods to enable PHE teams delivering a DHI to test all aspects of the service or product throughout the development journey. • The toolkit could include a guide for face-to-face research, approaches to and models for planning and prototyping, functionality for randomizing users, and digital solutions for validating propositions in the market and/or against existing services.	• As a digital professional • When deciding what to design and how to design it • I need to validate service propositions by testing assumptions • So that I can be confident in committing resources to develop them	"It's fundamental to my role...I'm the one who manages [metric company name] and...also the research we conduct with users to define and validate services prior to committing resources developing them. But also to maximize them later, so to use informal or design-led evaluation means to validate, to research, to prove assumptions prior to designing things."
Development history	• A tool for PHE to record the full development history of their DHI project. This will support decision-making, facilitate process evaluation, and enable successful assurance in line with the Government Digital Service pipeline approach. • This record would include user needs, decisions and rationale, testing methods and results, information about the underlying technology, and stakeholder mapping.	• As an academic evaluator • When doing evaluation • I need an in-depth understanding of the intervention and the pathway of action • So that I can properly evaluate it	"You need a really good understanding of how and why these things are working and what you're changing...which is often much more complex than people gather."

Concept	Concept proposition	Example underlying JTBD[a]	Sample user quote[b]
Data hub	• PHE's data hub provides access to high-quality, accessible, and understandable public health data for providers, academia, and the wider market. • Similar to Transport for London's Open Data, PHE will encourage developers to use PHE's data feed to solve public health problems in innovative ways. • By setting the standard for the metrics in the data hub and promoting collaboration, this data hub may, in the future, allow for longitudinal analysis of DHIs.	• As an evaluator • When evaluating a health product or service • I need access to clean, accessible and linked data from across the health system • So that I can do my evaluation	"A lot of their datasets are in silos, they're maybe not using data the most effectively."
Publish health outcomes	• A place for stakeholders to publish and share how DHIs have met or not met desired health outcomes. This promotes collaboration among teams working in similar areas and enables sharing of best practices. • Collaboration among PHE, public health professionals, academia, and suppliers working in digital public health aligns with the Government's Industrial Strategy and the NHS[e] Innovation Strategy.	• As a digital professional • When working with PHE • I need to understand clearly what clinical data is required • So that I can be clear what success or impact looks like and can provide clinical impact	"We moved away from a lot of input and process measures, and balanced it with output and outcome measures, so we know now what impact they're having with individuals that they're working on, particularly their mental well-being, the escalation of demand into adult social care, and how they're embedding into a neighbourhood context more than they used to before."

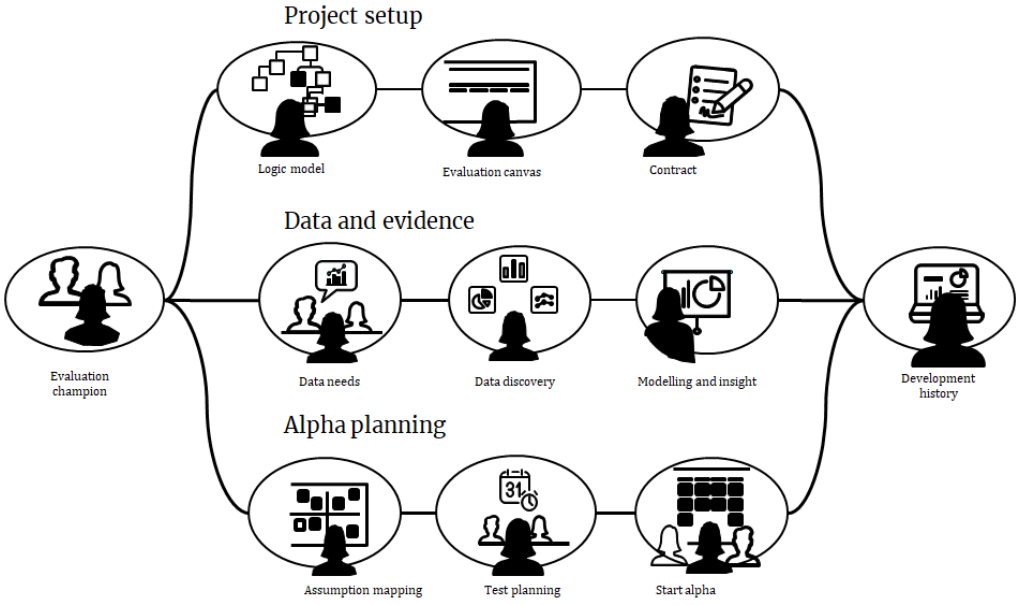
[c]PHE: Public Health England.

[d]DHI: digital health intervention.

[e]NHS: National Health Service.

Figure 3. Scenario of use illustrating how the final concepts fit together to facilitate setting up digital health intervention evaluations from conception (project setup) through collection of data and evidence to planning testing of minimum viable products (evaluation planning).



Corresponding Results

See Table 4 for the final seven concepts created to evaluate the DHIs. The concepts integrated perspectives and approaches from all three user groups and were combined into a *scenario of use* for PHE stakeholders. Figure 3 illustrates how the concepts fit together into a proposed Evaluation Service for helping teams evaluate their public health DHIs. Three concepts

were prioritized to take forward to the next phase of work: evaluation thinking, evaluation canvas, and testing toolkit. The evaluation thinking concept was taken forward in a separate work stream and is, therefore, not discussed in this paper. Textbox 2 illustrates how one of the final concepts, evaluation canvas, was derived and iterated through the methodology outlined in stages 1 to 5. This is an iterative process with multiple feedback loops rather than a linear one. See Tables S1 and S2 in Multimedia Appendix 1 for how the prioritized concepts, testing toolkit, and evaluating thinking were derived.

Textbox 2. Sample Jobs To Be Done life cycle from primary research (stages 1 and 2) to co-design workshops (stages 3 and 4) to refined concepts prioritized by Public Health England for further development (stage 5) in evaluating digital health interventions.

Evaluation Stage

- Stage 2: setup, information, guidance, and tools

Theme

- Evaluation methods

User Quote

- "You have a set of tools and paradigms that are going to be suitable for different types of problems. When you're investigating different types of problems, for particular types of stakeholders, which particular types of objectives, or even particular types of technology, or particular stages of innovation, you have to be careful about finding the right thing and not trying to squeeze a round peg into a square hole."

Jobs To Be Done

- As an evaluator
- When I design/set up an evaluation
- I need access to a range of evaluation tools and paradigms
- So that I can choose the one fit for the problem

Raw Concept From the Co-design Workshop 2

- Parallel playbook:

  a series of experiments to validate digital health intervention propositions and iterate these to validate impact

Refined Concept for Further Development

- Evaluation canvas:

  the evaluation canvas is Public Health England's validated and accepted portfolio of metrics, tools and methods for evaluating digital health interventions. This canvas is the first step to creating a knowledge base on the effectiveness of digital health in meeting health outcomes and will support decisions on policy, practice, and research.

Assumption Mapping and Experiment Design

Methodology

Assumption mapping and experiment design were performed to understand what needed to be true for each of the prioritized concepts to work in practice within PHE (project objective 5). This means, for example, that end users find the concept understandable, usable, desirable, and feasible within their workflow (project objectives 2 and 3).

For each concept, the project team identified assumptions and articulated a hypothesis in the form of "We believe [insert user] will [action]." This activity helped identify the circumstances in which a hypothesis would be considered true or false and therefore whether the assumptions were correct or erroneous. Experiments were conducted to test each hypothesis, including design artifacts for stimulating feedback. These experiments were a combination of thought experiments and practical tasks.

The outputs (prioritized concepts) from stages 1 to 5 and the subsequently articulated assumptions, hypotheses, and potential experiments (stage 6) formed the input for the paper prototypes (stage 7), which made the experiments tangible for the participants and project team.

Corresponding Results

The underlying assumptions and associated hypotheses were mapped for two concepts, evaluation canvas and testing toolkit, and for the proposed Evaluation Service overall. Ten assumptions were mapped with ten hypotheses (Table S3, Multimedia Appendix 1).

Paper Prototypes

Methodology

Testing sessions were held with both individual users and teams (Table 1) running a live DHI. These sessions differed from the semistructured interviews as they tested whole or partial solutions for the service using paper prototypes (project objective 5). These sessions were used to understand (1) all of the requisite steps, (2) the depth of each individual step, and (3) how the steps should be ordered and interrelated. They enabled the project team to iteratively test their understanding and clarify

the evaluation approach. For example, to build a project team's high-level understanding of the potential service (project objective 5), paper cards representing the stages of the emerging Evaluation Service journey were created (see Multimedia Appendix 3, item 2A showing the image of paper cards representing the stages of the emerging Evaluation Service journey used in stage 7, paper prototyping). Teams put these cards in the order that made the most sense to them and added any missing steps (see Multimedia Appendix 3, showing the image of paper cards representing the stages of the emerging Evaluation Service placed in order by user research participant in stage 7, paper prototyping).

Interactive design artifacts were also used to learn more about the individual steps of the Evaluation Service journey. This included testing logic models (conceptual models representing how a product is expected to work) and service blueprints [28] (diagrammatic representations of how the front- and backstage of a service function and dependencies) to learn how DHI teams align on the desired health outcomes and how they assess whether their DHI meets user needs.

The project team turned each of the aforementioned steps into interactive workshop activities to participate in DHI teams. First, they printed the logic model template and put it on the wall, with descriptions for each step (see Multimedia Appendix 3 showing the image of interactive workshop testing the logic model with a DHI team in Stage 7, paper prototyping). The DHI team then went through each step together. The project team observed the DHI team's conversations and interactions, noting whether the activity made sense to them, the questions they asked, and the group discussion.

The project team conducted a similar interactive workshop with the service blueprint (see Multimedia Appendix 3 showing the image of interactive workshop testing the service blueprint with a DHI team in stage 7, paper prototyping). In addition to describing the user's needs and actions, the service blueprint can include layers reflecting the service touchpoints and features, as well as the organizational delivery point of view, such as the people, processes, policies, and systems [29] required to bring each stage of the user experience to life.

The service experience tested had both analog (eg, in-person workshops) and digital components (eg, a digital platform). The proposed digital platform, which includes evaluation guidance and printable workshop materials, is referred to as the Evaluation Service. The Evaluation Service idea was tested with users using wireframes to represent the digital experience of a landing page and web pages for each step of the Evaluation Service. This enabled the project team to learn what users expect from a digital platform, as well as their feedback on content and design. The project team turned the outputs of stage 7 into a prototype of a full Evaluation Service, which was the input for stage 8 (proof of concept).

Corresponding Results

Seven partial service experience paper prototype sessions were conducted with a range of participants (Table 1). The project team collated insights from each session, presented below, which corresponded to the concepts and hypotheses tested (Table S3, Multimedia Appendix 1).

The outputs of the paper card sorting exercise resulted in ordered steps for evaluating a DHI: building an interdisciplinary team, creating a conceptual model (logic model), creating a detailed service blueprint, selecting relevant indicators against health outcomes, selecting relevant evaluation methods (testing toolkit), and learning how to use selected methods and indicators to evaluate a DHI (testing toolkit and evaluation canvas).

By testing different paper versions of conceptual models (logic models and/or theory of change), the project team learned that the logic model was the simplest tool. Participants expressed the benefits of a logic model: looking at the bigger picture, choosing KPIs, prioritizing important outcomes to aid decision-making, capturing and updating project elements such as objectives, explaining how a DHI worked, and cocreating DHI project value with stakeholders. These sessions also revealed that the more a DHI team presents the bigger picture of what they are trying to achieve, the better the resultant understanding of the team and stakeholders.

These testing sessions demonstrated that participants focused more on measuring the uptake of a DHI than the impact on health outcomes. Teams did not know about national resources, such as PHE's Public Health Profiles (Fingertips), and so did not link their DHI to nationally recognized health measures. The project team observed that participants would benefit from signposting and guidance in the proposed Evaluation Service to link nationally recognized and validated measures.

Participants preferred the printed workshop format of the logic model rather than a web-based version, as it was easier to collaborate. Participants requested more accessible language and the use of arrows to indicate causality. Participants liked referring to previous or example logic models to see whether their version made sense by comparison. It was suggested that example logic models and guidance should be part of the proposed Evaluation Service offering.

The result of testing the evaluation canvas was breaking it down into its constituent parts and merging it into the Evaluation Service. For example, the program elements were absorbed into the context section of a logic model.

From testing paper and digital versions of the service blueprint, the project team learned that participants responded well to the dimension of time it introduced and the ability to reflect on user experience throughout time as a result of a DHI (not) meeting a user's needs. By mapping a DHI to its place or impact on a user's journey (via the service blueprint), participants articulated that they could see the gaps in their understanding of user needs and the features of their DHI. Adding the backstage detail (ie, organizational elements: people, processes, policies, and systems) to the service blueprint also gave participants a better understanding of what their DHI did well and where it could be improved.

Overall, the paper prototype testing revealed that the proposed Evaluation Service should contain information about (refer to Table S3, Multimedia Appendix 1 for details on each hypothesis) the following aspects:

- How to determine the aim of a DHI evaluation with health and service outcomes as core elements of building an evaluation strategy (hypotheses G1, G3, T1, C1, C2, and C3).
- Set up an evaluation at the beginning of DHI development (hypotheses G2.1, G2.2, and T2).
- Process and steps for DHI evaluation (hypothesis T2).
- Constant revision and integration of evaluation strategy into DHI development (hypotheses T1, T2, and C1).
- Who is involved in DHI evaluation (hypotheses T3, C1, and C3).
- Different types of evaluation (impact, process, and health economics; hypothesis C1).
- Selection of evaluation methods and tools (hypotheses T1, T3, C1, and C2).
- Required capabilities and resources (hypotheses G2.1, T1, T3, and C3).
- Barriers that may be encountered during an evaluation (hypotheses C1, C2, and T1).
- External policy and stakeholder factors influencing an evaluation (hypotheses G1).
- Creating a common language and understanding among different disciplines involved in DHI evaluation (hypotheses G3, T1, T3, C1, and C3).

Proof of Concept: Prototype of the Full-Service Experience

Methodology

Stages 1 to 7 culminated in the project team conducting a proof-of-concept test in which a digital team followed the proposed Evaluation Service to build an evaluation approach for their DHI (project objective 5). The proof of concept was a series of workshops run with PHE's Couch-to-5K app in-house digital team (see Multimedia Appendix 3 showing the illustration of stage 8 proof of concept: prototype of the full-service experience conducted with PHE's Couch-to-5K app in-house team showing the paper prototyping interactive workshops and associated digital materials). For example, the Couch-to-5K team used the logic model workshop template to define the problem they were addressing and clarify the desired health and service outcomes. They used a service blueprint template to describe users' needs, experiences, and actions concerning service touchpoints and features, organizational and operational capabilities, and actions, as well as the desired health outcomes.

In addition to testing these sequential design artifacts, an evaluation facilitator role was tested in each workshop with the Couch-to-5K team. The Couch-to-5K team was provided with relevant materials and a brief introduction to the workshop aim and then invited to move through the activity as independently as possible. The Couch-to-5K team was observed to see what made sense to them and what they understood correctly. When the Couch-to-5K team needed help, the evaluation facilitator provided guidance; this helped identify when the guidance or materials were unclear and when a DHI team would need and value facilitator support.

Corresponding Results

The logic model workshop brought the Couch-to-5K team together around a shared view of the health outcomes they were trying to deliver for Couch-to-5K app users. By mapping user needs to the service blueprint and aligning them with service features, the Couch-to-5K team obtained a shared view of the user needs and their relation to the desired health outcomes. The Couch-to-5K team identified unmet basic needs (eg, incidents) and areas for improvement in the evaluation journey. The Couch-to-5K digital team was alerted to different evaluation methods and tools relevant to their product and its context (including maturity, budget, time constraints, and risk profile). Spending time reflecting on KPIs highlighted to the Couch-to-5K team additional pertinent indicators worth beyond what they already collected (eg, KPIs related to the broader physical activity market). The Evaluation Service experience subsequently informed the design of the Couch-to-5K behavioral database (incorporating newly identified KPIs aligned to desired health outcomes).

Discussion

Principal Findings

PHE collaboratively developed an Evaluation Service with digital developers, academics, and public health professionals involved in the commissioning, design and development, and evaluation of DHIs. Following an iterative UCD approach, which was novel for PHE, the project team worked across and synthesized each discipline's areas of importance in relation to evaluating DHIs. An in-depth collective understanding of how biomedical and digital evaluation activities map to and can be used during the design and development of a DHI resulted. Testing with PHE's Couch-to-5K app in-house digital team demonstrated the desirability, viability, and feasibility of the Evaluation Service and led to further investment by PHE.

The primary strength of the work was in PHE's organizational openness to UCD and service design methodologies that were, at the time, not commonly used by the national body. Although this sparked some cultural tensions, doing so led to knowledge sharing between the external supplier and internal PHE project team and stakeholders, facilitated the synthesis of biomedical and digital evaluation approaches, and grew PHE's understanding of the benefits of user-centered approaches for designing and evaluating DHIs. Through extensive user and stakeholder engagement throughout the project, we demonstrated to PHE senior leaders and other health system organizations that *design is your friend* and there is a place for design disciplines in public health.

As PHE adapted to the UCD project approach, the project team unearthed tensions among participants such as discomfort with the *fast pace* of the 2-week sprints, divergent expectations on what was considered *good enough* evidence for justifying a user need or concept, and hesitance to try new methods and work in the open. Although some of the PHE stakeholders were initially uncomfortable with the pace and *roughness* of concepts and prototypes, they appreciated that the quick, iterative UCD approach enabled more people to interact, provide feedback, and contribute to the development of the Evaluation Service.

The Evaluation Service was thereby informed by, and socialized with, a wider range of professionals involved in DHI development and evaluation. PHE's senior stakeholders also acquired substantial evidence of the user's need for the Evaluation Service before requesting further investment from the organization.

Limitations

We identified three key limitations of this study. First, the sample size in qualitative design research is often small compared with traditional academic qualitative research. This typical design research practice is based on the finding [30,31] that speaking with a representative sample of 5 to 10 people at a time is sufficient to uncover common challenges, understand underlying causes, and inform decisions. In design research and digital development, as outlined by the Government Digital Service [32], the limitation of small sample size is usually overcome by conducting iterative research and increasing the number of users testing and feeding back on the service as it progresses through the initial phases (discovery and alpha) to later phases (beta and live). In this way, the team's understanding continues to grow as the sample size becomes larger and more diverse with time. The sample size of participants was increased in the later stages of this project; however, this is not within the scope of this paper. Second, PHE's organizational remit and limited financial and human resources resulted in the underutilization of concepts, with only three of the final seven concepts (Table 4) prioritized for further development by PHE. As shown in the *scenario of use* (Figure 3), the seven concepts complemented each other, and, through the prioritization exercise, the potential of the scenario was not fully tested. Third, substantial time and input were drawn down from members of the working group and relevant PHE senior leaders to upskill service design project team members in evaluating DHIs and share tacit knowledge of evaluating DHIs. This was a strength of the project, as the project team was able to bring a fresh perspective to drawing insight from experts and users as they designed the Evaluation Service; however, the personnel cost must be recognized.

Conclusions

The potential of DHIs to combine the reach of large-scale population initiatives with the efficacy of individual treatments is yet to be fully realized. It will continue to be unrealized if how we evaluate and use evaluations to inform the iterative design and development of DHIs do not use the perspectives of both biomedical research and digital development. DHIs are an interdisciplinary endeavor, bringing together clinical or population health interventions, digital product development, product and service design, and communication and health promotion. Hence, the evaluation of DHIs is best informed by interdisciplinary approaches to evaluation to understand both the efficacy of a DHI and its usability and desirability, with measures of success that reflect the different stakeholders involved in the commissioning, design, and development of a DHI and its end users [11].

We have outlined the work undertaken by PHE, a national body, to ensure that DHIs contribute to the improvement of population health and that taxpayers receive the most value (improvement to public health) from investment in digital health. The project is a worked example of using UCD, particularly service design, methods to iteratively understand, synthesize, and embed needs and evaluation approaches of both biomedical researchers and digital product developers. Public health's traditional approach is complemented by the UCD approach, which in turn is made safer and more robust through its interaction with public health. The resultant Evaluation Service enables digital developers or nonacademics to apply evaluation thinking and techniques during the design, development, and implementation of their DHI. By doing so, it demystifies evaluation, traditionally the realm of academia, and harnesses people's motivations to ensure that their DHI is as good as it can be and improves end users' health and well-being. PHE has subsequently built a digital version of the Evaluation Service (named *Evaluating Digital Health Products*), which is openly available on the web [33].

Acknowledgments

The authors acknowledge and thank the PHE team who delivered the discovery and alpha phases of *Evaluating Digital Health Products* (in alphabetical order): Iain Cooper, Simon Dixon, Charlotte Fountaine, Felix Greaves, Bernie Hannigan, Kassandra Karpathakis, Vicki Litherland, Ros-Mari Mitova, Claire Rackstraw, and Joseph Reynolds. The authors acknowledge and thank the Livework Studio Ltd team who delivered the discovery and alpha phases (in alphabetical order): Anton Drachuk, Lilli Graf, Claire Henderson, Gene Libow, Nick Manson, Ben Reason, and Paul Sims. The authors acknowledge and thank the project's working group (in alphabetical order, affiliations at the time the project was delivered): Jamie Brown, UCL; Tim Chadborn, PHE; Darren Curry, NHS Business Service Authority; Kenny Deighton, PHE; Pall Johnson, NICE; Indra Joshi, NHSE/I; Scott Mahony, PHE; Elizabeth Murray, UCL; Felix Naughton, University of East Anglia; Claudia Pagliari, University of Edinburgh; Colin Pattinson, Department of Health and Social Care; John Powell, NICE; Susannah Robinson, World Health Organization; Mark Salmon, NICE; Tero Väänänen, NHS Digital; and Matthew Walmsley, PHE. The authors acknowledge the financial support received from PHE.

Authors' Contributions

KK, SD, and FG were involved in the conception of the project and funding acquisition. KK and GL led the methodology, data collection and curation, formal analysis, and project administration. KK, GL, SD, FG, and EM were involved in the validation of the project with SD and FG, which also contributed to the formal analysis. FG and SD provided the senior institutional

leadership. EM provided senior academic leadership. KK, GL, and EM wrote the first draft, and all authors reviewed and edited the subsequent drafts. HP and KK edited the final drafts. HP is the corresponding author. KK is the guarantor. All authors read and approved the final version of the manuscript.

Conflicts of Interest

KK was employed by PHE and at the time of writing was employed by NHSX. GL was contracted by PHE as an employee of Livework Studio Ltd to complete this project. HWWP was employed by PHE in an honorary academic contract. He received funding support from NHSE/I, and has done or is doing consultancy for Babylon Health and IpsosMORI and has had a recent project grant with Six to Start. He has PhD students funded by Patients Know Best and by AstraZeneca. SD was employed by PHE and is currently employed by NHSX. FG was employed by PHE and is currently employed by NICE. EM has no conflicts of interest to declare.

Abstract

Background: Perioperative anxiety is a major burden to patients undergoing surgeries with general anesthesia.

Objective: This study investigated whether a virtual operating room tour (VORT) before surgery can be used to ameliorate perioperative anxiety.

Methods: We employed a randomized parallel-group design with 2 study arms to compare VORT to the standard operation preparation procedure. The study included 84 patients. A validated inventory (state-trait operation anxiety-state) was used to assess perioperative state anxiety before (T1) and after (T2) surgery. In addition, trait operation anxiety was evaluated with an additional validated inventory (state-trait operation anxiety-trait). Moreover, user ratings on the usefulness of VORT were assessed with an evaluation questionnaire. Study arms were compared for perioperative state anxiety with two-tailed independent samples *t* tests. Subjective ratings were correlated with STOA-Trait values to investigate possible associations between perioperative anxiety with perceived usefulness.

Results: There were no significant differences in perioperative state anxiety between VORT and standard operation preparation procedures before and after the surgery. Nonetheless, patients' ratings of VORT overall were positive. The tour was perceived as useful and, therefore, showed acceptance for VR use. These ratings were unrelated to the degree of perioperative anxiety.

Conclusions: The subjective benefit of VORT could not be explained by a reduction of perioperative anxiety. Instead, VORT appears to serve the need for information and reduce uncertainty. In addition, VORT is perceived as beneficial regardless of the age of the patients. Considering this effect and the manageable organizational and financial effort toward implementation, the general use of VORT can be recommended.

Introduction

Fear and anxiety are very common in patients prior to surgery with anesthesia. This perioperative anxiety can lead to additional discomfort, increased pain sensation, and increased stress symptoms [1,2]. It is a significant burden for patients and a potential reason for decreased compliance.

Virtual stimulus exposure is successful in exposure therapy for the treatment of anxiety and tension [3]. Patients are not confronted with real anxiety-inducing stimuli but with virtual representations of them [3]. The effectiveness of virtual stimulus exposure is well documented, especially for specific phobias [4-8], where it is not inferior to in vivo exposition [4]. Therefore, virtual stimulus exposure could also be suitable for minimizing operation-associated fears.

However, much less is known about the application of virtual reality (VR) exposure in reducing situational fear in people without anxiety disorders. The potential of VR exposure to reduce anxiety before surgery with general anesthesia has recently been explored with respect to perioperative anxiety. Ryu et al [9] applied a virtual operating room tour for 69 children 1 hour before surgery with general anesthesia, leading to lower preoperative anxiety and stress levels and higher compliance. However, data on the issue is sparse and inconsistent, especially when evaluating adults.

This study aimed to evaluate the use of VR exposure via a virtual operating room tour (VORT) on perioperative anxiety in adult patients undergoing surgeries with general anesthesia. Previous research has shown that perioperative anxiety exists both as a state (ie, the acute emotional or cognitive reaction of a patient before or after the operation) and as a trait (ie, the patient's disposition to be more or less fearful about operations) [2]. We assumed that VORT reduced perioperative state anxiety in patients before and after surgery with general anesthesia. In addition to the exposure effect, information about anesthesia and treatment can be conveyed using VR at low cost and effort, thus strengthening individual health competence.

Methods

Ethics Approval

The study protocol was approved by the local Ethics Committee (EK 039/20). The study was designed and conducted in accordance with the latest version of the Declaration of Helsinki [10]. Moreover, the study was registered by clinicaltrials.gov on September 28, 2020 (NCT04579354).

Participants

All participants were patients of the Clinic for Anesthesiology, RWTH Aachen University Hospital. The inclusion criteria included age over 18 years, elective surgery with general anesthesia, and a good knowledge of German. Exclusion criteria included emergency surgery, thoracic surgery, neurosurgery, and tumor surgery, as these can be associated with increased anxiety or inability to provide consent. All participants signed an informed consent form before participating in the study.

Sample Size Planning

Sample size planning was based on a meta-analysis by Carl [4] on the effect of virtual exposure on anxiety. For comparisons of VR exposure with participants on a waiting list that receive treatment after the treatment groups, this study reported a mean effect size (Hedges's g) of 0.9, analogous to Cohen's *d*. Sample size planning using g multiplied by power for this effect size resulted in a sample size of 68 patients (34 per group) for a two-sided null hypothesis test (*t* test for independent samples), with a power of 0.95 and an α error probability of .05. To compensate for an expected dropout of 10%-15%, we targeted a total sample size of 80 patients (40 per group).

Study Design

The study employed a randomized parallel-group design to compare VORT to the standard operation preparation procedure (STOPP). We employed the state and trait anxiety scales from the state-trait operation anxiety inventory (STOA) [2] as outcome variables. STOA is a validated inventory with good psychometric properties which assess operation-related trait and state anxiety on separate scales. Trait anxiety (STOA-T, 20 items) is the relatively stable disposition of a person to be anxious about surgeries, whereas state anxiety (STOA-S, 10 items) assesses acute fear reactions in situations shortly before or after surgery on 2 dimensions (cognitive anxiety and affective anxiety, 5 items each). Measuring a relatively stable trait, STOA-T was rated only before the surgery, whereas STOA-S was assessed before (T1) and after the surgery (T2). As an additional outcome, we employed an in-house designed questionnaire to assess the participants' perception and evaluation of VORT after surgery. The questionnaire assessed different statements about VORT with 8 items on a 5-point Likert scale from 1 (do not agree) to 5 (strongly agree). Moreover, in 1 item, patients were asked to give VORT a school grade (according to the German grade system) between 1 (excellent) and 6 (very poor).

Participants were randomly assigned to one of the study arms (VORT vs STOPP) by a person not involved in data acquisition using the following procedure: for all patients (N=80), we created opaque assignment envelopes containing a folded paper with a study arm assignment (VORT or STOPP), with a total of 40 participants in each arm. The order of the envelopes was randomized before the beginning of the study. The assignment envelope for each patient was opened after these steps to avoid any bias in providing study information to the patient or the standardized explanatory interview. Thus, the assignment to the study arms was double-blind (to the study nurse or anesthetist and the patient) until after the standardized explanatory anesthesia interview. The procedural steps of the study can be described as follows:

Providing Study Information and Obtaining Informed Consent

Information was provided in written form, and the study nurse assisted the consent process by providing additional explanations and answered questions. Patients were informed about the study background, the study arms, and the content of the video. All patients received a paper copy of the information sheet. Informed consent was obtained in written form. This step was identical for all patients in both study arms (VORT and STOPP).

Standardized Explanatory Anaesthesia Interview

The interview consisted of a detailed explanation by the educating physician (anesthetist). A standardized information sheet was further used to explain the procedure and the anesthesia used, corresponding to the hospital's standard

operating procedure, and it was identical for all patients in both study arms (VORT and STOPP).

Unblinding of the Study Arm Assignment

Unblinding entailed opening the assignment envelope and according assignment of the patient to one of the study arms.

Arm 1: Virtual Operation Room Tour (VORT)

Patients in this study arm subsequently watched a virtual tour of the operation room using Oculus Go Standalone VR (product number 301-00105-01; Facebook). The tour began with the evening conversation between the patient and a nurse about the approximate time of the operation and the desired sleeping medication. The next scene showed the morning conversation about premedication and drug administration. Furthermore, the route through the hospital from the normal ward to the holding area was illustrated. In the holding area, aspects of the "safe-surgery saves lives" checklist, such as the operation side (left or right), were simulated in the conversation between the patient and a nurse. Finally, a scene from the operating room was shown in which the actual preparations for anesthesia (ie, breathing tube and intravenous access) up to the induction of anesthesia were simulated.

The total duration of VORT was 6 minutes 28 seconds. VR videos were recorded with an Insta360Pro 3D camera (Arashi Vision Inc), with 4k resolution and an internal microphone. The video can be found online [11]. VR videos were recorded from a third-person perspective with a static camera mounted on a tripod. Early in the study, we alternatively considered using a video from a first-person perspective. The decision against the latter was based on three observations: (1) 360° recordings led to strange camera images when shot from the perspective of a person lying in bed, (2) first-person perspective might evoke a strange feeling of alienation (eg, in women), given the fact that the male actor's voice was still audible, and (3) several pilot subjects reported simulation sickness when watching the first-person perspective video.

Arm 2: Standard Operation Preparation Procedure (STOPP)

Following the standard procedure of the hospital, patients in this study arm underwent no additional preparation.

Questionnaires T1 (Before Operation)

Assessment of STOA-T and STOA-S (T1). This step was identical for all patients in both study arms (VORT and STOPP).

Questionnaires T2 (After Operation)

The assessment of STOA-S (T2) for all patients was completed in both study arms within 48 hours after surgery. Simultaneously, patients in the VORT study arm completed the evaluation questionnaire.

Research Hypothesis

1. H1: VORT reduces perioperative state anxiety before the surgery with general anesthesia compared to the standard procedure.
2. H2: VORT reduces perioperative state anxiety after the surgery with general anesthesia compared to the standard procedure.

Moreover, concerning the application of VORT, we were interested in its overall patient evaluation. Also, we wanted to explore the possibility of perceived usefulness, especially in patients with higher trait anxiety, in other words, if the VORT rating was associated with perioperative trait anxiety. Finally, we wanted to evaluate whether the evaluation of VORT depended on the patient's age (eg, older patients' limited experience with VR). Therefore, we additionally investigated the following explorative research questions:

1. ER1: How is the use of VORT prior to surgery evaluated and accepted by patients?
2. ER2: Is there a possible relationship between the evaluation of VORT and perioperative trait anxiety?
3. ER3: Is there a possible relationship between the evaluation of VORT and patients' age?
4. ER4: Does VORT influence anesthesia-related STOA items?

Data Analysis

Data were analyzed with SPSS Statistics (version 25; IBM). STOA-S sum scores for the two dimensions (cognitive and affective anxiety) were compared between study arms with two-tailed independent samples *t* tests separately for T1 (H1) and T2 (H2). To quantify agreement to the Likert scale items in the evaluation questionnaire (ER1), we calculated the median of the responses. Furthermore, we recoded the responses to disagreement (values 1 and 2), neutral (value 3), and agreement (values 4 and 5) and descriptively quantified the percentage of agreement. To evaluate a possible relationship between trait operation anxiety and the evaluation of VORT (ER2), we calculated Pearson correlations between the items from the evaluation questionnaire and STOA-T values. Finally, we calculated correlations between the items from the evaluation questionnaire and the patients' age. A threshold of an α error probability of .05 (two-sided testing) was applied to all analyses.

Results

Overview

In total, 84 patients were included in the study. Dropouts (n=12; 14.3%) were in the expected range; however, since all dropouts occurred during the enrolment of the first 62 patients, we decided at this time point to create and randomize 20 additional assignment envelopes. The primary reason for dropouts was the early discharge of the patient. Other reasons included postponed or additional surgeries and postoperative complications. VORT-associated concerns or worries were not reported; therefore, VORT did not contribute to participation dropouts. One patient withdrew from study participation. Data from the remaining 72 patients (mean age 54.19, SD 15.94, with a range of 20 to 81 years), with 35 female and 37 male subjects, was analyzed (VORT: n=35 vs STOPP: n=37). Due to single missing data points, the numbers of included patients vary slightly for the different analyses. Results of the study are presented according to our hypotheses.

H1: VORT Reduces Perioperative State Anxiety Before the Surgery as Compared to the Standard Procedure

No significant differences in state anxiety emerged between VORT and STOPP before surgery. This was the case for both the affective (n=71; VORT: mean 10.49, SD 4.61 vs STOPP: mean 10.83, SD 4.09; t_{69}=–0.37; *P*=.74) and the cognitive dimension (n=67; VORT: mean 10.88, SD 4.32 vs STOPP: mean 10.70, SD 4.38; t_{65}=–0.18; *P*=.86).

H2: VORT Reduces Perioperative State Anxiety After the Surgery as Compared to the Standard Procedure

Similarly, no significant differences in state anxiety emerged between VORT and STOPP after the surgery. This was the case both for the affective (n=68; VORT: mean 8.53, SD 4.95 vs STOPP: mean 7.91, SD 3.26; t_{66}=0.61; *P*=.55) and the cognitive dimension (n=71; VORT: mean 9.11, SD 4.19 vs STOPP: mean 9.17, SD 4.00; t_{69}=–0.05; *P*=.96).

ER1: How is the Use of VORT Prior To Surgery Evaluated by Patients?

The median values of the responses and proportion agreement to the statements are listed in Table 1. Altogether, the patients' ratings of the VORT are positive. The results indicate that most patients perceived the VORT as helpful for preparation and can recommend it to other patients. A median school grade of 2 (corresponding to "good" in the German grade system) corresponds well with these ratings.

Table 1. Evaluation of the virtual operation tour.

Item	Median rating (1=do not agree; 5=strongly agree)	Agreement to statement (%)
The virtual operation room tour helped me to prepare for the surgery.	4	71.4
The information the operation room tour gave me was helpful for my preparation.	4	61.8
I found it helpful for my preparation to see the surgical environment before the surgery.	4	74.3
The virtual surgery tour calmed me down.	4	58.6
The virtual surgery tour was too detailed.	2	19.4
The virtual surgery tour was not detailed enough.	2	8.8
Should I be operated on again, I would like to do the virtual surgery tour again.	4	54.3
I can recommend the virtual surgery tour to other patients.	4	91.4

ER2: Is There a Possible Relationship Between the Evaluation of VORT and Perioperative Trait Anxiety?

There were no significant correlations between any of the items from the evaluation of the VORT (Table 1) and STOA-T values of the patients (all *P*>.19).

ER3: Is There a Possible Relationship Between the Evaluation of VORT and Patients' Age?

There were no significant correlations between any of the items from the evaluation of the VORT (Table 1) and the age of the patients (all *P*>.10).

ER4: Does VORT Have an Influence on Anesthesia-Related STOA Items?

Comparing VORT and STOPP with a two-tailed independent samples *t* test for all 7 items related to anesthesia treatment, the difference was only found in favor of VORT slightly below the predefined significance threshold (*P*=.047). Comparisons for all other items were not significant, resulting in no evidence that VORT addresses anesthesia-specific fear components.

Moreover, we calculated comparisons between men and women for all single VORT rating items in two ways to assure that men and women felt equally addressed by our video using a male protagonist. First, we calculated independent samples *t* tests for the Likert scale ratings. Second, we compared male and female participants using X^2 tests to assess possible sex-dependent differences in the agreement to the statements (recoded ratings). For the *t* tests, no significant sex differences emerged concerning the ratings of VORT (all *P*>.17); for the X^2 tests, we found one significant difference for item 6 ("the virtual surgery tour was not detailed enough"), with higher agreement among female participants (21.4%) compared to males (0%). Moreover, we compared male and female participants with respect to their overall rating of VORT (school grade) in an independent samples *t* test. Men and women did not differ in their school grades (*P*=.25), with women tending towards better grades (mean 1.86, SD 0.66) compared to men (mean 2.10, SD 0.54).

Discussion

VORT Effects

Although VORT did not affect perioperative anxiety, the tour received good patient ratings and was perceived as helpful for surgery preparation. Remarkably, the positive evaluation of the virtual surgery tour was independent of the fear of surgery (ie, the personality trait or trait anxiety). In other words, the subjective benefit of VORT for the patients could not be attributed to anxiety reduction. A possible explanation for this finding may be the beneficial effect of preoperative education and information. The assumption of uncertainty being a central element in the emergence of hospitalization stress was first

raised by Mishel [12] and later specifically adapted to operation situations by Kagan and Bar-Tal [13], who reported that preoperative uncertainty negatively affected mental and physical recovery after surgery. This aligns with the findings of Moerman et al [14], showing that more than 80% of surgical patients had a positive attitude towards receiving information, with more than half of them having high information requirements. Receiving information about health care interventions positively affects several aspects of patients' mental and physical health, such as recovery, pain levels, and psychological distress [15-17]. Thus, in our study, the positive ratings of VORT may be attributed to reducing uncertainty and satisfying the need for information. Similar to Moerman et al [14], we conclude that surgical fear and need for information are related but distinguishable factors and addressing either of them can reduce patients' distress. For future studies, physiological measures such as heart rate, blood pressure, and skin conductivity may be relevant indicators for assessing the arousal of the patients. Including these physiological measures might help disentangle physiological processes and their cognitive appraisal [18]. For example, it seems conceivable that VORT evokes physiological arousal due to the operation-associated settings and situations but reduces subjective stress via cognitive control.

Surprisingly, VORT is perceived as beneficial irrespective of the patient's age, indicating 2 interesting aspects. First, the need for information and the wish to reduce uncertainty seem independent of the patient's age. Second, the acceptance of VORT was equally high among elder and younger patients. Therefore, there is no evidence that experience with VR may play any role in the evaluation or that elderly patients may feel uncomfortable with the VR setup. Given the high number of elderly patients undergoing surgeries with general anesthesia, these findings favor the general use of VORT in preoperative preparations.

Furthermore, there was no evidence that VORT addresses anesthesia-specific fear components. Our experience shows us that there are two patient groups: those who fear the anesthesia and its consequences in isolation and those who are only afraid of the procedure, the surgical part. As far as we know, no questionnaire provides information on fear of anesthesia in isolation.

VR and Perioperative Anxiety

There is mixed evidence concerning the potential of VR in reducing perioperative anxiety. Some studies show no reduction in anxiety [19-21] by interventions as in our study, and others offer a detectable influence [22-26]. However, anxiety reduction has been applied preoperatively with good results, especially in children [9,26,27]. These inconsistencies may be partly attributed to the use of different anxiety inventories. The Spielberger State and Trait Anxiety Inventory (STAI) is frequently used [28]. However, the suitability of the STAI has been questioned for operation situations since it primarily measures anxiety in assessment situations [2]. Accordingly, more specific inventories have been developed, such as the STOA [2], the Amsterdam Perioperative Anxiety and Information Scale [14], and the Yale Preoperative Anxiety Scale [29], which was designed especially for children. The content of the items, length of the questionnaire, and other aspects vary considerably between these inventories, influencing study outcomes. For instance, Krohne et al [2] demonstrated that trait scores of STAI and STOA were correlated at r=.40, indicating that both inventories reflected a common factor of general anxiety but measured distinguishable facets of anxiety. Therefore, when comparing studies on VR interventions for perioperative anxiety, one must consider which inventories were used.

Limitations

One possible limitation of our study is that all patients received the VR tour after the "educating interview." Regarding patient compliance, it would be relevant to know whether there are fewer canceled surgeries when patients receive a VR education beforehand. Moreover, with the changed order, the VR tour could prepare patients for the anesthesia interview, enabling the patient to ask more detailed and specific questions. The second important limitation concerns the limited generalizability of our results to other types of anesthesia (eg, regional procedures). This is relevant in terms of distinguishing separate aspects of preoperative anxiety. Specifically, we assume that a distinction between fear of anesthesia and fear of the operation procedure by itself can be much more precise since several aspects of general anesthesia are not provided here (eg, fear of not waking up, lack of trust, or losing control while being unconscious).

Another limitation concerns whether the patients already had previous surgery with general anesthesia. Our study did not evaluate this aspect, and we cannot exclude the possibility it played a role in the VORT assessment. However, after careful consideration, we conclude that it is rather unlikely that prior surgical experience with anesthesia affected the VORT assessment. The probability of undergoing surgery increases with life age, suggesting that there was most likely a substantial correlation between life age and operations in the past in our study sample as well [30]. Our data found no correlation between life age and VORT ratings. We are aware the latter cannot distinguish between people who have experienced an operation and those who have not; however, we conclude that there is at least no indication from our data that having undergone an operation or not plays a role in the VORT rating.

Conclusion

VORT is beneficial for a patient's preparation for surgery with general anesthesia. Remarkably, this effect did not result in reduced perioperative anxiety. Instead, VORT seems to serve the need for information and to reduce uncertainty. Moreover, it is both accepted and recommended by patients. Considering the manageable organizational and financial effort and minimal time required in its implementation and the amount of time spent waiting in the perioperative outpatient clinic, the general use of VORT can be recommended.

Acknowledgments

The authors thank all participating patients and the premedication ambulance staff for their valuable support. This study was funded by the EU Fund, Interreg EMR, Clinic for Anesthesiology, and University Hospital RWTH Aachen and medical faculty in Aachen, Germany.

Authors' Contributions

LV, MK, and UG developed the study concept and study design. LV and MK had the primary idea for this study. Data were collected by UG. MK completed the ethical approval and performed statistical data analyses. LV drafted the article. SS and RR provided substantial intellectual input, and SS served as the senior supervisor. MK, SS, and RR critically revised the manuscript for important intellectual content. PE provided substantial media support and was responsible for the implementation of the virtual reality. All authors read and approved the final version of the article. All authors agreed to be accountable for all aspects of the work.

Abstract

Background: Over the last 2 decades, virtual reality technologies (VRTs) have been proposed as a way to enhance and improve smoking cessation therapy.

Objective: This systematic review aims to evaluate and summarize the current knowledge on the application of VRT in various smoking cessation therapies, as well as to explore potential directions for future research and intervention development.

Methods: A literature review of smoking interventions using VRT was conducted.

Results: Not all intervention studies included an alternative therapy or a placebo condition against which the effectiveness of the intervention could be benchmarked, or a follow-up measure to ensure that the effects were lasting. Virtual reality (VR) cue exposure therapy was the most extensively studied intervention, but its effect on long-term smoking behavior was inconsistent. Behavioral therapies such as a VR approach-avoidance task or gamified interventions were less common but reported positive results. Notably, only 1 study combined Electronic Nicotine Delivery Devices with VRT.

Conclusions: The inclusion of a behavioral component, as is done in the VR approach-avoidance task and gamified interventions, may be an interesting avenue for future research on smoking interventions. As Electronic Nicotine Delivery Devices are still the subject of much controversy, their potential to support smoking cessation remains unclear. For future research, behavioral or multicomponent interventions are promising avenues of exploration. Future studies should improve their validity by comparing their intervention group with at least 1 alternative or placebo control group, as well as incorporating follow-up measures.

KEYWORDS

virtual reality technology; nicotine dependency; nicotine addiction; smoking addiction; smoking intervention; smoking therapy; Electronic Nicotine Delivery Systems

Introduction

Background

Smoking addiction is a worldwide [1] and costly [2] problem. Tobacco smoking has been linked to cardiovascular disease [3], various types of cancer [4-6] and respiratory problems [7], among other diseases, reducing the consumers’ quality of life [8], and lowering life expectancy by up to 4 years [9]. Approximately 30% of all cancer deaths in high-income countries are caused by cigarette smoking [10].

The Diagnostic and Statistical Manual of Mental Disorders lists nicotine dependency (rephrased as tobacco use disorder in a more recent edition) as a psychological disorder [11]; 55% of US smokers try to quit every year [12], but it has been estimated that between 60% and 90% of them relapse within the first year [12-14]. Smoking addiction has a strong psychological component [15,16] in addition to physiological dependence. Physiological craving may only take a few weeks to wane [17], but the habit and psychological link between smoking, socializing, relaxing, and rewarding are much harder to abandon [16]. Thus, different therapies and interventions have been developed to overcome this link.

Interventions and Therapies

Therapies and interventions are both care strategies, but their main difference is the scope. Interventions usually aim to motivate someone to commit to a specific action, such as a teenager saying *no* when their peers offer a cigarette or a smoker entering treatment. Therapies, on the other hand, address more comprehensive goals, such as maintaining abstinence and altering habits or attitudes. In practice, there is often no clear distinction between the two and they can be thought of as lying on a continuum rather than reflecting 2 dichotomous categories [18].

Cue exposure therapy (CET) uses a classical conditioning approach to unlearn a response (craving) to stimuli (smoking-related items and situations). During the therapy sessions, craving is elicited by exposing participants to smoking-related cues such as cigarette packages and images of situations in which the participant usually smoked. In daily life, participants would relieve cravings through smoking, which reinforces the craving response. During CET, typically no nicotine reward is provided [19] (however, see the study by Kotlyar et al [20] and De La Garza et al [21] that combines CET with nicotine replacement therapy [NRT]). Once the craving has receded, the participant is exposed to smoking cues again, with the aim of repeating this procedure until the association between smoking cues and reward is weakened and eventually extinguished [19,22].

The approach-avoidance task (AAT) adopts an operant conditioning approach. This task can be used to measure and influence subconscious bias [23,24]. During the AAT, participants have to either pull or push away a lever in response to visual cues. People tend to be quicker to pull when presented with cues that elicit a positive (approach) bias than when cues have a neutral or negative association, whereas they are quicker to push away (avoid) negative cues than positive or neutral ones [23]. Thus, AAT can be used to measure existing subconscious biases, as smokers will be quicker to pull when presented with smoking-related cues than nonsmokers. In addition, AAT can be used as an instrument to break or reverse subconscious biases by instructing participants to respond to smoking cues with avoidance behaviors (eg, pushing away) over a number of trials or sessions until smoking cues are automatically associated with avoidance and negative affect [24,25].

Cognitive behavioral therapy (CBT)–based interventions often take a multicomponent approach: teaching smokers to recognize the thought patterns they engage in before smoking and to identify triggering factors in the environment. Smokers are then trained in alternative strategies to cope with craving and temptation [26].

NRT aims to reduce cravings and by extension smoking behavior by replacing the source of nicotine [27]. It is an accessible standalone intervention for smokers who do not have the resources or motivation to commit to a more substantial intervention but will not target the psychological component of the smoking habit [27]. To this effect, NRT is often combined with CBT [28,29].

One particular form of NRT includes the use of Electronic Nicotine Delivery Systems (ENDS), more commonly known as electronic cigarettes, e-cigarettes, or vapes. Invented at the start of the 2000s, these devices heat a solution usually containing nicotine and flavoring agents and deliver the vapor (aerosol) to the user to be inhaled [30], although the amount of nicotine varies and nonnicotine liquids are available as well [31,32]. ENDS were originally introduced as a device to help reduce the number of cigarettes smoked or even quit (conventional) smoking altogether [30,33,34]. However, there has been an ongoing debate in the scientific and medical community on the health risks associated with ENDS [35,36] as well as the potential of ENDS to form an introduction to smoking for previous nonsmokers (the gateway hypothesis; [37]). Recent meta-analyses suggest that although far from harmless, ENDS may still pose a lower health risk than smoking cigarettes [37,38] and that they may be more effective than NRT for smoking cessation [39]. The question of whether this makes ENDS an eligible form of NRT has yet to be resolved [40,41].

Virtual reality technologies (VRTs) have been recognized as potentially helpful in increasing the effects of these and other interventions. These technologies provide an immersive interface that can be used to enhance (augmented reality [AR]) or even replace (virtual reality [VR]) reality with computer-generated simulations. AR is commonly used on a screen that combines the display of the real world with some added virtual features; a well-known example is the game Pokémon Go (Niantic Inc), which displayed the camera view on screen but added virtual Pokémon creatures to the scene, which the user could interact with. In contrast, in VR apps, users often wear a VR headset such as a stereoscopic head-mounted display that projects video images in 3D. Although the focus in VR and AR generally lies in visual simulation, the experience can be enhanced through haptic, olfactory, and audio feedback.

There are multiple potential benefits of using the VRT. First, training smokers to respond to a potentially tempting situation will be more effective if the therapy can mimic those situations more closely [42,43], and VR has been shown to create a stronger feeling of being immersed than 2D images [44-46]. Second, VR offers a safe environment for coping skills [47]. Finally, it can be easily tailored to the specific needs of individual smokers [22,42]. Therefore, over the last 15 years, the potential of VR for smoking cessation therapy has been extensively studied. Although AR has not yet been widely embraced, it was still included in the current search strategy.

This Research

In this paper, we systematically review and summarize the findings from the literature on the adoption of VRT in smoking cessation therapy.

This paper is centered around three main research questions:

- Has VRT been used satisfactorily to elicit smoking cravings?
- What VRT interventions exist and how do they compare with regular interventions in terms of smoking cessation outcomes?
- What are the potential future directions for VRT in smoking cessation therapy?

The review will focus on the adult population (people aged ≥18 years) of smokers with no comorbidities. Randomized controlled trials, controlled trials, single group pre- and posttest studies, and case studies were all included, as well as protocols (to give an indication of future directions of research), meta-analyses (as those can detect effects with greater power than individual studies), and reviews (for the reference list search and to refer to as an overview for the interested reader). Intervention studies were included if they incorporated VRT in their intervention and measured either smoking cue reactivity or intervention effectiveness. With regard to the data extracted, the comparators were treatment, placebo, pre- and postcomparison, and waiting list. The outcomes were craving or smoking urge, nicotine dependence, number of cigarettes smoked, abstinence rates, and quit rates.

Some systematic review papers have been published [48-52], but their scopes only partially overlapped with that of this one; for example, some systematic reviews included nonadult subjects [50], focused exclusively on cue reactivity or CET [48-50,52], limited themselves to head-mounted display VR [51], studied a variety of addictions [48,50,51], or were simply published over 5 years ago, thus missing more recent publications [49,50]. This paper includes 15 papers that were not covered by the previous reviews and thus expands on previous findings by presenting a wider and updated overview of the potential of VRT in smoking cessation.

Methods

Search Criteria

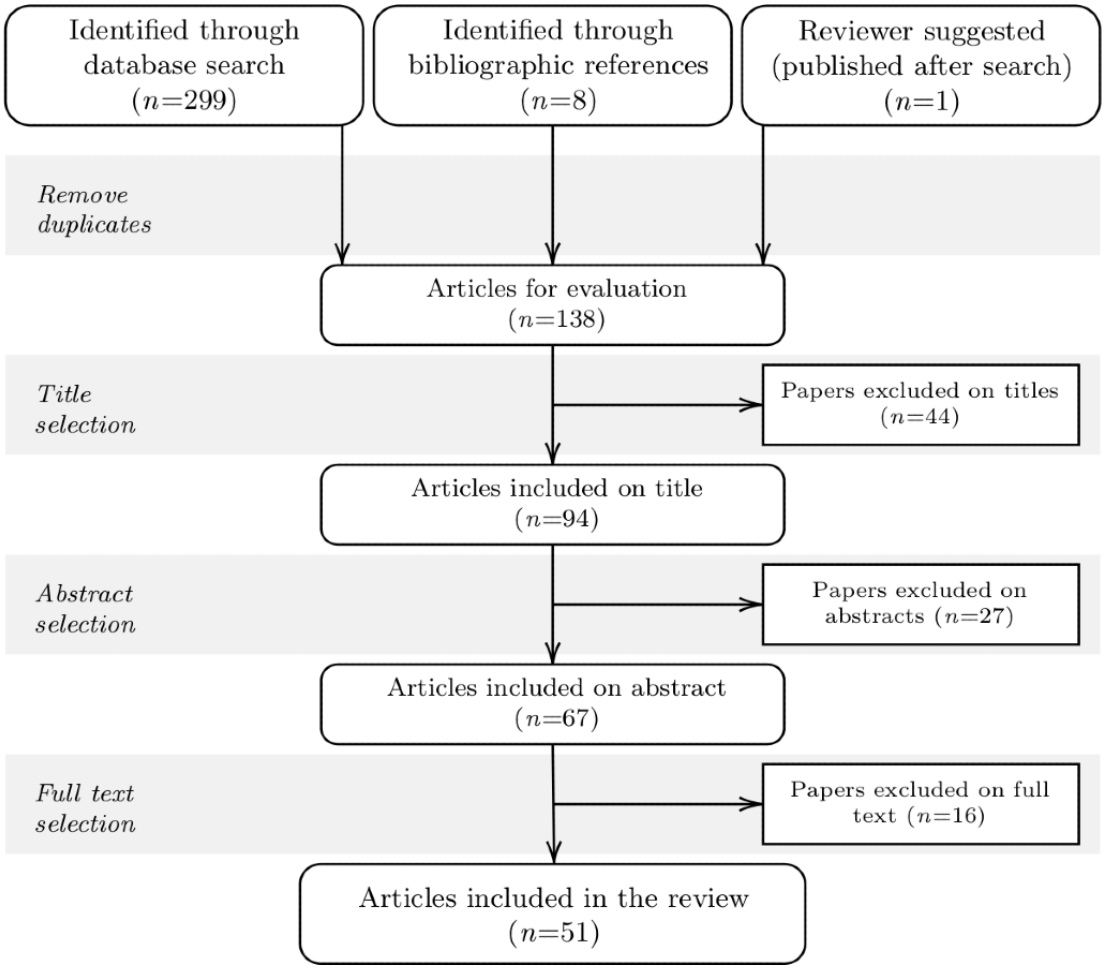
The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for review [53] were followed for the current review. The database search strategy was developed under the supervision of a trained subject librarian. After deliberation with the librarian, 5 databases (MEDLINE, Embase, Scopus, Cochrane, and EbscoHost) were identified to be searched using the following search terms: (*Virtual reality*, OR *Augmented reality*, OR *Mixed Reality*, OR *Augmented Virtuality*) AND (*smoking* OR *vaping* OR *tobacco* OR *cigarette* OR *nicotine* OR *vape* OR *e-cigarette*) AND (*craving* OR *crave* OR *withdrawal* OR *cue exposure* OR *cue reactivity* OR *urge* OR *cessation* OR *desire*). The reference lists of selected papers were also scanned for other relevant papers.

Literature Selection

The search was completed in July 2020, resulting in a total of 299 papers: MEDLINE (n=51), Embase (n=51), Scopus (n=88), Cochrane (n=52), and EbscoHost (n=57). After removing duplicates, 137 papers remained. Three rounds of selection were completed: exclusion based on title, exclusion based on the abstract, and exclusion based on the entirety of the paper. Inclusion and exclusion criteria were determined beforehand [54], with the inclusion criteria being as follows: the paper had to discuss the (potential) use of VRT for smoking cessation treatment; the target population had to be adults, with no pre-existing psychological or physiological conditions; only tobacco smoking in the form of cigarettes, cigars, or pipe and the vaping of nicotine were included (ie, no smoking of crack, marijuana, or any other substance; smoking a nargile or bong; or vaping of tetrahydrocannabinol S containing liquids). After 3 rounds of selection, 42 papers remained. Furthermore, 8 papers that had been identified through the reference list search and met the inclusion and exclusion criteria were added to this selection, as well as 1 meta-review that was published after the search but recommended by the paper reviewer, resulting in a final set of 51 papers. However, because the 2 studies by Pericot-Valverde et al [42,55] are based on the same data set (Pericot-Valverde, personal communication, January 30, 2021), we counted them as 1 study, reducing the total number to 50. Paper selection and data extraction were completed by one of the authors. Figure 1 shows a flowchart overview of the review rounds (see Multimedia Appendix 1 [20,21,42-44,46,48-52,55-95] for a list of the selected papers).

The timestamped literature selection plan, including search terms and inclusion and exclusion criteria, can be found [54], and the search terms, as well as the raw results from the individual databases, can be found [96] as well as in the Multimedia Appendix 1.

Figure 1. Overview of the screening and paper selection process.

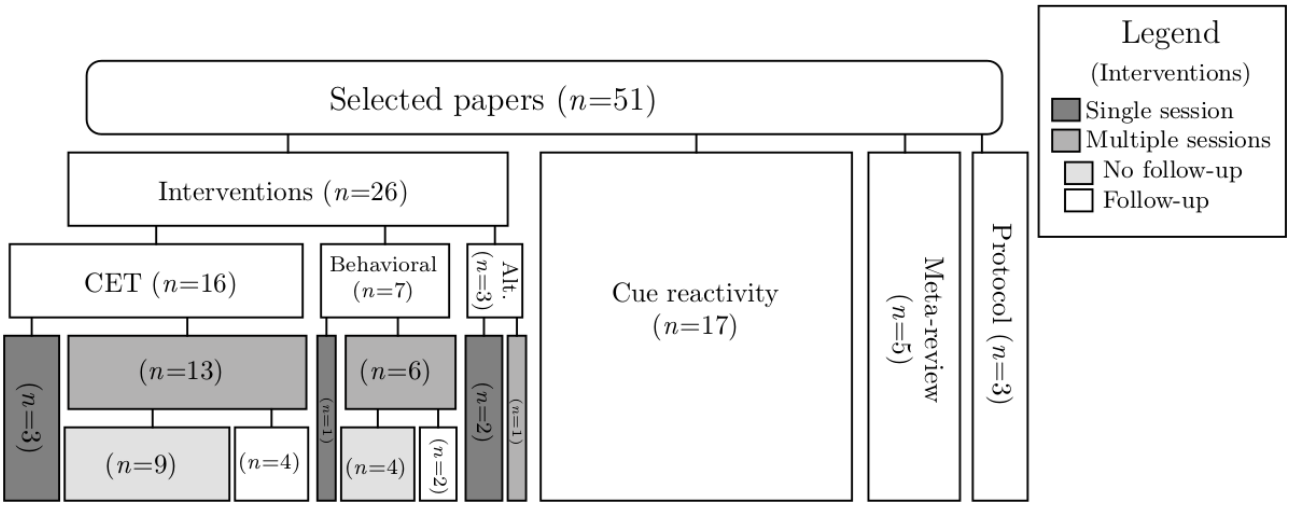


Results

Preliminary Analysis

A few general observations were made using the data set of papers. Of the 51 selected papers, 26 (51%) introduced or tested an intervention, 17 (33%) studied cue reactivity, 5 (10%) were meta-reviews, and 3 (6%) were protocols for studies yet to be conducted. In addition, 77% (22/26) of the intervention papers described a multisession intervention, stretching out from 3 to 10 weekly sessions. Furthermore, 27% (6/22) of these multisession interventions reported at least 1 follow-up measure, ranging from 1 week to 12 months after the final session. Follow-up measurements are a great asset to intervention studies as initial effects might fade over time (for example, the results in the study by Pericot-Valverde et al [42]). Figure 2 shows a flowchart indicating the division of the papers.

Figure 2. Overview of included studies. Alt: alternative (interventions that are neither based on cue exposure therapy nor behavioral therapy); CET: cue exposure therapy.



In addition, 54% (14/26) of the interventions were compared with an alternative therapy; however, only 15% (4/26) included a placebo condition. Although not including an alternative intervention or placebo condition does not invalidate the overall findings of a study, it also does not provide any information on the efficacy of one therapy over the other or indeed the efficacy of one therapy over an optimistic mindset.

Furthermore, of the 42 papers examining the effect of an intervention on smoking craving or behavior, 7 (17%) used smokers unmotivated to quit as participants; the rest of the papers was roughly equally divided between smokers motivated to quit (17/42, 40%) and smokers with undisclosed motivation to stop (18/42, 43%). All but 3 papers [44,56,57] used VR in their interventions.

Has VRT Been Used Satisfactorily to Elicit Smoking Cravings?

The prerequisite for VRT to have any (added) value in smoking interventions is whether or not these techniques can reliably induce craving through activation of smoking and smoking-related associations. Once these cravings have been elicited, any subsequent therapy can target the cravings. Cravings in non-VRT settings are usually elicited by using smoking-related paraphernalia [97], 2D images of cigarettes and scenes with people smoking [19], and imaginary procedures where participants are instructed to imagine themselves in a (personalized) high-risk situation [98]. VR can create a more immersive experience [44-46], which may add to the effectiveness of the therapy, and being virtual, it theoretically allows for tailoring specifically to the user's needs [42,58].

A plethora of studies (n=17) set out to test whether VR could induce nicotine craving and confirmed that craving can be successfully induced in VR by exposing participants to smoking-related cues [46,58-72] (see the study by Pericot-Valverde [49] for a meta-analysis). Moreover, exposing nonsmokers to VR smoking cues did not elicit cravings [46].

Furthermore, craving can be elicited using minimal cues. No explicit mention of smoking is needed; simply presenting an environment where cigarettes are usually handled (eg, a bar or the checkout counter of a newspaper kiosk) or providing smoking-related cues in the background (such as ashtrays) was sufficient to elicit cravings. The addition of olfactory cues [60,73] or branded cigarette packages [66,67] did not increase the craving response. Ferrer-García et al [74] tested different potential moderators of cue-induced craving and found that the (sense of) presence in VR was positively linked to craving.

Whether VR-cue exposure (CE) elicits craving to a greater extent than the more traditional methods has been less extensively studied. Bordnick et al [70] found that a VR environment elicited greater craving in participants than exposure to a 2D image of the same environment. In contrast, Karelitz [52] conducted a meta-analysis on different factors that may influence cue reactivity and found that although VR cues increased craving, they did not do so to a greater degree than 2D pictorial images or scripted imagery.

It is noteworthy that the number of years that participants had been smoking correlated negatively with cue reactivity [52]. The majority (11/17, 65%) of the cue reactivity studies did not report measuring the number of years smoking; of the 6 that did, 5 did not use it as a control variable or to assess whether the experimental groups were similar before commencing the experiment, thus potentially allowing for bias. Related to this, only 6 of the papers on cue reactivity reported participants' intention to quit. However, CE supposedly elicits craving in both types of cigarette smokers to an equal extent [62], so this lacuna in the data may not be problematic.

What VRT Interventions Exist and How Do They Compare to Regular Interventions in Terms of Smoking Outcomes?

Overview

Different VRT adaptations of smoking interventions were found. CET in VR (VR-CET) was the most frequently reported (n=16). In addition, VR has been combined with different behavioral interventions (eg, the AAT and gamified behavior training; n=7) and antismoking campaigns (n=3). Figure 2 shows a flowchart detailing the breakdown of the topics.

VR-CET Intervention

A total of 16 papers on VR-CET or a variation were included in the review. VR-CET has been successful in reducing smoking cravings over repeated exposures in most experiments [42,58,60,64,68,70,75,76] experiments. One study in the selected papers did not find a significant effect of VR-CET on long-term cravings [77], but their sample size was rather limited at n=8. The studies by Hone-Blanchet et al [50] and Segawa et al [51] present a meta-review on the effectiveness of VR-CET on craving and smoking behavior. A lower amount of smoking behavior after VR-CET treatment compared with the preintervention baseline was reported in the studies by Choi et al [67] and Pericot-Valverde et al [75]. Choi et al [67] measured a reduction from approximately 14 to 4 cigarettes per day based on self-reports, which was substantiated by a significant reduction in exhaled carbon monoxide (CO; 12.5 to 2.5 ppm). Pericot-Valverde et al [75] reported a reduction from 18 cigarettes per day before the intervention to a little under 4 cigarettes per day after the intervention (CO change from 13.2 to 5.0 ppm).

Furthermore, 4 studies investigated the added value of VR-CET to CBT [42,58,61,78]. Culbertson et al [58] compared craving and smoking behaviors between a group of smokers who received CBT and VR-CET and a group of smokers who received CBT and a placebo-VR training. Participants in the VR-CET group not only reported less craving and smoked less after the treatment but also had a significantly higher dropout rate. Thus, it is possible that the results could be biased, as only the participants for whom the VR-CET treatment worked well stayed in the program. Moreover, the intervention effects were only measured directly after intervention.

In addition, 3 studies [42,61,78] did not add a placebo-VR condition but instead compared the craving and smoking behaviors of participants receiving CBT. In the study by Papini et al [78], a group of smokers receiving VR-CET was compared with a group receiving CBT; in the other studies [42,61], both groups received CBT, but only 1 additionally received VR-CET

[42,61]. No added value of VR-CET to CBT was found in either of the 3 studies. Furthermore, similar data were found on reduction in dependence and craving [61], abstinence rates at the end of the treatment period [42,78], and decrease in the mean number of cigarettes smoked [78]. In order to further substantiate these findings, Pericot-Valverde et al [42] and Park et al [78] used follow-up measures that confirmed no added benefit of VR-CET to CBT. Relapse at 2 months postintervention was similar between the groups (47% for CBT and 53% for VR-CET) [78]. Pericot-Valverde et al [42] found a significantly higher relapse rate at 12 months postintervention for VR-CET compared with CBT alone (64.3% vs 37%). Relapse rates between 60% and 90% have been reported in the general literature for the first year of quitting. Thus, VR-CET may only marginally improve the odds of smokers successfully giving up their habits.

Three papers described a combination or adaptation of VR-CET with other interventions. First, Kotlyar et al [20] combined VR-CET with NRT by having a third of the participants ingesting a nicotine lozenge before the VR-CET session, thereby artificially reducing the body's craving for nicotine; the other two-thirds received either a placebo lozenge or none at all. They found that VR-CET combined with both lozenges that contained nicotine and the placebo lozenges reduced self-reported craving compared with no lozenge.

Second, in a similar design, De La Garza et al [21] combined VR-CET with ENDS, where the e-liquid contained different doses of nicotine (0 mg, 8 mg, and 16 mg). Compared with smoking a conventional cigarette, ENDS did not reduce elicited cravings as much, even if they contained a high dose of nicotine. However, the authors noted that the ENDS they used have been known to deliver inferior amounts of nicotine, even with high-nicotine liquids. Moreover, the study did not report whether it controlled for previous ENDS use by the participants.

These results show an interesting pattern in combination with the findings from Moon and Lee [77], who found that even as brain areas associated with addiction and craving became less active over time during VR-CET, participants still reported feeling similar levels of craving. Overall, these studies further underline that bodily craving and subjective feeling of craving only partially overlap, and that nicotine addiction has a strong psychological component as well that a therapeutic intervention should seek to address. This intricate set of motivations for smoking may partially explain why VR-CET as a smoking cessation therapy has resulted in such mixed results. However, more research on the effects of VR-CET in combination with NRT is needed to confirm and nuance this hypothesis. It will be interesting to see the results from one of the protocol papers, which outlined a planned clinical trial that combined VR-CET with NRT (eg, see the study by Papini et al [79]). This study will have a larger number of participants (n=102 vs n=41 [20] and n=7 [21]), and although it does not propose a multisession VR-CET intervention or a follow-up measure, it will still be interesting to see if the results from this intervention are in line with previous findings.

In the third study [80], VR-CET was combined with mindfulness training. Participants were taught mindfulness as a coping mechanism to regulate cravings after CE. Thus, the CET aspect in this intervention moved away from pure extinction in favor of a more cognitive response training component; however, as the authors presented their work as an adaptation of VR-CET, it is listed here as such [80]. This adaptation of VR-CET obtained good results: significantly more (23%) of the mindfulness VR-CET trained participants quit smoking at the end of the intervention compared with the control group (5%), who had received a smoking cessation manual for self-assisted quitting. Furthermore, 3 months after intervention, this significant difference remained, as the percentage of smokers who quit had grown to 33% for the intervention group and remained the same for the control group.

With regard to the entire group of papers on VR-CET, a little over half (n=9) of the papers did not report on participants' years of smoking. Of the 7 that did, 1 (14%) used it as a covariate and 3 (43%) used it to ensure that the experimental groups were similar. Given how smoking history may have moderated the cue response [74], the 12 papers that did not control for it may have been at risk of bias. About two-thirds of the VR-CET studies (n=11) reported using participants who were motivated to stop smoking; only 1 study targeted smokers who were unmotivated to quit. Although this may not have been problematic for eliciting craving [62], it is unknown whether the motivation to quit affects response extinguishing.

Behavioral Interventions

A total of 7 VRT-based smoking interventions that relied on a behavioral component were identified: 1 VR adaptation of the AAT (VR-AAT), 4 papers on gamified behavioral training, and 2 on skill training.

The AAT can be used to measure and break and reverse subconscious biases [23,24]. In a smoking intervention context, this is done by instructing smokers to carry out an avoidance behavior (eg, pushing or swatting away) when confronted with smoking cues, thus reconditioning smoking cues to be associated with avoidance rather than approaching behavior [24]. VR-AAT is a relative newcomer in the list of VR smoking interventions. The 2 papers (supposedly using the same sample, and therefore counted as a single experiment in this review) were published in 2019. As a result, the studies merely functioned as proof of concept for a VR adaptation of the AAT. Indeed, VR-AAT was found to be equally useful for measuring cognitive bias in smokers as regular AAT, and smokers displayed a stronger positive bias toward smoking cues than nonsmokers [81,82].

The 4 gamified interventions all appear to be inspired by the AAT: participants kicked and slapped away cigarette-related cues [56] and crushed cigarettes [83,84] or an alternative *cue*/*reaction* element was incorporated [85].

In a study [56], participants completed 3 weekly sessions in VR and reported on their smoking behavior a week after intervention. No statistical testing of the data was reported; hence, it is not clear if the results were statistically significant.

Participants in the studies by Girard et al [83,84] completed 4 weekly sessions in which they either crushed virtual cigarettes or played a VR placebo game, in addition to smoking cessation counseling. The game significantly reduced smoking behavior

as measured directly after the intervention, both in terms of the number of participants who quit and the number of cigarettes smoked by the still-smoking participants [84]. Moreover, 6 months after the intervention, participants who had played the VR crushing cigarette game reported significantly lower craving, as well as smoking fewer cigarettes, whereas a greater number had quit altogether [83]. In addition, fewer participants dropped out from the gamified intervention, and the participants who dropped out did so at a later stage in the program compared with the placebo game [83]. Given that dropout rates in smoking interventions can reach as high as 70% [99] and dropouts are more likely to have higher nicotine dependence and be heavy smokers, especially for early dropouts [99,100], lower dropout rates are a major advantage.

The third gamified VR intervention consisted of 9 weekly sessions [85]. The game is an adaptation of the game proposed by Girard et al [83,84] and has been explicitly designed around the psychological factors underlying motivation. It incorporates elements from both self-determination theory and cue or reaction therapy, thus combining operant (behavior) conditioning with psychological coaching. Although the only data available is a pilot sample (n=8) and no statistical tests have been performed because of the small sample size, the initial results are promising, with lower self-reported dependence as well as a reduction in smoking behavior.

Although these interventions were not phrased as an AAT type of intervention, their results suggest that avoidance behavior training (whether it is pushing away or crushing) could be a promising addition to smoking cessation therapy. What is particularly interesting is the multicomponent approach of the last intervention, which makes it similar to CBT. The behavioral component in CBT, however, is more specific: participants get taught a different response to situations in which they usually give in and smoke, instead of training an automatic, subconscious avoidance response. Although the gamified studies [83,84] included a control group, an aspect that remains unclear is whether VR, the gamification elements, or an interaction between the two were the efficacious components of the interventions.

The 2 VR skill training programs appear to be based more on CBT than on AAT. Bordnick et al [86] combined a 10-week VR coping skill training with NRT and compared this to a standalone NRT intervention. During the VR training sessions, participants were immersed in craving-inducing situations in VR, while the therapist assisted them in identifying high-risk triggers and training coping responses. The addition of VR training reduced smoking rates to a greater degree than NRT alone, both when measured directly after treatment and at the 6-month follow-up. However, similar to the gamified interventions, whether VR was necessary (ie, if it was an improvement over regular CBT) was not tested.

Pericot-Valverde et al [87] described a single case study that used a different CBT-inspired VR intervention, Virtual Stop Smoking therapy. This multicomponent intervention involves self-monitoring, information sessions about smoking, stimulus control procedures, strategies for relapse prevention, problem-solving procedures, strategies to cope with withdrawal syndrome, physiological CO exhalation feedback, and VR exposure, spread out over 6 weekly sessions. The participant had successfully quit smoking by the end of the intervention, but a replication with a larger sample as well as control conditions will be needed before any recommendations can be made.

Of the 7 behavioral interventions described, 2 [83,86] used mean years of smoking as a randomization control variable; none of the other studies reported on the statistic. It is unclear if this factor has an influence on behavioral interventions as it does on cue reactivity. Furthermore, none of the papers reported on using a sample of smokers unmotivated to quit; about half (n=4) used participants motivated to stop smoking.

Antismoking Campaigns

Finally, there is the use of VRT in information-based antismoking campaigns that warn about the consequences of smoking. VRT can create a deeper impression than 2D images or movies [88], elicit a stronger negative response, and enhance behavioral intentions to not smoke [44]. However, whether this impact translated to an actual change in behavior was not tested.

Future Directions

Given the underwhelming results that were achieved by VR-CET in terms of smoking cessation, future studies might want to explore the potential of alternative interventions. However, at present, the interest in VR-CET does not appear to have waned yet, as shown by the number of recent studies that attempt to obtain results by combining VR-CET with other therapies, such as CBT [42,89] and NRT [20,79]. It is possible that combining VR-CET with other interventions will result in a more successful intervention, as multiple aspects of nicotine addiction are addressed.

In contrast to VR-CET, interventions that used some form of behavioral intervention showed promising results. More work will be needed to solidify these findings, especially as a number of the studies reported were merely intended as pilot studies or proof of concept. One protocol study [43] laid out the design for a VR-AAT study, which would be timely as thus far only proof of concept has been reported for VR-AAT interventions. The results from the gamified interventions are promising and could lead to a lower attrition rate.

Possibly because of the ongoing controversy [38,40] surrounding ENDS, few studies to date have explored the potential use of ENDS in combination with VRT for smoking cessation therapy. However, ENDS and VRT both aim to mimic real life and allow for control over the surroundings as well as the amount of nicotine ingested, which could make them an alternative for therapy settings. De La Garza et al [21] reported a pilot study on the combination of VR-CET and ENDS as a form of NRT. The participants indicated that ENDS were not as *satisfying* as the conventional cigarette, even if it contained equal amounts of nicotine; at the same time, the placebo nicotine delivered in the study by Kotlyar et al [20] reduced craving in the same way as the actual nicotine treatment. These findings suggest that craving is a subjective experience and can be tweaked by participants' beliefs of what relief they will feel. Capitalizing

on this make-believe could be an interesting avenue for ENDS-based NRT.

Discussion

Principal Findings

The use of VRT could offer an alternative for, or addition to, smoking cessation interventions. VR can be used to recreate triggering situations in a more life-like and persuasive way than traditional methods. This may allow for the creation of an experience where both the environment and the triggers presented are tailored to the user's circumstances, which may further enhance the effectiveness of the intervention.

Although VR-CET has been the most extensively researched of all interventions, the results have been mixed at best. VR CE reliably elicited cravings, and most VR-CET interventions found that by the end of the therapy, craving in response to smoking-related cues was reduced. However, the effectiveness of therapy above and beyond alternative interventions such as CBT is debatable. These findings echo the conclusions from earlier meta-reviews [48,50,51] and analysis [49]. This lack of results is disappointing but may not be unpredictable as regular CET has been shown to have very limited behavioral effectiveness in battling addictions [22,101]. In fact, this lack of results in conventional CET has been one of the larger motivations for the adoption of VR; extinction of cue reactivity has been shown to be highly context dependent [102], and it has been suggested [46,61] that the discrepancy between the controlled laboratory environment where people were conditioned and the real-world situations where their therapy was put to the test was too large. Introducing VR would supposedly reduce these problems with generalization but still does not yield a significant effect. This may be due to the quality of the virtual environments, as they are far from photorealistic. Addiction remains a multidimensional problem, and CET (in VR or a more traditional setting) may target a component that is too small to be effective as a standalone intervention. Alternatively, the lack of results may be a consequence of the quality of the virtual worlds. Since its introduction, VR has improved greatly, but even as graphics and technology have improved the environments (or at least the ones usually developed for academic studies, ie, on a budget) are far from photorealistic and rarely closely mimic the actual world of the users. Future studies with current VRT may be able to create more realistic and personalized virtual scenarios and thus potentially obtain more reliable results.

Three other types of intervention with a behavioral component emerged: AAT-based [79,80], gamified behavioral training [56,83-85], and skill training [86,87]. The proof of concept has been provided for VR-AAT [81,82], and the 2 immersive games based on AAT demonstrated some success [56,83,84]. Similarly, tentative initial findings suggest a potential for gamified interventions that combine behavioral therapy with psychological coaching [85]. Overall, the potential of gamified interventions as an (effective) treatment program is further enhanced through the addition of a gaming element. Well-designed games lead the user to play out of intrinsic rather than extrinsic motivation [103]; thus, designing an intervention in this format could elicit higher participant engagement, which would, in turn, lead to better therapy compliance and lower dropout rates than conventional interventions. Given the high dropout rates of smoking cessation therapies [104,105] and the importance of compliance in the effectiveness of an intervention [105], these would be major advantages over conventional (nongamified) therapies and interventions.

Only 1 paper was found that combined VR and ENDS in a smoking intervention, possibly because of the ongoing controversy surrounding ENDS [36,37]. Although no consensus has been reached yet on whether the downsides of ENDS outweigh the improvements over conventional cigarettes [38,39], implementing ENDS in future interventions as an NRT component may be explored more as a viable method for smoking cessation.

A final factor that needs consideration in the discussion of VR-based interventions is cost. With the gaming industry's growing interest in the technology [51], VR has become increasingly accessible over the last few years, with a variety of affordable systems and VR template environments readily available. Nonetheless, developing VRT materials is far from cheap, and the technology thus ought to have a considerable benefit over conventional methods if it is to replace them. Considering this drawback, AR may prove to be an easier and more economical alternative, as it does not require an entire world to be created from scratch but rather uses the existing one as a template to be enhanced or altered.

Limitations

Overview

A few limitations must be noted when interpreting the outcomes of this literature review. Some of these are the consequence of the methodology and design of the papers and interventions reviewed, and some are the result of the methodology of this review itself. All of these are presented in the following section.

Limitations of the Reviewed Literature

The first limitation is related to the sample size and sample population reported in the studies. Sample sizes varied widely (between 8 and 102 or 541 for the meta-analysis). Large samples reduce the chance of false negatives and increase the chance of finding small effects [106]. In addition to the size of the sample, not all studies differentiated between treatment-seeking and nontreatment-seeking smokers, which may have been a relevant background variable. Bordnick et al [62] indicated that this may not be a problem for CE–induced craving, but there may still be an effect of motivation to quit on other outcome measures.

The second limitation concerns the experimental design of the studies. The lack of control for potentially confounding variables such as motivation to quit or the number of years of smoking addiction has been mentioned before. Many studies used a 1D measure of effectiveness; for example, some of the VR-CET studies only measured self-reported cravings. Assuming that a therapy or an intervention is considered effective when it has led to a reduction or even cessation of smoking behavior, extrapolating a single-dimension measure to indicate the overall effectiveness of a treatment introduces method bias [107].

Ideally, studies should target more than one type of measure. For example, adding physiological measures for stress (heart rate and skin conductance), smoking behavior (CO exhaled), behavioral measures such as the amount of time the participant is willing to wait until the next cigarette, how much they would be willing to spend on a cigarette, and actual smoking behavior could be included.

Moreover, few studies included control groups, a blinded design, or a follow-up measure. Together with multidimensional measurements that target psychological as well as behavioral responses, these are all methodological aspects fundamental to fully assessing the potential of an intervention. However, these were not implemented in the majority of the studies reviewed in this paper. The lack of assessment of these aspects means that the results obtained in these studies should be interpreted and generalized with care.

Limitations of This Review

With regard to this literature review, publication bias [108,109] most likely prevented some studies on VRT smoking interventions from being included in this review. By searching the Cochrane database, at least the study protocols could be found as an indication of the experiments that never made it to publication. It is encouraging that of the 3 protocols that were found with no publication of the results, only one [89] had set out to finish their study before 2020 and could thus conceivably have been published in time for this literature review. Although there is no perfect measure, this can be taken as an indication that publication bias may have been low.

In addition, the literature selection and data extraction were performed by a single researcher, without a second independent researcher confirming the results. Having these decisions depending on 1 person may introduce bias.

Conclusions

The studies presented in this review suggest that VRT can be considered a promising addition to smoking cessation therapies. Although VR-CET by itself has not yielded consistent results, tentative initial findings on behavioral interventions as well as the combination of VR-CET with these interventions are promising. Moreover, the potential of ENDS in combination with VRT may offer an alternative for future research. More rigorous testing, especially in terms of larger sample sizes, the inclusion of control groups or placebo interventions, and follow-up measures, is still needed.

Acknowledgments

Abstract

Background: Apathy is a frequent and underrecognized neurological disorder symptom. Reduced goal-directed behavior caused by apathy is associated with poor outcomes for older adults in residential aged care. Recommended nonpharmacological treatments include person-centered therapy using information and communication technology. Virtual reality (VR) in the form of head-mounted displays (HMDs) is a fully immersive technology that provides access to a wide range of freely available content. The use of VR as a therapy tool has demonstrated promise in the treatment of posttraumatic stress disorder and anxiety. In addition, VR has been used to improve conditions including depression, anxiety, cognitive function, and balance in older adults with memory deficits, Alzheimer disease, and Parkinson disease. Research using VR for the symptoms of apathy in older adults living in residential aged care facilities is limited.

Objective: This study aims to examine whether using HMDs as a tool for reminiscence therapy improves the symptoms of apathy compared with using a laptop computer and physical items with older adults living in residential aged care.

Methods: In this multisite trial, 43 participants were allocated to one of three groups: reminiscence therapy intervention using VR in the form of HMDs, reminiscence therapy using a laptop computer supplemented by physical items if required (active control), and a usual care (passive control) group. The primary outcome was apathy, and the secondary outcomes included cognition and depression. The side effects of using HMDs were also measured in the VR group.

Results: Mixed model analyses revealed no significant group interaction over time in outcomes between the VR and laptop groups (estimate=−2.24, SE 1.89; t_{40}=−1.18; P=.24). Pooled apathy scores in the two intervention groups compared with the passive control group also revealed no significant group interaction over time (estimate=−0.26, SE 1.66; t_{40}=−0.16; P=.88). There were no significant secondary outcomes. Most participants in the VR group stated that they would prefer to watch content in VR than on a flat screen (X^2_2=11.2; P=.004), side effects from HMD use were negligible to minimal according to the Simulator Sickness Questionnaire cutoff scores.

Conclusions: Although there were no significant results in outcome measures, this study found that participants engaged in the research and enjoyed the process of reminiscing using both forms of technology. It was found that VR can be implemented in an aged care setting with correct protocols in place. Providing residents in aged care with a choice of technology may assist in increasing participation in activities. We cannot dismiss the importance of immediate effects while the therapy was in progress, and this is an avenue for future research.

Introduction

Background

Apathy

Apathy is a neurological disorder with a high prevalence found in older adults living in residential aged care facilities [1,2]. Characterized as a lack of interest and diminished motivation [3], the presence of apathy results in reduced goal-directed behavior [4,5], which can result in withdrawal from activities. In long-term residential aged care facilities, lower engagement in activities and social interaction is associated with poorer quality of life [6].

Prognostic features of apathy include accelerated cognitive decline [7], and in aged care, apathy has been associated with an increased risk of mortality [8]. Although apathy is not as disruptive as other neuropsychiatric symptoms, including aggression and agitation, it can be a predictor of caregiver burden [9]. There is a lack of convincing evidence for pharmacological interventions for apathy [10-12]. Therefore, nonpharmacological individualized interventions are recommended [13,14].

Reminiscence Therapy

One such approach that can be individualized and tailored to a person is reminiscence therapy [15]. Commonly used in residential aged care facilities, reminiscence is a strength-based, person-centered approach that is recommended for consideration in clinical practice when caring for people with dementia [16]. The process of reminiscence involves recalling memories through the experience and discussion of past events and is commonly done with the assistance of familiar items [17]. The focus is on early memories. Reminiscence approaches can be classified into three types [18]. Simple reminiscence involves recalling positive memories to increase positive feelings [19]. Life review aims to consolidate both positive and negative previous life events into a meaningful life story, and finally, life review therapy involves redefining the negative interpretations of a person's past [19]. It is possible that the recall of both positive and negative memories may cause distress [20,21]; however, no reported harm has been found in a review examining reminiscence therapy [17]. In this study, a semistructured simple reminiscence approach was used, focusing on positive memories.

Positive outcomes of reminiscence found in people with Alzheimer disease include improvements in cognition, depression, and quality of life [22]. Results from a meta-analysis have reported medium effects for depression (g=0.57, 95% CI 0.44 to 0.70) and small effects for overall mental health symptoms (g=0.33, 95% CI 0.16 to 0.51) [18]. The retrieval of autobiographical memories through reminiscence also provides the social function of sharing memories with other people [23].

Autobiographical memories are an important aspect of the sense of self [24], which can be impaired in those with apathy [25,26]. In aged care, the sharing of memories or life stories can positively influence the sense of self for people with dementia [27]. Therefore, reliving autobiographical memories may translate into improvements in apathy. Although reminiscence can be performed in a group or individually, it has been recommended that individual approaches may provide increased benefits [28]. An individual approach allows sessions to be tailored specifically to a person by focusing on appropriate and relevant memories depending on the person's background. Apathy can cause a lack of interest in participation in traditional forms of activities or therapy and places the person at risk of loneliness, a prevalent problem in aged care [29]. Therefore, alternative solutions for treating apathy are required. Technology provides easy access to content and assists in maintaining engagement in therapy [15,30]. The use of immersive technology may increase therapeutic outcomes.

Virtual Reality

Technology can provide different levels of immersion, for example, computers or tablets are described as nonimmersive, and large screen televisions or projectors are semi-immersive [31]. An example of highly immersive virtual reality (VR) technology is the cave automatic virtual environment, where the image is displayed on the walls, and in some cases, on the floor and ceiling; however, this system is expensive, takes time to set up, and requires a dedicated room [32]. Another example of highly immersive VR technology is the head-mounted display (HMD); modern HMDs consist of a monitor for each eye to provide a stereoscopic image via a device worn on the head [33]. Available applications for HMDs can be passive, for example, providing a 360° view of a scenic virtual environment that changes as the viewer turns their head [34]. Applications can also allow users to pick up objects or physically move in a virtual environment, providing an interactive experience [34].

The successful use of HMDs as a tool for interventions includes exposure and distraction-based therapies [35,36]. Being a fully immersive technology, VR using HMDs eliminates any distractions and can increase the sense of presence, the psychological feeling of being in the virtual environment [37]. A high sense of presence may increase the response to the virtual environment [38]. For example, a study consisting of a sample of young adults found that autobiographical memory improved when content was viewed in VR using HMDs compared with a flat screen monitor [39]. Similar results of improved memory performance were found in participants who used HMDs compared with a desktop display in a sample of participants from a university campus and community [40]. Using HMDs

may provide increased stimulation in the process of reliving autobiographical memories in older clinical populations because of the use of a fully immersive and realistic environment. Whether this translates to improved outcomes for older adults living in residential aged care is uncertain.

Two recent reviews have reported that VR HMD applications demonstrated potential for rehabilitation in neurological diseases, including dementia, Parkinson disease, multiple sclerosis, and stroke, or of those with pain and memory deficits [41,42]. Positive outcomes, ranging from small to large effects, found in the review by Dermody et al [42], included improved pain scores in community-dwelling older adults using VR games (d=−1.54) [43], and improvements in long-term recall (d=0.70) using VR memory training in aged care residents [44]. However, no significant outcomes were reported in psychological health, activities of daily living, depression, and social life in the studies included in this review [43,45]. A recent study of 236 older adults from community centers used familiar VR content to stimulate memory. This study found significant increases in positive affect scores (mean difference 2.09) and decreases in negative affect scores (mean difference −1.99) [46]. There is evidence that using VR with HMDs with older adults can be successful [42]; however, there is a lack of comparison between VR and flat screen technology to establish the differences and advantages of using VR.

There is a paucity of evidence comparing nonimmersive or flat screen technology with fully immersive technology (HMDs) in a therapeutic context in clinical older populations. A single-session study in aged care residents compared viewing Google Maps Street View using a tablet and HMD [47]. This study found that both forms of technology provided emotional experiences for older adults. In addition, none of the 7 participants preferred using HMD over the tablet. However, an exercise study in aged care residents reported an increase in interest and enjoyment when using HMDs compared with when watching a flat screen [48]. In another study, greater improvements in physical well-being were seen in older adults in an assisting living community when viewing content related to their past, travel, and relaxation using VR as compared with television [49].

Exposure to virtual environments can cause side effects or after effects, including eyestrain, nausea, and headaches [50,51]. This can have health and safety implications when using HMDs. Therefore, there is a need to increase our understanding of the side effects of HMD use in older adults and clinical populations who are taking medication and have symptoms related to their condition that may exacerbate any VR side effects.

Objectives

The primary aim of this study is to examine whether using HMDs as a tool for reminiscence therapy improved outcomes compared with using a laptop computer supplemented by physical items if required (active control group). The primary outcome was apathy. Secondary outcomes included cognition and depression. Exploratory outcomes included loneliness and quality of life. The side effects of using HMDs were also examined in the VR group. We hypothesize the following: (1) the VR group would have lower apathy scores than the active control group using a laptop computer and physical items after the intervention and (2) both the VR group and active control combined would have lower apathy scores than the passive control (usual care) group after the intervention.

Methods

Study Design

This was a multisite nonrandomized controlled trial. Data were collected across 3 residential aged care facilities in Adelaide, South Australia. Each site was allocated a group determined by the aged care provider. Assessors conducting baseline and follow-up measures were blinded to group allocation. Participants in the intervention group were blinded to the presence of other conditions. The study was performed between December 2019 and February 2021. The CONSORT (Consolidated Standards of Reporting Trials) 2010 statement guidelines were followed [52]. A summary of the study methods is provided below, and further details of the study methods are available in the published study protocol [53].

Participants

Eligible participants were aged 65 years or older and included only those with up to moderate impairment according to the Psychogeriatric Assessment Scale [54] as assessed by the aged care facility. Participants had to be English speaking and willing to undertake follow-up assessments. Participants in the VR group had to be able to tolerate wearing an HMD and have vision that can be corrected using their eyeglasses. The eyeglass frame also needed to fit the HMD. Participants were excluded if their score on the Psychogeriatric Assessment Scale was higher than 15 or if they had significant disorders, conditions, or behaviors that would make assessment difficult. Those with confusion or disorientation issues and who might become distressed because of confusion regarding time and place were also excluded. Participants who were interested and met the eligibility criteria were provided written and verbal information about the study. A dedicated research nurse employed by the residential aged care facility or primary researcher obtained informed consent. All participants were given the opportunity to discuss their participation with family members or other responsible persons close to the participant. Consent was continually monitored during the research by asking participants at the start and end of each session if they wanted to continue. Ethics approval was obtained from the University of South Australia Human Research Ethics Committee. We refer to the published protocol for sample size calculation [53].

Materials

The terminology VR is an umbrella term that can refer to both nonimmersive and immersive technologies [55]; for the purposes of this study, VR will refer to immersive HMDs.

VR Software

YouTube VR (developed by Google LLC), a VR version of YouTube, was used to view personalized videos in VR. Wander (developed by Parkline Interactive), which uses data from Google Street View, was used to view personalized places of interest. The active control group used a laptop for viewing

content; therefore, Google Street View, YouTube, and the internet in general were used to view content on the laptop.

VR Hardware

The Oculus Quest [56] HMD, a commercially available stand-alone headset, was used for the VR group. This HMD provides stereoscopic vision at a resolution of 1440 × 1600 per eye with a 72 Hz refresh rate and provides access to the two VR software applications used.

Primary Outcome: Apathy Evaluation Scale Clinician Version

The Apathy Evaluation Scale (AES) clinician version, an 18-item scale, was used to measure apathy [3]. This scale also consists of an interview with the participant before completion to build rapport and gain an understanding of the participant. Each item is recorded with responses ranging from *not at all characteristic*, *slightly characteristic*, *somewhat characteristic*, and *a lot*. Four items were self-evaluated, and the remaining 14 items were assessed by the researcher. Five items assessed by the researcher need to be quantified, for example, a participant is required to give three or more examples to meet the criteria for *a lot*. Scores range from 18 to 72, with higher scores indicating increased apathy. The clinician version of the AES has a test-retest reliability of .88 and good internal consistency (α=.90) [3].

Secondary Outcomes

Addenbrooke Cognitive Examination III

Addenbrooke Cognitive Examination III (ACE-III) was used to assess cognitive ability [57]. ACE-III comprises subtests of attention, memory, fluency, language, and visuospatial functioning. Its maximum score is 100, with higher scores indicating higher cognitive functioning. ACE-III reported good internal consistency (α=.88) [58].

Geriatric Depression Scale Short Form

The Geriatric Depression Scale (GDS) was used to measure depression [59]. This scale was developed for older populations and is suitable for those with cognitive impairment and living in long-term institutional environments [60]. The GDS has 15 items that a participant needs to respond to with a *yes* or *no* answer. Scores range from 0 to 15. A score of >5 suggests depression, whereas a score of ≥ 10 indicates depression. The GDS has 92% sensitivity and 89% specificity when compared with diagnostic criteria [60], and good internal consistency has been demonstrated (α=.80) [61].

Exploratory Outcomes

The Quality of Life in Alzheimer Disease

Quality of life was measured using the Quality of Life in Alzheimer Disease (QOL-AD) 13-item scale [62]. Responses to items range from *poor*, *fair*, and *good* to *excellent*, with a score ranging from 13 to 52. Higher scores indicate a higher quality of life. Good internal consistency for the QOL-AD scale has been reported (α=.82) [63].

Three-Item Loneliness Scale

The Three-Item Loneliness Scale, a shortened version of the Revised University of California, Los Angeles Loneliness Scale [64], was used to assess the participants' level of loneliness. Three questions were rated on a three-point scale, with scores ranging from 3 to 9. Responses range from *hardly ever* to *some of the time* to *often*. Higher scores indicated higher levels of loneliness. Acceptable internal consistency has been reported for the Three-Item Loneliness Scale (α=.72) [64].

Simulator Sickness Questionnaire

The Simulator Sickness Questionnaire (SSQ) was used to measure the side effects of HMD for the VR group [50]. The SSQ comprises 16 items on a four-point scale, ranging from *none*, *slight*, and *moderate*, to *severe*. The three subscales measure symptoms related to nausea, oculomotor, and disorientation. Higher scores indicate higher symptoms of sickness. The SSQ is the most commonly used questionnaire in VR research [65].

Staff Questionnaire

The Staff Questionnaire was developed by the primary researcher to measure improvement or deterioration in participants from the staff members' point of view. Responses were reported on a five-point scale ranging from *not at all* to *very much so*. Domains measured included social involvement, cognitive awareness, pain, activities of daily living, behavior, and communication. The same domains were assessed for improvement and deterioration. Higher scores on the improvement questions meant more improvement, whereas higher scores on the deterioration questions meant more deterioration.

Session Record

To measure participant attendance and responses to the reminiscence sessions, a Bender session record [66] was completed for both the VR and active control groups after each reminiscence session by the researchers delivering the reminiscence content. This measure examined five subscales including *Attendance of session*, *Memory*, *Interaction*, *Responsiveness*, and *Enjoyment*. Each subscale was measured on a four-point scale ranging from 0 to 3. In addition, for both groups, participants were asked, "Would you like to do it again?" In the VR group, participants were additionally asked, "If given a choice, would you prefer to view content in VR or on a flat screen?" This was compared with the participants' previous experience of viewing television or large screen displays.

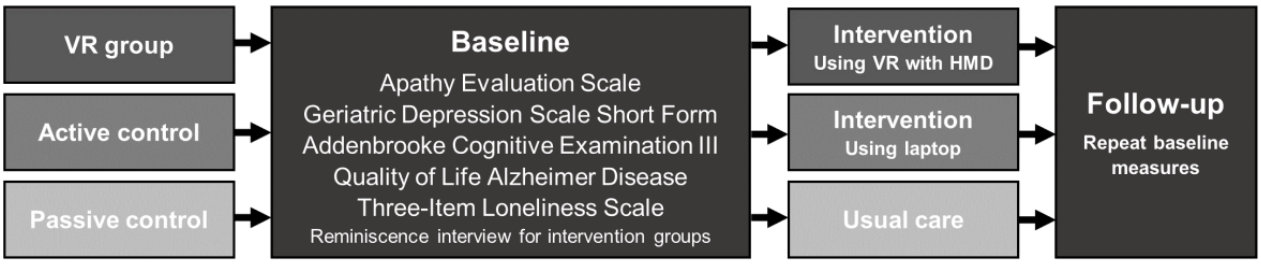
Procedure

Recruitment

Participants were selected for recruitment by senior staff at the residential aged care facility according to the inclusion and exclusion criteria. Recruitment was undertaken by a dedicated research nurse employed by the aged care facility or the lead researcher. Participants who were interested in participating in the VR group were given a demonstration of the HMD to ensure that they could tolerate wearing it and could view images to a

satisfactory standard before consent. The study flowchart is shown in Figure 1.

Figure 1. Study flow chart of procedure. HMD: head-mounted display; VR: virtual reality.



Baseline

During the baseline session, the AES, ACE-III, GDS, QOL-AD scale, and Three-Item Loneliness Scale were completed for all three groups by trained research assistants (blinded to group allocation). This process took approximately 60 minutes. For both intervention groups, a qualitative interview was conducted by a different trained researcher (unblinded to group allocation) to establish topics for the reminiscence sessions after the baseline measures were completed. This process took approximately 60 minutes. Therefore, the baseline sessions for the two intervention groups took approximately two hours. The qualitative interview was semistructured and covered themes throughout the lifespan of each participant. This included early childhood memories, adolescence, young adulthood, older adulthood, most recent memories, and musical memories. The focus was on positive experiences using reminiscence therapy guidelines [15,66].

Intervention

The VR and active control groups undertook three individual reminiscence sessions that were completed within a period of approximately 2 weeks at least 1 day apart. The reminiscence component was timed for 20 minutes. Additional time was taken to introduce and summarize the sessions. SSQ was completed before and after reminiscence sessions 1 and 3 for the VR group, adding approximately 10 minutes. Sessions were run by the lead researcher or a trained research assistant who was not involved in taking outcome measures. During the reminiscence sessions, there was continual conversation between the researcher and the participant regarding the content being viewed. Participants in the active control group viewed the reminiscence content on a laptop computer. The Oculus Quest HMD was used in the VR group. During the VR reminiscence experience, participants were seated in a swivel chair with arm rests when possible. If they were unable to sit in a chair, they remained in their bed; therefore, this was a passive VR experience. Content relating to the participant's background gained from the reminiscence interview was viewed using 360° videos from YouTube VR and street view content from the Wander app. All interactions were performed by the researcher, and sound was provided by the integrated speakers of the Oculus Quest HMD. Participants were closely monitored and asked about any symptoms or side effects of viewing content in the HMD during the sessions. Content from the HMD was mirrored onto a laptop computer to enable the researcher to select content for the participant and view the content simultaneously. The passive control group did not receive the intervention and continued with their usual care during the 2 weeks.

Objective Measures

This study collected data on objective measures that will not be reported here. Heart rate variability, galvanic skin response, and speech measures were collected for both intervention groups during the intervention sessions, and approximately 30 minutes were added to the sessions. Activity was measured 48 hours before baseline and 48 hours after follow-up for all three groups [53].

Follow-up

For both intervention groups, follow-up measures were completed the day after the final reminiscence session. The average time between baseline and follow-up for participants in all three groups was approximately 2 weeks plus 4 days for the measuring of activity, as described above. For 2 participants in the passive control group, restricted site access because of COVID-19 increased the time between baseline and follow-up sessions to almost 4 weeks. None of the participants were restricted from participating in lifestyle activities offered by the aged care facility during the research period. Lifestyle activities were reduced because of COVID-19 restrictions.

Statistical Methods

Data were entered using Research Electronic Data Capture [67] hosted by the University of South Australia. The analysis was performed using Jamovi (version 1.6.15) [68]. The primary outcome figure was created in R Studio (version 3.6.3) [69] using open visualizations [70]. The primary outcomes at baseline and follow-up were analyzed using linear mixed modeling with Helmert contrasts. This consisted of fixed factors of group (VR, active control, and passive control) and time (baseline and follow-up), with the intercept of the participant as a random factor. For comparisons of the two intervention groups with the usual care group, Helmert contrasts were used where the contrasts compared (1) combined intervention groups with the usual care group and (2) the two interventions. Additional analyses were performed by including only participants who met the criteria for a diagnosis of apathy at baseline using a cutoff score of 37.5 [3,71]. The influence of potential covariates, including depression and cognition at baseline, was examined. ACE-III, GDS, QOL-AD scale, and the Three-Item Loneliness Scale were analyzed as per the primary outcome. Assumptions of normality using the Shapiro-Wilk test found SSQ total and subscale scores to significantly deviate from a normal

distribution; therefore, Wilcoxon signed-rank tests were performed for all SSQ comparisons. Assumptions of normality using the Shapiro-Wilk test found session record total and subscale scores, except for memory, to significantly deviate from a normal distribution; therefore, Mann-Whitney U tests were performed for all session record comparisons. No adjustments for multiple comparisons were made for all planned analyses; therefore, significance was set at <.05. Effect sizes for linear mixed modeling were calculated using partial η^2 calculated from the *t* statistic and sample size with the following cutoffs: small=0.01, medium=0.06, and large=0.14.

Results

Demographic and Baseline Scores

A total of 74 participants were identified and approached to participate in the study, of whom 46 consented (Figure 2). In total, 28 participants declined because they were not interested in participating or for personal reasons. A total of 15 participants were initially allocated to each of the three conditions; 3 participants withdrew from the study. One participant in the VR group was admitted to the hospital after completion of the baseline measures and was unable to continue upon their return. A second participant in the active control withdrew after the baseline measures, as they did not wish to continue. A final participant in the passive control withdrew when follow-up measures began, as they did not wish to continue. As this was a per-protocol analysis, the participant in the VR group was replaced with another participant; however, COVID-19 restrictions prevented the replacement of participants in the other two conditions because of site access restrictions during the research period.

The background characteristics and baseline results of the outcome measures of participants who completed the study are reported in Table 1. Using a cutoff score of 37.5 for the AES [3,71], 65% (28/43) of participants met the criteria for a diagnosis of apathy at baseline. Of the remaining participants, 7% (3/43) scored 37, 12% (5/43) scored between 33 and 36, and 16% (7/43) scored between 22 and 28.

[a]ACE-III: Addenbrooke Cognitive Examination III.

[b]QOL-AD: Quality of Life in Alzheimer Disease.

Primary Outcome

For contrast 1 (pooled VR and active control groups compared with passive control), there was a significant main effect of group, with higher apathy scores in the passive control group. For contrast 2 (VR group compared with active control), the main effect of group was not significant (Table 2).

Table 2. Fixed effects parameter estimates for the Apathy Evaluation Scale.

Parameter	Estimate (SE; 95% CI)	*t* statistic (*df*)	*P* value	Partial η^2
Main effect				
Time	−0.54 (0.78; −2.06 to 0.98)	−0.69 (40)	.49	0.012
Contrast 1[a]: passive versus (active and VR[b])	5.60 (2.55; 0.61 to 10.59)	2.20 (40)	*.03*[c]	0.108
Contrast 2[d]: active versus VR	5.33 (2.91; −0.36 to 11.03)	1.84 (40)	.07	0.078
Interaction				
Contrast 1: time×passive versus (active and VR)	−0.26 (1.66; −3.51 to 2.99)	−0.16 (40)	.88	0.001
Contrast 2: time×active versus VR	−2.24 (1.89; −5.95 to 1.47)	−1.18 (40)	.24	0.034

[a]Contrast 1 compares the pooled interventions (virtual reality and active control) with the passive control group.

[b]VR: virtual reality.

[c]Italics indicates significant values.

[d]Contrast 2 compares both intervention groups (virtual reality and active control).

Contrast 1 (pooled VR and active control groups compared with passive control) revealed that an intervention did not significantly change AES scores from baseline to follow-up (ie, the interaction between group and time was not significant). Contrast 2 (VR group compared with active control) was also not significant (Table 2). The addition of covariates (cognition and depression) did not change the statistical significance.

When restricting the sample to the subgroup that met the AES cutoff of 37.5, the same pattern of results was found (Table 3). The sample size was reduced to 28 (7 in the VR group, 10 in the active control group, and 11 in the passive control group).

Figure 3 presents the baseline and follow-up AES scores for the participants in each group.

Table 3. Fixed effects parameter estimates for the Apathy Evaluation Scale for subgroup meeting the Apathy Evaluation Scale cutoff of 37.5 at baseline.

Parameter	Estimate (SE; 95% CI)	*t* statistic (*df*)	*P* value	Partial η^2
Main effect				
Time	−1.38 (1.01; −3.36 to 0.60)	−1.36 (25)	.19	0.069
Contrast 1[a]: passive versus (active and VR[b])	5.12 (2.10; 1.01 to 9.23)	2.44 (25)	*.02*[c]	0.193
Contrast 2[d]: active versus VR	2.30 (2.65; −2.90 to 7.50)	0.87 (25)	.39	0.029

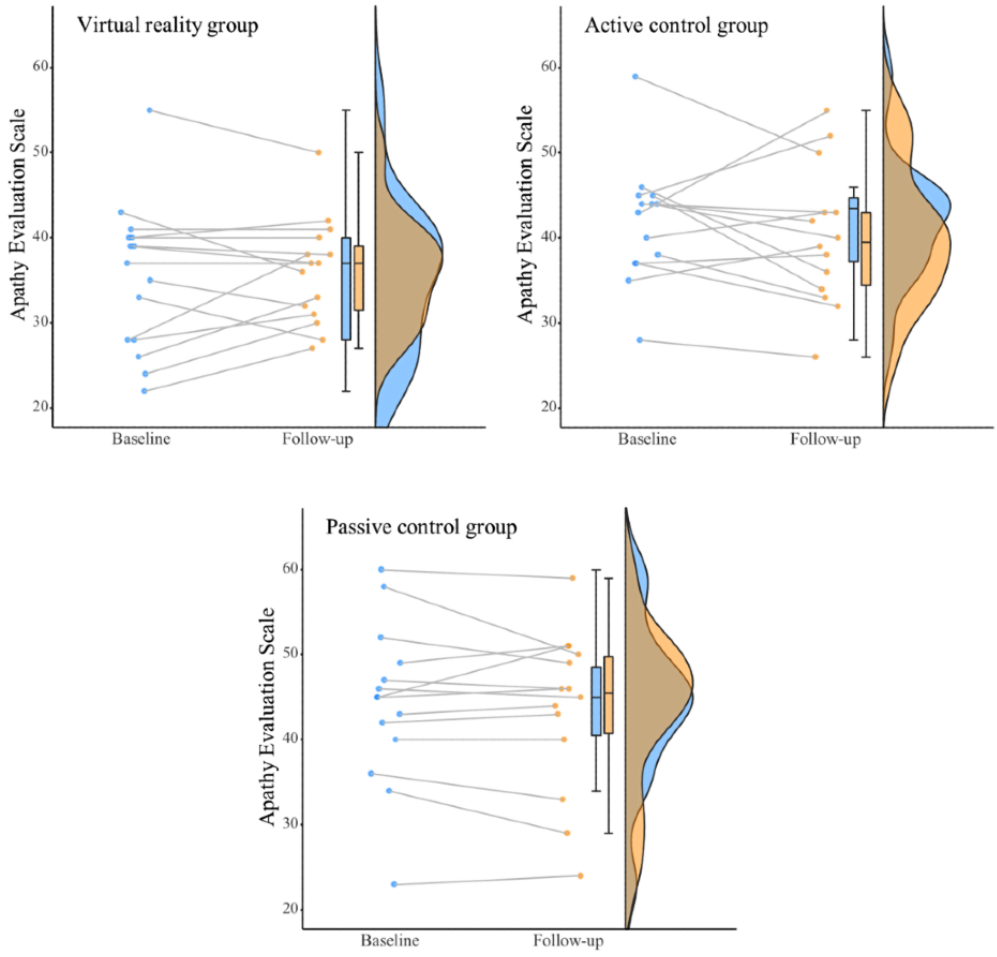
[c]Italics indicates significant values.

[d]Contrast 2 compares both intervention groups (virtual reality and active control).

Figure 3. Baseline and follow-up apathy scores for each group with each line representing one participant. Boxplots and raincloud indicate distribution in baseline and follow-up scores.



Secondary Outcomes

No significant results were observed for the ACE-III and GDS (Table S1 in Multimedia Appendix 1). Table S2 in Multimedia Appendix 1 presents results restricting the sample to the subgroup that met the AES cutoff of 37.5 at baseline.

Exploratory Outcomes

No significant results were observed for the QOL-AD scale and the Three-Item Loneliness Scale (Table S1 in Multimedia Appendix 1). Table S2 in Multimedia Appendix 1 presents results restricting the sample to the subgroup that met the AES cutoff of 37.5 at baseline.

SSQ Results

The average pre-VR SSQ scores and post-VR SSQ scores for sessions 1 and 3 were compared. The results were not statistically significant (Table 4). There were no dropouts because of side effects from the HMD use. Two participants reported back the after effects that occurred in the evening after their first morning VR session. This included a headache in one participant and a heavy-head feeling in another participant. The after effects were short-lived and did not cause significant discomfort.

Table 4. SSQ[a] means and SDs with statistics and effect size.

SSQ	Pre-SSQ, mean (SD)	Post-SSQ, mean (SD)	Statistic	*P* value	*d* value
Total	4.86 (6.11)	5.49 (5.98)	6.50	.46	−0.38
Nausea	5.72 (7.90)	6.36 (10.30)	5.50	.68	−0.27
Oculomotor	5.56 (7.14)	7.83 (9.11)	4.50	.25	−0.57
Disorientation	5.10 (10.01)	5.57 (8.40)	3.50	.71	−0.30

[a]SSQ: Simulator Sickness Questionnaire.

Staff Questionnaire

The Staff Questionnaire data were not included in the analysis. This was because of missing data for 12 participants caused by COVID-19 restrictions that did not allow follow-up with staff. Therefore, this would have made the results unreliable.

Session Record

The sum of the three sessions was used; therefore, the scores ranged from 0 to 9 for each subscale. The total score of the combined subscales ranged from 0 to 45 for all three sessions. Results comparing the VR group with active control for total and subscale scores were not statistically significant (Table 5). Results from the questions asked in the session record found that 73% (11/15) of participants in the VR group preferred viewing content in VR to a flat screen if given a choice, 7% (1/15) stated that they preferred a flat screen to VR, and 20% (3/15) were undecided. The proportion of participants who responded a preference for VR was significant (X^2_2=11.2; *P*=.004). Participants in both the VR and active control groups stated that they would like to do reminiscence again.

Table 5. Session record means and SDs for each group with statistics and effect size.

Session record	Virtual reality group, mean (SD)	Active control, mean (SD)	Statistic	*P* value	*d* value
Total	36.40 (7.21)	38.86 (5.02)	84.0	.37	0.20
Attendance	7.93 (1.44)	8.14 (1.61)	94.5	.60	0.10
Memory	5.60 (2.90)	7.36 (2.06)	66.0	.09	0.37
Interaction	8.20 (1.26)	8.50 (0.76)	99.5	.80	0.05
Responsiveness	7.53 (1.85)	8.57 (1.09)	72.0	.08	0.31
Enjoyment	7.20 (1.42)	6.29 (1.33)	68.5	.10	0.35

Discussion

Summary

To the best of our knowledge, this is the first clinical trial to compare the use of VR with flat screen technology for reminiscence in an aged care setting with a usual care control group. Well-established and validated measures were used, and there was a 100% adherence rate once the intervention commenced. It was also found that with correct procedures, side effects of using HMDs can be minimized and that VR technology can be implemented in an aged care setting. Participants also enjoyed the process of reminiscing indicated by the session record with all participants stating that they would like to do reminiscence again.

Content

It was found that the content for both intervention groups for all three sessions could be sourced using readily available apps, as per the feasibility study [72]. Common types of content the participants viewed included their original family home, the school they attended, places of employment, and travel destinations. In many instances, it was possible to tour inside buildings or places of interest and remote tourist destinations because of the increased access available in both the Wander app for the VR group and Google Street View for the active control group. Both YouTube and YouTube VR also provided access to travel destinations in addition to the music that the participant had memories of.

VR Group and Active Control Comparison

The results of this study are inconclusive, with no significant differences found between the intervention groups. Median scores for apathy decreased in the active control group and remained the same in the VR group from baseline to follow-up (Figure 3). Results from the session record for the VR group indicated that there was a preference for viewing content in VR than on a flat screen. In addition, a nonsignificant small effect size was found for enjoyment with higher scores in the VR group; however, similar small effect sizes with higher scores in the active control group were reported for responsiveness and memory. Anecdotally, there were more positive emotions observed in participants in the VR group when participants viewed familiar content compared with the active control group. The enjoyment or preference for VR did not translate to improved outcomes over flat screen technology. The findings from our study are consistent with those of a previous study [73] examining the use of VR by older adults with dementia, where no significant changes were found in outcome measures; however, VR did provide an engaging experience from the perspective of both participants and caregivers.

The availability of content when using the apps in the VR group (Wander and YouTube VR) was equivalent to that of the apps used for the active control group (Google Street View and YouTube); however, there were instances where the internet in general was used for the active control group, increasing the availability of content. In addition, in the active control, physical items were used in some instances (photo albums) if the participant requested this; however, the laptop was still always used, and the physical items only supplemented the reminiscence experience. This means that there were differences other than the display technology between the two intervention groups.

In both YouTube VR and Wander, participants had 360° vision by turning in the swivel chair and if the researcher used the controller to turn in the virtual environment. The Wander app provided increased movement backward and forward through the environment navigated by the researcher while participants remained stationary. The Oculus Quest HMD used in this study is capable of six degrees of freedom (head and body movement). As the participants were stationary and the apps used did not use the full capabilities of movement in the virtual environment, the participants were not provided with the optimum VR experience. Interactive VR with software using six degrees of freedom where the participant moves in the virtual environment has been found to increase the sense of presence and positive affect [34], which may not be an option for older adults in residential aged care because of safety aspects, including increased risk of falling. However, research using HMDs limited to three degrees of freedom (head movement only) for pain and posttraumatic stress disorder has reported positive outcomes [36,74].

Although VR provides increased immersion and realism, the interaction between the participant and researcher or therapist can be compromised by the HMD. Improving outcomes related to neuropsychiatric symptoms or quality of life may be influenced by interactions with the researcher or therapist. For example, reminiscence therapy traditionally involves attentive behaviors, including eye contact and body language [75]. Wearing the HMD during the interventions did not provide the same level of personal interaction as in the active control group. This may explain why VR in this study did not demonstrate the same positive outcomes seen in VR research using exposure and distraction-based therapies [35,36], where there is increased focus on the content being viewed rather than interaction with the therapist.

It is important not to discount the possibility that immediate effects provide enjoyment and stimulation during an intervention for participants that may not translate to longer-term measures [76]. Positive results related to apathy and emotion reported in previous studies using HMDs have been measured directly after a VR experience [46,72,77]. What has not been reported in this study is any immediate physiological effect when taking measures directly after the VR experience and how this compares with flat screen technology.

Effect of Reminiscence Therapy

There were no significant differences in outcomes from baseline to follow-up between the pooled intervention and passive control groups. These results contrast with the participant enthusiasm and enjoyment during the intervention in both groups evidenced by 100% participation once commencing, measured enjoyment levels from the session record, wanting to participate in reminiscence again, and anecdotal feedback from staff. Consistent with the meta-analysis by Pinquart and Forstmeier [18], a medium effect size was observed for depression, with reduced depression in the intervention groups over time, but this effect was not statistically significant (P=.09; partial η^2=0.069; Table S1 in Multimedia Appendix 1).

Compared with previous traditional reminiscence studies including apathy as an outcome, our study did have a relatively small dosage and was conducted over a short period [78,79], which may have contributed to the lack of statistically significant results. However, in an aged care setting, it may not be necessary to see improvement but a reduction or stabilization in the rate of decline of conditions, including apathy for the intervention to benefit participants [80]. Entry into aged care facilities results in accelerated cognitive decline compared with people living in the community [81]. It is unknown whether the intervention in this study was successful in altering the trajectory of decline from apathy to more severe symptoms that would require a longer intervention period. The number of sessions was selected to increase the feasibility of the trial, reduce attrition bias in an aged care context, and determine from immediate effects reported from our feasibility study [72]. Dose-effect models do have a nonlinear relationship [82], and previous studies have seen improvements in three sessions using reminiscence to improve agitation [83], verbal fluency and communication [84], increased engagement [85], self-esteem and depression [86,87], and anxiety [88]. As VR can provide increased stimulation compared with traditional therapies, the dosage required is yet to be established. There was also a significant difference between the groups at baseline, which may have also contributed to the lack of statistical differences.

The pooled scores of the intervention groups on apathy were significantly lower at baseline compared with those of the passive control group and may have accounted for a lack of treatment effect. Equality between groups is more likely to be difficult to achieve in smaller samples [89], particularly if the sample includes older adults [90]. In an aged care setting, this is further complicated because of the focus on providing support for people to age in their homes. This means that residents entering aged care are now older, have complex needs, and are taking multiple medications [91]. Although participants with severe cognitive decline were excluded and covariates controlled for baseline differences, there were day-to-day differences in a participant's condition commonly observed throughout the research period. Despite the use of reliable and valid measures, the selection of outcome measures is a challenging issue in residential aged care [92], and they may not be sensitive to changes in all residents at all times.

VR Side Effects

Results from SSQ revealed negligible to minimal side effects according to the cutoff scores [93]. There were 40% (6/15) of participants who reported symptoms before VR because of existing conditions. Therefore, it is important to take measures before exposure of this population to VR to accurately understand and differentiate symptoms occurring during HMD use. Two participants reported possible after effects in the VR group. This occurred in the evening after a morning VR session in 2 participants, one participant reported a headache and the second had a heavy-head feeling. The symptoms were not long-lasting and did not cause any significant discomfort. A consideration for future research is to advise the participants and staff that these symptoms may occur.

Limitations

Participants in this study were not classified as having apathy at baseline according to the AES; therefore, there were participants in the study who had relatively low scores at baseline, leaving little room for improvement. However, this was not supported by subgroup analysis. The approach of not using a cutoff score to classify participants as having apathy was taken because of positive changes seen in our feasibility study [72] in participants with low apathy scores below recommended cutoffs, and the high prevalence of apathy in aged care.

The study included participants with different conditions who were taking a range of medications, and the sample size was relatively small; these factors affected generalizability and was also a possible reason for the lack of significant differences in outcome measures over time. In addition, only those interested in reminiscing may have participated in the research in the intervention groups. Participant selection for recruitment was performed by staff at the aged care facility. This may have resulted in selection bias within the sample. Although 3 separate sites were used in this study, they were run by the same aged care facility, therefore providing a similar quality of care and within a 20-km radius of each other. To maximize comparability between participants, a cutoff score on the Psychogeriatric Assessment Scale was used; therefore, participants with severe cognitive impairment were not included in the trial. Maximizing comparability further would have severely restricted recruitment numbers and the feasibility of the trial. This was overcome by including covariates at baseline in the final analyses, which did not significantly affect the results. As participants with severe cognitive impairment were excluded from this study, we cannot make any assumptions as to whether using HMD is suitable for this stage of cognitive impairment. A sensory approach to reminiscence using physical objects or items, including pictures, may be the best approach for those with severe cognitive impairment [94].

The results of this study may have been affected by the global pandemic. Additional hygiene measures introduced during the research period included wearing masks. Many participants in this age group and setting can have hearing problems, and wearing a mask reduces the communication of facial expressions and reduces the projection of a person's voice and clarity. How this influenced both outcome measures and intervention sessions was not known. Apathy has been reported as one of the most affected symptoms in patients with Alzheimer disease [95] and increased caregiver burden in patients with neuropsychiatric symptoms [96] during the pandemic. Participants also had severely restricted visitations from family and friends at times during the research period, which may have exacerbated the symptoms and reduced the likelihood of statistically significant outcomes of the intervention.

Conclusions

This study examined changes in apathy using VR. Although no statistically significant difference was found between the VR group and the active control group, we have demonstrated that VR can be implemented in an aged care setting with correct protocols in place and that residents in aged care enjoy the process of reminiscing. The use of VR provides access to a wide range of content that is always increasing, and aged care facilities may be able to use VR in other contexts, for example, in lifestyle activities for music or travel.

To facilitate implementation in residential aged care, potential co-designers of VR activities could consist of key stakeholders, including management of aged care facilities, staff who organize and deliver activities, residents, and family or friends of residents. Staff members who deliver activities in residential aged care facilities would normally already have the necessary skills for dealing with and engaging with people in residential aged care. Clinician involvement in training in the use of HMDs would assist in managing health and safety risks and providing the best experience for both implementing it as an activity in residential aged care and for optimum data collection in research. This would include recommendations of HMD type, monitoring of side effects, correct fitment and setup of HMDs, and sourcing of content.

The success of using VR in exposure- and distraction-based therapies may not transfer to therapeutic uses in an aged care setting. However, the results from this trial are not definitive, and longer-term research including more sessions is required. Giving participants a choice between immersive and flat screen technology can assist in increasing enjoyment and participation rates in lifestyle activities, ultimately providing more engaged residents for aged care facilities, particularly for those with

apathy. Physiological measures for assessing immediate effects and the use of actigraphy as an objective measure of apathy are an avenue for further research that will be reported from this study.

Acknowledgments

DS was supported by the Australian Government Research Training Program Scholarship.

TL and HADK were funded by National Health and Medical Research Council Dementia Research Leadership Fellowships (GNT1136269 and GNT1135676, respectively).

The funding bodies listed above did not contribute to the design of the study, data collection, interpretation of data, or writing of the manuscript.

The authors would like to thank Veronica Ogilvy for recruiting the participants.

Abstract

Background: The experience of undergoing magnetic resonance imaging (MRI) can be anxiety provoking, particularly for pediatric patients and their families. Alternative methods to improve success and experiences without the use of sedation are needed.

Objective: This study aims to compare the effectiveness of a virtual reality (VR)—based simulation app (VR-MRI) with a standard preparatory manual (SPM) and a hospital-based Child Life Program (CLP) on success and anxiety during a simulated pediatric MRI scan. Our secondary aim is to compare caregivers' reported anxiety, procedural data, caregiver usability, child satisfaction, and fun.

Methods: This unblinded, randomized, triple-arm clinical trial involved 92 children aged 4-13 years and their caregivers. Recruitment was conducted through posters, public libraries, community centers, and social media. At a 2-hour session, participants were instructed to prepare for a simulated MRI head scan using one of three randomly assigned preparation materials: the VR-MRI app, SPM, or the CLP. Data were collected before preparation, during a simulated MRI head scan, and after the simulated scan. The primary outcomes were the success of the simulated MRI scan (MoTrak head motion tracking system), and child-reported anxiety (Venham picture test). We secondarily measured caregivers' reported anxiety (short State-Trait Anxiety Inventory), procedural data (minutes), usability (Usefulness, Satisfaction, and Ease of Use Questionnaire), and child-reported satisfaction and fun (visual analog scales).

Results: A total of 84 participants were included in the final analysis (VR-MRI: 30/84, 36%; SPM: 24/84, 29%; and CLP: 30/84, 36%). There were no *clinically* significant differences between the groups in terms of success during the MRI simulation (P=.27) or the children's reported anxiety at any timepoint (timepoint 1, P=.99; timepoint 2, P=.008; timepoint 3, P=.10). Caregivers reported being significantly more anxious after preparing with the manual than caregivers in the other 2 groups (P<.001). Child and caregiver anxiety had a significant relationship, increasing together with moderate effect (r_{84}=0.421; P<.001). Participants using VR-MRI took the most time to prepare (P<.001) and participants using the manual took the least time (P<.001). No statistically significant relationships were found between time preparing and time completing the simulated assessment (P=.13). There were no differences found in ease of use (P=.99), ease of learning (P=.48), and usefulness (P=.11) between the

groups; however, caregivers reported being significantly more satisfied with the VR-MRI app and CLP than SPM (P<.001). Children reported the most satisfaction with the CLP (P<.001). There were no differences in how much fun the preparation materials were perceived to be (P=.37).

Conclusions: Digital preparation experiences using VR-based media could be a viable solution to improve the success of nonsedated MRI scans, with outcomes comparable with hospital-based in-person preparatory programs. Future research should focus on validating the results in a real MRI setting.

Introduction

Background

Previous reports estimate that between 50% and 75% of pediatric patients experience elevated anxiety and distress before a new medical procedure, such as medical imaging [1,2]. Poor management of this anxiety has an impact on patient experience by causing undue psychological and physiological distress [1-4] and movement during the procedure, which can significantly reduce the diagnostic quality of medical imaging [5]. It also has a ripple effect by causing additional logistical, operational, and economic burdens on the health care system and patients [6,7]. Short-term consequences include pain or discomfort, anxiety, crying, and poor cooperation during the procedure [1,8,9]. In the long term, negative experiences can evolve into posttraumatic stress syndrome, fear, changes in pain perception and coping effectiveness, avoidance of medical care, and phobias, causing difficulties during future medical experiences [9,10]. These consequences can lead to additional resource requirements, system impacts, and costs of care that are reported to be 3.24-9.56 times higher for sedated patients than for those who can complete the procedure unsedated [6]. Thus, it is important to properly and effectively assess pediatric patients before medical procedures and improve compliance with appropriate preparation techniques whenever feasible.

At our institution, >4500 pediatric patients undergo magnetic resonance imaging (MRI) each year, with approximately 45% of patients requiring sedation. In the 2017 to 2018 fiscal year, the waitlist for sedated MRI reached a significant point where some patients were forecasted to endure a wait of >1 year for their scheduled appointments. To address this, the hospital launched a coordinated strategy that included increased operational capacity for medical imaging and funding for clinical and support services. Certified child life specialists (CCLSs), trained to prepare patients and families for procedures, were among these resources. CCLSs make targeted efforts to reduce the need for procedural sedation through training and exposure therapy techniques involving simulated procedures and therapeutic play [11-14]. Workshops or programs delivered by CCLSs have been implemented in >400 North American health care settings [13] and are considered a key factor in enabling some patients to undergo imaging without the use of sedation, where it may have otherwise been indicated to address high preprocedural anxiety [11,15].

The Child Life Program (CLP) at our hospital uses a replica of an MRI unit to orientate and practice the process with patients before the true imaging procedure. This method has been documented in the literature by other investigators [15-17]. However, capacity limitations still exist, and there are socioeconomic costs and logistical considerations of only having these units available on-site at tertiary care facilities. To mitigate this, our hospital offers physical materials such as preparatory manuals and telephone and email consultations to orient patients before the procedure. These methods have also been discussed in the literature [12,14,18,19]; however, there is some conflicting evidence regarding their efficacy [20].

Recently, virtual reality (VR), a computer-generated simulation of a 3D environment that can be explored and interacted with by the use of a head-mounted display (HMD), has emerged as an effective solution for reducing anxiety in a variety of pediatric psychological applications [21,22], including preprocedural anxiety [23-32]. Although the use of VR in hospital settings is promising, to our knowledge, only one study has compared it with the CLP regarding anxiety [30]. We also found only one small meta-analysis comparing different types of preparation programs regarding objective image quality [33]. Of the studies that have been conducted to evaluate VR in procedural preparation thus far, most have focused primarily on self-reporting and survey metrics [27,28,30]. There is a need for rigorous randomized clinical trials using innovative methods to establish the safety, feasibility, and efficacy of alternatives to sedation in preparing pediatric patients for medical imaging procedures before applying them in real pediatric clinical settings [21,34-36].

Objectives

In this context, this study aimed to compare the effectiveness of a custom-developed VR-based intervention with established hospital alternatives in preparing children aged 4-13 years for a simulated medical imaging procedure. We hypothesized that a VR app (VR-MRI) based on experiential learning [37] and social cognitive theory [38] would be effective in preparing pediatric patients for a successful MRI experience, reducing periprocedural anxieties and, thus, noncompliant behaviors contributing to poor image quality or acquisition. We secondarily hypothesize that:

- VR-MRI would reduce caregiver anxiety;

- Children's anxiety would be related to their caregiver's anxiety;
- More time practicing would result in periprocedural efficiency;
- Caregivers would be satisfied with VR-MRI, and it would be perceived as useful and easy to learn;
- Children would be satisfied with VR-MRI, and it would be perceived as fun to use.

Ultimately, we suggest that digital preparation apps using immersive media, such as our VR-MRI solution, could improve outcomes and patient experience by introducing standardized, accessible, and independently repeatable opportunities for experiential learning and preprocedural simulated practice. Furthermore, we suggest that interventions such as this could reduce costs and burden of health systems [7] through increased efficiency and reduced need for pharmaceutical intervention or anesthesia services to improve compliance during medical imaging.

Methods

VR-MRI Design

The VR-MRI media was custom-designed by the British Columbia Children's Hospital Digital Lab. The development process was informed by the literature [39], encompassing recent design strategy recommendations for VR [34]. The development of VR-MRI included iterative consultation and testing with a multidisciplinary team of approximately 8 stakeholders, including CCLSs, radiology technicians, child psychologists, health system administrators, and the research team. The curriculum focused on the same material included in the standard preparatory manual (SPM) and CLP: developing rapport with medical professionals, getting comfortable with the hospital setting and medical equipment, assessing reactions to pictures of a real MRI, discussing the upcoming medical procedure, and getting comfortable with earplugs, headphones, loud noises, restraints, the head coil, going into and remaining inside the bore, and holding still.

We used the agile development methodology to cycle through user experience design, development, alpha testing, and beta testing [40]. The content in our study was custom developed in Unity (Unity Technologies version 2018.4.9f1) and displayed on a Samsung S9 mobile phone that was used with a MERGE VR headset (Merge Labs Inc). The headset was selected for its balance of quality (eg, repeat use, compatibility with hygiene solutions, and interpupillary adjustments designed for children) and affordability, priced at Can $40 (US $32). The headset requires a mobile phone to be inserted into an embedded front panel that is viewable to the users. We used AirServer Connect (App Dynamic ehf) to mirror the VR-MRI sequence in real time on a tablet device for caregivers to watch in parallel.

VR-MRI App

Tutorial

A tutorial was designed to help the user learn how to interact with the different elements presented in the virtual environment. The tutorial included a dinosaur in outer space that taught the user how to interact with the elements, see in 360°, and interact with hotspots (referred to as teleportation devices). An image of the tutorial is shown in Figure 1.

Figure 1. A screenshot of the virtual reality magnetic resonance imaging tutorial.

Tour Sequence

The tour sequence aimed to get the user comfortable at the hospital, with the medical staff, and with the medical equipment. For creating a sense of safety in the hospital, users were first introduced to a radiologist and a peer in the reception area (Figure 2). They led the user through an interactive guided tour of the hospital reception areas, the imaging room, and the steps of a head scan. Each room can be passively explored by rotating the head in 360°. To introduce some autonomy, we also implemented interactive hotspots that needed to be activated by the user to transition between rooms or sequences (Figure 3).

Figure 2. A screenshot of the introduction to hospital staff and a peer in the reception area.

Figure 3. A screenshot of the interactive hotspots used to transition through rooms and sequences.

In the MRI room, the procedural steps of the head scan were introduced. The MRI procedure involved wearing earplugs, headphones, putting on the restraints (referred to as seatbelts), putting on the head coil (referred to as a helmet), listening to sounds (referred to as familiar sounds), and going into the bore (referred to as the tunnel). If the user was distracted during the introduction of important information, cued by not looking in the appropriate direction, the sequence would stall until the user's attention was refocused appropriately (Figure 4). To improve the child's ability to cope with the MRI sounds, which are very loud and noisy, we introduced them as familiar sounds using a narrative element while the sounds played. To further build comfort with the loud noises, users were given the opportunity to play with the sounds via buttons (Figure 5).

Figure 4. A screenshot of the sequence focusing the user's attention on the head coil.

Figure 5. A screenshot of narrative elements used to describe the magnetic resonance imaging sounds.

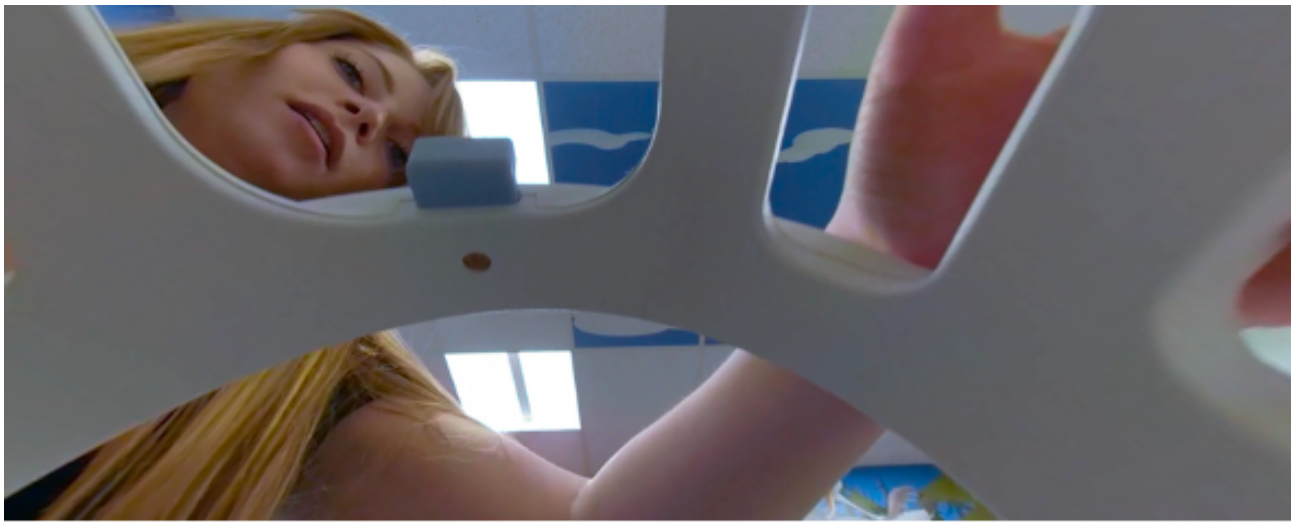
After the introduction to the procedure, the user was invited to watch a peer successfully complete an MRI scan and then invited to complete one themselves. At this point, the user could choose to either watch the peer again or attempt it themselves by selecting an interactive hotspot.

The Virtual MRI Experience and Real-time Feedback Game

During the user's virtual imaging experience (first-person view), the radiologist prepared them for the scan by inserting the earplugs and putting on the headphones (Figure 6). Once the safety equipment was put on, the user was instructed to lie down. For safety purposes, the research assistant helped facilitate this movement on a yoga mat. After the participant laid down, the scene progressed to attaching the head coil (Figure 7). The radiologist then placed them in the tunnel.

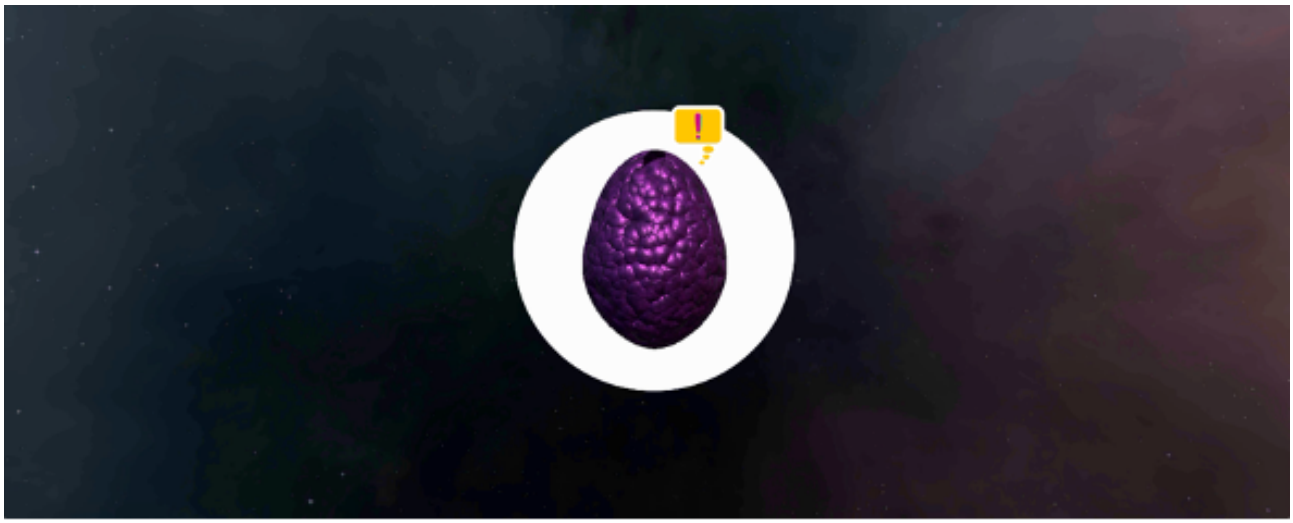
Figure 6. A screenshot of putting in earplugs during the user's virtual imaging experience.

Figure 7. A screenshot of putting on the head coil during the user's virtual imaging experience.



Once in the tunnel, a sequence began to engage the patient in game-based activities to build capacity for self-regulation of their movements during the scan. The user was invited to interact with a dinosaur egg that offered real-time feedback on indicators of movement (such as tilt, shake, rotation, or swing) measured by the mobile phone's gyroscope (Figure 8).

Figure 8. A screenshot of the real-time feedback during movement, measured using the mobile phone gyroscope.



As a means of progression, the game has three levels that become more challenging as feedback mechanisms are eliminated, and presence in the bore is reintroduced through sounds and visual cues (Figure 9). The time to complete each game differs between participants, as success can only be achieved by staying still. After the third level was achieved, users were invited to try again by staying still or exit the bore. Once the system was prompted to exit, the user was removed from the tunnel, and the experience was then noted as complete.

Figure 9. Screenshots of the levels where feedback mechanisms are eliminated and presence in the bore is reintroduced through sounds and visual cues.

Standard Preparatory Manual

The SPM group received the hospital's SPM for nonsedated MRI. The manual contains a series of photos showing the MRI experience step-by-step and is intended to help children and their families prepare for medical imaging (Multimedia Appendix 1). Caregivers were instructed to use the manual to prepare for an MRI as they would at home; however, standardized preparation was not enforced as this would not have been reflective of the environment. Materials (eg, chair and MRI sounds) referenced in the manual for practicing were provided.

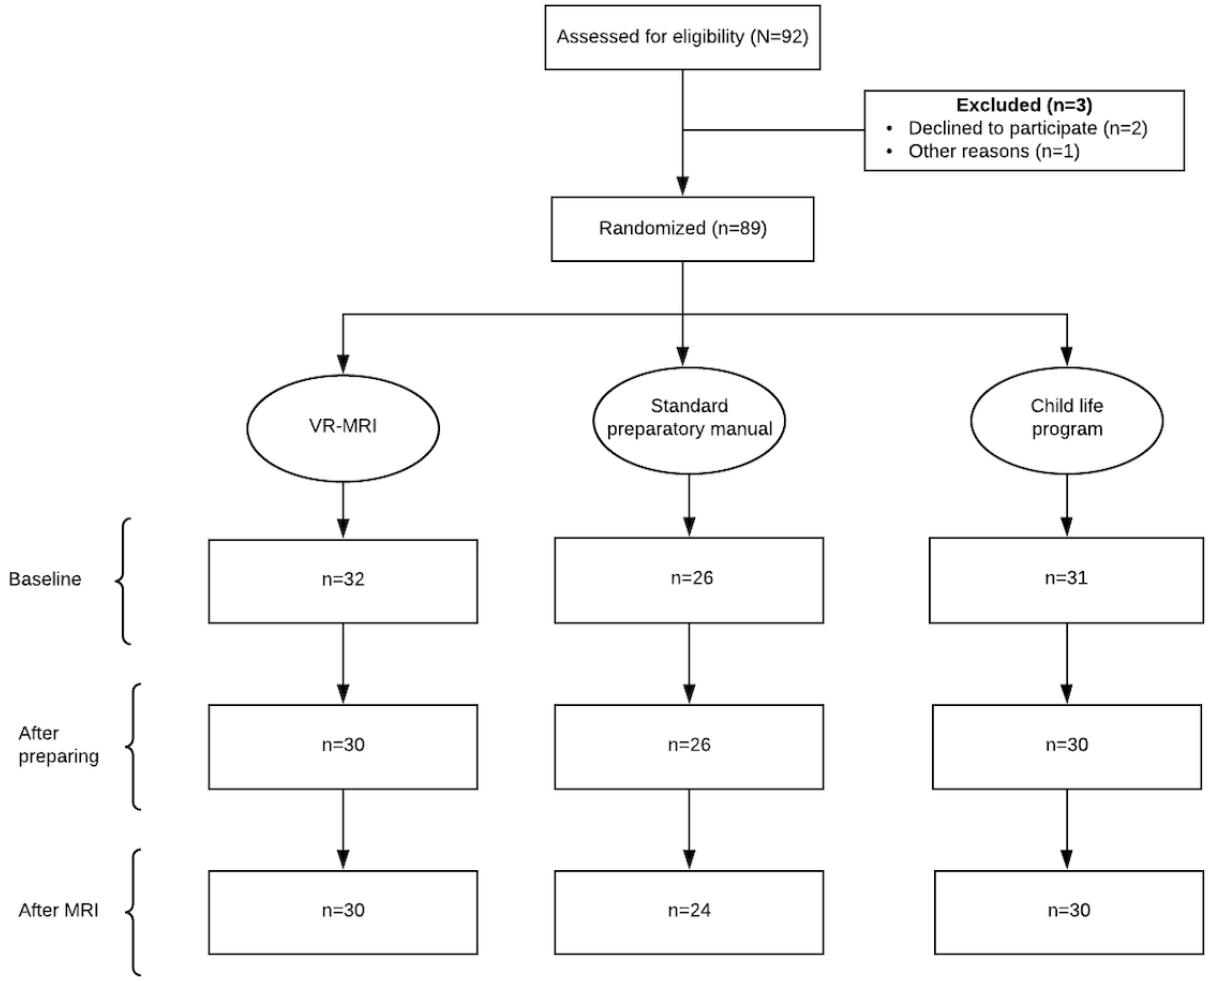
Child Life Program

The CLP group received conventional care, where a CCLS was introduced and prepared the participant with the hospital MRI simulator. The curriculum focused on developing rapport with medical professionals, getting comfortable with the hospital setting and medical equipment, assessing reactions to pictures of a real MRI, discussing the upcoming medical procedure, and getting comfortable with earplugs, headphones, loud noises, restraints, the head coil, going into and remaining inside the bore, and holding still. Preparation was not standardized as it would not have been reflective of the current environment. Individualization and adaptation are the tenets of CLP processes.

Principal Objectives

The primary objectives were to evaluate the effectiveness of VR-MRI in preparing children for the MRI simulator experience and reduce child-reported procedural anxiety compared with conventional methods. As a secondary aim, we evaluated caregivers' reported anxiety, procedural data, parental usability, and child-reported satisfaction with all the preparation materials. Data were collected at 3 distinct timepoints (Figure 10).

Figure 10. Flow diagram for virtual reality magnetic resonance imaging study. MRI: magnetic resonance imaging; VR-MRI: virtual reality magnetic resonance imaging.



Participants, Randomization, and Procedures

A nonblinded, triple-arm randomized clinical trial was performed at a large provincial hospital in Vancouver (British Columbia), between July 2019 and February 2020. Ethics approval was granted by the University of British Columbia Children's & Women's Research Ethics Board (#H19-00371), and the study was prospectively registered at the US National Library of Medicine (#NCT03931382).

The participants were aged 4-13 years. Participants were excluded from the study if they had mental disability, current concussion, significant visual or auditory impairment, inability

to speak and understand English, history of seizures or epilepsy, facial or head wounds, or inability to move their head in all directions. All children provided assent, and caregivers or legal guardians provided written consent. Participants received Can $20 (US $16) and parking remuneration.

Participants were recruited through posters at the hospital, public libraries, community centers, and through social media. We assigned participants in the ratio 1:1:1 to VR-MRI, CLP and SPM and then tested for compliance during a simulated 6-minute MRI scan of the head, designed to replicate an authentic scanning environment (Figure 11). Blinding was not feasible.

Figure 11. The magnetic resonance imaging simulation room.

Outcome Measurements

Primary Outcomes

The primary outcomes were success in the MRI simulation experience and child anxiety.

Success in the MRI Simulation Experience

Movement in the MRI simulation was captured by fitting participants with a motion sensor headband (MoTrak System 1.0, Psychology Software Tools Inc). The sensor system is susceptible to movements of the muscles of facial expression, and has been proposed as one of the most accurate ways to measure the movement of pediatric patients in the absence of estimates from actual MRI [41,42]. Head movement was collected at 8 samples per second, yielding approximately 3300 data points per axis per participant. The threshold for a *successful* MRI, as defined by the department of radiology, is approximately 3-4 mm. Consequently, if at any point during the scan the participant moved >4 mm of cumulative displacement, it was noted as a *fail*.

Child Anxiety

Child anxiety was measured with the Venham picture test (VPT; score 0-8) [43]. The VPT has been validated with children for assessing situational anxiety during medical procedures [44] and has a moderately high retest reliability of 0.70 and a high degree of internal consistency with a coefficient α of .838 [43]. Children completed the assessment at three timepoints (before preparing [T1], after preparing and upon entering the simulation room for their 6-minute *scan* [T2], and after the assessment [T3]). The level of the patient's anxiety was classified as *anxiety-free* (score 0), *low anxiety* (scores 1-3), *middle anxiety* (scores 4-6), and *high anxiety* (scores 7-8).

Secondary Outcomes

The secondary outcomes included caregiver anxiety, procedural data, parental usability, child satisfaction, and fun. We also administered a baseline survey to collect information about demographics and clinical characteristics predicted to influence or confound outcomes, such as previous experience with medical imaging.

Caregiver Anxiety

Caregiver anxiety was measured with the short State-Trait Anxiety Inventory (STAI; score 6-24), a 6-item, adapted version of the well-validated Spielberger STAI Scale [45]. This measure has a moderately high retest reliability ranging from 0.65-0.75 and a high degree of internal consistency with a coefficient α of .86-.95 [45]. Parents or caregivers were asked to complete the assessment on a tablet at the same time as children (before preparing [T1], after preparing and upon entering the simulation room for their child's 6-minute *scan* [T2], and after the assessment [T3]).

Procedural Data

Procedural data included preparation and assessment times. In accordance with the experiential learning theory [37], we postulated that children who prepared for longer would have a more efficient assessment. Side effects during preparation (eg, nausea and headaches), dropouts, and noncompliance were also recorded.

The *preparation time* started when the study staff finished describing the preparation program, and the researcher indicated that it was time to begin the active preparation. The preparation time was stopped upon indication that the participant felt ready to take the assessment. A maximum preparation time of 45 minutes was allowed. This time frame was selected as it was

the allotted appointment time provided by our hospital CLP to prepare patients and their families for medical imaging procedures.

The *assessment time* was defined as the time spent in the simulated MRI room until the participant was *discharged* from the simulation experience, either as successful or noncompliant. A maximum assessment time of 20 minutes was allowed. The time spent transitioning between activities or breaks required for reasons unrelated to the study was not accounted as time.

Caregiver Usability

The caregivers of our participants were prompted to provide usability feedback on the preparation materials at the end of the study. Caregivers were asked to complete the USE (Usefulness, Satisfaction, and Ease of Use) Questionnaire administered at the end of the study activities on a tablet. The USE Questionnaire is a 7-point Likert rating scale and is a validated and reliable measure for assessing the subjective usability of a product or service [46]. We limited our testing to the strongest factors of the survey [47].

In addition to this, we asked caregivers if they would be comfortable with their child using the preparation programs and if they had any recommendations for improvement.

Child Satisfaction and Fun

For measuring child satisfaction, participants were asked to indicate how satisfied they were with the preparation program by pointing to a visual analog scale ranging from 0 (terrible) to 100 (fantastic). After this, we asked the children if they would recommend the preparation to a friend who needed an MRI and if there was anything that would make their experience better.

Fun was measured using the Smilyometer Likert Scale, a part of the Fun Toolkit [48]. We selected this as a surrogate measure to inform potential adherence and uptake in the real world, assuming that fun would influence use. The Smileyometer was used before and after the children interacted with a preparation program. The rationale for using it before is that it can measure their expectations and for using it afterward is that it is assumed that the child is reporting experienced fun. It has been widely adopted in testing technologies with children to measure satisfaction and fun as it requires no writing [48-52]. After allocation to a preparatory program, children were asked how good they thought the preparation would be by pointing to the Smilyometer Likert Scale to indicate their expectation of using the intervention. After using the preparation and completing the assessment (timepoint 3 [T3]), the children were again asked how good they thought the preparation actually was using the same Smileyometer Likert scale.

Data Analysis

Power Calculation

A priori power analysis was performed using G*Power 3 [53]. Assuming a small-to-moderate effect size (Cohen f=0.20) with 90% power and the probability of a type 1 error of 0.1, a total sample size of 69 was needed (23 in each group).

Statistical Analysis

Statistical analysis was performed using SPSS (version 22, IBM Corp). Continuous variables were expressed as mean (95% CI) and ordinal variables as median (IQR). Categorical variables were expressed as percentages. Normality conditions were checked for all variables to apply a proper test of significance. Many of the outcome variables were ordinal in nature and were measured in scores. A chi-square test was used to test the independence of association between categorical variables. Analysis of variance (ANOVA; for normal distribution) or the Kruskal–Wallis test (for nonparametric distribution) was applied for 1-way analysis to compare the average scores of the three interventions among the three timepoints. Post hoc Bonferroni analysis was applied to statistically significant findings to confirm the differences between the groups. If the equal variance assumption was not met during the ANOVA process, pairwise comparisons were based on the statistics of Dunnett T3 [54]. To test for relationships between 2 continuous variables, we used the bivariate Pearson correlation. In the case of missing values, a single value was filled for each missing value by averaging the collected scores for each participant.

Results

Demographic and Clinical Characteristics

A total of 92 participants were recruited during the study period; 1 did not consent, and 1 participant did not show up for the appointment. One participant who provided consent initially later withdrew. A total of 89 participants were enrolled. Of the consenting participants, 5% (5/92) were excluded because of equipment malfunction. The remaining 84 participants were included in the analysis (VR-MRI: 30/84, 36%; SPM: 24/84, 29%; CLP: 30/84, 36%).

The demographic and clinical characteristics of the patients are shown in Table 1. Most participants were male (51/84 61%) and had no history of MRI (77/84, 92%) or simulator experience (81/84, 96%). Approximately half the participants (43/84, 51%) had experience with other medical imaging procedures, and many had used VR before participating in the study (70/84, 83%). Chi-square tests were conducted for demographic variables and ANOVA for continuous variables. No significant differences in demographic variables were found among the groups (Table 1).

Table 1. Demographics and clinical characteristics of participants (N=84).

Characteristics	Total population (n=84)	VR-MRI[a] (n=30)	Standard preparatory manual (n=24)	Child Life Program (n=30)	*P* value
Age (years), mean (SD)	9.1 (2.7)	9.3 (2.6)	8.9 (2.8)	9.2 (2.7)	.51
Males, n (%)	51 (61)	18 (60)	13 (54)	20 (67)	.64
History with, n (%)

[b]Not available.

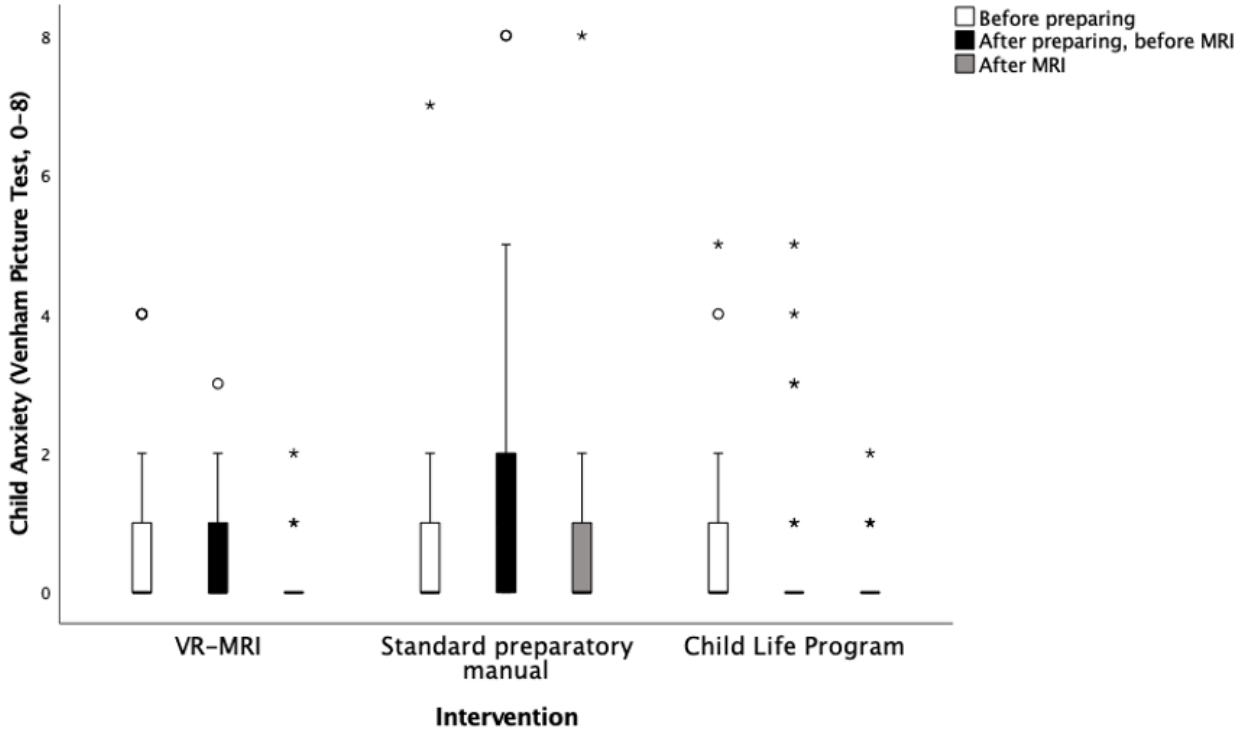
Success in the MRI Simulation Experience

Success was indicated if participants were able to complete a 6-minute head scan without surpassing 4 mm of movement at any of the 3300 data points collected. The average number of times participants scored above the threshold for the 3300 data points was not statistically significant between the groups (χ^2_2=2.7; *P*=.07). Similarly, no statistically significant differences were found when calculating success in the simulated MRI experience among VR-MRI, SPM, and CLP (χ^2_2=2.6; *P*=.27). On average, 30% (95% CI 13%-47%) participants in the VR-MRI group were successful, compared to 50% (95% CI 28%-72%) in the SPM group and 47% (95% CI 28%-66%) in the CLP group. Of the participants who failed, 8 (VR-MRI: 2/8, 25%; SPM: 3/8, 37%; CLS: 2/8, 25%) were noncompliant by declining to complete some or all of the requirements of the scan, automatically failing their assessment.

Child Anxiety

VPT was used to determine how anxious children were before preparing (timepoint 1 [T1]), after preparing and upon entering the MRI simulation room (timepoint 2 [T2]), and after completing the assessment [T3]). Participants reported that anxiety remained relatively stable, with no *clinically* significant differences between the groups at any timepoint (Figure 12; T1, *P*=.99; T2, *P*=.008; T3, *P*=.10). On average, children in the VR-MRI group reported being anxiety-free before preparation (median 0, IQR 1; SD 1.311), after preparation (median 0, IQR 1; SD 0.819), and after the assessment (median 0, IQR 1; SD 0.434). Children in the SPM group reported being anxiety-free before preparation (median 0, IQR 1; SD 1.521), having low anxiety after preparation (median 1, IQR 2; SD 2.311), and being anxiety-free again after the assessment (median 0, IQR 1; SD 1.738). Finally, children in the CLP group reported being anxiety-free before preparation (median 0, IQR 0; SD 1.240), after preparation (median 0, IQR 0; SD 1.350), and after the assessment (median 0, IQR 0; SD 0.468).

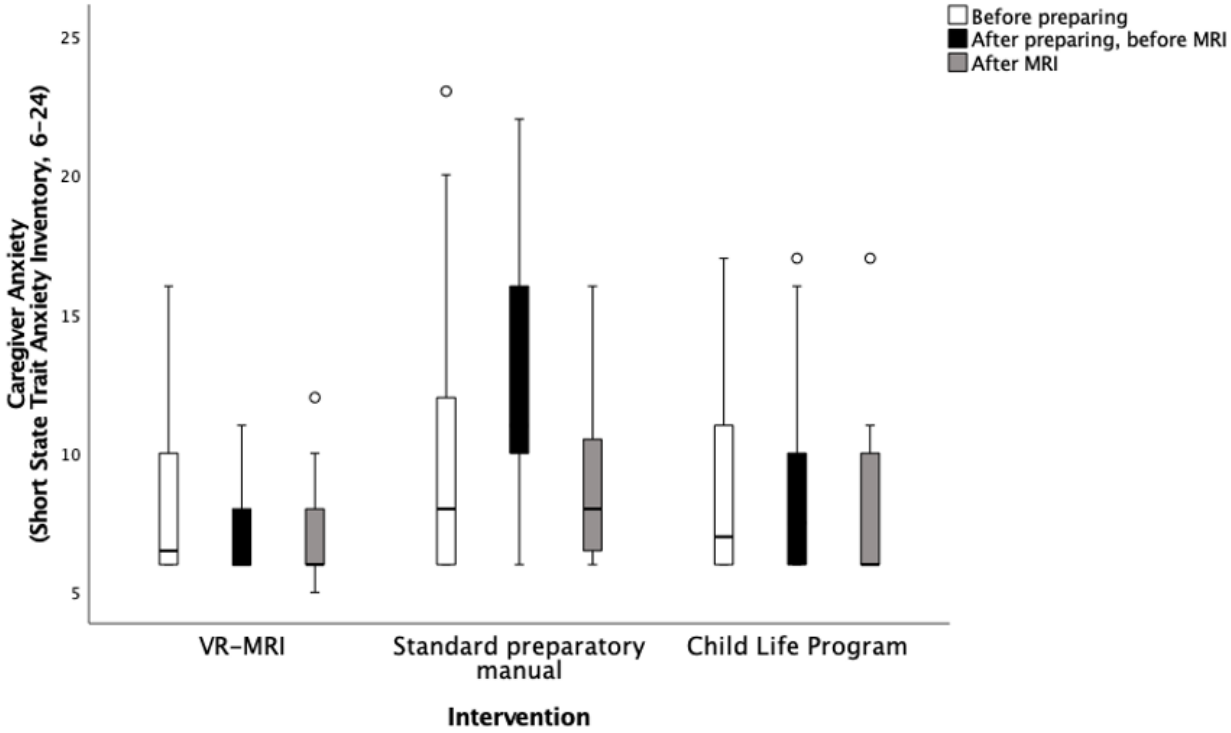
Figure 12. Comparison of self-reported child anxiety across groups and timepoints, measured by the Venham picture test (the circles denote outliers and the asterisks denote extreme outliers). No clinically significant results were indicated (timepoint 1, *P*=.99; timepoint 2, *P*=.008; timepoint 3, *P*=.10). MRI: magnetic resonance imaging; VR-MRI: virtual reality magnetic resonance imaging.



Caregiver Anxiety

The short STAI was used to determine how anxious caregivers were before preparing (T1), after preparing and upon entering the MRI simulation room (T2), and after completing the assessment (T3). As depicted in Figure 13, caregivers using the manual to prepare were significantly more anxious after preparing than caregivers in the VR-MRI (mean difference 5.33, 95% CI 2.93-7.74; Dunnett *P*<.001) and CLP groups (mean difference 3.73, 95% CI 1.07-6.40; Dunnett *P*=.004). The effect size was large (η^2=0.319, 95% CI 0.15-0.448). No clinically significant differences between the groups were found before preparing (T1) or after completing the assessment (T3). Caregivers in the VR-MRI group reported low anxiety before (median 6.5, IQR 4; SD 2.572) and after preparation (median 6, IQR 2; SD 1.744) and after the assessment (median 6, IQR 2; SD 1.810). Caregivers in the manual group reported low anxiety before preparation (median 8, IQR 6; SD 4.945), an increase in anxiety after preparation (median 10, IQR 6; SD 4.394), and again low anxiety after the assessment (median 8, IQR 4; SD 2.924). Finally, caregivers in the CLP group reported low anxiety before (median 7, IQR 6; SD 3.294) and after preparation (median 8, IQR 4; SD 3.224) and after the assessment (median 6, IQR 4; SD 2.545).

Figure 13. Comparison of change in self-reported caregiver anxiety between timepoints and across groups, measured with the short State-Trait Anxiety Inventory (the circles denote outliers and the asterisks denote extreme outliers). Clinically significant differences were found between the manual group in comparison with the virtual reality magnetic resonance imaging (Dunnett *P*<.001) and the Child Life Program (Dunnett *P*=.004). MRI: magnetic resonance imaging; VR-MRI: virtual reality magnetic resonance imaging.



We conducted a bivariate Pearson correlation analysis to determine whether child anxiety was related to caregiver anxiety. After preparation and upon entering the MRI simulator room, child and caregiver anxiety had a statistically significant linear relationship (r_{84}=0.421; *P*<.001), indicating that child anxiety increased with parental anxiety. The strength of this relationship was moderate.

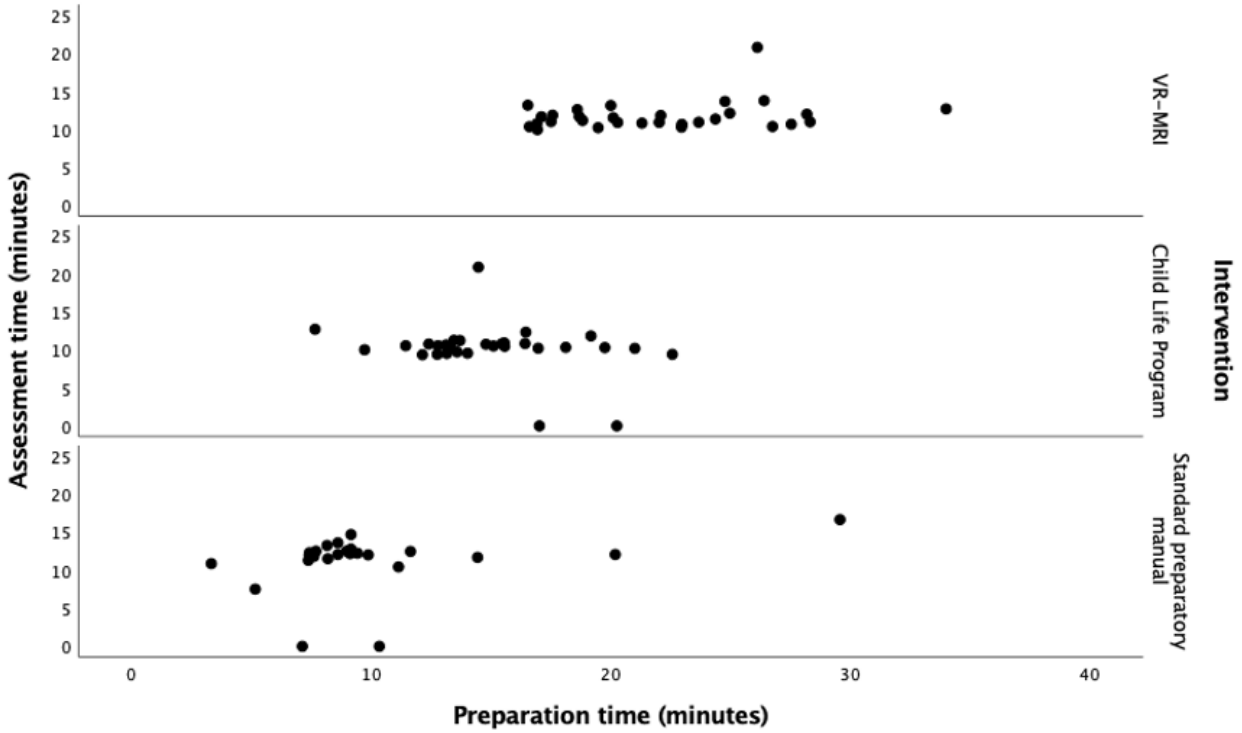
Procedural Data

Time was recorded during preparation and assessment. There was a significant difference in preparation times among all groups ($F_{2.81}$=53.261; Dunnett *P*<.001). The effect size was large (η^2=0.568, 95% CI 0.415-0.660). Participants in the VR-MRI group prepared for the longest time, which was 22.05 minutes (SD 4.41; 95% CI 20.40-23.69), compared with the CLP group, which was in the middle at 15.06 minutes (SD 3.32; 95% CI 13.82-16.30), and the SPM group, which prepared for the shortest time, at 9.98 minutes (SD 5.24; 95% CI 7.76-12.20).

No statistically significant differences were found among the groups in assessment time ($F_{2.81}$=2.063; *P*=.13). Participants in the VR-MRI group, on average, took 11.79 minutes (SD 1.99; 95% CI 11.05-12.55), compared with the SPM group who took 11.19 minutes (SD 3.80; 95% CI 9.58-12.78) and the CLP group who took 10.17 minutes (SD 3.44; 95% 8.89-11.45) to complete their assessment (regardless of success).

We conducted a bivariate Pearson correlation test to determine whether the time spent preparing affected the efficiency of the assessment. Preparation and assessment times did not have a statistically significant linear relationship (r=0.148; *P*=.18), indicating that preparation time did not have a significant effect on assessment time in our study (Figure 14).

Figure 14. Comparison of preparation and assessment times across groups, measured in minutes. No significant relationship was found (r=0.148; *P*=.18). VR-MRI: virtual reality magnetic resonance imaging.



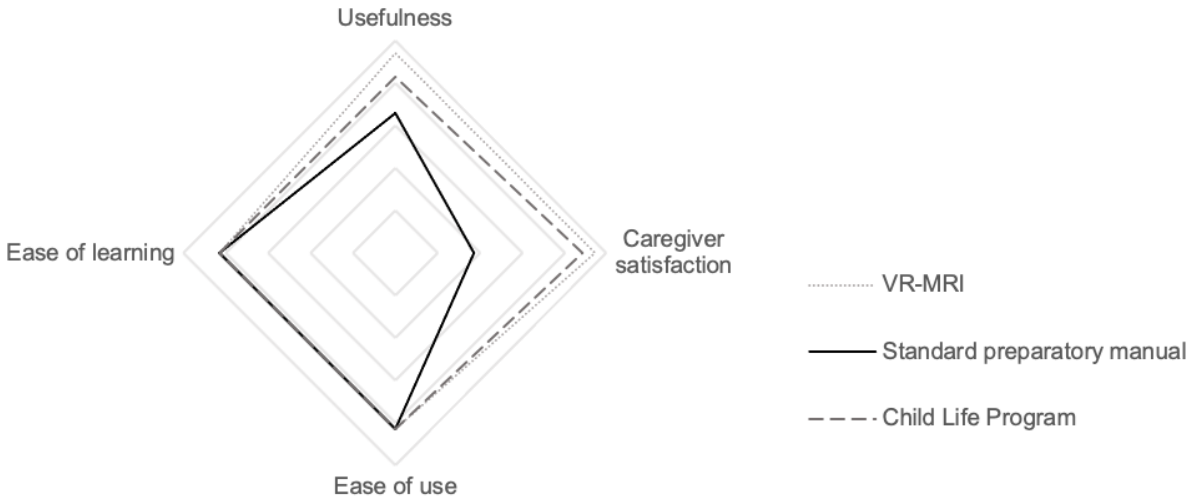
One child (aged 5 years) indicated eye strain and a blurry image when viewing VR-MRI that could not be mitigated by interpupillary adjustments. Two children (aged 6 and 4 years) reported the dinosaur graphic in VR-MRI was *scary*. Six participants (aged 4-12 years) in the manual group expressed being scared of pictures in the manual, particularly the sections of the intravenous or coil pictures. No other side effects were reported.

Caregiver Usability

Caregivers were asked to complete the USE Questionnaire [46] to report how easy the preparation materials were to learn and use, as well as how useful and satisfied they were with using them to prepare their children for the simulated MRI experience.

Caregivers did not report significant differences in ease of use (χ^2_2=0.01; *P*=.99), ease of learning (χ^2_2=1.5; *P*=.48), or usefulness (χ^2_2=4.4; *P*=.11) among the groups. On average, caregivers using VR-MRI to prepare their child agreed that it was useful (median 31, IQR 4; SD 3.562), easy to use (median 24, IQR 3; SD 2.448), and easy to learn (median 18, IQR 2; SD 2.366). As depicted in Figure 15, caregivers using CLP, on average, also *agreed* that it was useful (median 30, IQR 6; SD 4.163), easy to use (median 24, IQR 4; SD 2.937), and easy to learn (median 18, IQR 3; SD 3.059). Caregivers using SPM *somewhat agreed* that it was useful (median 28.5, IQR 6; SD 3.323) and *agreed* that it was easy to use (median 24, IQR 5; SD 2.167) and easy to learn (median 18, IQR 3; SD 2.183).

Figure 15. Comparison of median usability metrics collected across groups, adjusted to total scores of 100. Significant differences were found for caregiver satisfaction when comparing the manual with the virtual reality magnetic resonance imaging and Child Life Program (Bonferroni *P*<.001). VR-MRI: virtual reality magnetic resonance imaging.



However, when reporting satisfaction with the preparation materials, caregivers using VR-MRI and CLP were significantly more satisfied than the caregivers using SPM (Dunnett *P*<.001). The effect size was large (η^2=0.268, 95% CI 0.104-0.402). Caregivers in the VR-MRI (median 31, IQR 4; SD 2.837) and CLP (median 30.5, IQR 6; SD 4.173) groups reported high satisfaction. However, caregivers in the SPM group were only somewhat satisfied (median 26, IQR 6; SD 2.428).

When asked if they would be comfortable with their child using the preparation materials for an actual MRI, 100% of participants in all groups indicated *yes*. In terms of improvements, caregivers in the VR-MRI group indicated they wanted the ability to explore VR-MRI in tandem with their child and wanted more information about when their child would be ready for a successful MRI. Caregivers in the manual group recommended tailoring the manual to the specific procedures being conducted, offering more instruction to parents on how to coach their child through the MRI experience, and offering more interactivity (eg, videos and stickers) to guide children through the steps. Caregivers in the CLP group were pleased and had no recommendations for improvement.

Child Satisfaction and Fun

Child satisfaction is reported in Table 2. Children were asked to point to a visual analog scale, indicating their satisfaction with the preparation materials. Children in the SPM group were significantly less satisfied than those in the CLP group (mean difference −17.509, 95% CI −34.85 to −0.17; Dunnett *P*=.047). On average, children in the manual group were 73.5% (SD 27%; IQR 37%) satisfied compared with children in the CLP group who were 90% (SD 12%; IQR 23%) satisfied. Children in the VR-MRI group were 80% (SD 27%; IQR 22%) satisfied.

Table 2. Comparison of self-reported child satisfaction scores between groups, measured with a visual analog scale.

Characteristics	Participant (n=77), n (%)	Median score (IQR; SD)	Mean rank	Chi-square (*df*)	*P* value
Timepoint 1					
VR-MRI[a]	30 (39)	80 (22; 27)	36.15	7.7 (2)	.02[b]
Standard preparatory manual	20 (26)	73.5 (37; 27)	30.90	—[c]	—
Child Life Program	27 (35)	90 (23;12)	47.17	—	—

[a]VR-MRI: virtual reality magnetic resonance imaging.

[b]Statistically significant difference between study arms (Kruskal–Wallis, *P*<.05).

[c]Not available.

The Smileyometer was used to determine how fun children expected the programs to be and how fun they actually were after completing them. We did not find any statistically significant differences in how much fun children expected the preparation to be ($F_{2.81}$=2.224; *P*=.11). On average, the children in the VR-MRI and CLP groups thought the preparation would be *really good*, whereas children in the manual group thought the preparation would be *okay*.

When asked if they would recommend the preparation materials to a friend, 93% (28/30) of participants in the VR-MRI group said yes compared with 80% (22/27) in the CLP group and only 71% (14/20) in the manual group. Participants in the VR-MRI group thought the game was too difficult and that they spent too much time staying still. The participants reported that they wanted more options in terms of selecting a character in the experience and tailoring the language to their age group. Participants in the manual group recommended only including

the procedures they would encounter and providing more interactivity. The participants in the CLP group also commented on the length of time required to stay still and the importance of listening to the correct volume and repetition of the sounds.

Discussion

Effectiveness of VR-MRI in Preparing Children for the Nonsedated MRI Experience

In this study, we compared a VR preparation program (VR-MRI) with the hospital CLP and SPM for reducing anxiety and noncompliance during a simulated MRI scan of the head. To our knowledge, no other study has compared VR with these alternatives for nonsedated MRI using both anxiety and success as outcomes.

Although VR has been studied in some preprocedural situations, including anesthesiology and medical imaging, its effectiveness in comparison with mock-MRIs [15,16,55-57] and other behavioral techniques [4,12] used by CLPs has not been well examined [12]. We found no significant differences between VR-MRI, our hospital CLP, and our hospital SPM on our measure of success during a simulated MRI experience (P=.27). This finding is comparable with that of another recent study [56] which found cheaper versions of MRI simulations adequate in most cases to provide the desensitization and practice needed for a successful nonsedated pediatric MRI scan. VR-MRI adds to the options for affordable and viable alternatives discussed in recent reviews [12]. It can be used at home or in remote settings for further practice and can easily be stored when not in use. Thus, health care centers could use a digital preparatory sequence leveraging immersive media, such as our VR-MRI app, to prepare pediatric patients aged between 4 and 13 years without the financial, travel, and space requirements of traditional in-person MRI simulations.

VR-MRI and Child Anxiety

In addition to finding no differences in our measure of success, we also found no clinically significant differences among children's reported anxiety when using VR-MRI compared with the other standards of care (T1, P=.99; T2, P=.008; T3, P=.10). Other studies have reported low anxiety during medical imaging simulations [30]. The findings of this study and ours question the relationship suggested by many studies (that anxiety directly influences motion artifacts). Although our study participants reported low anxiety, many were still unsuccessful in the simulated MRI experience. A patient's understanding is another element that can contribute to motion artifacts [58]. However, our findings also question this as we did not find any relationship between success and prior experience with medical imaging. Our sample for this subset was quite small, which could explain why no relationship was found. Future studies could consider measuring heart rate and cortisol as objective measures of stress throughout the training and procedure, as well as a measure of patient understanding to further explore these concepts.

VR-MRI and Caregiver Anxiety

Whereas other research has focused primarily on patient anxiety, our study uniquely evaluated caregivers' anxiety during the process of preparing for and completing a simulated MRI experience. VR-MRI was not statistically different from CLP and was better than SPM in mitigating caregiver-reported anxiety when entering the MRI simulation room (P<.001). We also found that caregiver and child anxiety tended to increase together after preparation (P<.001). Given that it is generally accepted that clinicians provide the opportunity for parents to be present during their child's procedure [59], our study results suggest that preparation is just as beneficial to caregivers as it is to the children undergoing MRI procedures. To assist in caregiver preparation, we mirrored the experience on a tablet for parents to experience it at the same time as the children. To our knowledge, effective ways of engaging caregivers in the preparation process have not yet been studied, particularly in the context of VR.

Time Spent Preparing and Conducting Head Scans

Participants prepared the longest with VR-MRI and the shortest with SPM. This was largely expected given that VR-MRI was a standardized experience compared with the experience of the other two groups that received interventions tailored to the participant by the CCLS (in the CLP group) or the caregiver (in the SPM group). It is interesting to note that participants engaged in programs that provided opportunities for experiential learning (VR-MRI and CLP) for a longer duration than those that offered through didactic learning (SPM). However, these novel elements of preparation, which allowed patients to engage and participate in a practice MRI experience, did not result in differences in success. We did not find any significant differences in the assessment times across the groups (P=.13).

We did not continue to conduct training and assessments with participants until we obtained an appropriate image quality, which would be critical for clinical care scenarios. In fact, many of the children failed the assessments in our study, suggesting that the assessment was actually not efficient, and more training or sedation would be required for these children. An important element of experiential learning is the opportunity to reflect on experiences [37]. As our study comprised a single session on the same day as the assessment, and children aged ≥6 years benefit most if they participate in preparation programs for ≥5 days in advance of the procedure [4], offering VR preparation before a medical imaging procedure and with multiple opportunities to experience, reflect, and practice should be explored by future investigators. In accordance with patient-centered care, children may also benefit from interacting with different practice materials depending on their individual preferences. We echo other investigators in stating that deploying multiple strategies together may provide the best way forward to improve nonsedated medical imaging outcomes and experiences [12].

Experiences With VR-MRI

Caregivers' Experiences

As reported by other investigators [27,29-31], experiences using VR-MRI were positive in our study. Our data indicate that compared with CLP and SPM, the VR-MRI app was just as easy to use (P=.99), easy to learn (P=.48), and useful (P=.11). The technical concerns commonly reported as barriers to perceived ease of use of VR technologies [60] were not

mentioned by the caregivers in our study. In fact, caregivers were significantly more satisfied with VR-MRI than SPM (P<.001). It is important to note that SPM was the only preparation program to require support from the caregiver as the researcher assisted in the setup for the VR-MRI group, and the CCLS assisted in the CLP group. As such, we may not have seen the same result if participants were required to set up the hardware themselves without assistance. Nonetheless, VR-MRI was perceived as a valued and acceptable form of preparation by caregivers.

Children's Experiences

In addition to caregiver experiences, we also measured the children's experiences using VR to prepare for their simulated head scan. We only found significant differences in children's reported satisfaction between SPM and CLP (P<.001) groups. Children using the VR-MRI app generally thought it was *really good* for preparing them for the MRI assessment, meeting the children's expectations for fun. The results of the app meeting expectations are likely influenced by the VR-MRI design, which includes obtaining multiple perspectives for identifying the needs and values of pediatric patients undergoing medical imaging procedures [34,35]. However, it is interesting that there were no significant differences among VR-MRI and the other 2 groups in terms of fun. Other investigators using gamification in VR for preoperative anxiety in pediatric patients undergoing general anesthesia also found that satisfaction was not significantly different between their gamified and control groups [24]. The result suggests that integrating novel technologies does not inherently make a procedural preparation *fun*, and further product and design elements are required to create an optimal experience. On the basis of the feedback from children and their caregivers, the VR-MRI game design may need refinements in terms of tailoring the challenge of staying still to the user's initial skills, as well as more options for customization and immersion to create an optimal experience [21,34,39].

Product and Design

The selection of preprocedural scenarios and hardware that are best for integration with VR is not well understood and has not been the focus of previous pediatric studies [21,39]. In our study, we elected to conduct a head scan as it was one of the most common and anxiety-provoking scans at our hospital. However, pragmatically, the clinical characteristics of patients who require head scans may not be the most appropriate for the use of VR headsets as a significant proportion of patients who require head scans have traumatic brain injuries or are potentially epileptic (which typically precludes them from using VR). In addition, experiences could be affected by a patient's mobility of the head and neck when using HMDs. Further research is needed for safe use with these patients and may include delivering the program through immersive videos rather than with a headset. The program must also be adapted to make it available on other platforms (Android and iOS) and devices so that it can be versatile in deployment [39]. The lack of appropriate patients to recommend VR to had a significant impact on the uptake of VR interventions in other clinical settings [60] and should be an important consideration for development.

Our study responds to the literature calling for studies on products that engage pediatric patients and explore skill-building goals [34]. We introduce intervention and design elements that provide dynamic feedback to the patient and experiential learning to regulate movement in preparation for a nonsedated MRI. We designed and tested a virtual MRI with real-time feedback to explore skill building and introduced some product qualities that enabled the participants to be active in preparing themselves for the MRI experience. Our design considerations included tailoring simplicity and interactivity to improve control, improving a sense of presence, creating a sense of safety through familiar design elements and medical procedures, incorporating narrative elements, and cultivating growth and motivation [34]. The real-time feedback feature, facilitated through a mobile phone gyroscope, is a unique gamification element that aligns with anxiety management strategies [34]; to our knowledge, this has not been reported in the literature to date. Future apps should focus on refining and validating real-time feedback gaming elements in medical imaging preparation so that it could be used as a decision-making tool that informs parents and health care providers about when and if a patient might be ready to attempt a nonsedated MRI, thus reducing the burdens associated with anxiety and noncompliance.

Limitations

There are several potential limitations to this study. Our methodology focused on self-reporting of anxiety of children and caregivers. We used the short STAI for caregivers but VPT for children, which may have introduced confounding factors. The results may also have been affected if users did not fully understand the meaning or how to complete the surveys after the instructions. There may have been a response bias, as children often consciously or subconsciously give responses that they think adults want to hear.

Our study also had several additional biases. The study was subject to information and selection biases, as we recruited participants through posters at the hospital, public libraries, and social media and provided remuneration and parking reimbursements. Motivation and reported outcomes related to using the materials could have been affected by these extrinsic motivations (eg, remuneration). The study was also unblinded to the participants and research staff because of the practicalities of the preparatory processes and logistical limitations.

Our study had a small sample size that met the requirements of our power calculation. The effect sizes were smaller among groups than we anticipated, and, therefore, this study is at risk for type 2 error (accepting a null hypothesis that is actually false). A total of 5 participants did not have movement metrics because of technological malfunction. In our study, we used the MERGE VR headset as no other HMDs have been indicated for use specifically with children. This headset is indicated to match the interpupillary distance of children aged ≥10 years. Younger children may have smaller interpupillary distances than can be adjusted for. Eye strain and a blurry image that could not be mitigated by adjustment were reported by 1 study participant (aged 5 years), which is likely a result of that limitation. Currently available consumer-grade VR hardware has not been designed for use with younger children and, in

some cases, might not be adjustable for the parameters required by them.

Conclusions

The VR preparatory program with a novel real-time feedback feature had comparable findings with our hospital CLP and SPM in successfully preparing children to complete a simulated MRI experience. Furthermore, VR-MRI mitigated situational anxiety in children throughout the process of preparation and completion of a simulated MRI head scan. As such, digital preparatory apps that leverage immersive media, such as our VR-MRI app, may be a viable alternative for preparing children for nonsedated MRI. Further research is required to confirm the findings with actual pediatric patients in a real MRI machine, as our study used a high-fidelity MRI simulator. Nevertheless, the use of VR and the sequence of activities provided through the VR-MRI app show promise for preprocedural anxiety reduction in children and their caregivers.

Acknowledgments

The authors thank all the study participants, radiology and patient experience staff, research team members, and the volunteers who helped support the research activities: Aria Rezapour, Monique Sangha, Amit Sharma, and Jinny Choi.

Abstract

Background: Prior studies have shown that virtual reality (VR) is an efficacious treatment modality for opioid-sparing pain management. However, the majority of these studies were conducted among primarily White, relatively advantaged populations and in well-resourced settings.

Objective: We conducted a qualitative, theory-informed implementation science study to assess the readiness for VR in safety-net settings.

Methods: Using the theoretical lens of the Consolidated Framework for Implementation Research (CFIR) framework, we conducted semistructured interviews with current VR users and nonusers based in safety-net health systems (n=15). We investigated barriers and facilitators to a commercially available, previously validated VR technology platform AppliedVR (Los Angeles, CA, USA). We used deductive qualitative analysis using the overarching domains of the CFIR framework and performed open, inductive coding to identify specific themes within each domain.

Results: Interviewees deemed the VR intervention to be useful, scalable, and an appealing alternative to existing pain management approaches. Both users and nonusers identified a lack of reimbursement for VR as a significant challenge for adoption. Current users cited positive patient feedback, but safety-net stakeholders voiced concern that existing VR content may not be relevant or appealing to diverse patients. All respondents acknowledged the challenge of integrating and maintaining VR in current pain management workflows across a range of clinical settings, and this adoption challenge was particularly acute, given resource and staffing constraints in safety-net settings.

Conclusions: VR for pain management holds interest for frontline pain management clinicians and leadership in safety-net health settings but will require significant tailoring and adaption to address the needs of diverse populations. Integration into complex workflows for pain management is a significant barrier to adoption, and participants cited structural cost and reimbursement concerns as impediments to initial implementation and scaling of VR use.

Introduction

Immersive virtual reality (VR) has emerged as an efficacious treatment modality for a wide range of medical and neurocognitive conditions including pain. VR is delivered via a headset that displays computer-generated and oftentimes interactive audio and visual content that can be designed to reduce pain through techniques such as distraction, relaxation, and mindfulness. Randomized controlled trials and effectiveness studies demonstrate that VR improves pain scores among inpatients and during medical procedures [1-4]. Additionally, studies indicate that patients can use VR to help manage chronic pain [5-8]. In a prior study among predominantly non-Hispanic White patients, most patients found VR use for pain to be a positive experience [9]. VR is generally considered safe, with the most common adverse effects being dizziness and nausea. Motion sickness and seizure disorders are the most prevalent of the few medical contraindications to VR use.

Clinicians have demonstrated interest in VR therapy as a safe and effective adjunctive or replacement to opioid agents to avoid adverse consequences of opioid use [10]. Opioid misuse represents a growing epidemic in the United States, affecting 10.3 million people, 48,000 of whom died in 2018. Even in acute-care settings, initiation of opioids can lead to long-term use, the consequences of which include dependence and hyperalgesia [11]. There is an urgent need for safer pain management for the millions of chronic pain sufferers worldwide. This represents a public health challenge as well, as racial and ethnic minorities, the elderly, and patients who speak English as a second language are more likely to experience suboptimal treatment for their chronic pain [12].

Despite studies proving the efficacy of and great promise for VR therapy as a nonpharmacologic approach to pain management, VR has not become part of routine chronic pain management [2,13,14]. As with other complex interventions, there is little evidence to guide implementation [15]. Although we know that VR has been effective in clinical trial settings, understanding why and how it has been effective is required to translate this modality to diverse practice settings [16]. Most VR studies have also been conducted in settings that serve ethnically homogenous, relatively advantaged populations with high health literacy and educational attainment.

There are specific considerations in adapting digital innovations to diverse populations and to safety-net health care settings that disproportionately care for them [17]. A systematic review of digital innovations in the safety net found that externally developed interventions face significant challenges, including acceptability to providers, staff, and patients; staffing needs; and implementation costs [18]. We sought to elucidate the implementation climate specifically for VR [19]. Therefore, we conducted a qualitative, theory-informed implementation science study to assess the readiness for VR in safety-net settings.

Methods

This study aims to determine barriers and facilitators to the implementation of VR as a treatment for pain in safety-net settings. We obtained institutional review board approval (#19-29025) for this project from the University of California, San Francisco (UCSF) Human Research Protection Program.

Conceptual Framework and Interview Guide

We developed an interview guide based on the Consolidated Framework for Implementation Research (CFIR) [20,21]. We chose this framework because it accounts for a wide range of contextual factors and is widely used to characterize complex interventions in health care settings [22-26]. The CFIR framework includes 5 overarching domains: (1) the characteristics of the intervention itself; (2) the inner setting, that is, the specific environment in which the intervention will take place; (3) the outer setting, or larger environment, encompassing the broader landscape in which the inner setting sits; (4) the individuals involved in intervention delivery and the target population; and (5) the process by which the intervention is introduced.

Data Collection

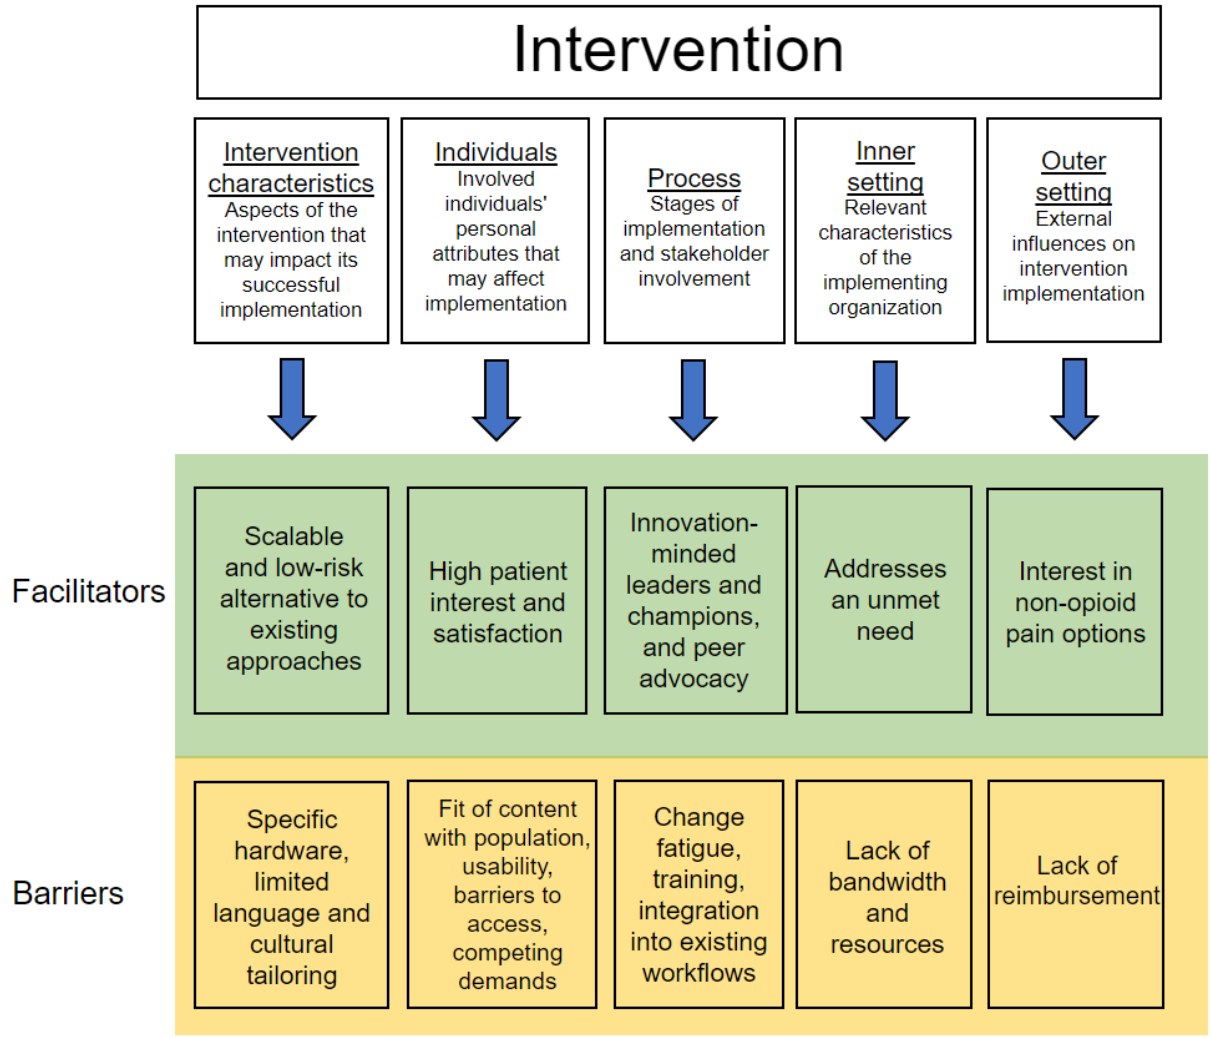
We used the snowball method of sampling to conduct 15 semistructured interviews (Multimedia Appendix 1) of 5 health care providers, leaders, and administrators who currently provide VR to patients (users) and 10 who do not use VR (nonusers). Most but not all nonusers practiced in safety-net settings, defined as public hospitals or federally qualified health centers serving the majority of patients on Medicaid or those who are uninsured [27]. We intentionally sampled nonusers as health care providers or staff without experience in using VR for clinical pain treatment, ensuring that every participant had expertise working with diverse patient populations in their practice (i.e., safety net or academic medical center sites serving Medicaid or racially/ethnically or linguistically diverse patients). We oversampled safety-net sites in particular because they are generally the last to be considered for implementation of innovation programs, and we sought to seek out their perspectives early to improve eventual broadscale implementation of this technology for diverse patient populations [28]. We conducted interviews from October 2019 to September 2020. Two members of the study team conducted the interviews via videoconferencing with screen sharing because of either logistical barriers or public health restrictions due to the COVID-19 pandemic for meeting in person. The team recorded the interviews with participant consent and transcribed the interviews without any identifying information. The participants received an incentive for their participation, with e-gift cards sent via email following interview completion.

Data Analysis

We used the qualitative software Dedoose (SocioCultural Research Consultants, Hermosa Beach, CA, USA) for analysis. Two authors, KN and JL, read all the transcripts in detail. For deductive coding, they assigned excerpts to 1 of the 5 overarching CFIR domains (intervention characteristics, individual characteristics, implementation process, inner setting, and outer setting) and met to discuss codes and resolve inconsistencies (Figure 1). They then independently analyzed 3 interview transcripts inductively to identify themes that arose from the interviews. They subsequently met to reach an

agreement on a comprehensive list of potential themes. One investigator (author JL) coded the remaining (12 total) transcripts under the supervision of KN for any relevant CFIR constructs and new inductive codes that emerged from participant responses. The entire study team met regularly to discuss discrepancies or resolve disputes regarding the coding. All authors iteratively revised and agreed upon the final list of themes and representative quotes. We reached thematic saturation after 11 interviews and elected to complete 4 additional interviews that had already been scheduled.

Figure 1. Overview of Consolidated Framework for Implementation Research (CFIR) domains and examples of barriers and facilitators.



Data Availability

The qualitative data generated and analyzed during the current study are not publicly available due to the risk of re-identification of participants, but codebooks are available upon reasonable request.

Results

We interviewed 15 participants from a variety of roles and organizations (Table 1).

We defined “user” as a health care provider or staff member interviewee with previous research experience implementing the AppliedVR platform for pain treatment at their delivery system; we defined “nonuser” as a health care provider or staff member interviewee without experience with AppliedVR or other VR platforms for clinical pain treatment.

Underlying these results was a strong sense of an unmet need for chronic pain management among users and nonusers. There was agreement among all interviewees that addressing pain management differently represents a high organizational/clinical priority. Building on that universally acknowledged need and prioritization, both users and nonusers of VR identified a range of factors related to the intervention itself and to the milieu in which it would be implemented that they expected would impact VR implementation. We described the major themes within each CFIR domain and provided exemplar quotes.

Table 1. Participant roles, user status, and organization characteristics.

Participant ID	Participant role	User/nonuser	Organization characteristics
1	Chief Medical Information Officer	User	Safety-net health system
2	Research physician	User	Academic medical center
3	Clinical research coordinator	User	Academic medical center
4a	Director for Innovation and Digital Health[a]	User	Academic medical center
4b	Program Manager for Innovation and Digital Health[a]	User	Academic medical center
5	Director of surgical subspecialty service	User	Nonprofit regional tertiary medical center
6	Primary care and addiction services physician	Nonuser	Safety-net health system
7	Associate Director of Research and Health Equity	Nonuser	Academic medical center
8	Chief Medical Officer	Nonuser	Safety-net health system
9	Chief Medical Informatics Officer	Nonuser	Safety-net health system
10	Primary care physician, pain clinic	Nonuser	Safety-net health system
11	Director of Telehealth	Nonuser	Safety-net health system
12	Psychologist, internal medicine	Nonuser	Academic medical center
13	Registered nurse, palliative care	Nonuser	Safety-net health system
14	Associate Chief Medical Informatics Officer	Nonuser	Safety-net health system
15	Psychologist, internal medicine	Nonuser	Safety-net health system

[a]These participants were interviewed simultaneously.

Characteristics of the Intervention

The VR intervention itself has attributes that both facilitate and inhibit implementation (Multimedia Appendix 2, Table S1). A key factor for the intervention is its relative advantage over existing approaches for pain. VR users and nonusers both mentioned the favorable safety of using VR compared to pain medications. Additionally, VR users also mentioned the option for patients to use the technology on their own on an ongoing basis after initial training from staff, as opposed to ongoing, clinician-delivered pain interventions, such as cognitive behavioral therapy. Similarly, nonusers appreciated the potential for scaling pain management activities through VR-enabled self-management approaches. Nonusers of VR commented on the face validity of VR as a chronic pain treatment. In terms of the intervention content, both users and nonusers noted that the platform is available only in English and therefore not usable in limited English–proficiency populations. The difference between users and nonusers was in how they prioritized this limitation. Interviewees based in the safety net described non-English language as a prerequisite, whereas it was considered a limitation of varying importance among those who were already using VR. The participants discussed the ability to culturally tailor VR scenarios in opposing ways. VR nonusers expressed some skepticism about the content's appropriateness for culturally diverse populations and for those with significant trauma histories. VR users noted that the currently available content does not always resonate across cultures, particularly for minoritized populations. However, they did consider the ability of VR to offer many culturally tailored content offerings to be a key attribute of the approach. Both users and nonusers acknowledged the specific contraindication of motion sickness and the overall low risk of the modality.

Individual Characteristics

For this study, we considered the CFIR domain of "individual characteristics" to refer to target patients for VR as a pain intervention (Multimedia Appendix 2, Table S2). A prevalent theme was comfort with technology, including challenges for older adults in navigating technology and digital literacy more broadly. Nonusers, in particular, raised concerns about patient mistrust of new or experimental treatments. Despite this, several interviewees emphasized that they would expect a significant proportion of low-income and diverse patients cared for in safety-net settings to willingly engage with VR. Participants who used VR expressed near-universal high levels of patient satisfaction with VR, and nonusers expected that patients with chronic pain would appreciate having additional treatment options. Nonusers did cite physical opioid dependence and a fear of opioid de-prescribing as expected barriers from patients, and users and nonusers alike referred to patients' more pressing social and health needs as significant barriers to VR implementation for pain. Nonusers specifically mentioned trade-offs for health systems in deciding whether to invest in innovations such as VR versus approaches to address patient needs such as housing and food insecurity.

Implementation Process

Both VR users and nonusers considered VR implementation to be a complex process (Multimedia Appendix 2, Table S3). There was consensus that patients would require specific orientation from staff in order to initiate VR use for pain and that staff support would be required for coaching and troubleshooting on

an ongoing basis. Both users and nonusers pointed to the requirement that frontline staff interact with VR and have a personal buy-in to facilitate successful implementation. Similarly, all participants highlighted the need for champions among clinicians who can share both evidence for VR as a pain treatment and successful treatment experiences. The availability of staff time was a dominant concern, with VR users emphasizing the need to plan for adequate staff effort to implement VR and nonusers expressing doubt about staff availability. Integration of VR into existing pain management workflows, a key aspect of the implementation process, highlighted barriers and facilitators. It emerged that implementation success would depend on the extent to which VR could be integrated into specific clinical settings. Some, but not all, nonusers focused on integration into the electronic health record. The participants cited some especially challenging settings, such as primary care, and some more feasible settings, such as the outpatient pain clinic. More specifically, the intervention requires a multistep process with each patient, which both users and nonusers believe complicates more widespread implementation.

Inner Setting

The inner setting for VR implementation is the specific health system and, within each health system, the specific clinical settings that currently treat pain (Multimedia Appendix 2, Table S4). One overarching inner setting barrier, seen across all participants, is that within health systems, pain management is a cross-cutting issue and therefore requires collaboration among departments and stakeholders, in contrast to other clinical conditions for which one clinical unit is entirely responsible. Both users and nonusers cited pressure to prescribe opioids and the providers' lack of familiarity with VR as barriers to use. Several participants mentioned the default habit and culture of addressing pain with medication. Among the nonusers, participants noted that their peers hold skepticism about corporate approaches to treatment. Both users and nonusers emphasized the importance of leadership attitudes. They described interest in VR as part of a larger mindset around openness to innovation. All participants emphasized the need for dedicated staff time and training and space for VR treatment, which require a leadership commitment. Resource limitations in safety-net settings were seen to preclude these needed actions for implementation. Most participants suggested that an innovative culture is a prerequisite for VR implementation, but safety-net participants described this as pervasive: "We seem to be late adopters." In contrast, VR users described few individuals as having an anti-innovation attitude. Some nonusers described local leaders as not being innovation minded but instead being focused on delivery of long-standing services. Similarly, nonusers described the wide array of stakeholders (eg, frontline staff, information technology [IT], and clinical leaders) within the local environment whose engagement was needed for success. In terms of concrete needs, both users and nonusers cited the need for adequate physical space for VR treatment and up-front investment in the VR hardware as inner-setting requirements. However, VR users experienced these needs as surmountable challenges, while VR nonusers highlighted space and initial costs as formidable obstacles.

Outer Setting

Challenges related to the outer setting of the intervention, such as external policies and incentives, arose as well (Multimedia Appendix 2, Table S5). In the broader health care landscape, use of VR is not a billable service. The participants viewed this lack of insurance reimbursement as a critical barrier to implementation at scale. Both VR users and nonusers mentioned philanthropic and private funding as a current or possible approach for the short term. There was consensus that expecting patients to bear the cost of pain treatment is a significant implementation barrier. Beyond cost, concerns around data privacy and security in digital health surfaced among nonusers. Nonusers also pinpointed the digital health industry's focus on wellness over developing treatments for specific conditions as a barrier to widespread use of digital therapies more broadly.

Discussion

Principal Results

Our results suggest that many of the factors affecting VR implementation, or, indeed, implementation of novel, technology-enabled therapeutic approaches, exist in both safety-net settings and more advantaged, resource-rich health care systems. We did not identify a completely different set of issues relating to VR in the safety net; rather, similar challenges seem to be magnified in safety-net settings. For example, among safety-net stakeholders who do not currently use VR, an English-only intervention would be impossible to implement for their linguistically diverse patient populations, whereas non-safety-net participants saw this limitation as less significant in impacting adoption. Similarly, the cultural relevance and acceptability of the content was a source of concern for safety-net interview participants but appeared to be surmountable to non-safety-net participants who were already testing VR at their sites. In other words, current VR users saw further cultural tailoring as an area for future improvement, whereas our safety-net participants saw it as a prerequisite for use because of the diverse populations served in safety-net settings. Both VR-use and VR-nonuse sites acknowledged that competing demands in patients' lives, relating to housing status, income instability, and other social challenges, would interfere with using a novel therapeutic approach like VR. Again, these challenges seemed more prevalent in the safety net.

Our findings in the CFIR domain of "inner setting" suggest that the process of implementing a complex intervention like VR requires a formal change management strategy encompassing leadership support, frontline champions, and a campaign for staff buy-in. Safety-net respondents reported a lack of capacity for implementing new approaches, particularly with regard to leadership commitment to innovation and resources to conduct change management activities. The outer setting or larger context for VR implementation has facilitators, such as the desire to appear innovative, while reducing the harm from opioid use. However, the lack of insurance reimbursement and available funding for VR interventions is a significant barrier. Competing priorities for leadership can also stymie innovations such as VR implementation, especially in safety-net health care settings

where resource limitations and "keeping the doors open" are perennially in question.

Our findings echo prior work about innovation in safety-net settings. Dating back to the early days of health IT, safety-net settings have lagged in implementation [29]. Prior studies suggest that frontline patient engagement and trust, appropriateness of innovative tools for diverse end users, and dedicated resources for innovation are particularly salient for the implementation of new health IT approaches in the safety net [18,28,30,31]. Implementation science studies in safety-net settings should specifically emphasize these concepts in applying, and, where necessary, adapting, conceptual frameworks such as the CFIR.

Our study lends weight to a previously developed evaluation framework for VR [19]. The VR1 study design phase emphasizes the importance of working directly with end users, and we found that implementation in safety-net health settings will require significant tailoring and adaptation of the VR intervention to address the needs of diverse populations (eg, racial and ethnic minorities, language barriers, and social complexity). Several actions can address the current barriers to VR use for pain management in safety-net health care settings. For example, our results underscore the need for cultural tailoring and translation (eg, VR content that features voices and images of racially and ethnically diverse individuals and is provided in languages other than English). Furthermore, more specific adaptations or considerations addressing structural issues disproportionately facing lower-income and racial/ethnic minorities in the United States (eg, unjust incarceration practices and historical trauma) might require deeper qualitative exploration with patients about their preferences or comfort in using VR headsets. A prior study of predominantly non-Hispanic White hospitalized patients demonstrated that many refuse to try VR [9]; the acceptability of VR to patients should be tested in more diverse patient groups. Following this, usability testing with diverse populations could evaluate concerns about the acceptability and usability of technology, disinfection, and adverse effects such as motion sickness. Any deployment strategy for VR should take into account the resource and workforce constraints of the safety-net environment. Developers of VR for chronic pain management should address implementation considerations in parallel with design and evaluation in order to foster higher uptake of VR and digital tools overall.

Strengths and Limitations

Our study has strengths, such as inclusion of multiple health systems and geographic areas. In addition, we compared and contrasted the experiences of health care system participants who are currently overseeing the use of a single VR platform with those of safety-net and academic providers across multiple sites who are not currently using VR. Furthermore, we used a well-known conceptual framework and reached thematic saturation in content analysis. Despite these strengths, the study does have limitations. The sample size was circumscribed, and we do not have information about the extent of VR use among the participants who are currently using the tool in their health systems.

Although our discussion focused on one technology approach, VR, for a single clinical problem (pain management), many of the themes that emerged are relevant across multiple innovative approaches to clinical care. The spread of innovations to safety-net health settings requires attention to patients' language and culture. Efforts to address resource constraints, such as providing staff training and detailed protocols encompassing workflow integration, can lower barriers to innovation. Inclusion of diverse populations and the health care settings where they disproportionately receive care will address issues that are relevant across other health systems as well.

Conclusion

This study contributes to the literature by revealing barriers and facilitators to implementing VR for pain management in safety-net settings. We demonstrate that frontline pain management clinicians and leaderships are interested in VR, but it will require significant tailoring and adaptation to address the specific needs of the diverse populations they serve. The participants cited integration into complex workflows, structural costs, and reimbursement concerns as major barriers to implementing and scaling VR use. Future studies should augment this approach with direct observation, quantitative measures of VR use, and direct usability assessment of the AppliedVR platform with diverse patient populations.

Acknowledgments

We would like to thank all interviewees for participating.

This publication was supported by the Food and Drug Administration (FDA) of the US Department of Health and Human Services (HHS) as part of a financial assistance award (Center of Excellence in Regulatory Science and Innovation Grant to University of California, San Francisco (UCSF) and Stanford University, U01FD005978) totaling $50,000, with 50% funded by the FDA/HHS, and $50,000, with 50% funded by a nongovernment source (AppliedVR). The contents are those of the author(s) and do not necessarily represent the official views of, nor an endorsement by, the FDA/HHS or the US government.

Conflicts of Interest

The study team received funding from AppliedVR, but AppliedVR was not involved in data collection, interpretation, or dissemination of findings.

Abstract

Background: Diabetes management is a growing health care challenge worldwide. eHealth can revolutionize diabetes care, the success of which depends on end user acceptance.

Objective: This study aims to understand the readiness and acceptance of eHealth services for diabetes care among the general population, perceived advantages and disadvantages of eHealth, and factors associated with eHealth readiness and acceptance in a multiethnic Asian country.

Methods: In this cross-sectional epidemiological study, participants (N=2895) were selected through disproportionate stratified random sampling from a population registry. Citizens or permanent residents of Singapore aged >18 years were recruited. The data were captured through computer-assisted personal interviews. An eHealth questionnaire was administered in one of four local languages (English, Chinese, Malay, or Tamil), as preferred by the participant. Bivariate chi-square analyses were performed to compare the sociodemographic characteristics and perception of advantages and disadvantages of eHealth services between the diabetes and nondiabetes groups. Multivariable logistic regression models were used to determine factors associated with eHealth readiness and acceptance. All analyses were weighted using survey weights to account for the complex survey design.

Results: The sample comprised participants with (n=436) and without (n=2459) diabetes. eHealth readiness was low, with 47.3% of the overall sample and 75.7% of the diabetes group endorsing that they were not ready for eHealth (P<.001). The most acceptable eHealth service overall was *booking appointments* (67.4%). There was a significantly higher preference in the diabetes group for face-to-face sessions for *consultation with the clinician* (nondiabetes: 83.5% vs diabetes: 92.6%; P<.001), *receiving prescriptions* (61.9% vs 79.3%; P<.001), *referrals to other doctors* (51.4% vs 72.2%; P<.001), and *receiving health information* (34% vs 63.4%; P<.001). The majority of both groups felt that eHealth requires users to be computer literate (90.5% vs 94.3%), does not build clinician-patient rapport compared with face-to-face sessions (77.5% vs 81%), and might not be credible (56.8% vs 64.2%; P=.03). Age (≥35 years), ethnicity (Indian), and lower education status had lower odds of eHealth readiness. Age (≥35 years), ethnicity (Indian), lower education status (primary school), BMI (being underweight), and marital status (being single) were associated with a lower likelihood of eHealth acceptance. Among only those with diabetes, a longer duration of diabetes (4-18 years), higher education (degree or above), and younger age (23-49 years) were associated with eHealth readiness, whereas younger age and income (SGD 2000-3999 [US $1481-$2961]) were associated with acceptance.

Conclusions: Overall, an unfavorable attitude toward eHealth was observed, with a significantly higher number of participants with diabetes reporting their unwillingness to use these services for their diabetes care. Sociodemographic factors associated with

acceptance and readiness identified a group of people who were unlikely to accept the technology and thus need to be targeted for eHealth literacy programs to avoid health care disparity.

KEYWORDS

eHealth; diabetes; general population; acceptance; readiness

Introduction

Background

Diabetes has significant social and economic consequences globally [1]. The prevalence of diabetes increased from 422 million in 2016 [1] to 463 million in 2019 [2], despite innovative disease prevention strategies [1]. This number is estimated to increase by 51% (to 700 million) by 2045 [2], which will lead to higher consumption of health care services [3]. Health care systems are not equipped to manage such a surge in the number of cases [4] and are expected to face additional challenges in the coming years, as a shortage of trained staff is expected because of falling birth rates [5]. The geographical isolation of people living in remote areas is another challenge for health care delivery [6]. This situation calls for a change in the way patients are managed without compromising the quality of health care services.

eHealth is defined by the World Health Organization as a "cost-effective and secure use of information technology in health-related fields: health care services, health surveillance, health literature, and health education, knowledge and research" [7]. Patients with diabetes require regular monitoring of their blood glucose levels, diet, physical activities, and medications to achieve glycemic control [8,9], which will reduce their risk of mortality and cardiovascular complications [10]. eHealth offers diverse treatments and management options in a cost-effective manner to facilitate these requirements [11] and thus allows both clinicians and patients to manage the disease efficiently in a collaborative manner. A meta-analytic review of 18 randomized controlled trials showed a significant reduction in glycated hemoglobin and better glycemic control in participants using eHealth compared with those monitored through routine methods [12]. Pereira et al [13] reviewed the literature on the delivery of health education through eHealth and concluded that the technology delivered better outcomes in terms of efficient management of diabetes. eHealth platforms can also be used for promoting a healthy lifestyle in patients with diabetes by facilitating exercise lessons through video games or other virtual environments [14,15]. Apart from the remote management of diseases, eHealth also offers services such as electronic prescriptions, referrals, teleconsulting, and health education. Thus, eHealth empowers patients to manage their disease and make decisions on their health care remotely, without the need to travel to hospitals.

An individual's decision to use or accept a technology is based on their perception of usefulness and ease of use, which shapes their attitude toward eHealth and intention to use the technology (Technology Acceptance Model). A positive attitude is an antecedent to intention or readiness to use the service. Thus, by modifying the perception of usefulness and ease of use, acceptance can be improved [16,17]. Hossain et al [17] reported that a positive attitude toward eHealth, perceived effectiveness, and access to cell phones were associated with eHealth acceptance in developing countries. The authors also showed that a positive attitude toward technology increased the odds of acceptance by 4.5-fold and reported that sociodemographic factors such as age, gender, and education have a significant influence on this choice. A study of patients with chronic respiratory disease reported higher acceptance of eHealth services for booking appointments, accessing laboratory results, educational purposes, and receiving e-prescriptions, than acceptance of eHealth for treatment-related services such as contact with the health care team and referrals to other clinicians [18]. The likelihood of acceptance was dependent on the duration of the disease, age, and education. A subsequent large-scale study from the author further confirmed that education and perceived usefulness determined eHealth acceptance [19]. Thus, the role of sociodemographic determinants, perception of usefulness, and ease of use in eHealth acceptance is irrefutable.

Although significant efforts have been made to study the efficacy of eHealth programs in cohort studies, there is a dearth of literature on the demographics and attitude-related disparity between members of the general population who have or do not have diabetes. In addition, many of the research studies gathered data from people who had already used specific services to assess the extent of user experience. The expectations and attitudes of those who had never used the technology were not addressed. These perspectives are imperative in the coming era, where the growing demand for health care services will prompt organizations to leverage eHealth for cost-effectiveness and efficient delivery of care. To date, no studies have been conducted at the population level to understand the readiness, acceptability, and attitudes of the general public toward eHealth services for diabetes care. eHealth was one of the most sought-after technologies in the COVID-19 pandemic phase, where many countries tried to deliver diabetes care through eHealth [20]. However, the patients were unwilling to accept the platform even in countries that had an integrated eHealth framework. The most accepted eHealth service is receiving prescriptions for insulin and other medications [20]. Thus, these data clearly show that understanding the readiness and acceptance of eHealth is critical in the future to manage health care services during pandemics.

Objectives

The objective of this study is to understand the (1) readiness and acceptance of eHealth services among the general

population (with and without diabetes) at a national level, (2) perceived advantages and disadvantages of eHealth services, and (3) sociodemographic and clinical factors associated with eHealth readiness and acceptance. This will help organizations to consider various factors that stem from the patient's needs or concerns when implementing eHealth services to avoid technology failure.

Methods

Participants

The detailed methodology of this study has been reported previously [21]. This study was part of a nationwide cross-sectional survey that was intended to understand the knowledge, attitude, and practices of the general public toward diabetes. Participants from the general public were randomly selected from a population registry database of Singapore comprising permanent residents and citizens through disproportionate random sampling (ethnicity and age). Surveys were conducted face-to-face by trained interviewers.

Eligibility

Participants who were aged ≥18 years; who were citizens or permanent residents of Singapore; and who could understand English, Chinese, Malay, or Tamil were recruited. Those who were nonresidents or noncitizens, incapable of doing an interview, living outside the country, or institutionalized during the entire survey period were excluded from the study.

Sample Size

Sample size calculation has been reported previously [21]. Briefly, the power calculations were based on the prevalence rates of knowledge in the general public and included calculations for binary proportions to determine overall sample sizes as well as those for subgroups to produce a margin of error of ≤0.05. A statistical power of 0.8 was targeted with the type 1 error limited to α of .05. The sample size was adjusted to accommodate deviations owing to random sampling. The study used 16 strata: four for ethnicity (Chinese, Malay, Indian, and others) and four for age groups (18-34 years, 35-49 years, 50-64 years, and ≥65 years). The sample was drawn in six replicates (total 5698) released at different intervals starting in February 2019. A target sample of 3000 was estimated to be sufficient to understand the knowledge, attitude, and practices of the general public. The study closed recruitment in September 2020 with a final response rate (total completed interviews / [total number of sample – eligible cases]) of 66.2%. The eligibility rate was 76.8%. The reasons for ineligibility included death, institutionalization (eg, incarceration), residing outside the country during the survey period, uncontactable, severe physical or mental condition that interfered with participation, and language barriers.

Procedure

An invitation letter was sent to all participants 1 to 2 weeks before the intended home visit by a trained interviewer. The trained interviewer approached the households and captured the responses via computer-assisted personal interviews in a language preferred by the participant (English, Chinese, Malay, or Tamil). Regular quality checks were conducted on the data collected [21]. Written consent was obtained from all the participants before the survey. All study procedures were conducted in accordance with the ethical guidelines (Domain Specific Review Board reference 2018/00430). The study was suspended during the *circuit breaker* (heightened safe distancing measures that were implemented to prevent the spread of the virus. This included closure of schools, workplaces, other venues, and avoidance of interaction with those who do not live together) period in response to the pandemic (March 2020 to July 2020) and restarted in August 2020 with interviewers and respondents adhering to safe distancing measures and mask policy.

Questionnaire

Sociodemographic Questionnaire

The information collected included age (as of last birthday), gender, ethnicity, employment status, educational qualification, average monthly personal income (including all allowances over the past 12 months), average household income, height, weight, BMI, and marital status.

Diabetes Questionnaire

The participants were asked two questions to ascertain their diabetes status: (1) "Have you ever been told by a doctor that you have Diabetes?" The response options were "yes," "no," or "I don't know." Those who answered "yes" were further probed with question (2) "What type of diabetes do you have?" The response options were "type 1 diabetes," "type 2 diabetes," "gestational diabetes," "others," and "I don't know." This analysis of the diabetes group included those who endorsed type 1 or type 2 diabetes.

eHealth Questionnaire

The eHealth questionnaire was administered after introducing the concept as "eHealth services refers to health care services (eg, Health Hub) delivered through internet which includes programmes such as online appointment booking, online prescription, online consultation with nurse/doctor/therapist, internet-based support programmes, online referrals, etc."

Readiness

The readiness of the participants toward eHealth was assessed using a single statement, "I am not ready for eHealth." Participants were asked to indicate the extent to which they agreed or disagreed with this statement. The responses were captured on a 5-point scale from "strongly agree" to "strongly disagree" with an option for "neutral" in the middle. For the regression analysis, the responses were grouped as "not ready" (ie, strongly agree or agree) versus "ready" (ie, neutral, strongly disagree, or disagree).

Acceptability

Acceptability of eHealth was assessed using two items: (1) "If you seek treatment for diabetes would you seek treatment delivered via the internet?" The responses were captured as five different options ranging from "definitely would" and "possibly would" to "definitely wouldn't," "definitely wouldn't," and "not sure." For the logistic regression analysis,

"definitely/possibly would" was combined into one category, "definitely/possibly wouldn't" was subsumed into another group, and those who indicated "not sure" (n=95) were removed from the analyses. (2) The acceptance of specific health services was assessed using a stem question, which asked, "Overall, which type of service would you prefer to use if you experience diabetes-related health problems?" The services listed included consultation, receiving prescriptions, booking appointments, receiving health information, and referrals to other clinicians. The participants were asked to indicate their preferred methods to each listed service with one of the three response options "face-to-face," "eHealth," or "both eHealth and face-to-face."

Perceived Advantages and Disadvantages of eHealth

This construct was captured using a series of statements with response options ranging from "strongly agree" to "strongly disagree" with an option for "neutral" in the middle (5-point scale). The items included "internet-based treatments" (1) are more convenient (do not have to travel to the clinic and can access anywhere), (2) save time, (3) are cost-saving, (4) ensure privacy and anonymity (personal information is kept confidential), (5) save from embarrassment related to face-to-face consultation, (6) might not be helpful for my health condition, (7) do not build clinician-patient rapport of face-to-face session, (8) require users to be computer literate, and (9) might not be credible. For bivariate chi-square analyses, the responses were grouped into three groups: strongly agree or agree, neutral, and strongly disagree or disagree.

Chronic Conditions Checklist

The chronic conditions checklist [22] captured 18 different chronic conditions (physical illnesses such as asthma, diabetes, stroke or major paralysis, high blood pressure, hyperlipidemia, arthritis or rheumatism, cancer, neurological conditions such as epilepsy or convulsions, Parkinson disease, congestive heart failure, heart diseases, back problems including disk or spine, stomach ulcer, chronic inflamed bowel, enteritis or colitis, thyroid diseases, kidney failure, migraine headaches, and chronic lung diseases [chronic bronchitis and emphysema]). The participants were asked to respond "yes" or "no" if they have ever been diagnosed with the condition. Diabetes, although captured in the list, was excluded when the number of chronic conditions was tabulated. The total number of chronic conditions was then grouped into *no chronic diseases*, *one chronic disease*, and *two or more chronic diseases*. The duration of each disease could be calculated through an additional question that asks, "How old were you when you were diagnosed?" However, only the duration of diabetes was used in this study. The quartile values were used for grouping the duration of diabetes into four categories (<4 years, 4-9 years, 10-18 years, and ≥19 years).

Analysis

To ensure the representativeness of the data to the general population, the following weights were used in the analysis: design weights to account for oversampling, poststratification weights for adjusting age and ethnicity distributions, and nonresponse weights. All statistical analyses were performed using Stata MP version 15 (StataCorp LLC), and all descriptive, chi-square, and regression analyses were weighted using survey weights to account for the complex survey design. Descriptive analysis was performed for the variables, and the data were represented as the frequency and weighted percentage of the events. First, bivariate chi-square analyses were performed to compare the sociodemographic characteristics of the diabetes and nondiabetes groups. Second, bivariate chi-square analyses were also conducted to examine how the diabetes and nondiabetes groups differed from each other in terms of the perceived advantages or disadvantages of eHealth. Third, within the full sample, multivariable logistic regression analyses (multiple predictor variables and a single binary outcome variable) were then conducted to determine significant sociodemographic factors (ie, age, gender, ethnicity, education, marital status, monthly personal income, employment, BMI, diabetes diagnosis, and chronic physical conditions) associated with readiness for eHealth (ready vs not ready) and acceptance of eHealth (would not vs would accept). The estimated odds ratios (ORs) for each predictor variable of the multivariable regression models were adjusted for other observable variables or potential confounders entered within the model. Finally, to examine the sociodemographic variables associated with readiness or acceptance within individuals with diabetes, a series of bivariate chi-square or Mann-Whitney U analyses were conducted before the estimation of multivariable logistic regression models. Owing to the limited sample size of individuals who endorsed having diabetes, only variables that showed a significant association in the aforementioned bivariate chi-square analyses were included in the final multivariable logistic models. Missing, refused, or do not know responses were removed listwise, as is the default in multivariable logistic regression models and bivariate chi-square analyses.

Results

Sociodemographic Characteristics of the Sample

In total, 2895 participants were recruited from the general population (screened=5698; response rate 66.2%; eligibility rate 76.8%), of which 15.06% (436/2895) had diabetes, whereas the 84.94% (2459/2895) did not have diabetes. An approximately equal number of all age groups, gender, and ethnicity (Multimedia Appendix 1, Table S1) were recruited. Most participants were married (61.7%) and employed (70.5%). Of the participants, 47.6% had no other chronic illnesses (excluding diabetes), 27.3% had at least one chronic disease, and 24.9% had multiple comorbidities (two or more chronic diseases). Detailed information is presented in Multimedia Appendix 1, Table S1. The diabetes and nondiabetes groups differed significantly in most of the characteristics analyzed (P<.001).

Readiness and Acceptance Toward eHealth

Nearly half of the participants acknowledged that they were not ready for eHealth (47.3%). Readiness varied significantly between the nondiabetes and diabetes samples, with the latter showing significantly lower readiness (Table 1; 54.9% vs 24%; P<.001). A lower acceptance level toward eHealth was observed overall (28%), with the majority (68.4%) unwilling to use eHealth for diabetes care. The diabetes group showed significantly lower acceptance (12.1%) than the nondiabetes group (29.6%; P<.001).

Table 1. Readiness toward eHealth and acceptability of eHealth services for diabetes care.

Response categories	Overall (N=2895)	Nondiabetes (n=2459)	Diabetes (n=436)	*P* value
Readiness toward eHealth technology ("I am not ready for eHealth"), n (%)[a]				<.001
Not ready	1460 (47.3)	1132 (44.4)	328 (75.7)	
Ready	1419 (52.1)	1314 (54.9)	105 (24)	
Do not know or refused[b]	16 (0.6)	13 (0.7)	3 (0.3)	
Acceptance of eHealth for diabetes care ("If you seek treatment for diabetes, would you seek treatment delivered via internet?"), n (%)				<.001
Definitely or possibly would	692 (28)	642 (29.6)	50 (12.1)	
Definitely or possibly wouldn't	2100 (68.4)	1733 (67.1)	367 (81.8)	
Not sure[b]	95 (3.3)	78 (3)	17 (5.9)	
Do not know or refused	8 (0.3)	6 (0.3)	2 (0.2)	

[a]Weighted percentage.

[b]Do not know or refused or not sure options were not included in the bivariate chi-square analysis.

Acceptance Toward Specific eHealth Services

A strong preference for face-to-face sessions over eHealth was observed, especially among the diabetes group for most of the services studied. eHealth services were acceptable for the majority of the participants (overall sample, Table 2) for booking appointments (eHealth only: 33.3%; both eHealth or face-to-face: 34.1%) and for receiving health information (eHealth only: 23%; both: 39.8%). Although the nondiabetes group had roughly the same general acceptance level as the overall sample for eHealth, the diabetes group differed significantly in their acceptance rates, preferring face-to-face services (eg, 55.7% for booking appointments and 63.4% for receiving health information; *P*<.001). Acceptance was lower for other services in the overall sample, such as receiving prescriptions for medications (eHealth: 11.3%; both: 24.8%), consultation with clinicians (eHealth only: 1.3%; both: 13.9%), and receiving referral to other doctors (eHealth only: 13.2%; both: 33%). The diabetes group reported significantly lower acceptance rates for all of the previously mentioned services than the nondiabetes group (*P*<.001). A strong preference for face-to-face services was observed for consultation with clinicians, with 92.6% of the diabetes group preferring face-to-face consultation sessions, compared with 83.5% of the nondiabetes group (*P*<.001).

Table 2. Comparison of acceptance of various eHealth services between diabetes and nondiabetes groups.

Response categories	Overall	Nondiabetes	Diabetes	*P* value
Booking appointment, n (%)				<.001
Face-to-face only	1076 (32.1)	794 (29.7)	282 (55.7)	
eHealth only	854 (33.3)	800 (35.6)	54 (10.8)	
Both	953 (34.1)	858 (34.3)	95 (31.4)	
Do not know, refused, or missing[a]	12 (0.5)	7 (0.3)	5 (2.1)	
Getting prescriptions, n (%)				<.001
Face-to-face only	1957 (63.5)	1599 (61.9)	358 (79.3)	
eHealth only	280 (11.3)	259 (11.7)	21 (6.4)	
Both	648 (24.8)	595 (26.0)	53(13.1)	
Do not know, refused, or missing	10 (0.4)	6 (0.3)	4 (1.2)	
Consultation, n (%)				<.001
Face-to-face only	2521 (84.3)	2118 (83.5)	403 (92.6)	
eHealth only	34 (1.3)	33 (1.5)	1 (0.1)	
Both	329 (13.9)	301 (14.7)	28 (6.1)	
Do not know, refused, or missing	11 (0.4)	7 (0.3)	4 (1.2)	
Health information, n (%)				<.001
Face-to-face only	1262 (36.7)	955 (34)	307 (63.4)	
eHealth only	588 (23)	555 (24.4)	33 (8.6)	
Both	1033 (39.8)	942 (41.2)	91 (25.9)	
Do not know, refused, or missing	12 (0.5)	7 (0.3)	5 (2.1)	
Referrals to other doctors, n (%)				<.001
Face-to-face only	1704 (53.3)	1359 (51.4)	345 (72.2)	
eHealth only	377 (13.2)	356 (14.2)	21 (3.6)	
Both	801 (33.0)	735 (34)	66 (23)	
Do not know, refused, or missing	13 (0.5)	9 (0.5)	4 (1.2)	

[a]Do not know or refused options and missing data were not included in the bivariate chi-square analysis.

Perceived Advantages and Disadvantages of eHealth

The most common disadvantages cited were the requirement of computer literacy to use the eHealth service (90.8%; Figure 1), followed by the perception that eHealth did not build clinician-patient rapport in comparison with the face-to-face sessions (77.8%), lack of confidence about the credibility of the eHealth services (57.5%), and the appropriateness of the eHealth services for their specific medical condition (48.7%). A significantly higher proportion of the diabetes group perceived the credibility of the eHealth services (64.2%) and appropriateness of the app for their specific medical condition (62.3%) as disadvantages compared with the nondiabetes group (56.8% and 47.4%, respectively). As a whole, the advantages cited included (1) eHealth services save time (79.8%; Figure 2), (2) it was more convenient than face-to-face sessions (62.5%), and (3) it was cost-saving (61.8%). Overall, the diabetes group perceived significantly lower advantages than the nondiabetes group, except that eHealth ensured anonymity and privacy. Nearly half of the participants in the diabetes (49.8%) and nondiabetes groups (47.6%) reported that eHealth ensures privacy and anonymity. Participants who showed acceptance (endorsed definitely or possibly would use the service) perceived the advantages significantly higher than those with lower acceptance (*P*<.001; Multimedia Appendix 1, Table S2).

Figure 1. Disadvantages of eHealth reported by the participants. The asterisk represents statistically significant values (*P*<.05).

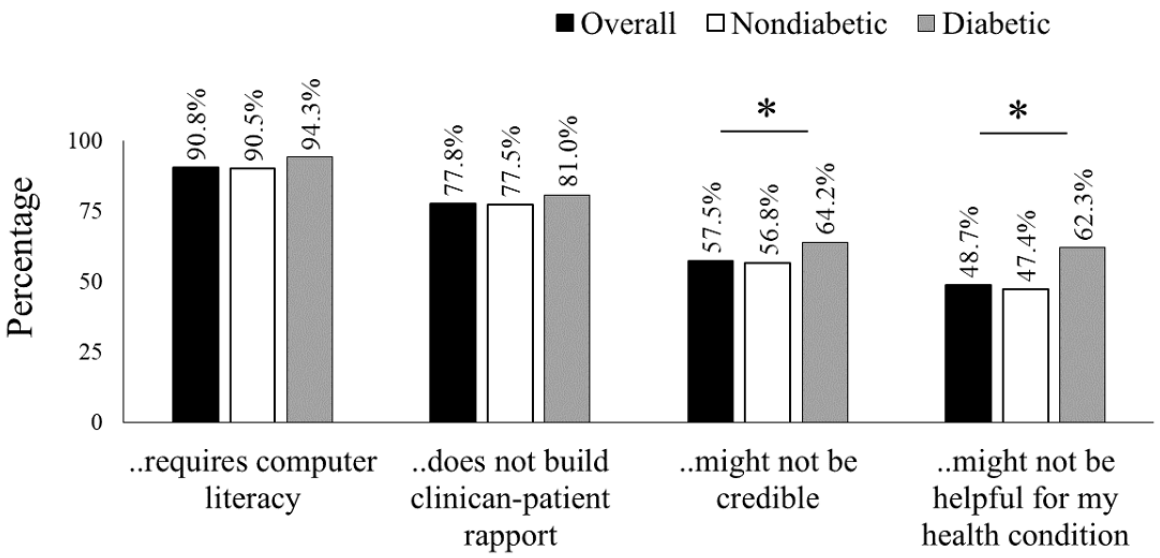

Figure 2. Advantages of eHealth as reported by the participants. Statistical significance is marked with asterisk (**P*<.05; ***P*<.001).

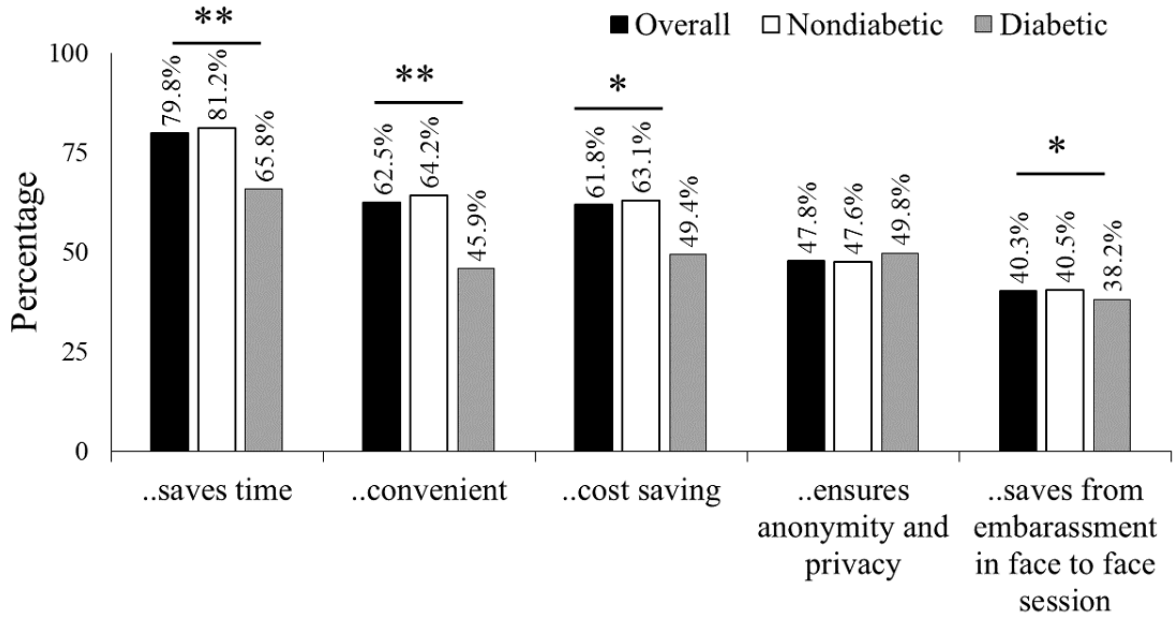

Factors Associated With eHealth Readiness and Acceptance

Factors Associated With eHealth Readiness

Frequencies and weighted percentage counts between sociodemographic variables and readiness toward eHealth are presented in Multimedia Appendix 1, Table S3. The results of the logistic regression analyses are presented in Table 3. The results indicated that age, ethnicity, and education status were associated with eHealth readiness (Multimedia Appendix 1, Table S3 for bivariate analysis). Older adults (aged ≥35 years) had lower odds of endorsing readiness for eHealth than those aged 18-34 years (*P*<.001). With regard to ethnicity, Indians had lower odds of eHealth readiness (OR 0.71, 95% CI 0.54-0.94; *P*=.02) than individuals of Chinese ethnicity. Those with primary school education or below (OR 0.24, 95% CI 0.14-0.44; *P*<.001) and secondary school education (OR 0.48, 95% CI 0.31-0.75; *P*=.001) had lower odds of eHealth readiness than those who had completed a degree or above.

Table 3. Factors affecting eHealth readiness.

Sociodemographic factors	Odds ratio[a] (95% CI)	*P* value
Age group (years)		
18-34 (reference)	__[b]	—
35-49	0.29 (0.19-0.45)	<.001

Factors Associated With eHealth Acceptance

Compared with younger adults (aged 18-34 years), adults in older age groups (aged ≥35 years) were less likely to accept eHealth in the overall sample (Table 4). Indians had lower odds of accepting eHealth (OR 0.54, 95% CI 0.41-0.72; *P*<.001) than Chinese participants. Those who were single (OR 0.62, 95% CI 0.42-0.91; *P*=.01) were less likely to accept eHealth than those who were married or cohabiting. Those with a preuniversity or junior college education (OR 1.90, 95% CI 1.03-3.51; *P*=.04) were more likely to accept eHealth than those with degrees and above. In contrast, those with primary and lower education levels (OR 0.39, 95% CI 0.21-0.75; *P*=.01) were less likely to accept eHealth. People with no income were more likely to accept eHealth than those with income below SGD 2000 (US $1481; OR 1.88, 95% CI 1.06-3.34; *P*=.03). Compared with those with normal BMI, those underweight were less likely to accept eHealth (OR 0.47, 95% CI 0.27-0.83; *P*=.01). A detailed table with results from the bivariate analysis can be found in Multimedia Appendix 1, Table S4.

Factors Associated With eHealth Readiness and Acceptance in Diabetes Subgroup

The frequencies of diabetes and sociodemographic variables and bivariate chi-square analyses are included in Tables S5 and S6 of Multimedia Appendix 1. Only significant correlates were entered into the final multivariate logistic regression model. Age, education status, and duration of diabetes were significantly associated with eHealth readiness in the diabetes group (Table 5). Those aged 50-64 years (OR 0.08, 95% CI 0.03-0.19; *P*<.001) and ≥65 years (OR 0.06, 95% CI 0.02-0.17; *P*<.001) showed lower odds of eHealth readiness compared with those aged 23-49 years. Participants with a diploma had lower odds of eHealth readiness (OR 0.21, 95% CI 0.06-0.76; *P*=.02) than those with an education level of degree or above. Those with a longer duration of diabetes had higher odds of readiness (4-9 years: OR 2.94, 95% CI 1.07-8.05, *P*=.04; 10-18 years: OR 4.03, 95% CI 1.46-11.18, *P*=.007) than those with <4 years of disease duration.

[a]Odds ratio >1 indicates higher likelihood of endorsing readiness for eHealth.

[b]Values not estimated for reference groups.

Age and income were associated with eHealth acceptance and rejection in the diabetes sample (Table 6). Those aged 50-64 years (OR 0.24, 95% CI 0.08-0.75; *P*=.02) had higher odds of rejecting eHealth than those aged 23-49 years. Compared with the participants with income below SGD 2000 (US $1481), those with incomes between SGD 4000 (US $2961) and SGD 3999 (US $2960) were more likely to accept eHealth (OR 7.17, 95% CI 1.61-31.95; *P*=.01). The detailed data from the bivariate analysis are included in Multimedia Appendix 1, Tables S6 and S7.

Discussion

Principal Findings and Implications

This study sheds light on the readiness, acceptance, and attitudes of the population, with and without diabetes, toward eHealth services. Nearly half of the population was not ready for the technology, which was more evident in people with diabetes (75.7%). The acceptance level was very low (12% in people with diabetes vs 29.6% in those without diabetes). Age, ethnicity, education, marital status, income, and duration of disease were associated with readiness or acceptance.

Overall, the participants favored face-to-face sessions over eHealth for most of the services surveyed. A strong preference for face-to-face sessions for consultation with clinicians was observed in 84% of the participants and 92% of the diabetes sample. Similar results were noted in other studies in patients with diabetes [23] and in patients with mental illness [24]. It is possible that patients with diabetes feel that diabetes is a complex disease with chances for further health complications; thus, periodic face-to-face sessions with their care providers are required. These sessions answer their queries and help them make important care decisions through discussions with their clinicians. Such interactions and rapport are important in the adaptation to medical conditions and engagement in treatment [25]. In agreement with this, 62.3% of the diabetes group in this study felt that eHealth might not be suitable for their condition, and the majority of the participants in both groups (diabetes and nondiabetes) felt that eHealth did not build clinician-patient rapport to the same extent as face-to-face sessions. Previous studies have identified potential challenges in patient-clinician interaction within the eHealth milieu, wherein 88% of the participants felt that eHealth does not build the same rapport as face-to-face sessions and sharing doctor's phone number or personal email could improve the clinician-patient rapport in the eHealth framework [26]. However, only 2% of the doctors were willing to share their phone number or email address [27] with the patients. Thus, in the absence of additional measures, individuals who value clinician-patient rapport are unlikely to accept eHealth as a replacement for face-to-face sessions [23].

A lower perception of ease of use was also observed in the sample. The most cited disadvantage was the requirement of computer skills, which was identified as a factor that affects the behavioral outcome (perceived ease of use and intention to use the technology) in the Technology Acceptance Model [16]. This observation has also been highlighted in previous studies [24,28]. The usage and navigation of the various functions of apps require training and support, which can adversely affect user acceptance, especially in older adults. This can be addressed by constant training and support by health care staff [29]. Perceived benefits are another factor that determines the acceptance of eHealth services [16,28], especially among people with diabetes [29]. Although the majority of the nondiabetes group agreed that eHealth was convenient and saves time and cost, the diabetes sample showed a significantly lower perception of advantages that could add to their decision to reject the services. Apart from these factors, a user's positive experience with eHealth services and eHealth literacy are important factors that can improve acceptance rates [29]. Thus far, none of the diabetes-related services in Singapore have been offered through eHealth platforms, thereby leaving the participants with no previous experience or knowledge of the technology. This could be the reason for the lower perception of benefits.

Age, education status, income, ethnicity, disease duration, BMI, and marital status were identified as factors associated with readiness and acceptance. We observed that a longer duration of diabetes was associated with higher odds of readiness but not acceptance in patients with diabetes, confirming previous reports. It is postulated that patients with a longer duration of diabetes prefer more personalized care, which involves regular face-to-face discussions with their health care team. In general, they lack trust in new technologies and are reluctant to embrace the new technology that has a lot of uncertainty to replace the comfort of face-to-face sessions [23]. However, as they tend to show readiness toward eHealth, the technology could be introduced slowly alongside their face-to-face session to give a positive experience with the technology that will influence their attitude toward eHealth. Jiang et al [30] studied the sociodemographic factors associated with the acceptance of eHealth in the management of chronic diseases (cancer), where the patients used eHealth for self-management. The study identified similar sociodemographic factors as determinants of eHealth acceptance. Younger adults and those with higher education exhibited higher eHealth literacy and thus had better chances of acceptance and outcome from eHealth use [31]. Gordon et al [32] and Eszes et al [33] also observed social determinants, such as age and ethnicity, to affect eHealth usage and acceptance. Thus, such social determinants should be given attention to avoid health care disparities in underprivileged groups. Overall, the present population in this study had an unfavorable attitude toward eHealth for diabetes care, and this was stronger among patients with diabetes. This is different from the reports from cohort studies where moderate or high levels of acceptance of specific eHealth apps were noted [24,34]. However, all these studies captured acceptance after implementing a specific eHealth program under the care of the attending health care professional, where the patients experienced remote glucose monitoring, diet, and/or physical activity monitoring. It is unclear whether these sessions supplemented their routine face-to-face sessions or replaced them. The participants in this study were technology naïve, as most of the services they encountered were offered face-to-face in the diabetes clinics with no remote monitoring in place. Hence, the lack of previous experience and literacy in eHealth might affect their perceptions and attitudes toward technology.

Overall, the diabetes sample showed a significantly lower readiness and acceptance of eHealth compared with the nondiabetes group. This can be explained based on the differences in sociodemographic characteristics between the two groups (Multimedia Appendix 1, Table S1). Most of the diabetes sample was older adults (aged >34 years), and only 1.8% of the participants were in the 21-34 years age group compared with 32.7% in the nondiabetes group. Nearly half of the diabetes sample (49.1% vs 24.5%) were aged between 50 and 64 years. Our results showed that adults who were aged ≥34 years had higher odds of not favoring eHealth, and the odds increased with age. Thus, the sociodemographic profile of the diabetes sample matches the archetype of individuals who tend not to favor eHealth. The diabetes sample also had a higher proportion of participants from the Indian ethnicity (15.1% vs 7.9%) and those reporting no income (10.9% vs 6.6%), all of which were associated with lower acceptance or readiness toward eHealth. It is also possible that those with diabetes had built a stronger therapeutic relationship with the clinical care team and thus were unwilling to accept new technology, as they feared that it would disrupt their relationship with the clinical team [23]. An in-depth qualitative study that captures the barriers to and facilitators of eHealth acceptance in this group is desirable to understand the needs of this group before introducing eHealth into their routine care.

It is possible that some participants were unaware of existing eHealth platforms in Singapore when answering the questions, and the survey did not capture this information, which is a limitation of this study. The questionnaire used in the study was developed by the study team and has not been validated previously. The diagnosis and duration of the disease were captured through a self-reported measure, which is a limitation of this study. For the duration of diabetes, the participants reported the age at which they were first diagnosed with diabetes, which was subjected to recall bias. It is currently unclear why a significantly higher proportion of patients with diabetes were not in favor of this technology. Age could play an important role, as older participants tend to reject eHealth. With the aging population in Singapore, it is essential to understand the barriers to and facilitators of eHealth acceptance to avoid the underutilization of services by this group. Future research should focus on an in-depth qualitative analysis of the population with and without diabetes with specific age groups to understand the reasons for the lack of acceptance of the technology.

It is also possible that people's perceptions and attitudes toward eHealth evolved during the pandemic period, as many services were disrupted as a consequence of the COVID-19 pandemic. We recruited only a small proportion of the participants (n=16) during this period, and therefore, it was unlikely to have an impact on the results. Globally, patients with diabetes have multiple complications and hyperglycemic episodes with no or limited access to medications or other health care platforms [20]. Although eHealth is a viable option, it is not available to the majority of people worldwide. On the basis of these experiences, the international consensus calls for a transformation of diabetes care to steer toward eHealth rather than going back to the pre–COVID-19 era to prepare better for future disasters [20].

Lower eHealth readiness and acceptance can be a significant barrier to the digitalization of health care services. The general public's eHealth literacy needs to be improved through education and communication before implementing any eHealth services to avoid patient and clinician distress. As patients value clinician-patient rapport, an organizational-level effort is required to improve the clinician-patient rapport in the eHealth framework and to assure patients that comparable care would be delivered under both platforms. Thus, a carefully planned deployment of eHealth to supplement face-to-face sessions rather than replace them would be ideal for improving acceptance and reducing patient dissatisfaction. A gradual transition based on an individual's preferences, capabilities, and needs would result in people feeling comfortable with the technology.

Conclusions

This study showed a negative attitude toward eHealth, with the majority unwilling to use eHealth for their diabetes care. The highest acceptance was noted for booking appointments on the web and receiving health information, whereas face-to-face sessions were preferred for the rest of the services. Participants were aware that eHealth saves time and is convenient; nonetheless, the lower perception of the benefits in patients with diabetes and higher perception of disadvantages is a challenge in accepting the technology for diabetes care. A strong preference for face-to-face sessions was observed with a larger proportion of participants with diabetes, citing the reason that eHealth might not be suitable for their health condition. The lack of clinician-patient rapport, requirement of computer skills, and privacy were highlighted by most of the participants, which needs to be addressed through awareness programs to improve acceptance. Younger age, higher education, marital status, BMI, higher income, and ethnicity were associated with eHealth readiness or acceptance. Attention must be given to the socioeconomic group who are unlikely to use the technology so that they are not affected by health and health care disparities.

Acknowledgments

This study was funded by the National Medical Research Council of Singapore (NMRC NMRC/HSRG/0085/2018).

Authors' Contributions

MS, SAC, ESL, PVAR, and CFS were involved in the conceptualization of the study. PVAR wrote and revised the manuscript. JAV, KR, FDSK, AJ, PVAR, MS, WP, SC, SAC, ESL, CFS, and SS were involved in the questionnaire design. MS, PVAR, FDSK, and KR conducted the cognitive testing of the survey questionnaire. MS, PVAR, FDSK, SS, WP, SC, CBY, and KR were involved in data collection. EA and LJH provided the statistical design and sampling strategy. CBY designed and supported the database. PVAR wrote the manuscript. All authors have reviewed and approved the manuscript.

Abstract

Background: eHealth literacy is significantly associated with patients' online information behavior, physician-patient relationship, patient adherence, and health outcomes. As an important product of the internet, online health communities (OHCs) can help redistribute idle medical resources, increase medical resource utilization, and improve patient adherence. However, studies on eHealth literacy in OHCs are limited. Therefore, this study examined patients' eHealth literacy regarding health information–seeking behavior and physician-patient communication in OHCs.

Objective: This study aimed to investigate the association between eHealth literacy in OHCs and patient adherence by employing social cognitive theory.

Methods: This was an empirical study, in which a research model consisting of 1 independent variable (patients' eHealth literacy), 3 mediators (physician-patient communication in OHCs, patient health information–seeking behavior in OHCs, and patients' perceived quality of health information in OHCs), 1 dependent variable (patient adherence), and 4 control variables (age, gender, living area, and education level) was established to examine the associations. Multi-item scales were used to measure variables. An anonymous online survey involving 560 participants was conducted through Chinese OHCs in July 2018 to collect data. Partial least squares and structural equation modeling were adopted to analyze data and test hypotheses.

Results: The survey response rate was 79.6% (446/560). The reliability, convergent validity, and discriminant validity were acceptable. Age, gender, living area, and education level were positively associated with patient adherence, and gender was positively associated with physician-patient communication and patients' perceived quality of internet health information in OHCs. Patients' eHealth literacy was positively associated with patient adherence through the mediations of physician-patient communication, internet health information–seeking behavior, and perceived quality of internet health information in OHCs.

Conclusions: Results indicate that physician-patient communication, internet health information–seeking behavior, and the perceived quality of internet health information are significantly associated with improving patient adherence via a guiding of eHealth literacy in OHCs. These findings suggest that physicians can understand and guide their patients' eHealth literacy to improve treatment efficiency; OHCs' operators should this strengthen the management of information quality, develop user-friendly features, and minimize the gap between the actual and perceived information quality.

KEYWORDS

online health communities; OHCs; eHealth literacy; patient adherence; health information; physician-patient communication

Introduction

Background

Health literacy is defined as "the degree to which an individual has the capacity to obtain, communicate, process, and understand basic health information and services to make appropriate health decisions," [1] but individual's skill to obtain and use health information needs to be redefined with the development of medical internet services [2]. Accordingly, eHealth literacy has emerged [3], which is defined by Norman and Skinner [4] as individuals' ability to "seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to addressing or solving a health problem." eHealth literacy is related to health literacy, and both of them involve the skills of seeking, appraising, and applying health information [5]. Gilstad [6] added the communication of health information into the definition of eHealth literacy, while Neter and Brainin [5] and Paige et al [7] suggested that eHealth literacy is associated with health-related behaviors, communication skills with physicians, self-management, and health outcomes.

In recent years, online health communities (OHCs) have provided the public with new platforms to obtain health information, share medical experiences, and communicate with physicians. OHCs can help redistribute idle medical resources, improve medical resource utilization, and enhance the physician-patient relationship [8-10]. Patients' eHealth literacy in OHCs has become an important topic to be studied. Previous studies show that patients with adequate eHealth literacy have a higher level of ability to seek internet health information and are more likely to obtain reliable and high-quality health information online than are patients with inadequate eHealth literacy [11,12]. In addition, a high level of eHealth literacy can enable patients to communicate with physicians and improve communication efficiency [11,13].

Physician-patient communication and health information–seeking behavior in OHCs are related to patient adherence, which is defined as "the extent to which a person's behavior (in terms of taking medications, following diets, or executing lifestyle changes) coincides with medical or health advice" [14-16]. Given that physicians cannot constantly participate in patients' daily life, the ability of self-management and self-monitoring is important for patients to maintain a healthy lifestyle. Treatments, medical regimens, and therapies are more likely to be effective if patients take medication in accordance with prescriptions and physicians' advice [17]. Therefore, we speculate that patients' eHealth literacy is likely to be associated with their adherence. Previous studies have focused on the relationship between health literacy and patient adherence or between OHCs and patient adherence [18,19]. However, studies on the association between eHealth literacy in OHCs and patient adherence are limited because of the short development time of medical internet services, OHCs, and eHealth literacy. Given the low level of medical resource utilization, uneven medical resource distribution, and serious hospital congestion in China, this study aims to identify the association between patients' eHealth literacy in OHCs and patient adherence through empirical study and by considering physician-patient communication, internet health information–seeking behavior, and the perceived quality of internet health information as mediators. We hope we can propose productive ideas for improving patient adherence that can ultimately alleviate these aforementioned problems. This study can enrich the theoretical study of OHCs, eHealth literacy, and patient adherence, and may have practical implications for managing OHCs and improving patient adherence through eHealth literacy in OHCs.

Patient Adherence

Patient adherence plays a vital role in health management and health care, especially for patients with chronic diseases [20]. Horwitz et al [20] proved that patient adherence is positively associated with health outcomes and that patients who adhere strictly to medical regimens and physicians' suggestions are relatively healthier than those who do not. Previous studies have confirmed that low adherence may lead to serious consequences for patients, the economy, and society. For patients with low adherence, diseases may be less likely to be controlled or cured, thereby increasing the morbidity and mortality [21]. For the economy, if patients do not adhere to medical regimens or physicians' advice, therapies cannot achieve the intended outcomes, which may waste medical resources [22,23]. In terms of social effect, the unbalanced medical resource allocation may be serious. For example, medical resources may be wasted in some hospitals in economically developed regions, while hospitals in some regions may lack sufficient resources. Moreover, some genuinely beneficial drugs may be mistaken as useless and then be discontinued because patients do not take medications in accordance with prescriptions [23].

Given that patient adherence is a dynamic parameter [24], patient adherence can be enhanced to improve patients' outcomes, increase the utilization of medical resources, advance the clinical testing of drugs, and promote the stable development of society.

Online Health Communities

This study mainly discusses the OHCs in which patients and physicians participate. Patients are increasingly using OHCs to seek health information and communicate with physicians about medical and emotional support because of certain benefits brought by OHCs [25,26]. First, patients can ask questions and communicate with physicians by creating posts and sending online messages anytime and anywhere without visiting hospitals [27]. Moreover, users can conveniently access OHCs' corresponding apps using smartphones. Second, patients' privacy can be protected as meeting face-to-face is unnecessary, and OHCs generally allow patients to ask questions anonymously [28]. Third, OHCs can help alleviate hospital congestion and integrate idle medical resources [9,10,15]. Specifically, patients can diagnose a few basic and simple symptoms by themselves based on the support from OHCs and do not need to visit hospitals frequently or wait extensively. In turn, physicians can spend their time communicating with patients in OHCs if there are only a few patients present in hospitals. In this way, medical resource utilization can be improved.

However, several drawbacks of OHCs must be considered. The observation of patients' breath, sound, and facial expressions is important for physicians in diagnosing illness accurately [29], which is difficult to achieve though OHCs. In this type of situation, physicians may misunderstand patients' conditions and provide inaccurate advice, which may decrease patients' satisfaction. In addition, some patients may worry that they cannot receive answers from actual physicians. Given OHCs' advantages and persistent development, studies on OHCs should be conducted to decrease or avoid these shortcomings.

eHealth Literacy

eHealth literacy is nested in the context of a digital environment. Based on Norman and Skinner [4], Gilstad [6] extended the definition of eHealth literacy to include an individual's skill in identifying, defining, and solving a health problem by communicating, seeking, understanding, appraising, and applying health information and digital technologies under a given cultural, social, and situational background [30]. Paige et al [31] further proposed a transactional model to update the definition of eHealth literacy to include a patient's skill in interacting with the external environment and in counteracting the negative effects of environmental factors. eHealth literacy is a central skill [31] and is significantly associated with health-related behavior [11,32], self-management skills, patients' health-related decision-making, and health outcomes [33,34]. For example, adequate eHealth literacy can help patients understand their conditions accurately, obtain health-related information and knowledge, and improve the ability to self-manage their health and communicate with physicians [11]. In addition, eHealth literacy is associated with health responsibility, self-actualization, and the relationship between patients and health care providers [35].

Previous studies have verified that patients with a high level of eHealth literacy are good at seeking, selecting, and assessing health information from many sources using additional search strategies [5,32], whereas patients with limited eHealth literacy may find the use of online health-related resources difficult. Freemann et al [36] asserted that eHealth literacy plays an important role in adolescents' daily life. Mitsutake et al [32] found that eHealth literacy can promote individuals' health behaviors, such as physical exercise and balanced nutrition. Bodie and Dutta [37] suggested that eHealth literacy can help develop patients' ability to solve specific health problems by themselves using information obtained from the internet, thereby possibly encouraging patients' health behavior. In this study, we focused on patients' eHealth literacy in OHCs. Specifically, we concentrated on patient behavior in seeking, obtaining, understanding, and evaluating health-related information in OHCs and the association between eHealth literacy and patient adherence.

Internet Health Information

In terms of content, health information can be divided into 2 categories: health care information and healthy lifestyle information [5,38,39]. The internet has become the main source for individuals to seek health information [40], and various institutions, such as governments, medical institutions, and business corporations, have established health-related websites to provide information-seeking platforms for the public [41]. According to Wilson [42], combined with the context of the internet, internet health information behavior can be categorized as internet health information–seeking behavior, internet health information use behavior, online communication behavior, and passive receiving of internet health information behavior. According to Neter et al [43], individual's online behaviors in the context of Web 1.0 are mainly consumption activities, such as reading others' experiences, watching videos, and sending or receiving emails, while behaviors in the context of Web 2.0 are mainly production activities, such as rating physicians and hospitals, communicating with others, and sharing their experiences. The aim of individual's use of OHCs is obtaining health information, which indicates that this behavior is active. This study intends to identify the association between eHealth literacy in OHCs and patient adherence. eHealth literacy requires the skill of seeking health information from digital sources. However, having a capacity to seek information online does not mean that the individual would like to perform health information–seeking behavior. Rather, eHealth literacy may be associated with an individual's internet health information–seeking behavior. Therefore, we mainly focused on the internet health information–seeking behavior and online communication behavior in OHCs, which includes Web 1.0 and Web 2.0 health-related activities.

Given the zero gatekeeping and zero-cost publishing of the internet, information can be published and spread quickly and in timely fashion [44], and patients can obtain health information conveniently through the internet, which may help improve their ability in health-related problem-solving [45]. However, in consideration of the universal accessibility of the internet, internet health information has several shortcomings, such as the quality of information [46]. For one, each person is allowed to publish health information online regardless of its correctness, as, for example, most websites in China lack a strict review mechanism for health information. For another, individuals may have inadequate eHealth literacy to appraise the quality of health information or select reliable facts [5]. With limited eHealth literacy, individuals are unable to accurately appraise health information and may at times regard actual high-quality information as low quality or regard actual low-quality information as high quality. For example, a person who does not have adequate eHealth literacy may not be able to find reliable health information from online sources, but sometimes he or she may consider the information obtained from an official health portal as high quality. Therefore, patients' eHealth literacy may be associated with their perceived quality of internet health information, and thus this study concentrated on patients' perception of internet health information quality in OHCs.

Physician-Patient Communication

Originally, the communication between physicians and patients could only occur in hospitals. A new form of physician-patient communication has emerged with the internet, and OHCs serve as important platforms. Because of the advantages of OHCs, patients are willing to communicate with physicians online before or after visiting hospitals [25,47], which is beneficial for improving the efficiency of offline treatments and saving time.

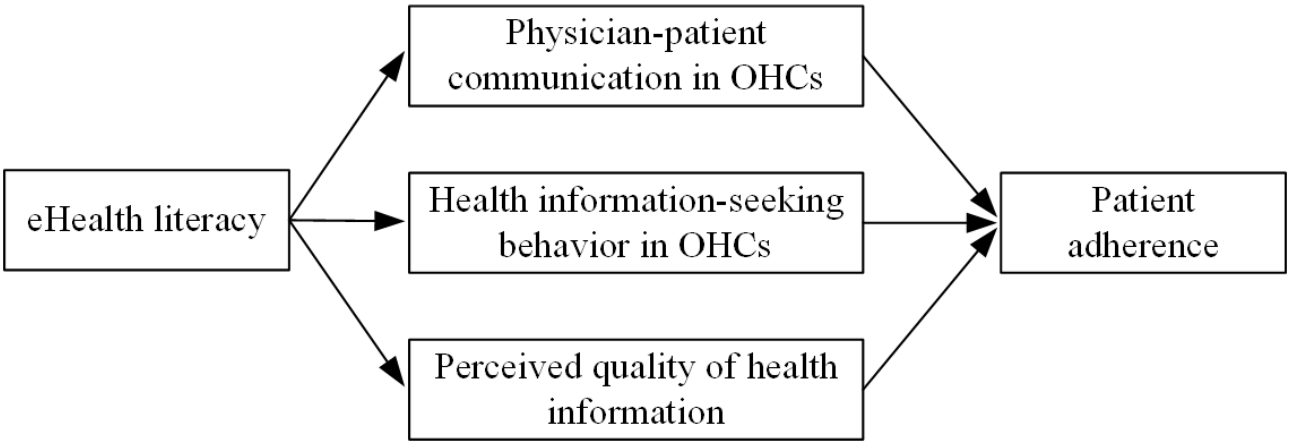
Patients can initially assess their conditions through communication with physicians in OHCs before visiting hospitals, which may help them select the relevant health care department and minimize unnecessary checks [48]. In addition, communicating with physicians in advance can help patients gain information of physicians and decrease the uncertainty in offline treatments [10].

The internet can provide more opportunities to communicate [49]. It is better to practice individuals' communication skills through online channels than on offline channels. Therefore, online communication may be more effective than offline communication. To specify, without a face-to-face meeting, patients and physicians do not need to answer immediately. Therefore, they have adequate time to reconsider their responses, and patients' sense of unfamiliarity and nervousness can be reduced. In addition, conflicts between physicians and patients may be avoided in OHCs, thereby improving communication efficiency and quality and promoting patients' satisfaction with physicians [45].

Model and Hypotheses

Human behavior can be associated with social information obtained from their environment [50]. Specifically, individuals can obtain information from their social environment when they lack knowledge, which may influence their opinions, beliefs, and behavior [51]. In the context of this study, patients actively obtain health information from OHCs by communicating with physicians and searching for information to satisfy their demand for health information and to improve their self-efficacy, which may be associated with patient health-related behavior. According to the review by Neter and Brainin [5], eHealth literacy is associated with individuals' health behaviors. Therefore, we established a research model (Figure 1), which involves 1 independent variable, 3 mediators, and 1 dependent variable to identify the association between eHealth literacy in OHCs and patient adherence through the mediations of physician-patient communication, patient health information–seeking behavior, and patients' perceived quality of health information by employing social cognitive theory. Social cognitive theory can be used to predict health-related behaviors [52,53]. Self-efficacy is a critical factor in social cognitive theory [54], and it can influence an individual's way of thinking, thereby self-regulating motivations of behavior. Specifically, a high level of self-efficacy can encourage individuals to change their behavior, while a low level of self-efficacy may make individuals feel frustrated and refuse to change.

Figure 1. Research model. OHC: online health community.



Communication is an important skill related to eHealth literacy [5,6], and patients' communication behaviors may be associated with individuals' eHealth literacy. Patients with limited eHealth literacy may not have favorable information communication skills and may not be able discuss their illnesses and conditions with physicians clearly [55]. The lack of eHealth literacy may decrease patients' self-efficacy in communication with physicians in OHCs. According to social cognitive theory [54], patients' intention to communicate with physicians may be reduced and they may not want to communicate with physicians through OHCs. We thus assumed that eHealth literacy is associated with communication between physicians and patients in OHCs and proposed the following hypothesis: H1*:* Patients' eHealth literacy is positively associated with physician-patient communication in OHCs.

Seeking health information is another way for patients to obtain health information in OHCs, and it may be associated with eHealth literacy. First, patients with limited eHealth literacy may not be familiar with OHCs. Even if these patients realize the existence of OHCs, they may not be aware that health information can be searched for through these portals [56]. Second, patients with low eHealth literacy may not be good at evaluating the quality of information obtained from OHCs [12], which may decrease patients' intention to seek health information online. Furthermore, patients with inadequate eHealth literacy may find it difficult to obtain high-quality health information. Third, inadequate eHealth literacy makes patients lack adequate confidence in seeking suitable health information in OHCs [11]. Accordingly, under the guidance of social cognitive theory [54], patients with limited eHealth literacy may have low a level of self-efficacy in seeking health information through OHCs, which may inhibit their information-seeking behavior in OHCs. We thus proposed the following hypotheses: H2*:* Patients' eHealth literacy is positively associated with patients' internet health information–seeking behavior in OHCs; H3*:* Patients' eHealth literacy is positively associated with

patients' perceived quality of internet health information in OHCs.

Patients' attitudes and behaviors can be associated with health information obtained from OHCs [50]. Therefore, we assume that, as two ways for patients to obtain health information in OHCs, communicating with physicians and seeking health information are associated with patient adherence. The physician-patient relationship can be enhanced through effective communication, which may promote information processing and decision-making [57,58]. Therefore, patients are likely to perceive high-quality health information and consider their physicians to be professional [59], ultimately improving their self-efficacy. A high level of self-efficacy can encourage patients to adopt health-related behavior [54], such as adherence with physicians' advice. Indeed, Roberts et al [60] confirmed that communication between patients and physicians can improve patient adherence. In terms of health information–seeking in OHCs, generally, the information obtained by patients in OHCs is often basic health-related knowledge, such as medical terminologies and diagnoses, which has been already grasped by physicians [47]. When patients are aware of that fact, they are more likely to trust in their physicians' professional competence. Thus, patients may be increasingly willing to follow the regimens and advice given by physicians. These considerations produce the following hypotheses: H4*:* Physician-patient communication in OHCs is positively associated with patient adherence; H5: Patients' internet health information–seeking behavior in OHCs is positively associated with patient adherence; H6: Patients' perception of internet health information quality is positively associated with patient adherence.

In addition, control variables (age, gender, living area, and education level) were included in this research model to examine and adjust the effects of demographic factors on the research model.

Methods

Instrument Development

The survey instrument (see Multimedia Appendix 1) was developed on the basis of scales validated by previous studies. Specifically, eHealth literacy was measured using a 10-item scale consisting of 8 main items adopted from Norman and Skinner [61] and 2 supplementary items adopted from Park and Lee [62]. Physician-patient communication was measured using a 14-item scale adopted from Makoul et al [63]. A 4-item health information–seeking scale reflects the means by which people search and apply health information actively and passively [64]. Laugesen et al [47] adopted a 16-item scale to measure the perceived quality of internet health information and a 5-item scale to measure patient adherence.

We conducted a formal investigation of Chinese individuals who had communicated with physicians and sought health information in Chinese OHCs. Therefore, the questionnaire was translated into Chinese. The translation process was divided into 3 stages [65,66]. First, 3 native Chinese speakers who had at least a master's degree in English and were skilled in scientific research translation were recruited to translate the instrument into Chinese. Second, we conducted a pretest to acquire advice for improving the comprehensibility, conciseness, readability, and cross-cultural adaptation of the instrument. Third, we recruited English professionals to translate the Chinese questionnaire back to English and to compare the final English version with the original English version to guarantee the conceptual consistency between the 2 versions.

Data Analysis

Our participants were those who had obtained health information by communicating with physicians and seeking health information in OHCs within the previous month. Thus, they could recall relevant experiences. The formal survey was anonymously conducted through several Chinese OHCs in July 2018, and we guaranteed that the privacy of participants would be strictly protected.

As a comprehensive and nonparametric structural equation modelling (SEM) approach, partial least squares (PLS)-SEM is effective in analyzing complex models, providing robust model estimations, and evaluating the quality of predicting results [67-69], especially in the case of complex models or small sample sizes. In addition, PLS-SEM can be used to conduct mediation analysis [68]. Therefore, this study used PLS-SEM to test hypotheses and analyze the research model [47,68] and adopted SmartPLS software version 3.2.8 to analyze data. First, we re-evaluated the reliability and validity of scales since the research context and participants in this study were different from previous works. Specifically, we calculated Cronbach α to assess the reliability and adopted confirmatory factor analysis to assess the convergent validity and discriminant validity. Second, we calculated the magnitude and significance of path coefficients to examine the effects of control variables and test hypotheses, and used multivariate coefficient of determination (R^2) to calculate Cohen f^2 and used goodness of fit (GoF) to analyze the effect sizes of the research model and the fit between the research model and observed data [70]. Third, we further examined the mediations of physician-patient communication, patient health information–seeking behavior, and the perceived quality of health information using the bootstrapping method (n=5000; 95% CI).

Results

We sent the questionnaire to 560 participants and received 446 responses, 381 of which were valid. Accordingly, the response rate was 79.6% (446/560), and the validity rate was 85.4% (381/446). As shown in Table 1, 58.3% (222/381) of the participants were 20 to 40 years old, 53% (202/381) were female, and 51.4% (196/381) had at least a bachelor's degree, all which accounted for more than half of the sample. Given that the participants were OHC users who tended to be young, female, and highly educated, our sample could be considered representative [71,72].

Table 1. Sample demographics (N=381).

Demographic characteristics	Value, n (%)
Age (years)	
<20	18 (4.7)
20-29	107 (28.1)
30-39	115 (30.2)

The Cronbach α of eHealth literacy, physician-patient communication, internet health information–seeking behavior, perceived quality of internet health information, and patient adherence were .849, .898, .709, .905, and .771, respectively. Therefore, the reliability of the scales was acceptable [73]. The Kaiser-Meyer-Olkin value was .964, so the collected data could be used to conduct factor analysis [74]. This study adopted the composite reliability and the average variance extracted (AVE) to evaluate the validity of scales. As shown in Table 2, for each construct, the composite reliability was above 0.700 and the AVE was above 0.500, indicating an acceptable convergent validity [75]. Table 3 shows the correlations between constructs, and the discriminant validity was acceptable because the square root of AVE was greater than the correlations between other constructs and themselves [75].

Table 2. Composite reliability and average variance extracted.

Construct	CR[a]	AVE[b]	Sqrt[c] AVE
eHealth literacy	0.916	0.522	0.723
Physician-patient communication in OHCs[d]	0.937	0.514	0.717
Internet health information–seeking behavior in OHCs	0.834	0.556	0.746
Perceived quality of internet health information in OHCs	0.943	0.506	0.712
Patient adherence	0.845	0.523	0.723

[a]CR: composite reliability.

[b]AVE: average variance extracted.

[c]Sqrt: square root.

[d]OHC: online health community.

Table 3. Correlations between constructs.

Construct	EHL[a]	PPC[b]	IHISB[c]	PQIHI[d]	PA[e]

In terms of the effects of demographic factors, results indicated that 4 control variables (age, gender, living area, and education level) were positively associated with patient adherence, and gender was positively associated with physician-patient communication and patients' perceived quality of internet health information in OHCs. Specifically, older patients were more willing to take medication and maintain a healthy lifestyle in accordance with medical regimens and physicians' advice than were younger patients; female patients were more likely to communicate with physicians through OHCs, perceive a higher quality of information, and be more willing to adhere to treatments and physicians than were male patients; patients who lived in rural areas were more compliant with physicians than those who lived in urban areas; highly educated patients were more willing to adhere to physicians than were patients with a low level of education. However, all path coefficients of relationships related to control variables were nearly zero, indicating weak effects. The multivariate coefficient of determination (R^2) was used to calculate Cohen f^2 to further evaluate the size of the control variables' effects [76] as listed in Table 4. We confirmed that the effect sizes of the control variables were so small that they could be considered insignificant.

Table 4. Multivariate coefficient of determination (R^2) results.

Variables	R^2		Control variable effects		
	In	Out	ΔR^{2a}	f^2[b]	Effects
Physician-patient communication					
Control variables	0.722	0.720	0.002	0.007	Insignificant
eHealth literacy	0.677	0.004	0.673	2.084	Large
Internet health information–seeking behavior

[a]ΔR^2: $R^2_{In} - R^2_{Out}$.

[b]f^2: Cohen f^2.

GoF was used to evaluate the fit between the research model and observed data [70,77] and was calculated as follows:

In this study, the GoF value was 0.578, which indicated that the fit between the data and the research model was good [78].

The magnitude and significance of path coefficients revealed that all 6 hypotheses were supported (Table 5). In particular, eHealth literacy was positively associated with physician-patient communication, internet health information–seeking behavior, and perceived quality of internet health information in OHCs. Physician-patient communication, internet health information–seeking behavior, and perceived quality of internet health information in OHCs were positively associated with patient adherence. We further analyzed the effect sizes of the independent variable and mediators, the results of which are presented in Table 4. We found that the effects of physician-patient communication, internet health information–seeking behavior, and the perceived quality of internet health information in OHCs on patient adherence were weak with small effect sizes, while the effects of eHealth literacy on physician-patient communication, internet health information–seeking behavior, and the perceived quality of internet health information in OHCs were strong with large effect sizes.

Table 5. Results of hypothesis testing.

Hypothesis	Path coefficient	*t*	*P* value
H1: Patients' eHealth literacy is positively associated with physician-patient communication in OHCs.	0.849	46.484	<.001
H2: Patients' eHealth literacy is positively associated with patients' internet health information–seeking behavior in OHCs.	0.732	26.479	<.001
H3: Patients' eHealth literacy is positively associated with patients' perceived quality of internet health information in OHCs.	0.822	33.227	<.001
H4: Physician-patient communication in OHCs is positively associated with patient adherence.	0.429	4.423	<.001
H5: Patients' internet health information–seeking behavior in OHCs is positively associated with patient adherence.	0.156	2.408	0.02
H6: Patients' perception of internet health information quality is positively associated with patient adherence.	0.247	2.918	0.004

According to Baron and Kenny [79], we adopted a bootstrapping method (n=5000, 95% CI) to further examine the mediations. The results of *a*, *b*, *c*, and *c*' are shown in Table 6, and the CIs (bias corrected) of *a* and *b* are shown in Table 7. Under the guidance of Wen and Ye [80], we could conclude that physician-patient communication and patient internet health information–seeking behavior in OHCs played partially mediating roles between eHealth literacy and patient adherence, and the mediating effect accounted for 30.07% and 13.25% of the total effect, respectively.

Table 6. Parameters of mediating effects.

[e]PQIHI: perceived quality of internet health information.

Discussion

Principal Results

This study explored the association between patients' eHealth literacy in OHCs and their adherence to treatment regimens and physicians' suggestions, and it has theoretical contributions and practical implications for studies on OHCs, eHealth literacy, and patient adherence. We constructed a research model which clarified that patients' eHealth literacy in OHCs can help improve their adherence by guiding their communication behavior with physicians, strengthening their health information–seeking behavior, and increasing their perceived quality of information in OHCs. This study enriches the theoretical research on OHCs, eHealth literacy, and patient adherence, and reduces the deficit in research related to improving patient adherence by strengthening patients' eHealth literacy in OHCs in the Chinese context. In addition, this study adopted social cognitive theory in developing the research model for examining the relationship between eHealth literacy in OHCs and patient adherence, which enriches the application of social cognitive theory in the field of health behavioral psychology.

In terms of practical implications, our findings suggest that physician-patient communication, internet health information–seeking behavior, and patients' perceived quality of internet health information are perspectives from which patient adherence can be enhanced by developing patients' eHealth literacy in OHCs. First, among the 4 mediators, patients' eHealth literacy was the strongest associated with physician-patient communication in OHCs, and physician-patient communication had the strongest association with patient adherence. Physician-patient communication plays a significant mediating role between eHealth literacy in OHCs and patient adherence, which suggests that physicians can encourage patients to communicate with them through OHCs in addition to offline treatments. OHCs can adopt some incentives to improve the possibility of patients' participation in communication with physicians.

Second, in OHCs, the association between patients' eHealth literacy and their perceived quality of internet health information was slightly weaker than that between eHealth literacy and physician-patient communication, but the effect size remained large. eHealth literacy can improve patients' ability to appraise information quality accurately, ultimately encouraging them to adhere to physicians and the recommended treatments. This finding suggests that physicians and OHCs should focus not only on the actual information quality but also the perceived information quality. Evidence from Silver [81] reveals that some patients prefer to trust online sources rather than health care providers, but the limited level of eHealth literacy may make the treatment difficult. Previous studies suggest that eHealth literacy can be enhanced by considering several factors, such as education, computer skills, physical exercise [82], and medical experiences [81]. Therefore, physicians should aim to understand the level of patients' eHealth literacy and their perception of quality during the communication process so as to better understand the possibility and extent of patients obtaining unsuitable health information. Physicians can then help patients improve the efficiency of treatment. OHCs should be developed to be convenient and easy to use, and to provide detailed guidelines that can aid patients' usage. This may bring benefits to improving patients' eHealth literacy and their perception of information quality in OHCs. In addition, to further improve OHCs, operators of OHCs should strengthen the management of information quality and acquire patients' feedback on the perceived quality of health information. Third, eHealth literacy is associated with patient adherence through the mediation of internet health information–seeking behavior although the associations between eHealth literacy and internet health information–seeking behavior and between internet health information–seeking behavior and patient adherence were relatively weaker compared with the other 2 mediators. Schulz et al [12] found that patients with adequate eHealth literacy are more willing to seek health information online than those with inadequate eHealth literacy. The positive association between patients' health information–seeking behavior and patient adherence is supported by Zhang et al [14]. However, some patients with limited eHealth literacy find it difficult to use or find suitable and reliable information through OHCs [56], thereby decreasing their intention to seek health information through OHCs. Given the advantages of OHCs, physicians can discuss the benefits and drawbacks of seeking information online with patients and encourage patients to obtain information by themselves. In addition, when patients find that their physicians have grasped the health information that the patients had themselves already acquired, they will consider their physicians to be professional and thus be more willing to adhere to their

advice. Although patients may be unwilling to seek heath information online, they can perceive that their physicians are sincere and indeed concerned about them. Accordingly, discussion between physicians and patients is beneficial for strengthening patients' trust in their physicians and improving the efficiency of treatment. Moreover, some medical professionals (eg, nurses) can actively discuss with patients the information obtained by patients through OHCs, thus possibly promoting patients' additional use. Furthermore, the popularity of OHCs can be improved to increase the possibility of patients seeking health information through OHCs.

Limitations

This study has several limitations and future directions. First, other mediators can be examined in future studies in addition to physician-patient communication, internet health information–seeking behavior, and perceived quality of internet health information. Second, the sample was a fairly specific one, and the results therefore cannot be generalized to a general or global context. To make these results more universal, further surveys in other countries could be conducted by comparing the similarities and differences between China and these countries. Third, our sampling did not capture the characteristics of the Chinese population because of the limitation of the research conditions, and the inclusion of Chinese census data can be considered in future studies. Fourth, in the research model, the 2 mediators, eHealth literacy and health information–seeking behaviour, may overlap. eHealth literacy includes the skill of seeking health information through OHCs, and eHealth literacy and health information–seeking behavior in OHCs may be related to each other. Fifth, the observed data were self-reported data, and we did not track the participants' use of the internet. Sixth, we conducted the cross-sectional questionnaire investigation only once, so we failed to capture the dynamic changes in participants' attitudes toward variables. Finally, the adherence measure we used has no recorded previous use. These issues can be addressed in future studies.

Conclusions

This study aimed to identify the association between patients' eHealth literacy in OHCs and patient adherence. The results revealed that eHealth literacy in OHCs is positively associated with patient adherence through the mediations of physician-patient communication, patient internet health information–seeking behavior, and the perceived quality of internet health information in OHCs. All 3 mediators are crucial for improving patient adherence. These findings suggest the following: physicians should encourage patients to seek health information and communicate with them through OHCs, understand the level of patients' eHealth literacy and their perception of information quality, and help patients during the treatment to compensate for the lack of eHealth literacy; OHC operators should strengthen the management of information quality, make OHCs user friendly by providing detailed guidelines, and increase their popularity; OHC operators should improve the reliability of high-quality information provided to patients to decrease the gap between the actual and the perceived quality of health information.

Abstract

Background: eHealth literacy (EHL) refers to a variety of capabilities that enable individuals to obtain health information from electronic resources and apply it to solve health problems. With the digitization of health care and the wide availability of health apps, a more diverse range of eHealth skills is required to properly use such health facilities. Existing EHL measurements focus mainly on the skill of obtaining health information (Web 1.0), whereas skills for web-based interactions (Web 2.0) and self-managing health data and applying information (Web 3.0) have not been well measured.

Objective: This study aims to develop an EHL scale (eHLS) termed eHLS-Web3.0 comprising a comprehensive spectrum of Web 1.0, 2.0, and 3.0 skills to measure EHL, and evaluate its validity and reliability along with the measurement invariance among college students.

Methods: In study 1, 421 Chinese college students (mean age 20.5, SD 1.4 years; 51.8% female) and 8 health experts (mean age 38.3, SD 5.9 years; 87.5% female) were involved to develop the eHLS-Web3.0. The scale development included three steps: item pool generation, content validation, and exploratory factor analysis. In study 2, 741 college students (mean age 21.3, SD 1.4 years; 52.2% female) were recruited from 4 Chinese cities to validate the newly developed eHLS-Web3.0. The construct validity, convergent validity, concurrent validity, internal consistency reliability, test-retest reliability, and measurement invariance across genders, majors, and regions were examined by a series of statistical analyses, including confirmatory factor analysis (CFA) and multigroup CFAs using SPSS and Mplus software packages.

Results: Based on the item pool of 374 statements collected during the conceptual development, 24 items (4-10 items per subscale) were generated and adjusted after cognitive testing and content validity examination. Through exploratory factor analysis, a 3-factor eHLS-Web3.0 was finally developed, and it included acquisition (8 items), verification (6 items), and application (10 items). In study 2, CFAs supported the construct validity of the 24-item 3D eHLS-Web3.0 (χ^2_{244}=903.076, χ^2_{244}=3.701, comparative fit index=0.924, Tucker-Lewis index=0.914, root mean square error of approximation [RMSEA]=0.06, and standardized root mean residual [SRMR]=0.051). The average variance extracted (AVE) value of 0.58 and high correlation between eHLS-Web3.0 subscales and the eHealth Literacy Scale (r=0.725-0.880, P<.001) indicated the convergent validity and concurrent validity of the eHLS-Web3.0. The results also indicated satisfactory internal consistency reliability (α=.976, ρ=0.934-0.956) and test-retest reliability (r=0.858, P<.001) of the scale. Multigroup CFA demonstrated the 24-item eHLS-Web3.0 to be invariant at

all configural, metric, strength, and structural levels across genders (female and male), majors (sport-related, medical, and general), and regions (Yinchuan, Kunming, Xiamen, and Beijing).

Conclusions: The 24-item 3D eHLS-Web3.0 proved to be a reliable and valid measurement tool for EHL in the Web 3.0 context among Chinese college students.

KEYWORDS

eHealth literacy; scale development; validation; college students

Introduction

With the digitization of health care and the wide availability of health applications, personal eHealth has become important for health management. The World Health Organization defines eHealth as "the use of information and communication technology for health" [1], and researchers have called for a broader understanding of the capabilities and skills required for individuals to use and benefit from eHealth services [2]. In 2006, Norman and Skinner labeled this ability as "eHealth literacy" (EHL) [3].

The definition of EHL was grounded in the health promotion theory, which referred to EHL as the "the ability to seek, find, understand, and appraise health information from electronic resources and apply that knowledge to solve a health problem or make a health-related decision" [3]. Based on this concept, an 8-item measurement tool named the eHealth Literacy Scale (eHEALS) was developed. The eHEALS is the most well-known and widely accepted tool for measuring EHL. Till 2015, there have been 45 studies that used the eHEALS, and it is the only tool used to measure EHL in more than 1 study [4].

However, with advances in technology, some people identified the need for updating the content of EHL to better fit it with the new internet environment. They also doubted on how accurately the eHEALS measured the use of new technologies to find and evaluate health information [5]. In 2011, the first critique of eHEALS was made, finding a weak correlation between the scale and eHealth behaviors beyond web-based information-researching skills, suggesting the need to revise the tool [6]. These observations were reasonable. According to the most widely accepted generation division of internet evolution, the current internet environment has gone through three stages. The first one, Web 1.0, refers to the read-only web, whereas Web 2.0 refers to a read-write mode, providing a "participative social web" with greater collaboration and interactivity between consumers, programmers, service providers, and organizations. Web 3.0 is the current environment, the so-called "semantic web," accessible in a "read-write-execute" mode, providing digital, personal, and intelligent services [7-9]. The eHEALS was developed 15 years ago for measuring the abilities related to page views; it is necessary to enrich and update it for better scaling of current eHealth usage [4,5].

To fill this gap, other measures of EHL have been developed. For example, van der Vaart et al [6] designed 9 assignments to test the "actual performance of eHealth literacy." However, those assignments were more for testing health-related internet skills rather than actual EHL. Moreover, the practical test approach would limit the number of participants. In 2017, another tool called the Digital Health Literacy Instrument was developed [10], which included 21 self-assessed items supplemented with 7 performance-related tasks that focused on handling digital information. They were mainly related to navigating the internet and messaging health professionals. The assignments developed by van der Vaart et al [6,10] were not the only ones to assess individuals' EHL. The Readiness Self-Assessment-Health Professions version [11] also measured participants' perceived ability and their actual ability to obtain and evaluate eHealth information. It is worthy to mention that the developers of the Readiness Self-Assessment-Health Professions version believed that the readiness to use internet-based resources should be seen as a component of EHL. The Patient Readiness to Engage in Health Internet Technology [12] measures readiness as well. It was developed based upon the groundwork of eHEALS but expanded the understanding of EHL to include two meta-factors: facilitators and barriers. Beyond task performance and readiness evaluations, several other measurements focused on evaluating people's Web 2.0 skills, specifically their literacy on web-based social activities. One of them was the 19-item electronic Health Literacy Scale (eHLS) [13]. It examined the behavioral, communicational, and attitudinal components of health literacy among eHealth information seekers, which expanded the conceptualization beyond the traditional document-based measures to include interactive and communicative aspects of literacy. Another scale for Web 2.0 is the eHealth Literacy Scale (eHEALS) [14], suggesting that the underlying social structure affects an individual's health status, computer literacy, intrinsic interest in health, and perceived ability to use the internet for health purposes. In addition, there were two other measurements that provided a different understanding of EHL. The eHealth Literacy Questionnaire (eHLQ) [15] comprehending EHL under a user-need perspective characterizing eHealth users paid attention to eHealth users' understanding, attitudes, and motives. The eHealth Literacy Assessment Toolkit (eHLA) [16] was a mix of existing and newly developed scales that viewed EHL as a combination of health literacy, computer and digital literacy, and information literacy. A recent study translated the eHEALS [3] into Chinese and examined its psychometric properties among the Chinese population [17]. However, the referenced study has not measured individuals' EHL in the context of Web 2.0 and 3.0, and the stability (eg, test-retest reliability and measurement invariance) of the EHL scale has not been examined.

Although previous studies have provided new ways to assess EHL with some of them scaling web communication abilities, all the tools mentioned above have not yet measured the skills of Web 3.0 technologies. Insufficient knowledge existed in the newly required competencies of EHL (eg, capacity for using mobile services, sense of information safety, and abilities of screening, communicating, and sharing). Furthermore, except for eHEALS, these scales have not been used by other researchers, which means there is still no well-developed scale for evaluating individuals' EHL worldwide.

The COVID-19 pandemic led to a decrease in interpersonal social activities, but increased individuals' EHL [18,19]. According to the annual report provided by a famous clinical virtual community in China publishing health care–related and clinical insights and findings [19], the visitor volume increased by 4.6 times compared to what it was earlier. Predictably, increased use of health information technology would change people's health care styles, shifting partially from offline to internet-based services. In such an environment, it is essential to develop a new instrument and provide a valid tool to measure current EHL levels. As college students are the major internet users and frequently turn to it for eHealth information [20], the current research aimed to develop a scale to measure EHL in the Web 3.0 context (eHLS-Web3.0) and examine its reliability and validity among Chinese college students. Accordingly, two studies were implemented; the first study aimed to develop an eHealth literacy scale (eHLS-Web3.0), including three steps: item pool generation, content validation, and exploratory factor analysis (EFA); the second study aimed to examine the validity (construct, convergent, and concurrent), reliability (internal consistency and test-retest reliability) and measurement invariance across genders (female and male), majors (sport-related, medical, and general), and regions (Yinchuan, Kunming, Xiamen, and Beijing) in Chinese college students. The current research was approved by the Research Ethics Committee of Hong Kong Baptist University.

Methods

Study 1

Participants

Step 1: Item Pool Generation

This step involved 28 college students, including 18 interviewees for item pool generation and 10 students for readability and cultural sensitivity examination. Snowball sampling [21] was applied in 2019 (before the COVID-19 pandemic) to recruit interviewees from three different Chinese cities (Beijing, Wuhan, and Putian). These three cities were selected based on the cultural geographic (north, middle, and south) and economic statuses (high, medium, and low) of these Chinese cities [22-24].

All eligible participants met the following inclusion criteria: (1) experience in using eHealth websites and tools, (2) having sufficient Chinese language skills, and (3) willingly consent to participate in the interview. Regarding the sample size, although there is no definite criterion for qualitative research, the number of participants should be in accordance with the creed of theoretical saturation, which means no new or relevant data emerge [25]. To achieve theoretical saturation, based on the "rule of thumb," the suggested number of participants for interview studies is approximately 12 to 15 [26]. In the current study, 18 Chinese college students participated in the semistructured interviews via telephone; they included 3 males and 3 females from sports, medical, and ordinary nonhealth-related majors. All the telephonic interviews were conducted in Chinese (Mandarin) language and recorded digitally with the interviewees' consent. An initial item pool was built based on the interview data and the existing literature. Next, 10 college students were randomly recruited to examine accessibility (eg, readability) and cultural sensitivity of those candidate items, and the participants' ability to complete the self-administered survey. An informed consent form was delivered to each student before data collection.

Step 2: Content Validation

Based on the guideline proposed by Lynn [27], 8 Chinese health experts were invited to validate the content of the selected items [27]. The selection of the health experts was based on the following criteria: (1) published at least one paper related to health literacy or eHealth, (2) have sufficient Chinese language proficiency, and (3) confirmed their willingness and consent for participating in the interview.

Step 3: EFA Process

The participants involved in this step constituted an independent sample with the recruitment criteria similar to those in the interviewees of step 1, except that the target cities for participant recruitment were changed. This is because step 3 was performed after the outbreak of COVID-19. The previous target city Wuhan was avoided to enhance the generalizability of the new scale. In step 3, four different representative Chinese cities were chosen, including Beijing, Xiamen, Kunming, and Yinchuan. These four cities were selected based on their geographic locations (north, southeast, southwest, and northwest), political status (country capital, provincial capital, and prefecture-level city), and economic status (high, medium, and low) [22-24]. Furthermore, these four cities were chosen considering the issues of "convenience and feasibility" [28].

The questionnaire was distributed via a survey distribution website, starting with prior informed consent, followed by the main content of the survey. The participation was voluntary, and all participants were allowed to withdraw from the study at any time. University lecturers from the target cities helped distribute the link to the questionnaire in the classes. Based on the suggestion of Bryman [25,29,30], at least 240 observations were required for EFA (1:10 item-to-response ratio) in the current study. Finally, 393 students responded to the questionnaire and provided information regarding their age, gender, major, and experience of using health-related electronic tools or websites, which led to an adequate sample size. It took approximately 5 to 10 minutes for the participants to complete the questionnaire. The characteristics of the participants in study 1 are presented in Table 1.

Table 1. Characteristics of participants in study 1.

Demographic information	Values
Interviewees (n=18)	
Age (years), mean (SD)	22.1 (1.02)
Age range	21-25
Gender (female), n (%)	9 (50)
Readability examiners (n=10)	
Age (years), mean (SD)	20.3 (0.95)
Age range	19-22
Gender (female), n (%)	7 (70)
Experts for content validation (n=8)	
Age (years), mean (SD)	38.3 (5.92)
Age range	30-46
Gender (female), n (%)	7 (87.5)
Sample for EFA[a] (n=393)	
Age (years), mean (SD)	20.5 (1.36)
Age range	18-25
Gender (female), n (%)	202 (51.4)

[a]EFA: exploratory factor analysis.

Procedure

Step 1: Item Pool Generation

There were three types of sources for forming the item pool. The first comprised well-established EHL instruments (eg, eHEALS, eHLQ, and e-HLS). The feasible items were selected and adapted to form the initial item pool. Second, items from well-known health or computer literacy scales were deliberately selected because they were measuring important elements of EHL. Third, items were generated from the previous interview results. For the first and second types of sources, some items were developed by western scholars. Those items were translated by two PhD students specializing in health promotion, and then back-translated by a senior Chinese English teacher unfamiliar with eHealth-literacy–related indices. Subsequently, 10 college students helped assess the comprehensibility, clarity, and length of the items via a dichotomous scale (applicable vs inapplicable). The inapplicable items were deleted or refined.

Step 2: Content Validation

The generated item pool was sent to the panel of experts. The experts assessed the relevance of each item to the understanding of EHL, using a 4-point Likert scale ranging from 1 (irrelevant) to 4 (extremely relevant). They were asked to provide ratings and suggestions for alternative items. The ratings were used to calculate the content validity index [27] of each item (I-CVI). The I-CVI was calculated by dividing the number of judges providing a rating above 3 by the total number of judges. The acceptable I-CVI score had to be above 0.83 [27,31]. The invalid items were either eliminated or revised based on the experts' suggestions.

Step 3: EFA Process

The items generated in step 2 were placed in the format of a 5-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree). The distribution pattern of the items was examined. The ones with non-normal distributions were eliminated. EFA was performed for the remaining items. Principal component factoring with direct oblimin rotation was performed. Factor extraction was based on an eigenvalue higher than 1 and a confirmatory inspection of the scree plot. Items with primary factor loadings of 0.4 and above were considered interpretable [32,33]. Items with cross-loading were deleted, which refers to those having a second highest factor loading of 0.3 or higher or having a small gap (less than 0.2) between the primary and secondary loadings [32,33]. Bivariate correlations between the subscales were also tested.

Study 2

Participants

The participants were independent samples with the recruitment criteria similar to those used in the EFA step. Considering the item-to-response ratios of at least 1:10 [29] and the recommendation for a minimum sample size of 200 in confirmatory factor analysis (CFA) [34], 741 college students were invited to participate in the current study. After 1.5 months, a follow-up retest was distributed to the same group of people, and 306 of them responded. A summary of the CFA participants is presented in Table 2.

Table 2. Sample characteristics for confirmatory factor analysis (N=741).

Demographic information	Value
Age (years), mean (SD)	21.3 (1.39)
Age range	17-25
Gender (female), n (%)	387 (52.2)
Major	
Medical, n (%)	41 (5.5)
Sport, n (%)	128 (17.3)
Nonhealth-related, n (%)	572 (77.2)
Region	
Beijing, n (%)	124 (16.7)
Xiamen, n (%)	287 (38.7)
Kunming, n (%)	216 (29.1)
Yinchuan, n (%)	114 (15.4)

Measures

The eHLS-Web3.0 instrument was developed in study 1, consisting of 24 items classified based on 3 factors: acquisition (8 items), verification (6 items), and application (10 items). The answers were indicated on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). The internal consistency (Cronbach α) for the total scale was .971 and those for the subscales were 0.913-0.962 in Chinese college students.

The eHEALS was initially developed by Norman and Skinner [3] as the first and most widely used tool for measuring EHL. It is an 8-item unidimensional scale whose validation was performed in a population of adolescents (aged 13-21 years) from 14 secondary schools in a large Canadian city. The Chinese version of eHEALS was tested in 110 senior high school students by Guo et al [35]. The internal consistency (Cronbach α) for the total scale was .913, and the factor loading coefficients were between 0.692 and 0.869 [35] in Chinese senior high school students.

Procedure

The procedures for data collection were identical to those of the EFA step. Participants were selected from four target cities, Beijing, Xiamen, Kunming, and Yinchuan, by snowball sampling. The eHLS-Web3.0 was distributed to participants who were independent of those participating in the EFA step via the internet. University lecturers from the target cities independent of those in the EFA helped distribute the link to the questionnaire in the classes they taught; they consciously avoided the classes that had participants in the EFA step. Informed consent forms were delivered to the participants before the survey. It took approximately 10 minutes for the participants to finish the questionnaire. A retest was delivered to them 1.5 months later.

Data Analysis

To test the construct validity of the current scale, the items were analyzed through CFA with structural equation modeling using Mplus (version 7) [36]. After testing the distribution of the items in the measurement model, the maximum likelihood robust estimator was employed [37]. The chi-square statistic (χ^2) was used to test the model's overall goodness of fit [38]. Multiple model fit indices were examined further, including the comparative fit index [39] and Tucker-Lewis index [40], with a cutoff value of approximately 0.9 and above indicating a satisfactory fit between the CFI and TLI [41]; the standardized root mean residual (SRMR) [39,41] with values near 0.08 indicates adequate model fit; the root mean square error of approximation (RMSEA) and its 90% CI [42] indicate good fit at values less than 0.08. The standardized factor loadings and standardized residuals were examined. Items with factor loadings below 0.4 and large standardized residuals (≥2) were removed. The concurrent validity was examined by calculating the bivariate correlations between the subscale of the eHLS-Web3.0 and eHEALS using SPSS (version 24.0, SPSS Inc). The convergent validity was tested by examining the average variance extracted (AVE), for which values above 0.5 indicated an acceptable measurement. Internal consistency reliability was examined by analyzing the Cronbach α and the composite reliability coefficient (CR), for which the CR values above 0.7 [43] were considered acceptable. The test-retest reliability was measured by examining the bivariate correlation between the score of eHLS-Web3.0 determined in the CFA stage and the follow-up stage after 1.5 months. A multiple-group covariance structure analysis approach was employed to examine whether the measurement was invariant across genders, majors, and regions [44]. A ΔCFI value smaller than or equal to 0.01 between incrementally constrained models should be accepted as evidence of adequate fit [45].

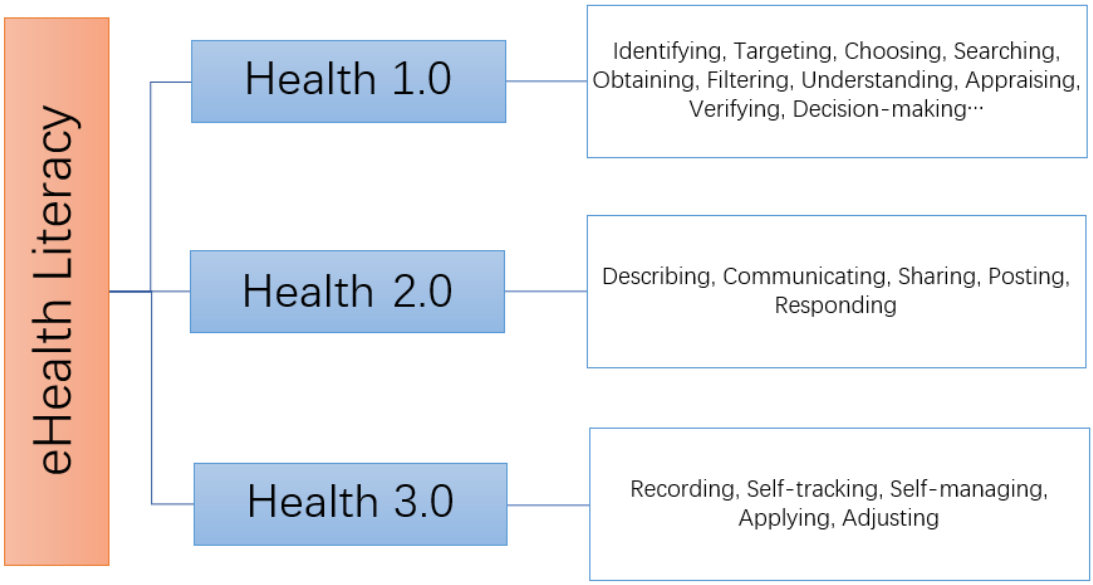
Results

Study 1

Step 1: Item Pool Generation

Previous interviews yielded 374 tags and a conceptual framework for EHL, as shown in Figure 1.

Figure 1. Conceptual framework of eHealth literacy.



The Health 1.0 part was consistent with existing research [3,4,6,10-12]; some Health 2.0 behaviors (describing, communicating, and sharing) [14,15] have also been mentioned by other researchers. In contrast, this study presents a first look at behaviors related to Web 3.0 and delves deeper into the social network services with respect to eHealth, finding that the application of information is currently much more complicated than before; other than researching on the internet or applying the information to make health-related decisions or solve problems, individuals could also create their own health data, use the information to communicate, respond (ie, giving suggestions and advice, and responding to help seekers), socialize with others, and share and post information (ie, forward helpful information or post their own health or fitness data).

Based on the abovementioned tags and existing well-established scales, 266 items were developed, taking the form of eHEALS (eg, I know how to find helpful health resources on the internet) in the Chinese language. Specifically, there were 114 items for Health 1.0 skills, 39 for Health 2.0 ones, 55 for Health 3.0 ones, 42 for readiness-related ones (mostly retrieved from earlier studies) [11,12], and 16 for health literacy ones (as per an earlier study) [10]. To ensure the relevance, readability, comprehensibility, and clarity of the scale to the targeted Chinese population, it was assessed by 10 college students who were conveniently selected. Suggestions were given by the participants to improve the comprehensibility of the preliminary pool. Among the items, 7 duplicated ones were discussed, 3 of them were deleted, and 4 of them were merged into 2 items. Next, 5 items were removed owing to unclear text. Further, 56 items were excluded because they were considered inapplicable for testing EHL by more than 3 students. After that, 200 candidate items were retained for the next step.

Step 2: Content Validation

Following the adjustments of the item pool, the candidate items were forwarded to 8 specialists in the health literacy and eHealth areas to review the content and assess its validity. Based on their quantitative ratings, the I-CVI was calculated for individual items. Items rated “1” or “2” indicating inapplicability according to two reviewers (I-CVI<0.83) were subsequently deleted. Additionally, suggestions regarding refinement of the scenario or item pool were elicited.

Based on the specialists’ quantitative feedback, 128 items were considered irrelevant and excluded. For the remaining 72 items, a discussion among specialists was arranged via a web-based group chat and videoconferencing for obtaining more detailed suggestions. Some mergers and adjustments were made to make the scale the clearest and the most easily understandable one. For instance, in the initial version, the abilities to choose proper forums and apps were measured separately following expert suggestions; these items were merged into one using the term “eHealth tools.” The questions on web-based celebrity and official accounts were also conflated. Some items testing attitudes for eHealth, especially the readiness-related ones, were considered not related to “ability” and eliminated. After the creation and refinement steps, the final number of items for field testing was 50.

Step 3: EFA Process

The 50 refined items were randomized and administered to 393 college students via the internet. Descriptive statistical analysis was performed with SPSS (Version 20) examining the distribution pattern of each item. Items 2, 10, 37, and 50 were non-normally distributed (their kurtosis ranges were beyond –1 and 1). For the 46 remaining items, EFA was performed. The results of the Kaiser-Meyer-Olkin **(**KMO) and Bartlett tests performed during EFA showed that the KMO statistic for these

items was 0.966, which is higher than 0.6, thus proving that the factor analysis model was appropriate and useful to analyze current data sets. Principal component factoring with direct oblimin rotation was used. Factor extraction was based on an eigenvalue higher than 1 and a confirmatory inspection of the scree plot shown in Figure 2. Items with primary factor loadings of 0.4 and above were considered interpretable. We excluded 5 items (#1, #11, #27, #28, and #36) with inadequate factor loadings were excluded. Subsequently, 13 other items were found to have a second highest factor loading of 0.3 or higher, and 4 other items (#22, #29, #33, and #41) had a small gap (less than 0.2) between the primary and secondary loadings. They were identified as items with cross-loading and were deleted as well. Therefore, 5 factors were extracted from initial factoring, and 3 strong factors were identified with the 24 items remaining, as shown in Table 3.

Figure 2. Confirmatory inspection of the scree plot.

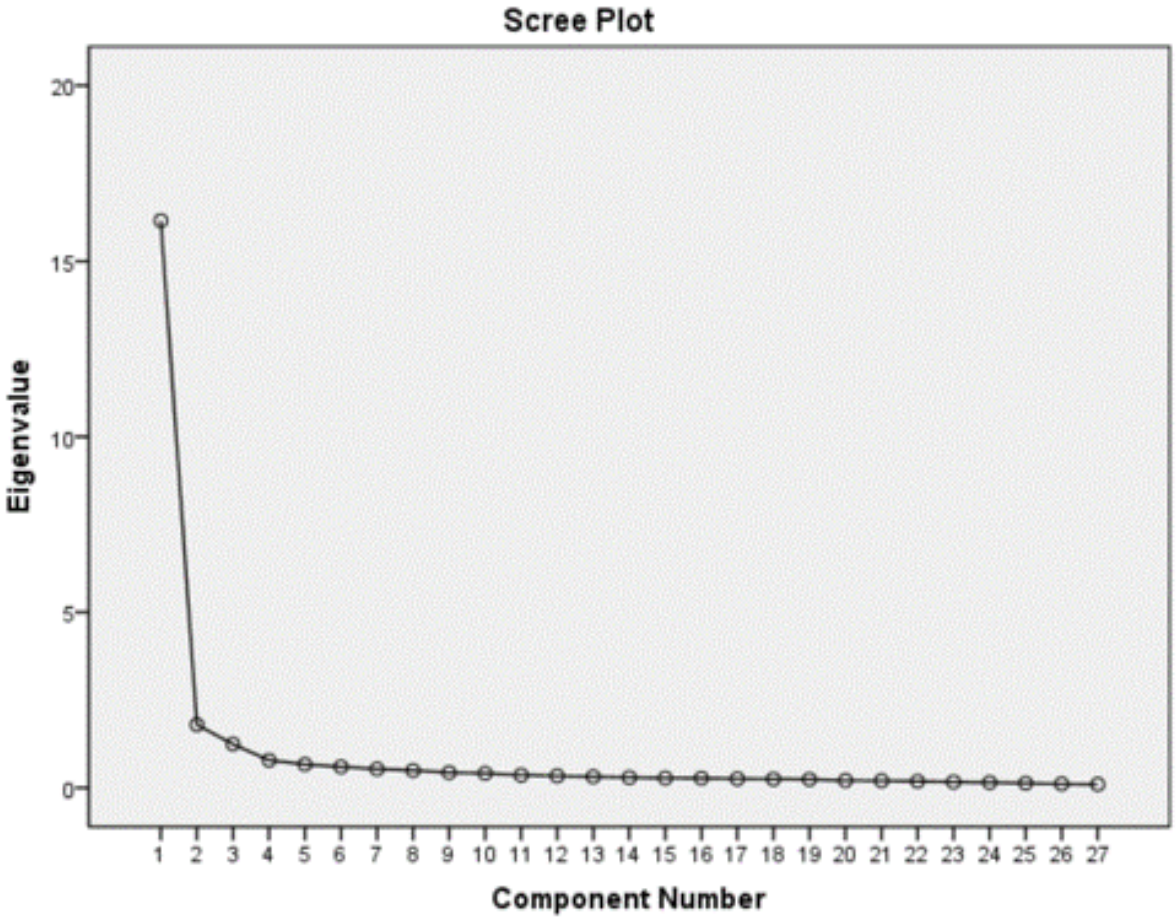


Table 3. Principal component analysis of the electronic Health Literacy Scale-Web3.0.

Item	Component		
	1	2	3
#3: I know which kind of eHealth tool I should choose to fit my health needs (ie, checking drug description, seeking health advice, or making weight loss plan).	__[a]	—	–0.817
#4: I can judge whether the eHealth tool is credible or not.	—	—	–0.659
#5: I will prefer to obtain the health information (ie, information about medical, sport or daily care) via offline channel.	—	—	0.880
#6: I know where to find useful health resources on the internet.	—	—	–0.424
#26: When communicating with others on the internet, I can articulate my health-related concerns clearly.	—	—	–0.530
#30: When replying to others' health-related help-seeking on the internet, I can provide responsible response (which means my answer can neither mislead others, nor)	—	—	–0.547
#31: I can judge whether the health information available on the internet has a commercial interest (ie, the person providing the information is for the sale of a product).	—	—	–0.557
#35: When using the eHealth tools, I will protect the originality of the information (ie, never plagiarize others' original content, report an offense to those infringing ones).	—	—	–0.550
#14: When searching the health information on the internet, I will check the credentials and affiliations of author.	—	–0.979	—
#15: When searching the health information on the internet, I will check who owns the website.	—	–0.938	—
#16: When searching the health information on the internet, I will check the date of its last update.	—	–0.864	—
#17: When searching the health information on the internet, I will check whether other print or web resources had confirmed this information.	—	–0.903	—
#18: I know how to verify the eHealth information from multiple sources.	—	–0.510	—
#20: Even if the health information I obtained is from someone I trust, I will still check it on the internet.	—	–0.444	—
#38: I know how to use the eHealth tools to record my health behaviors.	0.873	—	—
#39: I know how to make use of the records on the eHealth tools to provide reference for my daily health management.	0.852	—	—
#40: I know how to use the eHealth tools to track my health behaviors (ie, acquainting my exercise frequency or the change curve of body fat rate).	0.869	—	—
#42: I can continuously use a certain eHealth tool (ie, apps, intelligent body fat scale, fitness bracelet) for a long time.	0.919	—	—
#43: I can use the eHealth tools with a clear plan.	0.863	—	—
#44: I can adjust my frequency, strength, and usage pattern timely when using the eHealth tool according to the actual condition.	0.879	—	—
#45: I know how to use the eHealth tools to post and share my eHealth behaviors (ie, post my motion trails on health apps or moments on WeChat).	0.922	—	—
#46. I know how to use the sports functions on social network services (such as WeRun on WeChat) to interact with others (eg, thumb up, forward).	0.688	—	—
#47: I will target the advanced players I follow on the eHealth tools, learn from them, and catch up with them.	0.793	—	—
#48: I will try out some health-related suggestions available on the internet and control the risks (ie, get injured or take the wrong medicine).	0.811	—	—
Eigenvalue	14.439	1.658	1.114
Variance (%)	60.163	6.909	4.643
Cumulative (%)	60.163	67.072	71.715

[a]Not available.

Thus far, the current instrument has 24 items that were sorted based on 3 factors: acquisition (8 items), verification (6 items), and application (10 items). The total variance of this scale explained by these 3 factors was 71.715%. The internal consistency of each factor was also tested using the Cronbach α, as shown in Table 4. The result was satisfactory.

Bivariate correlations between the subscales were tested, and they are shown in Table 5. The moderate strength of the correlations indicated that the subscales were measuring related but distinct constructs.

Table 4. Reliability statistics.

Scale	Score, mean (SD)	Cronbach α
Scale in total	86.27 (14.5)	.971
Subscale of Factor 1	36.25 (7.5)	.962
Subscale of Factor 2	21.96 (7.5)	.934
Subscale of Factor 3	28.06 (4.0)	.913

[a]Not available.

It was surprising that positive and negative factor loadings existed simultaneously in the principal component analysis. Reviewing the scale showed that only item 5 was asked in a reverse manner, which might have confused participants and led to such a case. After discussion, the authors decided to refine item 5 as "I will obtain the health information (ie, medical, sport, or daily care information) on the internet." In addition, a conditional statement "If needed, I can…" was added to items 18 and 19 in case some participants did not use eHealth tools frequently. As a result, the adjusted 24 items in 3 dimensions comprising 6, 8, or 10 items in each were developed to yield the new eHLS-Web 3.0 instrument (see Multimedia Appendix 1).

Study 2

Construct Validity of eHLS-Web3.0

The primary CFA showed that the model did not fit the data very well, with fit indices of χ^2_{249}=1351.230, χ^2_{249}=5.427, CFI=0.873, TLI=0.860, RMSEA=0.077, and SRMR=0.056. According to the model modification indices, the residual errors of 5 items (#1, #15, #19, #21, and #23) were corrected. After modification, the eHLS-Web3.0 met the criteria for good model fit, with χ^2_{244}=903.076, χ^2_{244}=3.701, CFI=0.924, TLI=0.914, RMSEA=0.06, and SRMR=0.051. The factor loadings (see Multimedia Appendix 2) obtained using the 3-factor model were found to fit well with the data. The standardized loadings were all above 0.6, most of which were greater than 0.8. Correlations between the 3 factors were moderate to high.

Convergent and Concurrent Validities of eHLS-Web3.0

The AVE was calculated as 0.52 using the data collected in the EFA stage, showing an acceptable convergent validity. For the concurrent validity, the bivariate correlations between the subscale of the eHLS-Web3.0 and eHEALS were significant, showing a satisfactory result, as indicated in Table 6.

Internal Consistency and Test-Retest Reliabilities of eHLS-Web3.0

The Cronbach α, composite reliability coefficient, and the item-total correlations were calculated to examine the internal consistency reliability of the new instrument. The specific results are presented in Table 7, indicating satisfactory internal consistency reliability.

An acceptable test-retest reliability was achieved, showing that the eHLS-Web3.0 was relatively stable over time, as shown in Table 8.

Table 7. Internal consistency reliability statistics.

Statistic	Value

Measurement Invariance of eHLS-Web3.0

Multigroup CFAs were employed to examine whether the measurement was invariant across genders, majors, and regions. Results of the invariance analyses are provided in Tables 9-11.

For the gender invariance analysis presented in Table 9, it was found that the configural model (M0) showed satisfactory fit to the data. The matric model (M1) and strong model (M2) displayed satisfactory fit to the data, and their △CFI was less than 0.01; the △RMSEA was less than 0.01, and the △SRMR was less than 0.025. These indices supported the invariance of factor loadings and intercepts across genders. The strict model (M3) reflected acceptable fit to the data. Although the △SRMR in M3 showed poor fit, the other indices showed a satisfactory goodness of fit (△CFI and △RMSEA<0.01), indicating that the residual errors were equivalently invariant across genders.

For the major invariance analysis, the model fitness tests and comparisons were performed across all three samples, including general (nonhealth-related), sport, and medical major students. The configural model (M0) showed satisfactory fit to the data between general and sport as well as general and medical, whereas the configural model reflected a marginal-to-acceptable

fit (CFI=0.849) between sport and medical majors. This is most likely because the medical group had a much smaller sample size than the sport group. As for the goodness of model fit, the matric model (M1), strong model (M2), and strict model (M3) displayed satisfactory and acceptable fit to the data between general and sport as well as general and medical, and marginal-to-acceptable fit to the data between sport and medical groups. The △CFI and △RMSEA of all these models were less than 0.01, and the △SRMR was less than 0.025. These indices supported the invariance of the factor loadings, intercepts, and residual errors across majors, as observed in Table 10.

[e]△RMSEA: change in the root mean square error of approximation.

[f]SRMR: standardized root mean residual.

[g]△SRMR: change in the standardized root mean residual.

[h]M0: baseline configural invariance model.

[i]Not applicable.

[j]M1: metric invariance model.

[k]M2: strong invariance model.

[l]M3: strict invariance model.

For the region invariance analysis, the model tests and comparisons were conducted across all the four groups of samples, including students from Kunming, Yinchuan, Xiamen, and Beijing. The configural model (M0) showed acceptable fit to the data across all the four regional samples. For the goodness of model fit, the matric model (M1) and strong model (M2) for every group displayed acceptable fit to the data. For every group, the △CFI and △RMSEA of the models were less than 0.01, and the △SRMR was less than 0.025. These indices supported the invariance of the factor loadings and intercepts across regions. The strict model (M3) for each group also reflected acceptable fit to the data. However, between Kunming and Yinchuan, Kunming and Xiamen, Yinchuan and Xiamen, and Xiamen and Beijing, the △SRMR of the strict model (M3) reflected a poor fit, as shown in Table 11. Despite this, the other indices showed a satisfactory goodness of fit (the △CFI and △RMSEA were less than 0.01), proving that the residual errors were equivalently invariant across the regions.

In summary, these findings supported the measurement invariance of the eHLS-Web3.0 model (factor loadings, intercepts, and residual errors) across genders, majors, and regions.

Table 11. Invariance analysis of the electronic Health Literacy Scale-Web3.0 across regions (nKunming=216, nYinchuan=114, nXiamen=287, and nBeijing=124).

Discussion

Principal Findings

The current study developed and tested a new measurement tool for EHL in Chinese with the Web 3.0 context named eHLS-Web3.0. A multistage program was applied, generating 24 items that represent the updated content of EHL in the current internet environment. In comparison with other eHealth models [3,5], the new instrument measures not only the skills for searching eHealth information (Health 1.0 skills) or communicating with service providers (Health 2.0 skills), but also the skills for building personal health data sets, self-tracking, and protecting privacy (Health 3.0 skills). Although the items were built upon the groundwork laid by the eHEALS [3], with the insights from the participants' usage of the Web 3.0 technology, eHLS-Web3.0 went beyond the computer skill and media literacy components of the eHEALS. It provided a much deeper understanding of people's interactions with different types of eHealth tools and the application of the information they obtained or created. Construction and validity testing in a broad range of target groups generated clear evidence of construct, convergent, and concurrent validities, as well as composite and internal consistency, and test-retest reliability. Measurement invariance was also found across genders, majors, and regions. This initial validity test indicated that the eHLS-Web3.0 was likely to be valuable for the characterization and understanding of EHL.

Study 1

An effective eHealth literacy scale was developed in this study. When generating the item pool, it was hypothesized that the eHLS-Web3.0 would be categorized into 3 dimensions, namely Health 1.0, Health 2.0, and Health 3.0, for the items were generated based on the use experience of eHealth tools in different information technology (IT) generations. However, the result was different from what was hypothesized. Each item was applicable for evaluating the usage of eHealth tools in all the IT generations. The result revealed that current EHL is a comprehensive constellation of abilities where the 3 factors were correlated, distinguished, and combined, together influencing people's usage of eHealth tools, irrespective of the generations of the tools. Moreover, during the development, the features of EHL were examined by EFA, which revealed that the data supported a 3-factor structure. This 3-factor structure differed from those in other concept-based EHL scales used in previous studies. For instance, the most widely used one, eHEALS, is a unidimensional tool that only focuses on individuals' Health 1.0 abilities [3]. As an updated measurement tool, it is reasonable for eHLS-Web3.0 to be categorized into more factors. The 8-subscale Patient Readiness to Engage in Health Internet Technology [12] and 7-subscale eHLQ [15] considered the internal perceptions (eg, need, motivation, sense of safety, and anxiety) and external environment (relationship with service provider and access to the tools) along with the skills and abilities. In accordance with Norman and Skinner [3], this study defined EHL as the set of capabilities for people to properly understand all types of web-based health information and maintain their health and did not consider other internal and external factors for item generation so that the eHLS-Web3.0 could have a concise and targeted structure. It is worth mentioning that the factor structure of eHLS-Web3.0 is similar to the 3D eHLS [14]. The eHLS was developed following a thorough literature review, including functional, interactive, and critical dimensions of the eHLS. In the eHLS, the functional dimension is about understanding and calculating, the interactive one is about filtering, and the critical one is about cross-checking and evaluating applicability. No Web 2.0- or 3.0-related item was mentioned in the eHLS. Comparing the eHLS and eHLS-Web3.0 showed that the acquisition subscale in eHLS-Web3.0 was similar to the first and second dimensions in the eHLS (functional and interactive), whereas the verification part of eHLS-Web3.0 was close to the critical subscale in the eHLS. The application part is a newly developed dimension in the current EHL scale, which is consistent with daily experiences, as the application of information has become much more complicated than before. Others than apply the information to make health decisions or solve problems; individuals could also create their own health data, use the information to communicate, respond (ie, giving suggestions and advice, and responding to help seekers), socialize with others, and share and post information (ie, forward helpful information or post their own health or fitness data). Therefore, it is essential to enrich and include the abilities of information application into EHL. It was confirmed that the factorial structure of the eHLS-Web3.0 was reliable and valid based on statistics and theories, and in line with the actual situation.

Study 2

The aim of this study was to examine the validity (concurrent, convergent, and construct), reliability (composite, internal consistency, and test-retest reliability) and measurement invariance (gender, major, and region) of eHLS-Web3.0. The construct validity was determined through CFA; the goodness-of-fit indices supported the 3D model structure in study 1 and confirmed the factorial composition of eHLS-Web3.0. The concurrent validity was supported by its high correlation with other well-established and validated measures of EHL (eHEALS) [3]. The convergent validity was confirmed by the AVE values, with values above 0.5 indicating acceptability. Regarding the reliability, the Cronbach α estimation showed adequate internal consistency reliability for eHLS-Web3.0 and its subscales. The item-total correlations were also tested, and they showed relatively high positive values, indicating that the items in eHLS-Web3.0 discriminated effectively between high- and low-performing participants. Given the limitation of the Cronbach α approach [46], the composite reliability coefficients were also calculated for eHLS-Web3.0, providing further positive evidence for the

reliability of eHLS-Web3.0. Furthermore, the measurement invariance was measured for eHLS-Web3.0 across genders, majors, and regions. The establishment of configural, metric, strong, and structural invariances demonstrated that eHLS-Web3.0 is an appropriate and a meaningful instrument to measure EHL across diverse groups and perform comparisons. Compared with previous studies evaluating EHL among Chinese people [17,35,47], the current research had the advantage of using student samples drawn from different regions in China and from different majors. Besides, a follow-up questionnaire was designed to check if eHLS-Web3.0 was stable over time. Most importantly, this study explored the latest usage behavior related to eHealth, based on which new factors were meticulously developed to enrich the contents of EHL.

Limitations, Strengths, and Future Directions

The study has several limitations. First, the generalizability of the findings might be hindered by the snowball sampling. As a result, a stratified sampling approach is desirable in future [48]. In addition, the results are only based on the responses provided by Chinese college students; therefore, the applicability of this tool in other groups needs to be examined. Although a purposive sample was sought, it is possible that those who responded were more interested in eHealth than nonrespondents, and this may have biased the result and the level of EHL. Moreover, self-reporting questionnaires were used, which may result in unreliability and inaccuracy because of the inherent drawbacks of self-reporting (ie, recall bias, over- or under-reporting, and social desirability) [49]. Finally, the nonhealth-related major participants were over-represented in the sample, which reflected certain realities and may also lead to some bias. Consequently, further invariance tests across majors are required with acceptably equalized sample sizes in different groups.

Despite the limitations mentioned above, the current study fills a gap in the literature, as no specific measure of EHL considering the Web 3.0 IT environment has been previously developed. A comprehensive understanding of EHL was achieved in the context of new IT and Chinese culture. By developing this reliable and valid measurement tool, this study provides an up-to-date tool to measure the level of EHL among Chinese college students and evaluate the efficacy of EHL interventions in future experimental studies on EHL. Moreover, the relationships among EHL and other health-related variables could be explored using this new tool. Apart from the previously stated theoretical values, the newly developed EHL scale may also be applied to eHealth-related interventions, such as providing new and valuable information for constructing EHL training methods.

Conclusions

A new 24-item instrument for measuring eHealth literacy termed the eHLS-Web3.0 was developed and initially validated in this study. Three factors were identified in this tool, namely acquisition, verification, and application. This study validated the eHLS-Web3.0 in terms of its construct validity, convergent validity, concurrent validity, internal consistency reliability, and test-retest reliability in Chinese college students. The measurement invariance of the eHLS-Web3.0 was also confirmed across genders, majors, and regions. The 24-item eHLS-Web3.0 is a valid and reliable instrument for assessing eHealth literacy in the Chinese context.

Acknowledgments

HXL is grateful for the immense support provided by Qing-jian Liu, Guang-ze Zhang, Xiao-yi Yang, and Hong Wei in reaching participants and distributing the questionnaire. The authors appreciate Chun Hu and Ming-Wa Kwai for their valuable inputs.

Abstract

Background: Although previous studies have shown that a high level of health literacy can improve patients' ability to engage in health-related shared decision-making (SDM) and improve their quality of life, few studies have investigated the role of eHealth literacy in improving patient satisfaction with SDM (SSDM) and well-being.

Objective: This study aims to assess the relationship between patients' eHealth literacy and their socioeconomic determinants and to investigate the association between patients' eHealth literacy and their SSDM and well-being.

Methods: The data used in this study were obtained from a multicenter cross-sectional survey in China. The eHealth Literacy Scale (eHEALS) and Investigating Choice Experiments Capability Measure for Adults were used to measure patients' eHealth literacy and capability well-being, respectively. The SSDM was assessed by using a self-administered questionnaire. The Kruskal-Wallis one-way analysis of variance and Wilcoxon signed-rank test were used to compare the differences in the eHEALS, SSDM, and Investigating Choice Experiments Capability Measure for Adults scores of patients with varying background characteristics. Ordinary least square regression models were used to assess the relationship among eHealth literacy, SSDM, and well-being adjusted by patients' background characteristics.

Results: A total of 569 patients completed the questionnaire. Patients who were male, were highly educated, were childless, were fully employed, were without chronic conditions, and indicated no depressive disorder reported a higher mean score on the eHEALS. Younger patients ($SSDM_{\geq 61\ years}$=88.6 vs $SSDM_{16\text{-}30\ years}$=84.2) tended to show higher SSDM. Patients who were rural residents and were well paid were more likely to report good capability well-being. Patients who had a higher SSDM and better capability well-being reported a significantly higher level of eHealth literacy than those who had lower SSDM and poorer capability well-being. The regression models showed a positive relationship between eHealth literacy and both SSDM (β=.22; *P*<.001) and well-being (β=.26; *P*<.001) after adjusting for patients' demographic, socioeconomic status, lifestyle, and health status variables.

Conclusions: This study showed that patients with a high level of eHealth literacy are more likely to experience optimal SDM and improved capability well-being. However, patients' depressive status may alter the relationship between eHealth literacy and SSDM.

KEYWORDS

eHealth literacy; shared decision-making; well-being; eHEALS; ICECAP-A

Introduction

Background

eHealth literacy refers to the acquisition and use of web-based information and communication technology to make appropriate health decisions [1]. Unlike collecting health information through traditional methods (eg, hospital pamphlets and medical magazines), acquiring information from the internet requires extended skills [2-4]. For this task, people need to have professional knowledge about specific health issues, computer and mobile phone literacy, knowledge and skills to navigate the internet, and the ability to analyze and digest web-based information [5,6]. In recent decades, the rapid proliferation of web-based information about health and health care has significantly changed individuals' health-seeking behaviors, such as participating in web-based communities or purchasing products on the internet and services to improve health and well-being. The internet increasingly serves as a major source of health information for individuals to understand their health concerns, instead of seeking professional advice [2,7].

The internet provides a convenient way to approach health-related information to the public; however, a low level of eHealth literacy may lead, in contrast, to serious harm [8] and health-related social inequality [9,10]. Previous studies have shown that individuals with a low level of eHealth literacy are more likely to report insufficient use of preventive health services [11], negative health-related attitudes [12], unhealthy behaviors and lifestyles [13], and poor medical adherence [14]. However, globally, the relationship between patients' eHealth literacy and well-being remains insufficiently explored. Nabi et al [15] indicated that seeking information from social networks (eg, Facebook) impacts people's stress levels and, in turn, influences their physical and psychological well-being. Another systematic review found that providing breast cancer patients with access to digital systems or technological devices could improve their health and well-being [16]. Given the complex and fragmented nature of the current health care systems and the high prevalence of chronic conditions, the internet has been increasingly identified as an essential and valuable information source to support patient-centered care and help patients and their families seek cost-effective health care services [17].

Recently, shared decision-making (SDM) has been reported to be an effective way to improve trust in patient–doctor relationships, reduce negative emotions, and promote patients' well-being [18,19]. eHealth literacy, as an important concept rooted in the practice of patient-centered care, is increasingly suggested to be used to improve SDM in clinical practice. For example, Nejati et al [20] found that low levels of eHealth literacy can limit patients' trust in the health care system and their communication patterns and are a barrier to patient participation in the decision-making process. As the global population becomes increasingly reliant on the internet to locate and obtain health information and services [21,22], patients and their caregivers struggle to possess adequate eHealth literacy to engage in the decision-making process. The limited availability of web-based health information restricts patients from participating in their health care decision-making process. For example, Car et al [23] pointed out that poor eHealth literacy limited patients' ability to make decisions in medicine management. Netjati et al [20] also showed that lower levels of eHealth literacy are associated with poorer SDM among patients with multiple myeloma. However, in China, there is no evidence regarding the relationship between eHealth literacy and medical decision-making.

As reported, there are more than 980 million internet users in China, accounting for more than 20% of the users worldwide [24]. In 2018, the State Council of China, jointly with the National Health Commission, released a series of decrees to encourage integration of traditional industries with internet technologies to improve the quality and efficiency of health care services [25]. A new nationwide web-based service system will be developed to provide patients with a novel way to approach quality health care information and facilitate their active engagement in clinical decision-making. This could help health care providers not only in understanding patients' preferences, needs, and satisfaction but also in clarifying their health care situations, treatment options, and likely outcomes [26]. Thus, an individual's level of eHealth literacy is the key to searching and using internet-based health care services to improve their health outcomes and well-being [27]. In 2020, the COVID-19 pandemic further proved that innovative eHealth approaches are vital for delivering health services and supporting patients to prevent contracting COVID-19 and increase their willingness to get vaccinated [28,29]. However, in China, there is a dearth of information regarding patients' level of eHealth literacy and whether eHealth literacy could improve their satisfaction with SDM (SSDM) and well-being in clinical practice. Without adequate information about these associations, there is a risk that internet-based interventions may lead to some negative outcomes, such as producing a digital divide, solidifying current health disparities, and perpetuating inequities, all of which could result in poor health outcomes and well-being [21].

Objectives

This study aims to (1) assess the relationship between patients' eHealth literacy and their socioeconomic status (SES) and (2) investigate the association between patients' eHealth literacy and their SSDM and well-being.

Methods

Study Design and Data Collection

The data used in this study were obtained from a multicenter cross-sectional survey that investigated patients' attitudes toward patient-centered care (PCC) in Guangdong province, China, from November 2019 to January 2020. Patients were recruited from the inpatient departments of 8 hospitals from 5 cities (Guangzhou, Shenzhen, Zhanjiang, Meizhou, and Shaoguan). All patients from the target hospitals were invited to participate in the survey during the survey period. The inclusion criteria were as follows: (1) being aged ≥18 years, (2) being able to read and speak Chinese, (3) having no cognitive impairment, and (4) being able to provide informed consent. With the assistance of ward nurses, all eligible patients were invited to

participate in the survey. The patients who agreed to participate in the survey and provided written informed consent were asked to complete a structured questionnaire that included questions about their demographic characteristics, SES, health conditions, well-being, use of health services, lifestyle, and attitudes toward PCC. A convenience sample of 569 patients (569/800, 71.1% response rate) successfully completed the questionnaire and provided valid responses. The study protocol and informed consent were approved by the institutional review board of the Second Affiliated Hospital of Guangzhou Medical University (reference ID: 2019-ks-28).

Measures

eHealth Literacy

The eHealth Literacy Scale (eHEALS) was used to measure consumers' combined knowledge, comfort, and perceived skills at finding, evaluating, and applying eHealth information to manage health problems [30]. It was developed based on a framework that comprised six dimensions to understand and use eHealth information [31]. The eHEALS has eight items that are rated on a 5-point Likert scale (including "strongly disagree," "disagree," "neutral," "agree," and "strongly agree"). The sum score ranges from 8 to 40, where a higher score indicates greater perceived eHealth literacy. To compare it with the results of other measures, in this study, the eHEALS sum score was converted to an overall score between 0 and 100 based on minimum-maximum normalization. A simplified Chinese eHEALS was used in this study [32].

Well-being

The Investigating Choice Experiments Capability Measure for Adults (ICECAP-A) is a generic and preference-based instrument that evaluates an individual's capability well-being [33]. Each dimension of the ICECAP-A comprises 1 item with 4 response options that range from "not capable" to "fully capable," to measure the different aspects related to capability well-being. The results of the ICECAP-A can convert to a summarized utility score that ranges from 0 to 1 to support the economic evaluation of social care interventions [34]. In this study, the ICECAP-A sum score was calculated using the scoring formula provided by the University of Birmingham. To facilitate comparability with the other measures, in this study, we converted the original ICECAP-A utility score to a range between 0 and 100. The Chinese version of the ICECAP-A was used [35].

Patient SSDM

Patient SSDM was assessed using a self-administered questionnaire. It was developed based on our previous patient engagement framework [36] and index [37], findings from literature review, focus group interviews (including patients, doctors, nurses, and policy makers), and expert discussion. It assessed patient satisfaction with decision-making, along with doctors in clinical practice. The SSDM comprises 5 items to measure different dimensions of satisfaction with the SDM. They are (1) "Did doctors provide several selections for you when making decisions (selection)," (2) "Did doctors carefully listen to your health problems when making decisions (Listen)," (3) "Did doctors respect your willingness when making choices (Respect)," (4) "Did doctors fully discuss your concerns with you when making decisions (Discussion)," and (5) "Did doctors fully understand your preferences and needs when making decisions (preference)?" Each item was rated on a 5-point scale ranging from "strongly disagree" to "strongly agree." The instrument showed good content, construct (Multimedia Appendix 1), convergent validity (Multimedia Appendix 2), and high internal consistency reliability (Cronbach α=.93). The overall score of the SSDM was calculated by adding up the scores of each item, which were then converted to a range of 0 to 100 based on minimum-maximum normalization.

Depressive Disorder

The Patient Health Questionnaire-2 was used to assess whether patients experienced depressed mood over the past 2 weeks. An individual with a score of 3 or above (range: 0-6) was recognized as someone with a depressive disorder [38].

Statistical Analysis

Patients' background characteristics (section 1: demographics; section 2: SES; section 3: lifestyle; and section 4: health status) were presented with the mean and SD of the eHEALS, SSDM, and ICECAP-A sum scores. The Kruskal-Wallis one-way analysis of variance (multiple groups) and Wilcoxon signed-rank test (2 groups) were used to compare the differences in the eHEALS, SSDM, and ICECAP-A sum scores of patients with different background characteristics. The Wilcoxon signed-rank test was also used to assess the relationship between level of eHealth literacy and SSDM and well-being. Patients' level of eHealth literacy was recategorized into high (≥30) and low (<30) on the basis of the median of the original eHEALS sum score. In addition, patients' depressive status was considered in the analysis of the relationship between 3 measures. Three ordinary least square multivariate regression models were developed to assess the relationships between measures adjusted by patients' background characteristics. In the first model, the dependent variable was eHealth literacy, and the independent variables were SSDM, well-being, and patients' background characteristics. In the second model, SSDM was the dependent variable, and the independent variables were eHealth literacy and patients' background characteristics. In the third model, the dependent variable was capability well-being, and the independent variables were eHealth literacy and patients' background characteristics. The objective of the first model was to assess the relationship between patients' eHealth literacy and their socioeconomic determinants, whereas the other two models assessed how patients' eHealth literacy can predict the changes in their SSDM and well-being, after adjusting for background characteristics. The Bland-Altman (B-A) plot was used to assess the agreement between three measures. The mean scores of the eHEALS, SSDM, and ICECAP-A were plotted on the x-axis, and the differences between them was plotted on the y-axis. The observations clustered evenly around a horizontal line representing y=0, reflecting good agreement between the measures [39]. R software (R Foundation for Statistical Computing) was used to perform all statistical analyses. The level of statistical significance was set at $P \leq .05$.

Results

Participants' Characteristics and the Results of Measures

Table 1 shows that more than half of the patients were male (288/569, 50.6%), and approximately 18.6% (106/569) and 19.2% (109/569) were aged <30 years and >60 years, respectively. Nearly 51.1% (291/569) of the patients indicated living with at least one kind of chronic condition, and 27.9% (159/569) reported having a depressive disorder. Patients who were male ($eHEALS_{male}$=68.5 vs $eHEALS_{female}$=64.3), were highly educated ($eHEALS_{tertiary}$=69.6 vs $eHEALS_{no\ or\ primary}$=62.9), were childless ($eHEALS_{no\ child}$=72.7 vs $eHEALS_{with\ child}$=59.4), fully employed ($eHEALS_{fully\ employed}$=68.5 vs $eHEALS_{nonemployed}$=61.7), were without chronic conditions ($eHEALS_{no\ chronic\ conditions}$=68.5 vs $eHEALS_{with\ chronic\ conditions}$=64.4), and indicated no depressive disorder ($eHEALS_{no\ depression}$=67.6 vs $eHEALS_{with\ depression}$=63.3) reported a higher level of eHealth literacy. Younger patients ($SSDM_{\geq 61\ years}$=88.6 vs $SSDM_{16\text{-}30\ years}$=84.2) tended to show higher SSDM. Patients, who resided in rural areas ($ICECAP\text{-}A_{rural}$=79.3 vs $ICECAP\text{-}A_{urban}$=75.7) and were well paid ($ICECAP\text{-}A_{\geq Chinese\ ¥6401\ (US\ \$960.15)}$=81.9 vs $ICECAP\text{-}A_{\leq Chinese\ ¥1800\ (US\ \$270)}$=73.5) were highly likely to report better capability well-being.

[a]eHEALS: eHealth Literacy Scale.

[b]SSDM: satisfaction with shared decision-making.

[c]ICECAP-A: Investigating Choice Experiments Capability Measure for Adults.

[d]*P* value was calculated based on a Kruskal-Wallis one-way analysis of variance (multiple groups) and Wilcoxon signed-rank test (2 groups).

[e]Not available.

[f]FHS: free health care scheme.

[g]UEBMI: urban employee basic medical insurance.

[h]URBMI: urban resident basic medical insurance.

[i]NRCMS: new rural cooperative medical care system.

[j]BMI: normal: 18.5≤BMI<23; abnormal: BMI<18.5 or BMI≥23.

Relationship Among eHealth Literacy, SSDM, and Well-being

Table 2 presents the outcomes of SSDM and well-being in patients with different levels of eHealth literacy. Patients with a higher level of eHealth literacy reported higher SSDM and better well-being than those with a lower level of eHealth literacy. For patients with depressive disorder, the difference in SSDM in patients with different levels of eHealth literacy was statistically nonsignificant.

Table 2. Satisfaction with SDM[a] and well-being in different groups of eHealth literacy and stratified by patients' depressive disorder and chronic condition status.

	Satisfaction with SDM	Well-being
Overall		
High eHealth literacy, mean (SD)	88.7 (14.7)	81.1 (14.7)
Low eHealth literacy, mean (SD)	82.4 (18.7)	73.7 (16.1)
P value[b]	<.001	<.001
With depressive disorder		
High eHealth literacy, mean (SD)	86.2(16.2)	73.3(18)
Low eHealth literacy, mean (SD)	82.2 (18.4)	66.1 (16.8)
P value	.10	.004
Without depressive disorder		
High eHealth literacy, mean (SD)	89.5 (14.2)	83.6 (12.4)
Low eHealth literacy, mean (SD)	82.5 (18.9)	77.1 (14.6)
P value	<.001	<.001
With chronic conditions		
High eHealth literacy, mean (SD)	88.4 (14.7)	82.6 (14.4)
Low eHealth literacy, mean (SD)	80.5 (20.1)	75 (15.8)
P value	<.001	<.001
Without chronic conditions		
High eHealth literacy, mean (SD)	89 (14.8)	79.1 (14.8)
Low eHealth literacy, mean (SD)	83.9 (17.5)	72.7 (16.4)
P value	<.001	<.001

[a]SDM: shared decision-making.

[b]*P* value was calculated based on Wilcoxon signed-rank test.

Results of the Regression Analysis

The results of multivariate regression models showed that there was a significant and positive relationship between eHealth literacy and SSDM and well-being after adjusting for patients' background characteristics (Table 3). Model 1 demonstrated that patients who were living alone (β=−6.82; *P*=.03) and nonemployed (β=−4.55; *P*=.02) showed a lower level of eHealth literacy. Models 2 and 3 showed that, after adjustment, eHealth literacy was a statistically significant factor predicting the change in SSDM (β=.17; *P*<.001) and well-being (β=.15; *P*<.001), respectively. There was a positive relationship between patients' well-being and their educational level, income, and depressive status.

[a]Reference: female, 16-30 years, no or primary education, single, rural resident, no child, no caregiver, live with family or others, income ≤ Chinese ¥1800 (US $270), free health care scheme insurance, normal BMI, no smoking, few healthy diets, no exercise, no chronic conditions, no depressive disorder, and severe threat to life.

[b]DV: dependent variable.

[c]eHEALS: eHealth Literacy Scale.

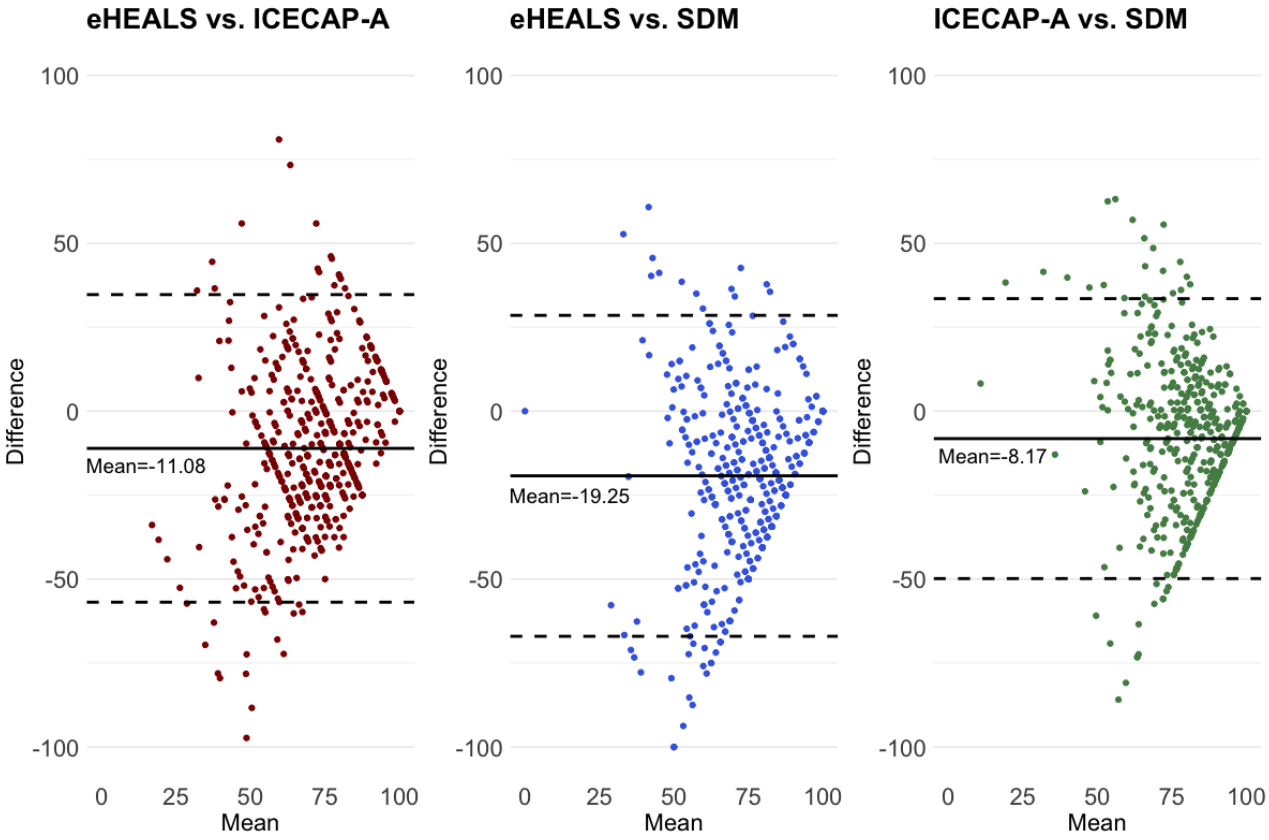
[d]ICECAP-A: Investigating Choice Experiments Capability Measure for Adults.

[e]Not available.

Agreement Between Measures

Although the B-A plot shows a wide limit of agreement interval between the three measures, systematic differences were detected. A good agreement was observed in patients who reported a high level of eHealth literacy, SSDM, and well-being; however, patients who reported a low level of eHealth literacy, SSDM, and well-being were more likely to show less consistent results across the measures, indicating low agreement (Figure 1).

Figure 1. Agreement between scores of the eHEALS, satisfaction with SDM, and ICECAP-A. eHEALS: eHealth Literacy Scale; ICECAP-A: Investigating Choice Experiments Capability Measure for Adults; SDM: shared decision-making.



Discussion

Principal Findings

This study extended the findings of previous studies by demonstrating a statistically significant association between eHealth literacy and SSDM and capability well-being in a sample of Chinese patients. However, when patients reported a low level of eHealth literacy, its association with SSDM and well-being turned to weak and inconsistent. Our findings suggested that providing training to improve patients' eHealth literacy may be a useful way to strengthen their ability to search and use web-based health and health care information to improve their activity in clinical decision-making and well-being. However, although the internet carries a vast range of information resources and services to help people manage their health, we noticed that disparities in using the internet are persistent in people with low SES (unemployed status and unhealthy lifestyle) and, therefore, affect their potential to maintain and improve eHealth literacy and limit their ability to navigate the health care system. In addition, there seemed to be a negative relationship between patients' mental health status and their use of internet-based knowledge and skills to improve SSDM. However, further research is needed to support this finding, as it has not been studied extensively.

Comparisons With Previous Studies

Our results firstly exhibited that there is a positive relationship between eHealth literacy and Chinese patients' SSDM, which is in line with the findings of previous studies. For example, an Iranian study indicated that eHealth literacy is positively associated with SDM and patient communication patterns in patients with multiple myeloma [20]. Another German study noted that the regular use of eHealth services facilitated the decision-making process for patients with cancer and their families [40]. Other studies have reported that the internet and web-based courses are fundamental in improving patients' communication skills with medical personnel [3,41], reducing their overall medical expenses [42], and increasing their confidence and knowledge to be involved in decision-making [43]. In addition, we found that patients who reported being very satisfied with SDM (satisfied with all five dimensions of the SSDM) obtained a similar mean score on the eHEALS (Multimedia Appendix 3). This indicated that improving eHealth literacy might be a multifaceted strategy to promote all the existential dimensions of the SDM [44] and, in turn, positively associated with patients' physical, psychological, social, and spiritual well-being [45]. Considering that the internet is increasingly serving as a major source of health information for both medical professionals and patients, improving eHealth literacy could be a cost-effective way to transfer the current paternalistic pattern of medical services to a more patient-centric model [2]. Moreover, doctors' attitude toward SDM was identified as another important factor that supported SDM in improving patients' well-being in clinical practice [46], which should be considered for future studies.

Studies examining the relationship between patients' well-being and eHealth-related interventions have recently been explored. For example, Villani et al [47] indicated that eHealth interventions can significantly reduce emotional suppression of patients with cancer and increase their cancer-related emotional well-being. Pagliari [48] and Patel et al [49] found that the proliferation of personal health information technology has enhanced people's ability to manage their own health care, communicate with providers through social networks, meet their informational needs, search patient educational resources, and make preferred health decisions. However, research examining the role of eHealth literacy in using these techniques to improve patients' well-being is in its infancy. This study found that patients who reported a high level of eHealth literacy were more likely to show full capability well-being than those who reported a low level of eHealth literacy. This supports the notion that patients with high levels of eHealth literacy are confident and capable of handling internet-based tools to improve their health and well-being [21,22,50]. Further, unlike studies that used nonpreference-based instruments to measure well-being, in this study, the ICECAP-A, a preference-based measure, generated outcomes that not only reflect a patient's current well-being status but also provide information to support the estimation of social care–related quality of life and facilitate a cost-effectiveness analysis of eHealth-related interventions and policies [33]. Furthermore, the results of the B-A plot exhibited a poor agreement between eHEALS, SSDM, and ICECAP-A when patients reported a low score on those measures, unlike those who reported a high score. Methodologically, this may be because, in this study, few patients reported having low well-being and unsatisfactory SDM, and less than 19.8% (113/569) of the respondents reported having poor health. Thus, we could not validate our findings in these populations. Due to the cross-sectional design, no causal relationships can be concluded. Therefore, further studies are required.

The results of bivariate analysis indicated that patients with high SES and healthy lifestyle are more likely to indicate a high level of eHealth literacy; however, the multivariable regression analysis showed a different picture. This is consistent with the mixed findings of the relationship between individuals' socioeconomic determinants and their level of eHealth literacy, as reported in previous studies. For example, Lwin et al [51] found that women and men did not differ in their reported frequencies of evaluating eHealth information; however, no older adult respondents (>55 years) were involved in their study. Conversely, a study in China found that female respondents showed a higher level of eHealth literacy than male respondents; however, they used a revised version of the eHEALS, and all the respondents were older than 45 years [52]. In addition, Stellefson et al [53] indicated that women and older adults living with chronic obstructive pulmonary disease showed a low level of eHealth literacy in the United States. Wong and Cheung [54] also indicated that older primary care service users in Hong Kong are highly likely to report low levels of eHealth literacy. The findings of multivariable regression analysis showed that, when adjusted for patients' background characteristics, there was no significant relationship between patients' eHealth literacy and their educational level. This suggests that eHealth literacy does not comprise only basic literacy but also an accumulation of knowledge and skills to navigate the internet to use health care services. Norman [31] noted that eHealth literacy is not

just a combination of the capability to use computers and traditional health literacy but is a meta-literacy comprising different facets of literacy. For example, an undereducated patient with chronic conditions may show higher eHealth literacy than highly educated patients who have recently been diagnosed with cancer. Our findings highlight the importance of promoting eHealth literacy.

When patients reported having depressive disorders, the difference in SSDM between those with high and low eHealth literacy was statistically insignificant. This is not inconsistent with previous findings in those patients with good skills in searching, assessing, and correctly using web-based health care information may lead to decreased levels of hospitalization-related mental disorders and improve their long-term quality of life and well-being [55-57]. However, no study has directly investigated the relationship between eHealth literacy and SDM considering the potential effect of patients' mental health status. Neter and Brainin [11] confirmed that there is insufficient evidence on the association between eHealth literacy and emotional states of anxiety and depression. A US-based study indicated that social media could benefit patients with chronic obstructive pulmonary disease by helping them cope with mental health issues such as anxiety and depression [53]. Another study found that African Americans who researched depression, anxiety, and stress on the internet showed a significantly higher mean score of the eHEALS than those who did not [58]. Interventions focused on internet-related health literacy, such as mental eHealth literacy, require further investigation. Furthermore, in this study, depressive status was assessed using the Patient Health Questionnaire-2, the sensitivity of which has been disputed by some previous studies [59,60]. Other mental disorders, such as anxiety and stress, should be evaluated in future studies.

Limitations

It is important to address the limitations of this study. First, this was a cross-sectional study; thus, no causal relationships could be concluded. Second, all the respondents were recruited from inpatient departments in hospitals; the issue of a single information source may affect the validity of our findings. In addition, compared with the data from the 2019 Guangdong census, our respondents were slightly older and comprised a higher proportion of rural residents (Multimedia Appendix 4). This implies that there was some degree of selection bias, which may affect the generalizability of our findings. Third, we did not assess the associations between eHealth literacy, well-being, and SDM stratified by patient disease groups, which might also affect the generalizability of our findings. Fourth, the ICECAP-A score was not estimated based on the preference weight of the Chinese population, which is currently unavailable. This may have affected the validity of our findings. Fifth, all the information was self-reported by the patients, which may have generated recall bias. Finally, the information of patients who refused to participate in the survey was not recorded, which might have led to a degree of information bias.

Conclusions

According to the findings of this study, patients with a high level of eHealth literacy were more likely to experience an optimal SDM and improved capability well-being. This suggests that the implementation of interventions to strengthen patients' eHealth literacy could improve their optimal use of health care services and the efficiency of the health and social care system. In addition, univariable analysis demonstrated that patients with low SES showed insufficient eHealth literacy, which may affect their ability to buffer against the negative impacts of an adverse event on their health. It is important for policy makers to understand the facilitators and barriers to improve patients' eHealth literacy and to develop strategies to enhance their health behaviors and health outcomes. Moreover, the effects of patients' mental health status on the relationship between eHealth literacy and SSDM require further investigation.

Acknowledgments

This study was funded by a grant from the Guangdong Basic and Applied Basic Research Foundation (Ref ID: 2021A1515011973).

Authors' Contributions

RHX was involved in the study conceptualization and design, data analysis and interpretation, software use, the writing of the original draft, review, and editing. Abstract

Background: Measuring weight bearing is an essential aspect of clinical care for lower limb injuries such as sprains or meniscopathy surgeries. This care often involves the use of forearm crutches for partial loads progressing to full loads. Therefore, feasible methods of load monitoring for daily clinical use are needed.

Objective: The main objective of this study was to design an innovative multifunctional desktop load-measuring software that complements GCH System 2.0–instrumented forearm crutches and monitors the applied loads, displaying real-time graphical and numerical information, and enabling the correction of inaccuracies through feedback technology during assisted gait. The secondary objective was to perform a preliminary implementation trial.

Methods: The software was designed for indoor use (clinics/laboratories). This software translates the crutch sensor signal in millivolts into force units, records and analyzes data (10-80 Hz), and provides real-time effective curves of the loads exerted on crutches. It covers numerous types of extrinsic feedback, including visual, acoustic (verbal/beeps), concurrent, terminal, and descriptive feedback, and includes a clinical and research use database. An observational descriptive pilot study was performed with 10 healthy subjects experienced in bilateral assisted gait. The Wilcoxon matched-pairs signed-rank test was used to evaluate the load accuracy evolution of each subject (ie, changes in the loads exerted on crutches for each support) among various walks, which was interpreted at the 95% confidence level.

Results: GCH Control Software was developed as a multifunctional desktop tool complementing GCH System 2.0–instrumented forearm crutches. The pilot implementation of the feedback mechanism observed 96/100 load errors at baseline (walk 0, no feedback) with 7/10 subjects exhibiting crutch overloading. Errors ranged from 61.09% to 203.98%, demonstrating heterogeneity. The double-bar feedback found 54/100 errors in walk 1, 28/100 in walk 2, and 14/100 in walk 3. The first walk with double-bar feedback (walk 1) began with errors similar to the baseline walk, generally followed by attempts at correction. The Wilcoxon matched-pairs signed-rank test used to evaluate each subject's progress showed that all participants steadily improved the accuracy of the loads applied to the crutches. In particular, Subject 9 required extra feedback with two single-bar walks to focus on the total load. The participants also corrected the load balance between crutches and fluency errors. Three subjects made one error of load balance and one subject made six fluctuation errors during the three double-bar walks. The latter subject performed additional feedback with two balance-bar walks to focus on the load balance.

Conclusions: GCH Control Software proved to be useful for monitoring the loads exerted on forearm crutches, providing a variety of feedback for correcting load accuracy, load balance between crutches, and fluency. The findings of the complementary

implementation were satisfactory, although clinical trials with larger samples are needed to assess the efficacy of the different feedback mechanisms and to select the best alternatives in each case.

Introduction

Gait is a basic motor function of humans [1-3]; thus, many health (eg, physiotherapy, orthopedics, biomechanics) and engineering (eg, computing, mechanics, robotics) professionals, among others, have pooled their efforts to analyze and assess gait for recovery or optimization purposes.

New feedback-based technologies are especially useful in the field of rehabilitation [4] to reeducate an altered function or teach a new one, such as in the functional recovery of walking [5,6]. These aspects are fundamental objectives of physiotherapy [7,8], which enable subjects to voluntarily control and modify certain body functions or biological processes if they are given new information about these functions and processes. This is the basic principle underlying feedback mechanisms [7,9,10].

This paper focuses on *extrinsic feedback*, which is provided by external sources [11,12]. The wide range of well-known feedback technologies include visual [5,13-15], acoustic [16-18], and haptic [11,16,19] technologies, which are usually adapted to each individual user in a coherent manner [20]. Other classifications and types of feedback depend on when the information is applied, what type of data it offers, or what objective it pursues, among other factors. Some confusing terms in the literature are clarified below.

First, when feedback is given, it can be *concurrent* (ie, *simultaneously* provided during the intervention) or *terminal* (ie, retarded or postresponse feedback, provided when the action is finished). Concurrent feedback can be *continuous* or *intermittent*. Terminal feedback can be *immediate* [21], *delayed*, or even *summary* (provided after several repetitions of the movements or actions) [22].

Second, according to the type of information received, the feedback can be classified as *knowledge of performance* (KP) [23], which offers performance features (eg, if the subject keeps looking ahead while walking) and *knowledge of results* (KR) [24,25], which involves judgment of a correct or wrong action, or calculation of scores using rating scales. Feedback can also be *descriptive* or *prescriptive*, providing information about how to correct the errors [22]. For example, a physical therapist may describe a gait error by saying that patients are looking at their feet, or will try to correct the error by explaining that they should look at a fixed point ahead of them because the ground is smooth and they do not need to look down.

The extraordinary diversity of available feedback and the creativity in how it is applied have increased the opportunities for adapting and optimizing each intervention based on the user's needs.

Technological advances have prompted the development of new retraining walking techniques based on feedback provided by monitored instrumentation systems and associated software, as confirmed in various studies [14,15,26,27]. In general, these instruments capture real-time information on the gait [2,4,6,13,15-18,20,21,27], allowing the clinician to decide whether the user should receive concurrent feedback or whether it is more convenient to delay the information and verbally provide terminal feedback.

Functional recovery of walking and assisted gait are generally related to different areas of health, including neurology [28,29], gerontology [30-32], and rheumatology [33]; however, one context in which the need to control and optimize the loads applied to the forearm crutches is most clearly evident involves patients with a lower limb musculoskeletal injury [34], who have to relearn how to automate the walking gesture correctly [35]. Traumatological physiotherapy therefore very often involves using forearm crutches to partially unload the injured lower limb, progressing to full weight-bearing. Examples of such applications include sprained knees [36] or ankles [37], surgery for knee meniscopathies [38], and hip arthroplasties [21]. Consequently, the load exerted on the body part in question is an essential assisted gait parameter [39], and therefore this load must be objectified and controlled to optimize it in line with the pathology, recovery process phase, and user's characteristics. Another factor is the current tendency to strongly recommend that the affected lower limb support as much weight as possible without damaging the injury. Underloading could lead to circulatory and muscle tone deficits, resulting in a decrease in osteoblastic action and increase in osteoclastic action, as well as inhibition of the joint and muscle plantar proprioceptive receptors that would imply a functional deficit. In contrast, overloading could lead to compressions or undue stress of structures even without regeneration or in the recovery process [6].

Load-measuring tools are required to both determine the ideal load in each case, which entails specific action protocols based on scientific evidence, and to objectively and progressively increase the loads [4]. At present, there are some instruments available that measure loads, such as insoles [4] or force platforms [2,15]; however, these tools do not allow for monitoring the loads exerted on the forearm crutches in every type of support, the balance between them (in bilateral-assisted gait), the simultaneity of their supports, or even their rhythm, among other relevant factors. These drawbacks are overcome by the use of instrumented forearm crutches such as the GCH

System [6] that can monitor the loads applied to them so that the loads applied to the structure in question are reduced. However, these tools must be used together with a program that allows users and/or health professionals, in clinical or laboratory conditions, to obtain as much information as possible about the assisted gait performance. To the best of our knowledge, there is no scientific evidence related to the control software of instrumented forearm crutches and its implemented feedback mechanisms. As a result, the main objective of this study was to design an innovative multifunctional desktop load-measuring software that complements the GCH System 2.0–instrumented forearm crutches and monitors the loads applied to them, displaying real-time graphical and numerical information, as well as the correction of inaccuracies through feedback technology during assisted gait. The secondary objective was to perform a preliminary implementation study of the newly developed software.

Methods

GCH System 2.0

GCH Control Software implements GCH System to measure the loads applied to forearm crutches. Its application is particularly suitable in physiotherapy and traumatology, fields that frequently work on the functional recovery of gait for patients with lower limb musculoskeletal injury [40,41]. The rehabilitation process starts with total or partial unloading of the injured limb, followed by a gradual increase in loads aided by crutches until achieving complete functional recovery [42].

The instrumented crutches must first be described to understand how the software works. GCH System involves the coupling of a miniature force sensor inside the distal area of the crutch, and the measures are wirelessly transmitted. Each crutch contains an ultralow-power microcontroller with an input voltage of 2.4 V direct current and battery/autonomy of 6000 mAh (8 hours). The outgoing signal is detected by a USB receiver connected to a computer (“fixed system”) using a virtual communication port, or by a receptor built into a watch, mobile phone, pendant, or other portable device. In the latter case, patients have autonomy to practice aided gait outdoors with the usual obstacles encountered in daily life, such as steps and slopes, without any professional supervision. The technical specifications of GCH System 2.0 are reported elsewhere [6]. Each of these fixed and portable systems requires an independent implementation program with different features to allow each patient to achieve their specific therapeutic goals. The fixed system is described below in line with the main objective of the study.

GCH Control Software 1.0

Design

GCH Control Software is an instrumentation program that has to be used on a PC; therefore, it was designed for use during patient care in the clinic or in a laboratory for research purposes.

GCH Control Software was programmed in C# in a Windows operating environment, and another program is needed as a server (GCH Server). Several GCH Control Software sessions can run simultaneously on the same server so that several patients can use the instrumented crutches at the same time. Other specific programs such as Framework 4.0 by Microsoft’s SqLite libraries for Windows and the Codejock graphical software libraries may have to be installed.

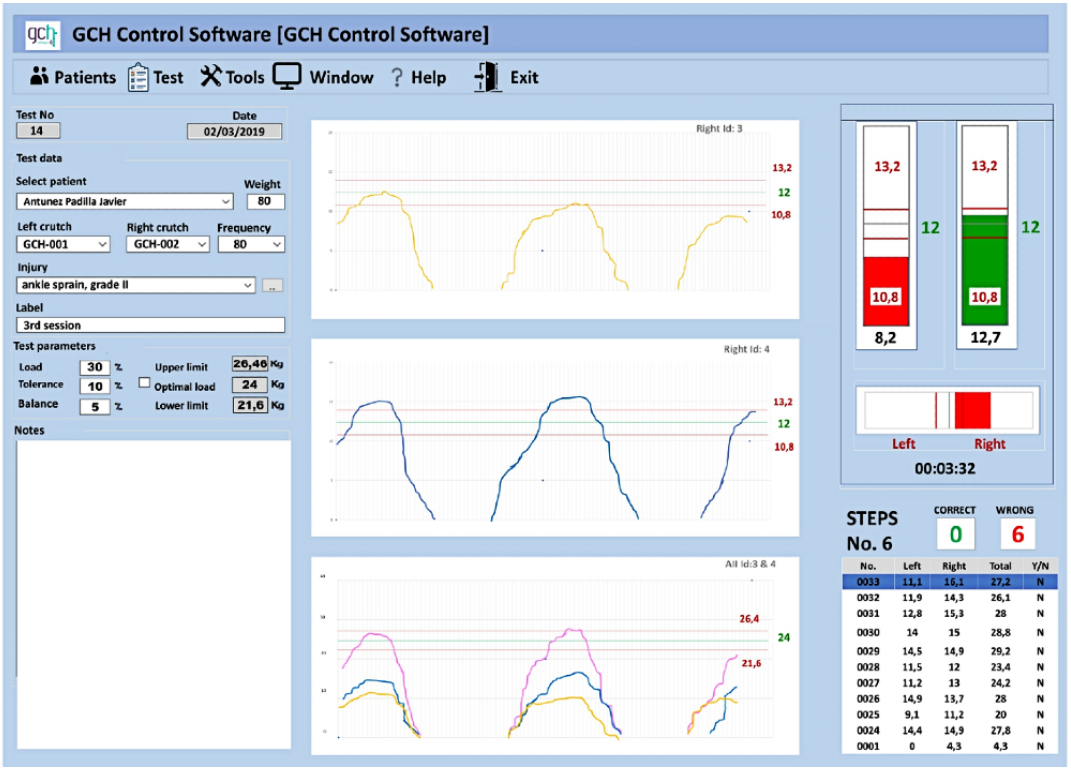
The software was developed by the first author (GC) and is registered in the Andalusia Regional Intellectual Property Registry under file number SE-690-15 and registration number 201599901533465. The source code is not available. Note that the Spanish language is used in all messages as the software was designed for use with Spanish patients.

The software translates the crutch sensor signal in millivolts into units of force (kilogram-force, which is a nonstandard unit but commonly used in our clinical context), records and analyzes the data, and provides a real-time on-screen numerical and graphical display of the loads exerted by the subject on one crutch if the assisted gait is unilateral or on two crutches if it is bilateral. The program records data up to 80 Hz, providing effective curves of weight-bearing at each crutch support.

Figure 1 shows the general interface of the program, displaying data about patients, pathologies, crutch loads recommended by the physiotherapist, permitted plus or minus tolerance margins of error in the maximum loads of each crutch step and in the load balance between crutches, and a notepad. The line graphs display the independent loads of each crutch, unified load of both crutches, and overlapping of the three previous loads. Bar graphs display the following loads: independent loads for each crutch (double bar), with the option to view the unified load (single bar), and a horizontal bar that represents the load balance between both crutches (balance bar). All of these data are displayed numerically, with a correct and wrong crutch step count (according to the load accuracy).

A detailed step-by-step description and operation of the software is provided after identifying the crutches to be used in the GCH Server.

Figure 1. Program interface screenshot. From top to bottom: the left column shows user's data, clinical test data, and observations; the middle shows line graphs of right crutch load, left crutch load, right and left crutch overlapping graphs, and the sum of both loads; and the right column shows double bar (right and left crutch vertical bars), balance bar, and correct and wrong crutch step counter (according to the load accuracy).

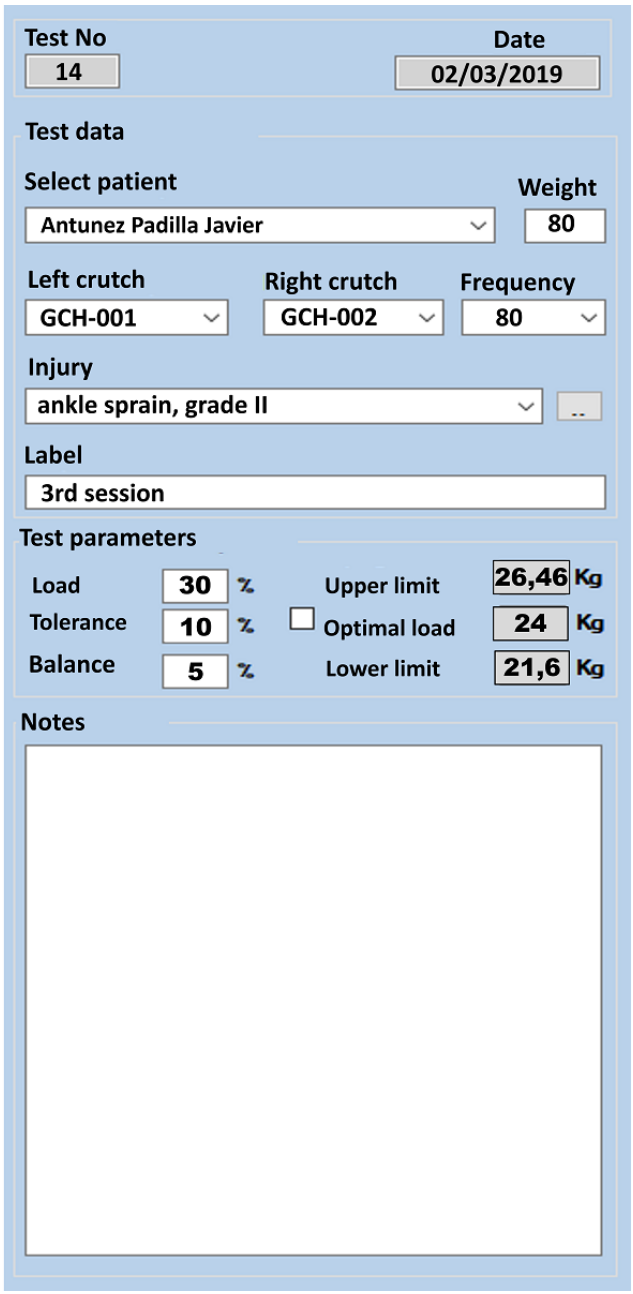


Data Logging Database

The database includes user registration information such as the patient's affiliation data and clinically relevant personal background. Each crutch is identified as "right" or "left," and the gait is classified as unilateral or bilateral. Preoperative clinical and technical data (Figure 2) are required for an autonumber test, such as the subject's current weight (because body weight percentages will be used), the frequency at which the data will be collected (20, 40, or 80 Hz), the current pathology, and a possible test identification label.

The next step is to record the ideal load to be exerted on the crutch, as recommended by the physiotherapist (ie, the load reduction applied to the injured limb, in percentage body weight or kilograms, which changes automatically); the permitted margins of error for overloading or underloading; and the permitted tolerance in the load balance between the two crutches, only in the case of bilateral assisted walking.

Figure 2. Left-hand column of the general interface shown in Figure 1, including (from top to bottom): autonumber test, date, patient's name, current weight, crutch identification, data frequency, lesion, test label, test parameters (ideal load requested, tolerance for load accuracy errors, tolerance for imbalance between both crutches), and notepad.



Graphical and Numerical Data Provided by the Software

The program uses several graphics to display the user's walking performance in real time: line graphs (see Figure 1, middle column) and bar graphs (see Figure 1, right column).

Line graphs are only for use by the professional, in which the right crutch load, the left crutch load, and their sum are shown in different colors. There are three possible versions of line graphs: "L+R" (left + right), which shows the crutches separately; "L and R" (left and right), where a graphic overlay of the crutches is added to display both of them simultaneously; and "ALL," which displays the superimposed graph of the two crutches plus the total load graph.

Both the researcher and clinician can view bar graphs on the computer (see Figure 1, right column, upper), and the user can see these graphs displayed on an extendable screen by a projector. In this case, there are three main display options. The first is a double-bar display, which involves two vertical bars (one for each crutch), showing the different loads. This method is useful for monitoring the load amount and how it is distributed during bilateral walking to ensure it is balanced and simultaneous, without fluctuations. This version offers the most complete information. The second option is a single bar that adds up the total loads exerted by both crutches. In this case, patients focus their attention on the total load, provided that they do not have any load asymmetry problems between crutches. The information is interchangeable with the double-bar feedback display. The third display option is the balance bar. With this horizontal bar, the user's attention focuses on

balancing loads between both crutches; therefore, this display is not used in unilateral assisted gait.

All of the line and bar graphics have three horizontal lines (see Figure 1): the middle green line shows the ideal load, and the red lines above and below indicate the permitted plus or minus tolerance margin (numerical data already included in the software).

The program interface displays other interesting data such as the number of correct and wrong crutch steps in each test, along with the respective load of each crutch (see Multimedia Appendix 1).

Each test is recorded and automatically dated in the database, making it possible to access, display, and analyze graphs and numerical data regarding load accuracy, mistakes made, patient progression, and other factors, thereby enabling comparisons and statistical analyses (Figures 3 and 4).

Figure 3. Screenshot of an example database with load results (Hz), displaying crutch identifiers, left crutch load, right crutch load, total load, time (ms), and time stamp. In this case, the right crutch starts the load earlier than the left crutch. The maximum peak of strength of the left crutch is greater than that of the right, but both coincide in time. Finally, the support time of the crutches is higher than 1 second.

Feedback Mechanism

GCH Control Software gives professionals numerical and graphic information about the loads exerted on the crutches, the precision and homogeneity of these loads, and the simultaneity or balance between crutches. All of these data can be used to assess the subjects' assisted gait and give them oral feedback for correcting their mistakes. The software also includes a useful and feasible feedback mechanism that tells patients directly about their performance and warns them if they make mistakes while walking, which they can then self-correct. For design of the software, the most frequent and efficient feedback methods described in the literature were identified (ie, immediate visual feedback followed by terminal and immediate acoustic feedback [43]), and the most appropriate approaches were selected and implemented in the system's user interface.

We implemented a simple beep as auditory feedback. A high-pitched beep is used when the subject overloads the affected limb, and the most annoying sound is used in this case owing to the clinical risk involved. The beep length must be short enough (ie, 0.3 seconds) to start just after the stand phase (crutch support and foot) ends and before the crutches and the foot next touch the ground. Different alternatives such as line charts, gauge charts, and bar charts were tested. Among them, vertical bar charts were found to be easier to interpret, especially if there are two bars (one for each crutch), which also makes it possible to compare the load amount and simultaneity between the two crutches.

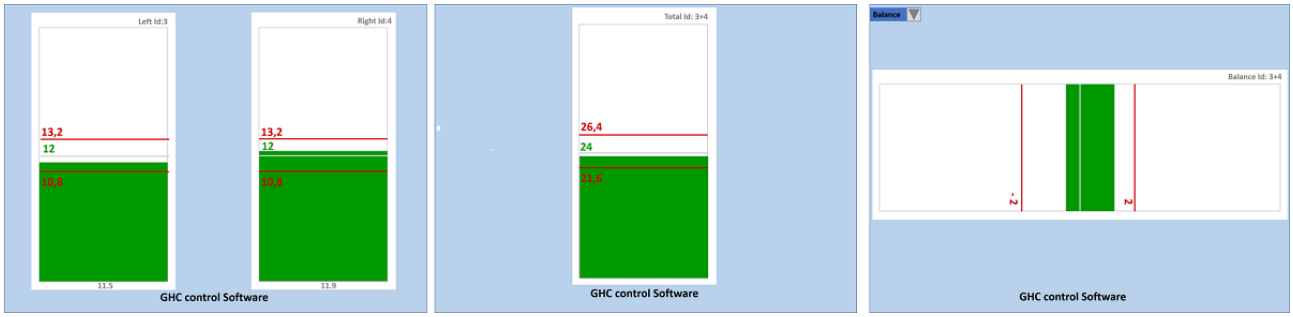
The bar graphs mentioned above are preferably displayed to patients on an extendable screen (Figure 5), using a projector that is large enough to show straight line paths at least 16 meters long (see Clinical Implementation section). The bar graphs are applied one at a time, as each graph is designed to focus the user's attention on the parameter that the physiotherapist considers to be the most necessary. Thus, priority is given to correcting the most serious mistakes first and the least significant mistakes last, until the assisted gait is improved, enabling the subject's functional recovery.

Similar to the graphics that professionals see on the computer, all of the bars feature a green line to show the ideal load recommended by the physiotherapist and two red lines to indicate the minimum required or maximum allowed load (Figure 5). In the first two double-bar and single-bar versions, the bar content turns red when it is outside the tolerated load range or turns green if it is in the correct range. The error beep is therefore only heard when the red color appears to complement the visual feedback.

If a balance bar is displayed, as long as the right and left crutch load balance is maintained, the bar content stays green in the

middle or slightly shifts to the side bearing the most weight (Figure 5), but without exceeding the red lines that show the error tolerance margins. If the margins are exceeded, the bar content turns red and the subject hears a beep. It does not make any sense to use this screen if the assisted gait is one-sided (ie, with only one crutch).

Figure 5. Screenshots of the three possible extendable screens projected in front of patients to show them visual feedback of the loads exerted on the forearm crutches during bilateral assisted walking. From left to right: double bar (one for each crutch), single bar (sum of both crutches), and balance bar (balance between the two crutches). The bars are green in this case because the loads are within the tolerated margins of error. The balance bar shows that the subject is applying more force to the right crutch than to the left crutch, but within the permitted margin of error.



Clinical Implementation

Study Design

Once the desktop software had been designed and developed, and the numerical and graphic measurements had been confirmed in a validation and reliability study [6], a pilot observational descriptive study was performed to obtain preliminary information on the clinical performance of the feedback mechanism implemented by GCH Control Software.

Participants

The sample consisted of 10 participants, including 5 women (50%) and 5 men (50%), with an age range from 21 to 55 years (mean 37.40 years, SD 11.86) and weight range between 52.6 and 81.7 kilograms (mean 64.21 kilograms, SD 9.90), all selected by nonprobability and convenience sampling. Details are given in Multimedia Appendix 2. All subjects had a normal BMI according to the US National Heart, Lung, and Blood Institute.

Inclusion criteria were healthy subjects aged between 18 and 60 years; had previous experience in partially unloading an affected lower limb by bilateral assisted gait with forearm crutches; scoring 3-4 in each of the Chamorro Assisted Gait Scale (CHAGS) items [1] (10 items, 0-4 points each); with normal gait, and asymptomatic when walking at a free cadence; and passing a simple static equilibrium test, consisting of keeping one's balance on each foot for 30 seconds without moving the body [44].

Exclusion criteria were suffering from an evident disorder of overall coordination and physical skill that could alter the aided gait with crutches, or suffering from visual or acoustic disorders that would prevent the individual from receiving biofeedback during the intervention.

This research protocol was approved by the Ethics Committee of Virgen Macarena University Hospital (Seville, Spain). All subjects provided written informed consent before participating in the experimental study.

Measurements and Data Collection

Measurements were taken with GCH System 2.0 [6], and numerical and graphic data were monitored by GCH Control Software. The maximum vertical ground reaction force on the crutches was measured immediately after each support (ie, after each stride). The monitored data were immediately logged in the software database for subsequent use. The pilot implementation was carried out under laboratory conditions.

The subjects walked at a free cadence, taking steps as frequently as they considered most comfortable, along 15.5 linear meters (for a minimum of 10 strides or 20 steps) on an even ground and facing a projector that displayed the image projected on the outward journey (Figure 6). They were asked to walk bilaterally with forearm crutches in two stages [1] to partially unload their previously injured lower limb. In other words, the lower limb to be unloaded is supported by the crutch (if unilateral) or by both crutches (if bilateral) at the same time. Thus, the vertical ground reaction force is applied simultaneously to the sole of the foot and to the crutches so that the subject's body weight is distributed evenly (Figure 7).

When the subjects leaned on the injured lower limb, 50% of the body weight had to be unloaded. In other words, 50% of the ground's vertical reaction force was applied to the crutches. A ±10% load tolerance margin was permitted (±5% of the ideal load). The crutch balance tolerance margin was 5%. For example, the two crutches should ideally bear a weight of 50 kilograms for a patient weighing 100 kilograms, but a 47.5-52.5 kilogram distribution would be considered correct. This is easy to observe in the single-bar graph (which unifies the loads). In the double-bar graph, each crutch should ideally bear 25 kilograms and a 23.75-26.25 kilogram distribution would be considered correct. Furthermore, a difference of more than 2.5 kilograms between the load of one crutch and the other is not allowed in the balance bar.

Participants were allowed to practice for 2 minutes and were reminded of the homogeneous nature of the maximum loads. Since they had mastered this type of walking, no more time was needed to confirm their automation and check that they met the correct CHAGS scale rating [1] (as described above for the inclusion criteria).

Figure 6. User walking toward the screen with double-bar feedback. The aided gait is bilateral (two forearm crutches) with a two-stage partial load (simultaneous heel and crutches support).

Figure 7. Bilateral aided gait with a partial load in two-stages, with simultaneous heel and crutches support.

Users received visual and beep-based acoustic feedback at the same time. The physiotherapist gave no verbal feedback. The 10 participants were assessed to see if they applied the correct or wrong maximum loads requested by the physiotherapist (ie, ideal load) to the forearm crutches during bilateral assisted walking. Each participant took a minimum of four walks. They began each walk with both feet on the same line and then took their first step with the foot to be unloaded together with both crutches simultaneously. Participants performed the first walk (walk 0) without any feedback to obtain capacity baseline data, and then walked three more times with the double-bar feedback (Figure 5). That is, they were warned both visually and acoustically if they applied the wrong load to the crutches immediately at the end of each crutch support. The two independent bars also showed them when the loads applied to both crutches were simultaneous and balanced. Since this can provide too much feedback in some cases, extra walks with other simpler types of feedback (eg, three walks with a single bar or three walks with a balance bar) were applied in line with participants' needs (up to a maximum of 10 walks). The physiotherapist decided who had to continue based on observational assessment and computer screen feedback to

evaluate the tests. The system recorded 10 strides for each walk, or 10 crutch weight-bearing per stride or unloaded step. In other words, for 10 participants×10 loads (crutches)×a minimum/maximum of 4 of 10 walks, there were at least 400 measurements and a maximum of 1000 measurements available for analysis.

Statistical Analysis

The descriptive analysis included the means and percentages of maximum loads applied to the crutches at each support. The Wilcoxon matched-pairs signed-rank test was used to evaluate the load accuracy evolution. The analysis provided the *P* value to evaluate each subject's progress, comparing each of their walks. The practice walks of different subjects were not compared with each other. A confidence level of 95% was considered, and the experimental *P* value was evaluated at a significance level of 5%. The data obtained were organized and analyzed with IBM SPSS statistical software (version 22.0).

Results

Table 1 describes the crutch loads of the first 4 walks (1 without feedback, 2-4 with feedback). Loads are displayed as a percentage of the ideal load requested (50% of each subject's body weight), with the optimum load subsequently set to 100%. The ideal load permissible tolerance was ±10% (ie, ±5%, or a load of 95% to 105%). See Multimedia Appendix 3 for a more general visual presentation of these data.

A total of 96/100 errors were observed in the first walk (walk 0, no feedback), most of which involved crutch overloading by 7/10 subjects (subjects 1, 2, 3, 4, 5, 7, and 9). Errors ranged from 61.09% (subject 8) to 203.98% (subject 1). The loads of subjects 2, 6, and 9 were particularly nonhomogeneous.

The first walk with double-bar feedback (walk 1) began with errors similar to the no-feedback walk errors, generally followed by attempts at correction. Therefore, progress toward the ideal load and fluctuations above and below the optimal load were observed until the optimal load was achieved and maintained as much as possible in the successive walks.

Table 1. Percentage of the loads applied on the crutches during the first 4 walks, with an optimum load of 100% and permitted error range of 95%-105%.

[a]Only for physiotherapist/researcher.

[b]O: overloaded.

[c]U: underloaded.

[d]Correctly applied loads are in italics.

[e]For patients.

Figure 8 presents the number of errors in the loads applied on the crutches in the first 4 walks, distinguishing between underload errors, overload errors, and the total for each subject and walk. The numerical data are shown in Multimedia Appendix 4.

Table 2 and Figure 9 show the mean percentage loads exerted on the crutches in each walk. The optimal load is considered to be 100%, and the error tolerance range (10%) was between 95% and 105%. The mean error table (Table 2) would be meaningless without Table 1 and Figure 8. For example, if a subject makes extreme overload and underload errors, the mean might seem to be within the tolerated range and therefore correct, but it is not. However, if all errors are overload or underload errors, or the loads are homogeneous, the clinical interpretation of the results in Table 2 would be different.

The Wilcoxon matched-pairs signed-rank test, which was used to evaluate each subject's progress, showed significant differences in the reduction of overload errors when comparing the baseline values to each of their feedback walks: walk 0 vs walk 1 (P=.02), walk 0 vs walk 2 (P=.03), walk 0 vs walk (P=.02). However, there were no significant differences in the values of the underload errors. The practice walks of different subjects were not compared with each other. A confidence level of 95% was considered, and the experimental P value was evaluated at a significance level of 5%. The table with all P values is provided in Multimedia Appendix 5.

Figure 8. Graphical representation of the number of errors in the weight supported by the crutches on each walk and per subject.

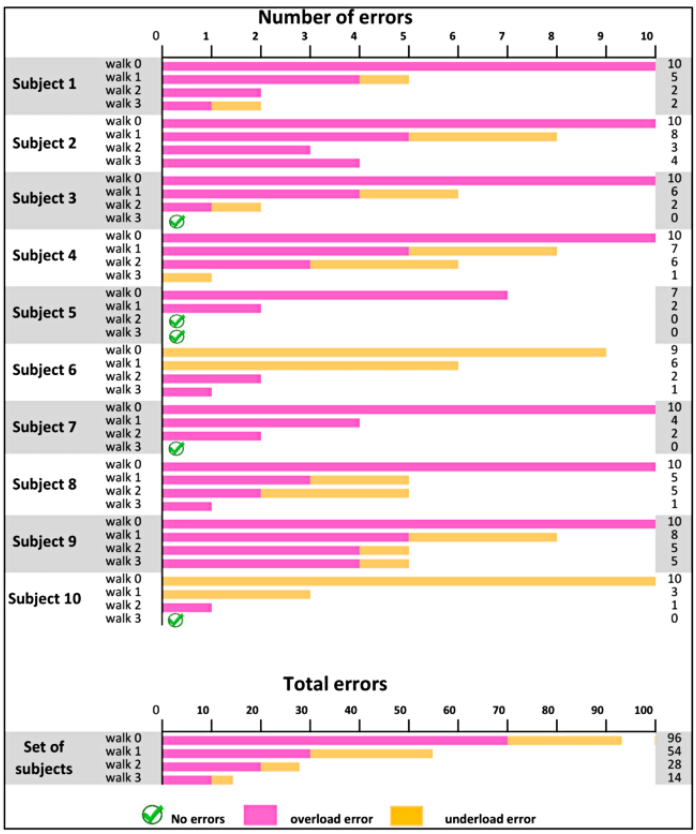

Table 2. Mean percentage (range) loads applied on the crutches during the first 4 walks, with an optimal load of 100% and a permitted error range of 95%-105%.

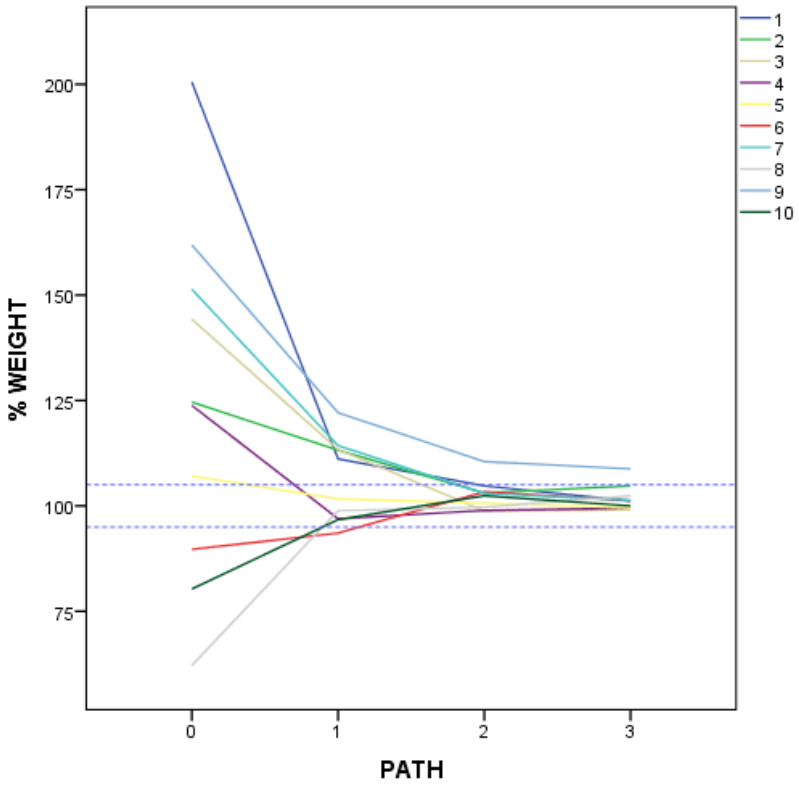
[a]U: underload mean error.

[b]Correctly applied mean loads are in italics.

[c]O: overload mean error.

Figure 9. Line graph representing the mean percentage loads (y-axis) for each subject (different colors) in the 4 walks (x-axis).



The results regarding the right and left crutch load imbalance errors made during the three double-bar walks were as follows: 0 errors for subjects 1, 3, 5, 6, 7, and 10; 1 error for subjects 4 (walk 1), 8 (walk 2), and 9 (walk 1); and 6 fluctuation errors for subject 2 (3 errors in walk 1, 2 errors in walk 2, and 1 error in walk 3).

Subjects 2 and 9 performed extra walks with other types of feedback, namely balance bar and single bar. The research physiotherapist made this decision after noting that these subjects were finding it difficult to achieve their objectives and needed to focus attention on a specific aspect.

Subject 9 performed 2 more walks with the single-bar feedback to focus on the total load, and progressed from 8, 5, and 5 errors in the three double-bar walks (Figure 8 and Multimedia Appendix 4), respectively, to 3 (first single-bar walk) and 1 (second single-bar walk) errors, thereby completing the test.

Subject 2 performed 2 more walks with the balance-bar feedback to focus on the left and right crutch load balance, and progressed from 3, 2, and 1 imbalances with load fluctuations in the three

double-bar walks, respectively, to 2 imbalances with fluctuations (first balance-bar walk) and 0 without fluctuations (second balance-bar walk), thereby completing the test.

Discussion

Principal Results

The innovative multifunctional desktop program GCH Control Software 1.0 monitors crutch loads, which can be controlled by real-time graphic and numerical displays during assisted gait practice. The software contains a versatile feedback mechanism correcting any wrongly applied loads, ensuring greater clinical accuracy. The integrated database can be used not only to objectively evaluate the progress in loads of the subjects but also to comparatively analyze the system's efficiency and draw up clinical action protocols. Moreover, we performed a pilot implementation trial to assess the functionality of the feedback mechanism.

The application environment is basically associated with orthopedics and traumatology [6,38,41,45], and particularly to temporary processes of functional gait recovery of patients with lower limb injuries or surgeries [45] such as ligamentoplasty of the anterior cruciate ligament of the knee [36], a knee or hip prosthesis [21], or a knee osteotomy [40]. In all of these cases, treatment of the lesion starts with no load on the injured limb, which is followed as recovery progresses by partial loads that gradually increase up to a total body weight load. The GCH System is also useful in the fields of gerontology [31,32], neurology [46], pediatrics [46,47], or rheumatology [33], as mentioned earlier. If the applications are extended to these fields where the lesions tend to be chronic, orthotic devices must also be maintained over time [48], increasing the opportunities of using the method. New research prospects providing innovative clinical action protocols for users with disabilities or even normal age deterioration are therefore possible.

This study, like many other research projects [4,15,23,43,49-51], advocates technology and information technology effectiveness in functional recovery processes in general, and specifically in gait. However, effectiveness does not only refer to the intervention itself, in this case based on technological feedback, but also extends to the (global or analytical) initial, continuous, and final assessments of each essential gait parameter [52]. GCH Control Software evaluates the maximum force applied to the crutches in each support and therefore indirectly the unloading of the affected lower limb, which is one of the essential parameters [1,39] in assisted gait with two-stage partial unloading. This peak clinical moment matches the midstance phase of the affected limb (ie, where the limb remains upright and with single stance or without the help of the other limb in the air; midswing phase of the contralateral limb) [53,54]. Unloading relies exclusively on the crutches. The software also monitors if the assistive devices touch the ground at the same time and if their loads are balanced and increase progressively without fluctuations. These data are related to other essential parameters of two-stage gait with forearm crutches, as shown by the CHAGS [1] scale of observational aided gait assessment. Three of its ten load-independent items are directly related to this information: "simultaneous support of both crutches and foot," "step rhythm" (all steps have to be carried out in the same time), and "fluency" (assisted gait is performed automatically, decisively, and without hesitation).

The consequence drawn by the authors is that mutually complementary and objective technological and observational measurement tools need to be applied [55]. Similarly, despite a major goal of technology system-based clinical interventions to offer patients autonomy, they must also rely on the human eye, hands, intuition, and professional decisions [20]. In the specific case of the GCH Control Software feedback mechanism, the physiotherapist's presence is shown to optimize the technology features.

Versatile Feedback

GCH Control Software can be adapted very easily to each patient's specific characteristics, regardless of their main disease, such as their level of coordination skills [56], previous experience [56] in handling forearm crutches, age, and visual or acoustic disorders. This is because the software provides a wide range of extrinsic feedback, ensuring individualized interventions for achieving specific or general therapeutic goals when recovering gait functions. This feedback can be provided to the clinical professional, the user, or both at the same time, although the clinical professional, usually a physiotherapist, receives more detailed and extensive information than the user who is performing a dual task [57], and should only be given very specific feedback in small amounts for the intervention to be effective.

As for the feedback modalities considered (ie, acoustic, visual, and acoustic-visual), patients receive two kinds of acoustic feedback: computer-based verbal feedback from the physiotherapist and the beeps generated by the software. The advantage of the verbal feedback [49] is that the physiotherapist can decide what information to give in line with the patient's needs. This is particularly useful if the subject has poor coordination skills, as noted in the dual tasks [49]. Subjects can be given only information about their results (KR feedback) or also about their performance (KP feedback), and can receive information that only describes a mistake (descriptive feedback) or that suggests the strategy for correcting it (prescriptive feedback). The clinician can also choose between giving the information while the patient is walking (concurrent feedback) or afterward (terminal feedback), and among immediate terminal feedback, delayed terminal feedback, or summary terminal feedback (after several walks). The beeps are immediate terminal feedback, because subjects receive the signal immediately when they begin to take a step using support for the affected limb with crutches. The acoustic signal tells subjects if they have reached the correct maximum load at the end of each support, which is why it is given immediately. However, during free cadence walking [58], steps are taken very quickly, and the period of time between the maximum load and end of the support is too imperceptible so that the signal can be considered a real-time signal, and thus it can be interpreted clinically as concurrent feedback. This is particularly true if the gait is regarded as a cyclical process [59] and each crutch support or step is not assessed independently.

With regard to visual information, the main advantage is its continuity (continuous concurrent feedback) by showing how the loads applied on the crutches steadily increase and decrease in double-bar, single-bar, and balance-bar feedback. Moreover, the double-bar and single-bar feedback show if each crutch support is correct or incorrect (immediate terminal feedback).

The software's multiple independent biofeedback options can be extended by using various combinations of these options. Numerous studies have assessed the effectiveness of various types of feedback [26,27,49,60,61] and their combinations. A recent systematic review [43] of technology-based feedback and its efficacy in improving gait parameters concluded that immediate visual feedback was the most widely used, followed by terminal and immediate acoustic feedback.

GCH Pilot Implementation

In line with several previous studies [11,23,27,51], the results obtained in this study suggest that feedback mechanism–based interventions are satisfactory. The pilot experiment showed that subjects applied significantly more accurate loads on the forearm crutches after only a few minutes, or even a few seconds in some cases. These preliminary data should be confirmed in subsequent longer studies with larger samples. Nevertheless, these findings suggest that interventions are more effective, and even more efficient, owing to the feedback immediacy. Although the participant inclusion criteria were favorable to achieve positive results (ie, all participants had to have experience in two-stage bilateral assisted walking with partial unloading, and their technical gesture had to be acceptable based on a score of 3-4 points for each CHAGS item [1]), only one participant (Subject 5) had previous experience of load measurements, and with the same software.

The crutch load measurements without feedback (ie, walk 0) showed that all subjects made significant overload and underload mistakes (even with twice the requested load). Most of the subjects (7/10) overloaded the crutches, thereby unloading their body weight more than necessary, with associated clinical disadvantages. For example, in older patients with osteoporosis [32,42], unnecessary unloading is not appropriate because it inhibits osteoblastic action and increases osteoclastic action. Even if there is no underlying disease, the tendency is always to use the largest possible weight-bearing load [42], without damaging the injury, to stimulate circulation and muscle tone, and therefore optimize the patient's overall functional recovery. This is why frequent two-stage assisted walking without the injured lower limb touching the ground (foot in the air) is not recommended, unless necessary. The negative clinical consequences of underloading the crutches can be even more severe with certain injuries or types of surgery such as noncemented knee or hip prostheses, osteotomy [40,41], or autologous chondrocyte implantation [62]. In such cases, overloading the injured area can lead to further surgery, longer functional recovery times, or other side effects or sequelae, among other drawbacks [42]. Several subjects (3/10), despite being coordinated and having used crutches previously, made these mistakes constantly without feedback. The case of Subject 10 was particularly interesting, whose technical gesture with homogeneous loads were perfect, and remained well below the requested load on the crutches without feedback. This is a clear example of the usefulness of GCH Control Software, even with skilled and experienced patients.

In the three double-bar feedback walks, maximum crutch load accuracy errors decreased in all participants from the first to the third walk. At the start of the tests, and especially the first test, participants made more mistakes and differences between the requested and applied force were larger. Shortly afterward, the visual and acoustic information provided by the software helped them to adjust the loads. The biggest errors were made during the first walk; however, 3 subjects did not make any mistake in the third walk, and another 3 subjects only made one mistake, representing a minimum difference. One subject did not make any mistakes in the second or third walk. However, two of the subjects did not achieve the expected results in the double-bar walk.

Subject 2 began with very high loads and made 8/10 mistakes in the first walk, which decreased, but to a lesser extent than observed for the majority of participants (ie, 3 errors made in the second walk and 4 errors made in the third walk). During the 3 walks, it was observed that the crutches did not always load evenly, and the right and left bars fluctuated, even though the final weight of each crutch met the requirements (6/30 crutch balance errors). The physiotherapist decided to continue the intervention and apply the third type of feedback (balance bar) to allow the subject to focus their attention on leaning on both crutches at the same time and ensure even crutch loads, regardless of the total amount. As expected, the subject's performance improved remarkably with only one walk, after scoring 3/4 points in the CHAGS scale item on simultaneously using both crutches and the affected limb [1]. Therefore, occasionally, the subject did not meet this goal. The GCH Control Software feedback seems to not only facilitate load monitoring and accuracy but can also detect and correct other erroneous parameters that are equally essential in crutch-assisted gait (eg, leaning on both crutches simultaneously as in the case of Subject 2). This subject is a clear example that technological assessment and feedback (GCH System linked with GCH Control Software), combined with observational assessment and direct feedback from the physiotherapist (CHAGS score), can be used together and in a complementary manner, thereby individualizing each intervention [1].

The number of errors made by Subject 9 dropped in the double-bar feedback walks (from 7 to 5); however, there were still numerous disparate inaccuracies, in line with the prefeedback walk. Nevertheless, the subject maintained the crutch load balance. After analyzing these data, the physiotherapist asked the subject to continue the intervention with the single-bar display, and the subject made only 3 mistakes in the first walk and 1 mistake in the second walk. This improvement was explained by having focused the subject's attention [56] on the total load without displaying independent data from each crutch, which were not necessary in this case. The subject also walked more times and therefore spent more time practicing, which must also be taken into account for interpreting this improvement [56].

At the end of the pilot experiment, the subjects commented that they had been surprised by the difference between how they actually performed and how they thought they had performed. They found the test to be easy, comfortable, and effective. Even those who needed a few extra screens spoke positively about GCH Control Software and GCH System in general. They also stated that despite hearing the acoustic signals, they were generally more aware of the visual signals.

Limitations and Prospects

This study was limited to an extent by the sample size and short duration of the intervention. Longer prospective clinical trials should be performed, with large samples and control groups to ascertain the effectiveness and efficiency of the different types of graphical biofeedback (double bar, single bar, and balance), acoustic feedback (verbal and/or beep), or combined feedback available with GCH Control Software. For example, acoustic feedback using beeps and visual feedback could be applied separately, followed by evaluation of whether (and in which cases) acoustic feedback alone suffices in the long term. As explained earlier, the more options there are, the easier it is to customize or adapt the system to each patient during the treatment, both in line with individual characteristics (eg, coordination) and specific temporary musculoskeletal injuries or chronic situations due to illness or age. Clinical trials are therefore required to address different pathologies and contexts in the various branches of medicine to develop effective clinical action protocols.

Given the rapid progress of information technology, future adaptations of GCH Control Software to new communication systems will be necessary. However, these adaptations would be implemented at the lower levels of the software stack. The way feedback information is presented to patients and physiotherapists would not be affected by these adaptations.

Conclusions

This study describes GCH Control Software, the multifunctional desktop software associated with GCH System 2.0, which measures loads exerted on forearm crutches by patients who need to partially unload a pathological lower limb.

The program graphically and numerically monitors loads in real time during assisted gait interventions, and uses a versatile, efficient feedback mechanism to correct the accuracy of wrongly applied loads. It also shows if subjects use both crutches at the same time in bilateral walking and how evenly they distribute the load between them. The program features a patient and test database that can be used to objectify applied load progress and comparatively analyze the system's effectiveness in different clinical contexts, enabling drawing up clinical action protocols based on scientific evidence.

Satisfactory findings were obtained in the complementary pilot implementation tests of the feedback mechanism functionality. Although an ideal sample was selected, all subjects made errors exerting loads on the forearm crutches during bilateral gait in the baseline test, indicating the necessity or appropriateness of the method presented. They achieved greater accuracy with only one brief session. Although one subject found it difficult to balance the loads between the two crutches and fluidly apply the loads, these issues were ultimately resolved with feedback. However, any clinical data provided herein should be interpreted with caution. Future research should focus on how participants' accuracy changes over several weeks to confirm the findings.

Acknowledgments

The authors would like to thank the Telefonica Chair "Intelligence in Networks" and the "Area of Physiotherapy CTS-305" Research Group of the University of Seville, Spain, for their collaboration.

Authors' Contributions

GC conceptualized the idea for the study and software. GC and JS wrote the Introduction and Methods (GCH Control Software 1.0) sections. GC and VP wrote the Methods (Clinical Implementation) and Results sections. GC and JS drafted the Discussion. GC, JS, and VP critically reviewed the manuscript for important intellectual content. All authors contributed to the final version and approved the final paper for publication.

Conflicts of Interest

Abstract

Background: Advancing the use of genomic data with routinely collected health data holds great promise for health care and research. Increasing the use of these data is a high priority to understand and address the causes of disease.

Objective: This study aims to provide an outline of the use of genomic data alongside routinely collected data in health research to date. As this field prepares to move forward, it is important to take stock of the current state of play in order to highlight new avenues for development, identify challenges, and ensure that adequate data governance models are in place for safe and socially acceptable progress.

Methods: We conducted a literature review to draw information from past studies that have used genomic and routinely collected data and conducted interviews with individuals who use these data for health research. We collected data on the following: the rationale of using genomic data in conjunction with routinely collected data, types of genomic and routinely collected data used, data sources, project approvals, governance and access models, and challenges encountered.

Results: The main purpose of using genomic and routinely collected data was to conduct genome-wide and phenome-wide association studies. Routine data sources included electronic health records, disease and death registries, health insurance systems, and deprivation indices. The types of genomic data included polygenic risk scores, single nucleotide polymorphisms, and measures of genetic activity, and biobanks generally provided these data. Although the literature search showed that biobanks released data to researchers, the case studies revealed a growing tendency for use within a data safe haven. Challenges of working with these data revolved around data collection, data storage, technical, and data privacy issues.

Conclusions: Using genomic and routinely collected data holds great promise for progressing health research. Several challenges are involved, particularly in terms of privacy. Overcoming these barriers will ensure that the use of these data to progress health research can be exploited to its full potential.

Introduction

Background

The progression of genomics in the last few decades has been remarkable. Since 2001, when the Human Genome Project mapped and sequenced virtually every gene in the human genome, genetic sequencing technology has advanced rapidly in both the public and private domains. Next-generation sequencing costs have plummeted by almost 100%, and research opportunities have grown exponentially as a result [1]. For example, a simple search in the medical database, PubMed, shows that research on genomics has more than quadrupled since 2000, from around 340,000 published articles on this topic growing to 1.5 million by 2020. This increase has translated into quicker diagnoses, better outcomes, and more effective health care for patients [2-4]. Great strides have been made in cancer research, for example, where patients are now being treated according to their own or the tumor's genomic data [5].

Being able to use genomic data in conjunction with routinely collected data holds even greater potential to advance knowledge by including factors wider in scope. Precision medicine requires that novel correlations of genotype, phenotype, and the environment be identified to inform new methods for diagnosing, treating, and preventing disease in a way that is responsive to the individual [5]. Knowledge of gene-environment interactions can also contribute on a population level by informing health and public health services in areas such as service planning, population genetic testing, disease prevention programs, and policy development [6]. Routinely collected data, electronic health records (EHRs) in particular, already hold vast amounts of clinical and environmental information on large numbers of people and preclude the need for lengthy and expensive data collection. Adding these phenotypic data to knowledge about a person's genome can elucidate new knowledge, such as that about gene-environment and gene-drug interactions, and can thus provide a richer understanding of health and disease [7].

Increasing the use of genomic data for health research is a high government priority to understand and address the causes of disease. The potential of integrating genomic and routine data sets has been recognized in the United Kingdom by the Welsh Government [8] via their *Genomics for Precision Medicine Strategy* and by Genomics England [9] with the inception of the 100,000 genome project in 2018, both of whom are investigating ways to link genomic data and EHRs. From a more international perspective, the former president of the United States, Barack Obama, launched the Precision Medicine Initiative to improve individualized care by combining genomic data and EHRs with diet and lifestyle information from US citizens [10]. The UK Chief Medical Officer, Dame Sally Davies's "genomic dream" of mainstreaming genomic medicine into National Health Service (NHS) standard care is becoming ever closer, which means that data from a person's genome will likely be directly recorded into EHRs, making this type of research far more accessible [11].

Objective

As this field prepares to move forward, it is important to take stock of the current state of play in order to highlight new avenues for development, identify challenges, and ensure that adequate data governance models are in place for safe and socially acceptable progress. Previous work has examined the benefits and logistical challenges of integrating genomic and routinely collected data in health care practice, but less is known of this specifically in a research setting [6,12,13]. Therefore, our objective is to add to this literature by conducting a narrative literature review and a series of interviews that would provide an outline of the use of genomic data alongside routinely collected data in health research to date. It focuses on the types of data that have been used, the role of routinely collected data in these studies, the data sources, how researchers access the data, and the challenges surrounding their use. This will inform further work in developing a framework for working with genomic and routinely collected data [14].

Methods

Literature Review

First, we conducted a literature search of research that used genomic data in conjunction with routinely collected data. We define routinely collected data as data collected as a matter of course and not specifically for research [8]. Genomic data refer to the data generated after processing a person's genome, in full or in part, for example, by sequencing [7]. Studies were eligible for inclusion if they had used both types of data in combination to answer a health research question. We included studies of any design published in either peer-reviewed journals or gray literature in the English language.

We searched the following databases to identify these studies: PubMed, Ovid, CINAHL, OpenGrey, CENTRAL, LILACS, and Web of Knowledge from inception until January 31, 2019. We also searched for books, gray literature, and websites. We used a piloted search strategy that included keywords representing genetic and routinely collected data, and the following is the search strategy used for PubMed and modified for use with the remaining databases:

1. (Gene OR Genetic* OR Genome* OR Genomic*)
2. (*Administration record** OR Anonymised OR Anonymized OR Anonymisation OR Anonymization OR *Big data* OR *Clinical record** OR *Data linkage* OR *Data mining* OR *Data science* OR *Education record** OR *Ehealth* OR EHR OR *Electronic data* OR *Health record** OR *Housing record** OR Encrypt* OR *Insurance* OR *Linked data* OR *Medical record** OR *Patient record** OR *Prison record** OR *Publically available* OR *Publicly available* OR Register OR Registry OR Registries OR *Routine data* OR *Routinely collected* OR *Safe haven*)
3. #1 AND #2

This search in PubMed resulted in more than 50,000 hits. After initial pilot screenings, for example, by restricting to only publications within the last 10 years, it was clear that, given the number and heterogeneity of potentially relevant articles, neither a systematic review nor a meta-analysis would be practical. We took a pragmatic approach by scanning these articles to retrieve information on the following items until we reached data saturation, when no new information appeared in the text: types of genomic data; types and roles of routinely collected data; data sources; and data access models, that is, how researchers access the data. We chose examples from each criterion to ensure that we included a range of health conditions and presented them in a narrative format, which followed the format of the criteria given above.

Interviews

To understand the use of genomic and routinely collected data in context, we recruited a purposive sample of individuals who have been involved in leading research projects using a combination of genomic and routinely collected data. We identified potential participants from the literature search outlined above and sent 19 interview invitations via email. Reminders were sent after 2 weeks, and if there was no response, we made no further contact. In total, 11 individuals agreed to

participate in either an in-person or teleconferencing interview, depending on their geographical location. Participants were involved with the following projects: the Swansea Neurology Biobank (Swansea, Wales); Dementia Platform UK (Oxford, England); PsyCymru (Swansea, Wales); UK Biobank (Stockport, England); BC Generations Project (British Columbia, Canada); the Province of Ontario Neurodevelopmental Disorders (POND) Network, IC/ES (Ontario, Canada); Electronic and Medical Records and Genomics (eMERGE) Network (Vanderbilt, United States); and the Sax Institute's 45 and Up study (New South Wales, Australia). We omitted any further information on the participants to maintain their anonymity. We developed interview questions with our advisory board: a group of UK geneticists and data scientists who were interested in using genomic data and our discussions centered around these:

1. What is the purpose of integrating the genetic data with health data?
2. What types of genetic data are being included?
3. Were there particular approvals you had to obtain? And if yes, what were these?
4. What were the main challenges encountered?
5. How did you address the challenges?
6. What is your main model for storing these data?
7. What access model(s) do you use? For example, safe room only, remote access, data released externally to researchers;
8. What are the conditions for access to data?

We followed up interviews by email if any answers needed clarification.

Results

Textbox 1 provides a summary of the results of the literature review and interviews. Multimedia Appendix 1 Table S1 [15-32] provides a detailed summary of the results.

We included 19 studies in this literature review that provided broad examples of the different types of genomic and routinely collected data that can be used together to answer a health-related research question. The countries where this research was based were the United Kingdom [15-20], China [21], United States [22-29], Canada [19,30,31], and Australia [32].

Textbox 1. Summary of results.

Type of genomic data

- Single nucleotide polymorphisms
- Polygenic risk scores
- Gene activity scores
- DNA methylation status

Purpose of combining data

- Genome-wide association studies
- Phenome-wide association studies
- Longitudinal studies
- Candidate gene studies
- Gene profiling studies
- Exploratory studies

Types of routinely collected data

- Electronic health records
- Disease registry data
- Disease registries
- Mortality registers
- Deprivation indices
- Health insurance

Role of routinely collected data

- Identifying cases and controls
- Baseline data
- Deep phenotyping
- Long-term follow-up
- Sociodemographic information

Sources of data

- Databanks
- Biobanks

Governance models for data access

- Publicly available on the web
- Released to researchers
- Data safe havens

Challenges

- Data collection
- Data storage and costs
- Technical and/or software issues
- Data privacy and data protection laws

Types of Genomic Data

Examples found of the types of genomic data used in these studies included single nucleotide polymorphisms (SNPs), gene activity scores, and DNA methylation status. The most frequently used were SNPs [16,17,19,23-29], which represent a single base-pair change in the DNA sequence and are highly

granular; hence, they are popular in health research [33]. Research studies tend to refer to SNPs by their reference SNP number, a unique identifier given to a SNP, or a cluster of SNPs by the National Center for Biotechnology (NCBI) [34].

Polygenic risk scores are closely related to SNPs and were used in 2 of the studies included in this review [15,16]. These predict a person's likelihood of developing a particular disease based on the cumulative effect of a number of genetic variants [15]. Our literature search found other instances of quantitative measures of gene activity combined with routine data, including the 21-gene Recurrence Score, which measures the activity of 21 genes (16 cancer-related and 5 reference) for patients with breast cancer [33] and the enzyme activity score for the *CYP2D6* (cytochrome P450 family 2 subfamily D member 6) gene, which codes for an important drug-metabolizing enzyme, and is highly polymorphic in humans [34]. Rusiecki et al [29] measured changes in DNA methylation status in their participants to investigate whether this predicted posttraumatic stress disorder in US military service members.

Purpose of Combining Genomic and Routine Data

Conducting genome-wide association studies (GWAS) [15,17-19,21], phenome-wide association studies (PheWAS) [24,25], and a combination of both [26,27] were the main purposes of combining genomic and routine data. Both these methods use powerful statistical techniques to find associations between genetic variants (SNPs) and phenotypes, which can then be used to predict the genetic risk factors of disease, levels of gene expression, and even social and behavioral characteristics such as educational attainment, impulsivity, and recreational drug experimentation [35,36]. Given the number of tested associations, these studies require large sample sizes to yield enough statistical power to detect differences in genetic variation between cases and controls [37]. Other study designs included longitudinal studies [16,18,30-32], a candidate gene study [23], case control studies [19,29], a gene profiling study [22], and an exploratory study [28]. Each of these studies was designed either to identify genetic risk factors of the disease or to investigate drug safety or efficacy (Multimedia Appendix 1 Table S1).

Types and Role of Routinely Collected Data

EHRs appear to be, by far, the most common form of routinely collected data used in the studies identified in this review. For the type of research discussed here, data in EHRs have been used to identify eligible participants, for phenotyping, and to provide long-term follow-up on specific health outcomes. These data are collected as a matter of course in health care systems, and depending on their country of origin, EHR content can vary, although usually this digital record will include the patient's name, address, demographics, medical history, care preferences, lifestyle information (such as diet, exercise, and smoking status), and free-text notes [38]. An example of EHR data used in the identified studies was the International Classification of Disease (ICD) coding. This allows clinicians to record the status of a patient in a standardized way, whether it is for disease, disorder, injury, infection, or symptoms [39]. Hebbring et al [26] used ICD codes in EHRs to identify appropriate cases and controls for their PheWAS study of the *HLA-DRB1*150* gene involved in immune regulation. Rusiecki et al [29] used ICD codes to identify cases with a postdeployment diagnosis of posttraumatic stress disorder in their study on the link between gene expression and posttraumatic stress disorder in US military service members.

EHRs were also used to describe and validate a phenotype of interest, which is particularly important for PheWAS studies. The large number of phenotypes used in these analyses need to be clearly defined to ensure that any associations made with genetic variants are precise and replicable [40]. For example, Breitenstein et al [23] used EHRs to define the type 2 diabetes phenotype needed for their candidate gene study based on diagnoses, medications, and laboratory tests. The algorithm used to achieve this was developed by the eMERGE Network (see below for more details on this organization) and has been used successfully many times since [41].

In addition to providing a baseline snapshot of the patient, EHRs are also longitudinal in nature, and this makes them ideally placed to provide long-term follow-up to study participants. An example of this is the Genetics and Psychosis (GAP) study, which looked at a purported association between a variant of the *ZNF804A* gene and poor outcomes after first-episode psychosis [20]. Using individual-level linkage between EHRs and genotype data, this study followed the clinical outcomes for 291 patients over a period of 2 years, and subsequently found strong evidence for their hypothesis.

Other examples of routine data used in genomic research include disease registry morbidity and mortality records [20,22]. Disease registries collect information on clinical outcomes and care for a specific patient population over time. EHRs often feed data into these registries, but registry data can also include patient-reported outcomes and other biometric data, and therefore provide a more holistic view of the patient than an EHR would in isolation, for example, the UK MS Register [42]. Routine data sets need not be individual-level or person-based to prove useful in genetic research. A case in point is the Scottish Index of Multiple Deprivation, which gives an indication of a geographical area's socioeconomic deprivation based on data about employment, income, health, education, housing, crime, and access to services [43]. Clarke et al [15] were able to link participants' postcodes to the Scottish Index of Multiple Deprivation and generate socioeconomic deprivation variables to investigate their association with polygenic risk scores for alcohol dependence.

Sources of Genomic and Routinely Collected Data

Overview

Although individual research projects often collect biological samples and generate their own genomic data for combination with routinely collected data [19,29], studies can also make use of the many sources of genomic and routinely collected data already available. Our interview participants spoke to us about the different data sources they used in their research and provided details on the use of these data and the participants of their projects. From this information, there seem to be two general categories of these sources: databanks and biobanks, the former where only the data are stored, and the latter, which

store both biological samples and genomic data. Below are illustrative examples; therefore, this is not an exhaustive list.

Dementias Platform UK

Dementias Platform UK (DPUK) [16] is a data portal funded by the Medical Research Council that hosts the data of 2 million people from over 40 cohorts relevant to dementia research. Combining these data enhances the individual research power of each study and brings together knowledge from a number of stakeholders to facilitate and accelerate new discoveries. Examples of these cohorts are the GENetic Frontotemporal Dementia Initiative (GENFI; genotype data for *GRN*, *MAPT,* and *C9ORF72* genes) and the Genetic and Environmental Risk in Alzheimer's Disease (GERAD) Consortium (whole exome sequences) [16]. Presently, DPUK provides EHR linkage for Welsh participants via the Secure Anonymized Information Linkage (SAIL) databank [44].

UK Biobank

UK Biobank [45] is a national resource with data from 500,000 participants aged between 40 and 69 years who have donated blood, urine, and saliva samples, have undergone a number of baseline measures, and have provided detailed health and behavioral information about themselves. Genomic data are available for 488,000 participants and comprise SNPs, genotypes, and haplotypes. The UK Biobank holds a number of routine data sets, including hospital inpatient episodes, cancer registrations, and deaths. Studies using the UK Biobank genomic and routinely collected data include genome-wide meta-analyses of depression [17] and identifying candidate gene and disease associations that could help predict adverse drug reactions [26].

Personal Genome Project

The Personal Genomes Project (PGP) is a databank founded in 2005 at Harvard University and now extends worldwide. It provides a web-based platform for individuals (over 100,000 people to date) to share their genomic data publicly, along with their EHRs, and other trait information to progress science without many of the governance restrictions of traditional research. Most of the genomic data on the PGP database are in SNP format, although files of raw sequence data are available for some participants [43].

eMERGE Network

The eMERGE Network is a consortium of American medical institutions whose goal is to use EHR data in combination with a variety of genomic data types to advance translational research. The network also releases its genomic data, including GWAS, whole genome, and whole exome sequence data, along with a subset of phenotypic elements to the broader community of researchers via the dbGaP—an NCBI [46] database of genotypes and phenotypes. Through this mechanism, any research project can be applied to the uploaded data. A wealth of publications have resulted from eMERGE's work; these are available to view on the web [24,25,47].

POND Network

The POND network is an IC/ES [31] initiative based in Ontario, Canada, and involves a cohort of children and young people (the total number of the sample is approximately 3000) with a neurological development disorder, with a particular focus on autism. This is a highly phenotyped cohort with all participants having undergone multiple clinical tests, including those for attention-deficit/hyperactivity disorder, obsessive-compulsive disorder, and family history and demographic data. A subset (n=667) provided consent for linkage with administrative data held in IC/ES via health card numbers. The aim is to identify subgroups of autism based on the co-occurrence of other developmental conditions, other comorbidities, and health service use, and to characterize these groups based on clinical attributes and genomics. The network data are project-level only, although it is anticipated that linkage of genomic data to administrative and health data will become more routine in the future.

BC Generations Project

The BC Generations Project [48] is British Columbia's (BC) largest ever health study and is part of a national initiative—the Canadian Partnership for Tomorrow Project—to aid researchers in answering questions about how environment, lifestyle, and genes contribute to cancer and other chronic diseases. Almost 30,000 participants were involved in the project, and they provided baseline information about their health, diet, lifestyle, and medical and family history. Many have also donated blood and urine samples, and the type of genomic data generated from these samples is based on the needs of the researchers (subject to approval). The BC cohort is one of several provincial cohorts that can be combined for national studies or can be linked to provincial administrative data via PopDataBC [49].

Sax Institute and the 45 and Up Study

Based in Australia, the main business of the Sax Institute is to manage the *45 and up* study, which has been following 260,000 people for over 12 years who provide both routinely collected and self-reported health data [32]. The aim of this study was to collect samples from 50,000 individuals for full genome sequencing. The Sax Institute has a partnership with the Garvan Institute of Medical Research [50], which acts as a genome sequencing facility and makes data available for research subject to approval. The Garvan Institute retains all the genomic data, but with data linkage to the Sax Institute.

Data Governance Access Models

Overview

We surveyed the data access models and information governance systems of genomic and routine data sources identified by our literature search and interviews. From the additional information given to us by our interview participants, we were able to categorize data access models as follows: (1) publicly available on the web, (2) released to researchers, or accessed via a (3) data safe haven.

Publicly Available on the Web

There are a wealth of free, genomic data sources on the web, made available because of individual projects or from the pooled results of a variety of different projects. These data are either downloadable or viewable on the web. For this type of resource, data tend to be at the gene or variant level (eg, GIANT Consortium [51]; GWAS Catalog [52]), but some do hold

individual-level data, eg, Database of Genomic Variants [53]. The Personal Genome Project, described above, is the only data source that provides identifiable, individual-level genomic data [43]. All other data were deidentified.

Released to Researchers

Currently, the most common way for genomic data to be accessed for research is through secure electronic file transfer to the researcher. This generally occurs after successful application to an internal review board (IRB) and signed data use agreement (DUA). All of the published research studies identified by our literature search used this model, unless the genomic data were generated specifically for that particular project. For instance, Cronin et al [24] received genomic data regarding 54 SNPs, and also demographic, vital sign, and billing data derived linked EHRs by the eMERGE network. Other biobanks using this model include Mayo Genome Consortia [23], China Kadoorie Biobank [21], UK Biobank [17,26], BioVu [24], and Generation Scotland [17], although access to BioVu data is only granted to Vanderbilt faculty members [54]. In addition to IRB and DUA procedures, the use of individual-level EHR data supplied by Generation Scotland also requires an application to the NHS Research Ethics Committee [55].

Data Safe Havens

The use of large-scale population data in health research has become increasingly popular in the last few decades, and this has seen the evolution of data safe havens as a way to ensure its safe and secure use. Lea et al [56] defined data safe havens as a system that invokes procedural, technical, and physical controls, including access to data within a secure environment (rather than data release), in order to safeguard the identities of people providing the data. Despite there being a greater tendency in the literature for releasing data to researchers, we have seen from our work with interview participants, a trend toward using a data safe haven system for both younger and more well-established organizations.

The PsyCymru study [18] and the Swansea Neurology Biobank [19] have deposited polygenic risk scores and SNPs, respectively, into the SAIL Databank [44], a data safe haven based at Swansea University. The SAIL Databank provides remote access to many linkable anonymized data sets, and both of these studies have used SAIL to link their genetic data and other phenotypic data to EHRs and other routinely collected data. These data are available only for project access, and currently cannot be shared. However, their intention is to make linked genetic and routinely collected data available for research in the near future [57,58].

The Sax Institute operates in a similar way to the SAIL Databank in that it provides access to genomic and health data via a virtual lab by remote access anywhere in the world. Data access requires approval by two data access committees: one at the Garvan Institute and one at the Sax Institute. The BC Generations Project said, “should the researcher access the project’s data via PopDataBC then they would only be allowed to use the data on within the secured research environment” (Participant 5, BC Generations Project).

For the UK Biobank, the current *modus operandi* releases anonymized data externally to researchers. However, they stated that this is unlikely to be sustainable because genomic data files are too large. The UK Biobank will likely be changing to a remote access model in the near future. The eMERGE Network also confirmed that they are experimenting with remote access into a data safe haven. One of our participants who used IC/ES data explained that “as the data are considered highly sensitive, access is only by an ICES analyst, with results provided to the project lead” (Participant 4, IC/ES).

Challenges

Combining genomic and routine data does not come without its challenges. Our participants, who are currently working with these data, spoke to us about these different challenges during their interviews, and their experiences are summarized below.

Data Collection

A challenge described by several participants concerned data collection. Conducting long-term follow-up over long periods and at regular intervals means that participants need to be invited and reconsented to provide more blood and other health information. In addition, poor quality sequence alignment could render the samples useless, and with repeated use by researchers, blood samples will eventually become exhausted. Each of these issues necessitates a lengthy and expensive process of resampling thousands of individuals and imposes a burden on participants. A possible solution to this, as one participant suggested, is to “join up with others biobanks in order to work towards epidemiologically valid sample sizes” (Participant 1, 45 and Up Study)

Data Storage and Costs

Genomic data are huge, approximately 90 GB for the raw data of 1 whole genome, and this is often the source of technical issues surrounding its use [59]. One participant told us that their main challenge was data storage capacity and that “it may no longer be cost or space efficient for organisations to hold multiple datasets” (Participant 2, UK Biobank). They go on to explain that there is certainly a case to be made for storing genomic data as VCF files only, which keep record only of gene sequence variations and are much smaller and easier to work with. However, this restricts the type of analyses possible, particularly in the advent of new discoveries about the anatomy of the genome. There may be a need to find solutions regarding storage space for raw genomic data and for specialist platforms required to conduct analyses.

Technical and/or Software Issues

Many of the challenges faced by participants working with these data are technical in nature. Participant 3 (eMERGE) described creating a sequencing platform from the ground up, which was much longer than initially projected. Furthermore, they described that multiple sequencing centers needed harmonization, as well as the needs across sites and projects for network-wide data collection. Another participant found difficulties surrounding analysis software and analyst capacity, since this is a very specialized skill (Participant 4, IC/ES). Researchers often conduct genetic data analysis using publicly available, downloadable software applications, which are subject to

frequent updates for improvements. This is a challenge to incorporate this software and keep it up to date. Several other participants spoke of similar software issues. Potential solutions discussed during our interviews were to upscale and have dedicated servers for genomic data, as well as to install specialist toolsets within the secure research environment.

Data Privacy and Data Protection Laws

Given the possibility of identifying individuals from genomic data [60], privacy is of primary concern. We were told that, for one research project using IC/ES data (Participant 4), the privacy approval group was concerned about identifiability due to the genomic data being unique, particularly where there are rare variants. This means that the genomic data contained in variant call files have been brought into the databank to show the feasibility of transfer but has to be integrated into the analytical platform.

The General Data Protection Regulation [61] in the United Kingdom states that if researchers are to rely on the lawful basis of consent to process medical genomic data, the reasons for doing so must be described in an explicit and transparent way. The rapid decrease in the cost of whole genome sequencing in the last few decades has opened many new avenues for genetic research, but this means that it is impossible to predict what this research will actually look like in the future [55]. One participant felt that this means they would need to seek consent from the participant for each new research proposal [62], rather than just once when their sample was taken. They expressed concerns that "continued and lengthy re-contact with participants was not only costly and difficult, it may also be invasive and burdensome" (Participant 11, Swansea Neurology Biobank). Also mentioned was Canada's antidiscrimination laws (Bill S-201: Genetic Nondiscrimination Act) to avoid prejudice on the grounds of genetics (including insurance and employability) [63] (Participant 5, BC Generations Project). Several participants believed that the public acceptability of their work was important, but they "weren't sure how to go about ensuring it" (Participant 7, Dementia Platform UK).

Discussion

Principal Findings

Using genomic and routinely collected data holds great potential for health research. The genomic data we identified in our literature review included SNPs, polygenic risk scores, and gene activity scores. Routine data primarily consisted of EHRs, but we did find other routine data types including registry data and deprivation indices that had been combined with genomic data. This paper shows how genomic research has progressed in recent years—from basic GWA and PheWA studies—to more complex methodologies in which health records are linked to genomic data at the individual level. Associations between genetic variants and phenotypes, identification of drug targets, knowledge about drug toxicity, and effectiveness can all be studied from the combination of genomic and routine data and leveraged for public benefit.

The EHRs created during routinely collected care provide the large sample sizes needed for GWAS analysis without the need for costly and time-consuming prospective data collection. These larger samples allow for greater validity, generalizability, and yield adequate statistical power, while also minimizing participant burden and reducing attrition during follow-up [64]. In addition, these data sets are not limited to a circumscribed number of phenotypes in the way that a traditional research study might be [40]. This richness and diversity of EHR data means that the large number of phenotypes used in PheWAS can be very clearly defined (referred to as deep phenotyping), which enhances the accuracy of phenotype-genotype associations [40].

Most importantly, with regard to EHRs, perhaps, is the additional information that routinely collected data provide about an individual's environment. This can include lifestyle factors, education, work history, pollution, and even traumatic events. Genetic determinism has long been rejected, and we now widely accept the powerful influence that lifestyle and the environment have on the way that our genes are expressed [65-67]. Precision medicine requires novel correlations not only between genotype and phenotype to be made but also with an individual's environment to inform new methods for diagnosing, treating, and preventing disease in a way that is tailored to that individual. Linking genomic data to routine data promises to elucidate important findings for precision medicine research, which will enable researchers to understand the relationship between an individual's genome and their complete life course [68]. More of these types of studies are needed for precision medicine to reach its full potential, to make the intricate genotype-phenotype associations needed to advance the understanding and treatment of disease.

From our interviews, we identified 3 main ways that researchers can access genomic and routine data: publicly available on the web, released to researchers, and via a data safe haven. We also observed that biobanks and databanks seem to be moving toward renouncing a data release model and instead favoring a data safe haven approach. Aside from potentially solving data storage issues, this will also help assuage privacy and governance concerns. Reidentification and disclosure from genomic data is possible [69,70] and can lead to many undesirable consequences: discrimination by health or life insurance companies, societal stigma, and the discovery of a genetic predisposition to a condition when one does not want to be told. This is complicated further because of the familial nature of genes, and disclosure could cause some devastating effects for biological relatives as well [71-73].

Despite this, we must keep in mind that simply because genomic data are unique, this in itself does not render it identifiable. Rather, the reidentification risk of genomic data depends on the way they are accessed, the type of analyses that are conducted, and the format in which the results are finally published [70]. This means that decisions to use certain data access models based on practicality and decreased costs are not sufficient. Genomic research relies heavily on human participation, and the public should be consulted to inform the way in which their data are accessed [74]. There is a plethora of activity taking place to consult the public about health research in general, and the success and acceptability of large-scale data research is owed, in part, to the extensive public engagement activities that

have been taking place [75,76]. Organizations such as the Global Alliance for Genomics and Health [77] are engaging with the public on the use of genomic data in research, but there is still more work to be done regarding the use of genomic and routinely collected data [78].

Limitations

This review was not intended to be exhaustive or systematic; therefore, it does not include all health research studies that have used genomic and routinely collected data. We also excluded biobanks and databanks that do not house routine data; therefore, we only include examples here. This may have resulted in inadvertently excluding some countries and institutions where this research takes place and the types of genomic and routinely collected data that have been used. Not implementing systematic methods in study selection may have introduced bias in this review's conclusions; however, the pragmatic approach used here was deemed sufficient to meet our objectives.

We included 19 studies in this review, only one of these involved data and research from a non-Western country (China) [21]. We did not come across any research that had taken place in low- to middle-income countries, although as this review was not conducted systematically, we may have unintentionally overlooked these. However, the absence of any studies from such countries may be, as Tekola-Ayele and Rotimi [79] explain, a result of having a limited number of well-trained genomic scientists and poor research infrastructure, and due to a less well-established routine data collection infrastructure and procedures such as EHRs [80].

Qualitative interviews may be subject to recruitment bias, which means that some viewpoints and experiences were excluded. In addition, there is limited information about participants; however, as this is a relatively small field of research, it was deemed necessary to maintain participants' privacy.

Conclusions

Given the projected increase in the availability of genomic data, the potential to be obtained from its combination with routine health data is vast. This review has shown examples of what has been done in this field so far with, for example, GWAS and PheWAS plus other study designs. For fields such as pharmacogenomics, these methodologies need to be used further, where using routinely collected data will simplify the process of tracking longer-term outcomes of personalized medical treatments, and elucidate new findings on the effects of the environment on drug-gene interactions. Our take away from this study is that there are several challenges involved in using these data, particularly surrounding privacy. Therefore, it is imperative that appropriate data governance be documented and that public engagement activities take place to ensure socially acceptable practices. Overcoming these barriers will ensure that the use of these data to progress health research can be exploited to its full potential.

Abstract

Background: Urinary tract infections (UTIs) are one of the most common conditions in women. Current information on the presentation, management, and natural course of the infection is based on paper diaries filled out and subsequently posted by patients.

Objective: The aim of this study is to explore the feasibility of a smartphone app to assess the natural course and management of UTIs.

Methods: A smartphone app was developed to collect data from study participants presenting with symptoms of UTI in general practice. After initial demographic and treatment information, symptom severity was recorded by the patient after a reminder on their smartphone, which occurred twice daily for a period of 7 days or until symptom resolution.

Results: A total of 181 women aged 18-76 years downloaded the smartphone app. The duration of symptoms was determined from the results of 178 participants. All patients submitted a urine sample, most patients were prescribed an antibiotic (163/181, 90.1%), and 38.7% (70/181) of the patients had a positive culture. Moderately bad or worse symptoms lasted a mean of 3.8 (SD 3.2; median 4) days, and 70.2% (125/178) of the patients indicated that they were cured on day 4 after consultation. This compares with other research assessing symptom duration and management of UTIs using paper diaries. Patients were very positive about the usability of the smartphone app and often found the reminders supportive. On the basis of the feedback and the analysis of the data, some suggestions for improvement were made.

Conclusions: Smartphone diaries for symptom scores over the course of infections are an efficient and acceptable means of collecting data in research.

Introduction

Background

Urinary tract infections (UTIs) are one of the most common conditions for which women consult their general practitioner (GP) [1]. More than half of the women consult their GP for a UTI at least once in their lives [2,3].

UTIs are considered self-limiting infections [4,5], but antibiotics are generally prescribed empirically [6-8]. The prescription of antimicrobials for UTI accounts for a substantial amount of prescriptions in primary care and contributes to an increased risk of adverse drug effects, the burden of resistant infections [9,10], and increased costs [11]. In women presenting in primary care with suspected UTI, which turned out to be susceptible to the antibiotic prescribed, the duration of more severe symptoms was 3.3 days on average [2]. However, the duration increased to 4.7 days for women with resistant infections and 4.3 days for women with symptoms but no significant bacterial growth (urethral syndrome) [2]. An international comparison of the presentation and management of UTI in four European countries found wide differences in management, with antibiotics prescribed for 59%-95% of the presenting women; however, there were no differences in the time taken to resolve moderately bad to worse symptoms, which took a median of 4 days [12].

All studies reporting on the management of UTI base their findings on the use of paper diaries, which are provided to women at the time of consultation and are requested to be returned by post after symptoms are resolved [5,13-15]. Such diaries are also used in UTI trials where antibiotic treatment is compared with symptomatic treatment for UTI in general practice [16,17].

In one observational study that recorded the natural course of UTIs, 64% of the symptom diaries were recovered [2], and in another observational cohort of four countries, 70% of the diaries were recovered [18]. A Danish study observing the effect of point-of-care testing for UTI recovered 85% of the patient diaries [19]. All of these studies have used additional resources to contact patients and urge them to post their diaries.

Compliance with paper diaries has been compared with electronic diary keeping for patients recording pain three times daily for 21 days. The difference between electronic and paper recording was analyzed, and the results showed a high level of feigned compliance in the use of paper diaries [20]. Different versions of electronic diaries have been piloted and tested in various environments to record symptoms, such as in inflammatory bowel disease [21], overactive bladder [22], and asthma [23].

Smartphone apps are increasingly used in care innovation research and provide new opportunities to develop interventions [24]. In pain settings, apps have been most widely used to record diary entries both in observational [25] and clinical trial settings [26]; however, apps have also been implemented for other conditions [27-29]. In these studies, smartphone diaries have been shown to be highly efficient and generally perform better than paper-based diaries.

In our own SIMPle (Supporting the Improvement and Management of Prescribing for UTI) study, we used an observational study to follow patients with UTI using a smartphone app [30]. The results of this feasibility study showed that a smartphone app was well received and that once a patient committed to reporting their symptoms, they would continue doing so for the duration of the study [31].

Objective

The objective of this study is to develop and evaluate the feasibility of a smartphone app to assess the natural course and management of UTIs.

Methods

Aim

This study explored the feasibility of a smartphone app to assess the natural course and management of UTIs in women presenting in primary care and to document the outcomes of urine culture, antibiotic resistance of bacterial growth, and antibiotic prescription using a smartphone app with reminders for data collection.

Design

This study is an observational feasibility study of women presenting with symptoms of UTI.

Setting and Participants

Between November 2018 and December 2019, 6 GPs in the west of Ireland enrolled adult female patients with symptoms of UTI. After obtaining consent, the patient received a patient number, which was texted to a central number to record the patient's phone number, and a link to download the app was returned. Both patients and practitioners received a payment for each download of the smartphone app.

Follow-up

A telephone call was made to all patients on days 4 and 28 (or as soon as possible after this day). The aim of the day 4 phone call was to confirm the symptom score. In addition, information on adverse events, experience using the app, and return consultation with a GP were recorded.

Smartphone App

A smartphone app was developed to collect data from the participants (Figure 1). At enrollment, patients were requested to record demographic information (age, recent UTI, marital status, children, and medical card) as well as treatment details (antibiotic treatment: yes or no, name of antibiotic, and duration).

Figure 1. Smartphone app.

To record the severity of symptoms, patients received a reminder twice a day, once in the morning at 9 AM (or 10 AM and 11 AM if no entry was made) and once in the afternoon at 6 PM (or 7 PM and 8 PM if no entry was made). Patients were reminded to provide their symptom score for 7 days and, if no recovery occurred, up to 14 days or until symptom recovery. Symptom recovery was defined as a score of <2 (moderate) for each symptom.

Symptom severity included four symptoms: dysuria (painful and/or burning urination), frequency of urination, urgency of urination, and lower abdominal pain. Symptoms were scored from 0 (not at all) to 4 (as bad as it gets). An additional question—*Do you feel cured?*—was included after the symptom score to allow comparison with a Scandinavian trial in which this was the main outcome score [32].

On days 0 and 5, patients were also asked to fill out a UTI-related questionnaire on impairment to daily life activities on the Activity Impairment Assessment (AIA) [33] as well as self-rated health in general and on the particular day (on a visual analog scale from 0 to 100) [34]. The AIA is a five-item questionnaire that assesses the amount of times an individual's work or regular activities has been affected because of their UTI. Patients respond to the AIA items on a five-point Likert scale, with the response options *none of the time*, *a little of the time*, *some of the time*, *most of the time*, and *all of the time*. The questions were as follows: did you have to cut down on time at work, could you accomplish less, were you limited in the kind of work you did, did you have difficulty performing work, and did your UTI interfere with social activity?

Sample Size

Considering a mean difference of half a day clinically significant, a sample of 92 patients (α=.05 and β=.2) should detect such a difference in the mean duration of symptoms (score moderate or worse on the four items: dysuria, frequency of urination, the urgency of urination, and lower abdominal pain [5]) of 3.8 (SD 3.0) on day 4.

Data Analysis

The duration of symptoms included the day the patient consulted their GP. The mean duration of symptoms was based on the day their mean total symptom score was moderately bad or worse and similarly for the duration of each symptom separately. The mean duration to cure is based on a yes answer to the question *Do you feel cured?* Symptom resolution was based on the day that all symptoms were 0. As the app was filled out for a duration of 7 days, the return of symptoms within the 7 days was included in the duration of symptoms. The end of symptoms was also indicated on the first day when a patient ceased making any more entries.

Antibiotic prescriptions were recorded on the day of the consultation, and patients were asked every day if they were still taking the antibiotic. The antibiotic prescribed was assessed retrospectively in the context of the microbiological culture results to assess if the organism tested was susceptible to the antibiotic chosen empirically.

Urethral syndrome was defined as having symptoms of suspected UTI, with no significant bacterial growth detected on culture [2].

Analysis was performed using STATA 13.0 (StataCorp LLC) and IBM SPSS, version 26. Tableau was used to visualize the data.

Laboratory Analysis

Urine samples were collected from each patient. Samples were sent to the Microbiological Lab of the University Hospital Galway for analysis. A positive sample was based on a colony count of >10,000 cfu/ml pure growth observed after overnight incubation on chromogenic agar. Mixed growth was also recorded and included for further analysis. Organisms detected in pure culture were identified by matrix-assisted laser desorption ionization–time of flight (Bruker). Susceptibility testing was performed using the EUCAST (European Committee on Antimicrobial Susceptibility Testing) disk diffusion methodology and interpretive criteria.

Ethical Approval

Ethical approval was obtained from the Irish College of General Practitioners. Individual informed consent was obtained from all participants before enrollment in the study. Consent had to be confirmed at registration when downloading the smartphone app.

Availability of Data and Materials

Access to anonymized patient data can be obtained from the corresponding author upon request. The code for the smartphone app can be obtained from the corresponding author and used freely if referenced appropriately.

Results

Overview

A total of 181 patients downloaded the smartphone app. Their mean age was 29.7 (SD 14; median 22, range 18-76) years. Of the women, 28.1% (51/181) were married or in a relationship, 69.1% (125/181) did not have children, 18.2% (33/181) had one or two children, and 12.7% (23/181) had three or more children. More than one-third (67/181, 37%) of the patients were entitled to free medical and GP care, whereas 62.9% (114/181) had to pay for their GP visit as a private patient. Of the participants, 65.7% (119/181) had or were pursuing a university degree and 34.2% (62/181) had secondary education. A total of 39.8% (54/181) were working, 6.1% (11/181) were homemakers, and 54.1% (98/181) were students.

Of the 181 patients, 3 never filled out any symptom score, whereas all others provided at least one symptom score. On day 4, 39 did not provide a symptom score, but 13 of them provided one on the previous day.

Of the 181 patients, 163 (90%) were prescribed an antibiotic. Nitrofurantoin was most frequently prescribed (66.3%, 108/163), followed by trimethoprim (20/163, 12.3%), co-amoxicillin (11/163, 6.7%), amoxicillin (8/163, 4.9%), fosfomycin (5/163, 3.1%), and quinolone (2/163, 1.2%).

The question that was asked at every entry, that is, if they took their antibiotic or if they used any pain medication, was filled out irregularly and could not be analyzed.

Symptom Duration

Symptoms started on average 5.6 days (SD 6.3) before they consulted their GP, with a median of 4 days (IQR 5). The mean duration of symptoms after they consulted their GP was 4.2 days (SD 3.0) and the mean time to cure (indicated by the patient) was 3.8 days (SD 3.2). Table 1 and Figure 2 show the mean duration of moderately bad or worse symptoms in more detail. The most common symptom rated moderately bad or worse on the first day was the urgency of urination (114/178, 64%), followed by frequency of urination (110/178, 61.8%), lower abdominal pain (98/178, 55.1%), and dysuria (71/178, 39.9%); the duration of each symptom is shown in Multimedia Appendix 1. There were no significant differences between the types of UTI and if an antibiotic was prescribed or not. An overview of the percentage of patients who indicated that they felt cured each day since the consultation is presented in supplementary Figure 2. Overall, 70.2% (125/178) of patients indicated that they felt cured on the fourth day after consultation (day 5), and this was 71.8% (115/160) among those who had an antibiotic prescribed.

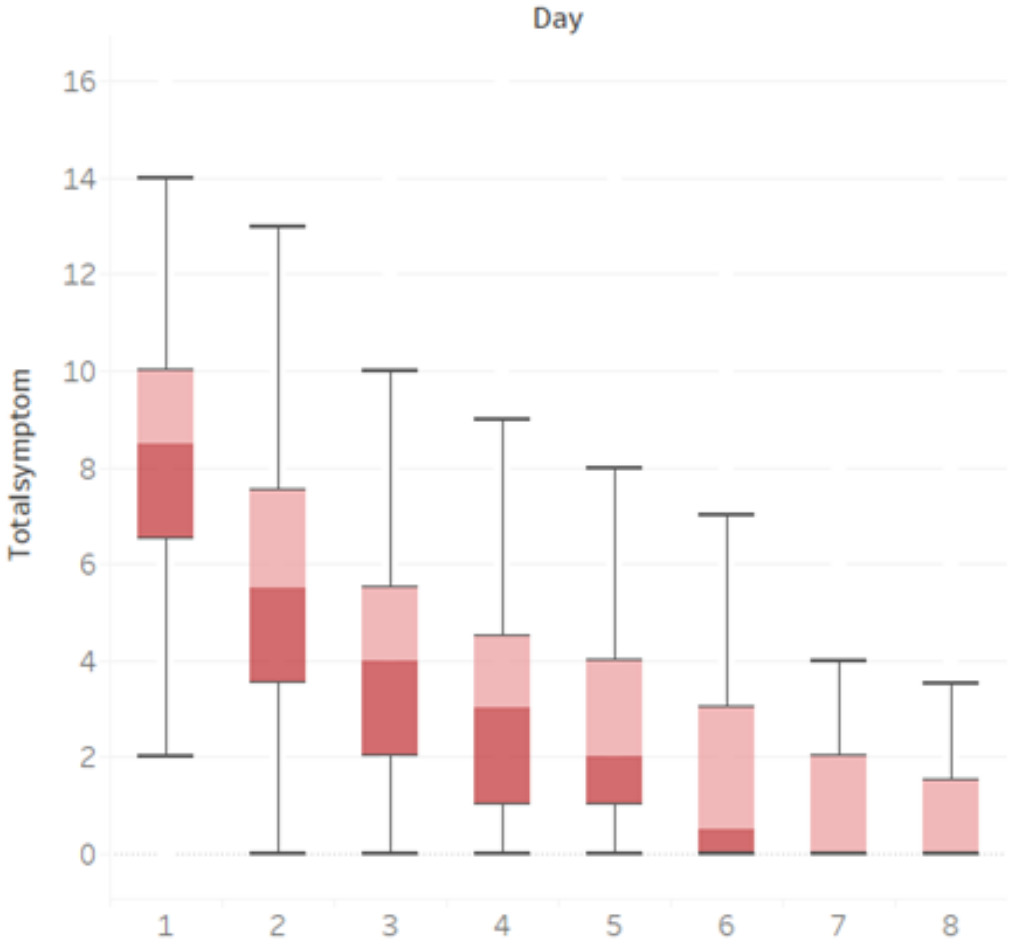
Table 1. Mean (SD) and median of the duration of symptoms according to urinary tract infection type and antibiotic prescription (N=178).

Variables	Symptoms	Dysuria	Frequency of urination	Urgency of urination	Lower abdominal pain	Resolution	Cured
Duration (days)							
Value, mean (SD)	4.2 (3.0)	2.0 (2.6)	2.6 (2.6)	3.0 (2.9)	2.9 (3.3)	10.7 (20.9)	3.8 (3.2)
Value, median	4	1	3	2	2	6	3
UTI [a] type, mean (SD)							
UTI sensitive to AB[b] (n=36)	4.7 (3.5)	3.0 (0.6)	3.1 (3.3)	3.5 (3.5)	3.7 (3.6)	13.4 (26.3)	3.5 (3.1)
UTI resistant to AB or no AB (n=7)	5.0 (2.7)	3.6 (3.6)	3.4 (2.1)	3.4 (2.5)	3.0 (2.9)	6.3 (4.0)	4.3 (4.1)
UTI unknown sensitivity (n=26)	3.4 (1.8)	1.7 (1.6)	1.7 (1.2)	2.4 (1.7)	2.0 (1.9)	5.4 (2.2)	3.2 (2.0)
No significant bacterial growth (urethral syndrome; n=92)	4.3 (3.2)	1.6 (2.1)	2.8 (2.7)	2.9 (2.9)	3.1 (3.5)	12.0 (23.2)	4.1 (3.5)
Antibiotic, mean (SD)							
Yes (n=160)	4.3 (3.0)	2.0 (2.5)	2.7 (2.6)	3.0 (2.9)	3.0 (3.2)	10.3 (20.4)	3.8 (3.2)
No (n=18)	3.4 (3.5)	2.3 (3.6)	2.2 (2.6)	2.9 (3.5)	2.2 (3.6)	10.4 (22.3)	4.2 (3.6)

[a]UTI: urinary tract infection.

[b]AB: antibiotic.

Figure 2. Total symptom score by day. Each box represents the interval of 50% of the symptom scores, with the difference in color at the mean score. Whiskers indicate the range of the symptom score on each day.



Overall, 90% (163/181) of patients had moderate to worse dysuria for 4 days or less, 85.1% (154/181) had a frequency of urination, 81.2% (147/181) had the urgency of urination, and 66.9% (121/181) had lower abdominal pain. Overall, symptoms lasted 4 days or less for 56.9% (103/181) of the patients after seeing their doctor (Multimedia Appendix 2).

Microbiology

Overall, 38.7% (70/181) patients had a positive culture. Enterobacteriaceae (mainly *E. coli*) were cultured from 27.6% (50/181) of patients, followed by *S. saprophyticus* from 5.5% (10/181) of patients. A total of 17.7% (32/181) were mixed cultures and 12.2% (22/181) were <10,000 cfu/ml. Resistance to at least one of the tested antibiotics was recorded in 61% (33/54) of isolates for which this could be assessed. Comparing the antibiotic prescribed with the isolate and its resistance showed that 55% (36/66) of the isolates tested were susceptible to the antimicrobial prescribed, whereas for 41% (27/66), this was not known. For 3 patients, the cultured organisms tested resistant to the antibiotic prescribed. One of these patients was contacted to change the antibiotic (from co-amoxyclav to nitrofurantoin).

AIA and General Health

Little difference was observed for the AIA score (Table 2); the mean AIA score on day 0 was 6.6 (SD 5.0), and on day 5, it dropped to 4.1 (SD 4.6). A paired two-sided *t* test of patients providing a score on both days showed significance (P=.03), and patients were asked to rate their general health on day 0 (mean 75.6, SD 17.3) and day 5 (mean 76.3, SD 18.2; Figure 3). Their health was rated at 55.8 (SD 20.1) on day 0 and 71.9 (SD 19.0) on day 5. The difference between their rated health on days 0 and 5, as well as the difference in overall health, was significant. On day 5, their health scores were still significantly different from the overall health scores, but the overall health scores on days 0 and 5 were not statistically different.

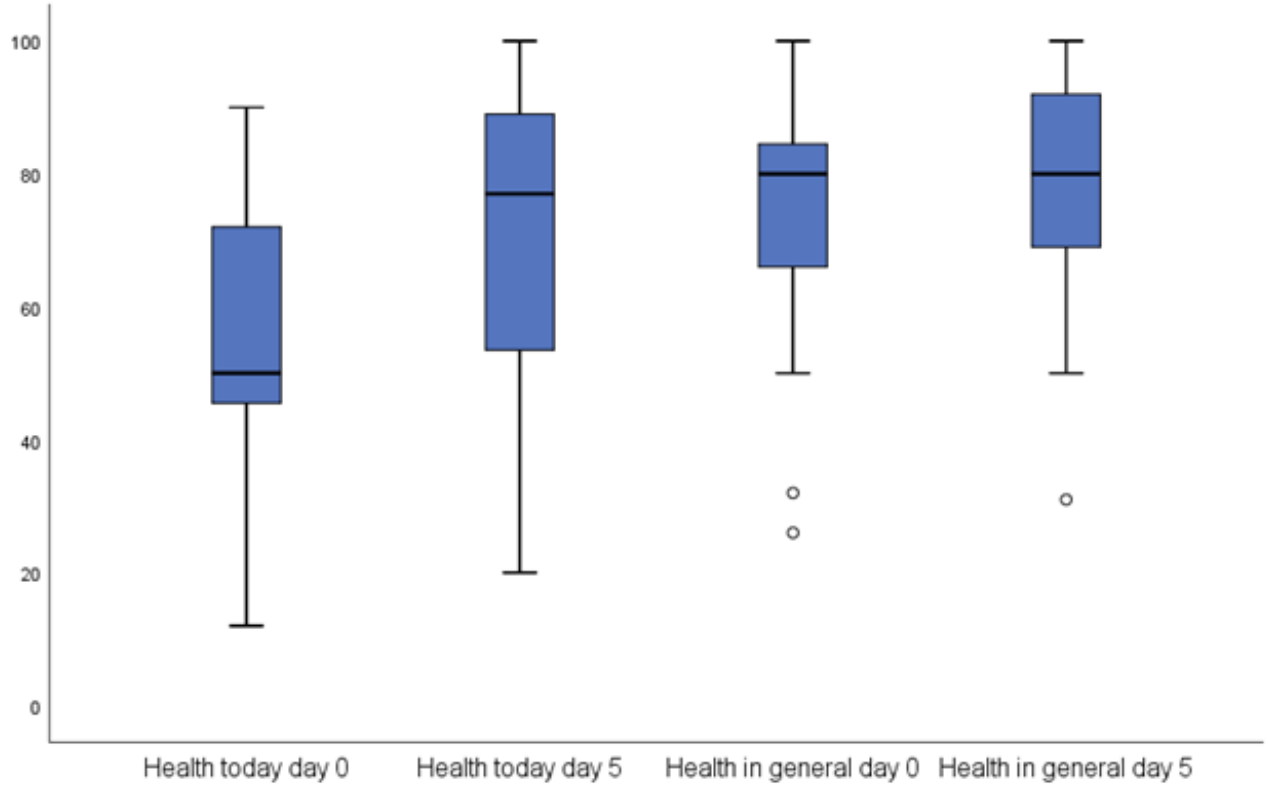
The total symptom score on day 0 was correlated with the AIA (R^2=23%) and similarly with the health score (17%) on day 0 and day 5.

Table 2. Overview of the Activity Impairment Assessment (urinary tract infection–related questionnaire on impairment in daily life activities on the Activity Impairment Assessment) and self-rated health in general and on the particular day (on a visual analog scale from 0 to 100).

	Day of consultation (n=111), mean (SD)	Day 5 (n=96), mean (SD)
AIA[a] item		
Cut down on time at work	0.95 (1.2)	0.6 (1.0)
Accomplished less	1.5 (1.2)	0.8 (1.0)
Limited in type of work	1.2 (1.2)	0.7 (1.0)
Difficulty performing work	1.4 (1.1)	0.8 (1.0)
Interfered with social activity	1.6 (1.2)	1.1 (1.2)
Total AIA score	6.6 (4.9)	4.1 (4.6)
Health score in general	76 (17)	76 (18)
Health score today	56 (20)	72 (19)

[a]AIA: Activity Impairment Assessment.

Figure 3. Health score indicated on a sliding scale (0-100) answered for the questions how is your health today? and how is your health in general on day 0 and day 5. The box represents 50% of the answers, whereas the whiskers cover 100% of the answers. The line in the box represents the mean score. Outliers are indicated by the dots.



Associations

There was no difference in duration of symptoms, total symptom score on the day of consultation, AIA, and health status on the day of consultation between those who did and did not go to university or between students and nonstudents. Only the total symptom score was significantly higher (P=.03) for those not in a relationship compared with participants who were married or with a partner, but no other differences were observed. Age was not correlated with any outcome (duration, total score, days with symptoms before consultation, health score, or AIA).

Day 4 and Day 28 Phone Call

A call was answered by 152 participants on day 4, and 128 patients answered on day 28.

On day 4, 39.8% (71/178) indicated that they felt cured, compared with 70.2% according to the app data. A comparison showed that 67.7% (103/152) indicated the same on the call as they did on the app, 3.9% (6/152) indicated that they were cured over the phone but not on the app, and 41/152 (26.9%) said they were cured in the app but not when asked over the phone. The total symptom score on day 4 according to the phone call was 3.8 days (SD 3.5) according to the call and 2.6 days (SD 2.6)

according to the app, which was significantly different, that is, symptoms were rated more severe when asked over the phone.

When asked about side effects, 28.9% (44/152) reported side effects from the medication. The main side effects recorded were stomach upset or diarrhea (17/152, 11.2%) and thrush (4/152, 2.6%), and 18 did not specify any side effects, and five reported urine discoloration (all patients reported that they had received nitrofurantoin).

Of the patients who answered a call on day 28, 25% (32/128) consulted the GP again for symptoms of UTI during the 28 days after the initial consultation. Patients who consulted their GP had significantly (P=.006) higher symptom duration (5.7 days, SD 4.3 vs 3.9 days, SD 2.6) but no difference in symptom score on the day they consulted. There was no difference in antibiotic or painkiller prescription between those who did and did not reconsult. Patients who reconsulted were significantly older (mean 35.9, SD 17.8 vs mean 27.9, SD 12.4). On day 5, the AIA score (6.9% vs 2.9%) was significantly higher, and the health score (59.7% vs 75.1%) was significantly lower for those who reconsulted.

Evaluation of the App

On the day 4 call, 116 patients provided further comments on their UTI and/or the use of the app, whereas 128 patients provided further comments on their UTI and/or the use of the app on day 28. In general, the comments were positive. Some patients liked the fact that the app reminded them of their medication and improvement of their symptoms:

> *Handy for reminding in morning and evening to take my medication and think about my symptoms more and if they were improving or not.*
>
> *App was good as made me check in with myself, showed me how it was a recovery process.*
>
> *App was good, not time consuming, interesting for herself to track day to day feelings.*

Overall, the app was received well:

> *App was good, quick and easy to use.*

However, a few comments were made in relation to the repetition of questions:

> *Felt like they were the same questions over and over again.*

Discussion

Principal Findings

It was shown that the use of a smartphone app to track patients' symptoms of UTI is an efficient and effective approach to replace paper diaries. Our estimates of the mean and median duration of symptoms from the date of the consultation were 4.2 days and 4 days, respectively. This is comparable with the observations made in previous studies of the natural course of infection in which paper diaries were used [2,12]. However, the mean and median duration of individual symptoms were rated lower in the app than in the paper diaries from both studies. Comparing our results with other trials using paper diaries showed a mean duration of moderate to worse symptoms at 4.6 days [16] compared with 4.3 in our study. The *do you feel cured* question as the main outcome in the Scandinavian trial was also included in our study; 74% indicated cured on day 4 after the consultation when taking the antibiotic, whereas in our study, 71.8% indicated cured in the group where an antibiotic was prescribed. In general, the outcomes are similar to the outcomes of other studies. The main difference and challenge in comparing different studies and trials is the day on which outcomes are measured, that is, whether this includes the day of consultation or not. Inclusion of the method of measuring in a core outcome set for UTI should be clearly defined [35].

UTIs are considered self-limiting infections [4,5], but antibiotics are generally prescribed empirically [6-8]. The prescription of antimicrobials for UTI accounts for a substantial number of prescriptions in primary care, contributing to an increased burden of resistant infections [9,10] as well as increased costs [11]. Our study showed that 90% of the patients presenting were prescribed an antibiotic, of whom 81.6% received a first-line antibiotic [8]. Only 38.7% of the patients had bacteriological confirmation of UTI. Very similar figures of prescribing were confirmed in Wales, England, and Spain, whereas the Netherlands showed much lower prescribing (59%); however, confirmed UTI was approximately 17% in Wales and England, 42% in Spain, and 64% in the Netherlands. Although more literature is emerging suggesting that symptomatic treatment of UTI is often sufficient and acceptable [16,17], most GPs are hesitant to do so. Compared with the last 10 years, GPs are prescribing more in line with guidelines. In 2010, in a study conducted in the same region, findings suggested only 26% GPs prescribing a first-line antibiotic [7]. The efforts made since then to decrease the use of co-amoxyclav in general practice and encourage the use of (first line) prescribing guidelines seem to be having an effect [30,36].

Our overall AIA score on the day of the consultation was 6.6 and 4.1 on day 4, compared with the trial of Gagyor et al [16], in which 8.9 and 1.1 were recorded, respectively. However, it is unclear why such large differences were observed. The validation of the AIA score showed a total score of 7.6 on the day of consultation, which is still higher than our finding, but they do not provide a follow-up score [33]. The inclusion of the health score might better measure general well-being on the day of the consultation, and it shows high concordance between the general health score on day 0 and day 4. This general health score may provide a better insight into the severity of the UTI and its impact on well-being.

The day 4 phone call was included to see how the smartphone scores compared with the answer provided over the phone, and 39.8% indicated that they felt cured, compared with 70.2% indicating to be cured when recorded on their smartphone. The total symptom score according to the app was also lower than that according to the phone call. Again, it is not clear why people report lower scores on the app than on a phone call.

During the follow-up period, 25% reported a reconsultation and 28.9% reported side effects of some sort, which is in line with the reported reconsultations in the four-country study.

In relation to the use of a smartphone app to collect data and considering the comments as well as the analysis of the data, a number of conclusions can be made (Textbox 1).

Textbox 1. Conclusion made based on the use of a smartphone app to collect data, comments, and analysis of the data.

Conclusions

- A smartphone app is an efficient and effective tool for collecting real-time data in research on infections.
- Our app asked for daily scores twice, which were decided to capture differences between morning and afternoon scores. Many did not fill out the app twice a day, and those who did, did not show major differences between morning and afternoon. It also introduced an additional step in the analysis, using the mean score for the day, or if only one score was provided, to use this score.
- Patients were interested and committed to using their app at the start of the study. At this stage, a few additional questions could be included to improve its use:
- The app should request at the start what time of the day is most convenient to fill out the app. This should then be the trigger for the reminder on the phone to fill out their app.
- Type and duration of antibiotic prescribed: On the day after their course is intended to finish, patients can be asked if they have any medication left. This would avoid repeatedly asking if they had taken their antibiotic.
- For painkiller use, this should only be included if it is part of particular interest to the main research question.

Strengths and Limitations

To our knowledge, this is the first prospective study to describe the natural course of a UTI using a smartphone app. Smartphone apps are frequently used for chronic conditions, where patients have more time and are not in distress when asked to enroll in a study. The acceptability and ease of use of the smartphone app have been shown for both patient use and completeness of data. However, participants may have been selectively rather than randomly invited to participate, but no reliable logs of potentially eligible patients were retained. We encouraged GPs to enroll any age group, and the age range (18-76 years), clearly shows that age was not a limitation to participate in our study. The overall mean age of participants was, however, younger than previous studies by our group, in which the mean age was 56.1 years (SD 20.7), and is probably due to the inclusion of a student GP center for enrolment of patients [30]. In the pilot study of our smartphone app to record symptoms of UTI, we found GPs to favor inviting younger patients to participate, which we subsequently and in this study, aimed to avoid by asking GPs to include all ages [31]. The restrictions to enrollment are most likely because of the additional time necessary to consent patients to the study, particularly as UTI consultation is usually considered straightforward and short.

A few questions arise with the results obtained, particularly in relation to discrepancies between phone call scores and smartphone scores from the same day. Other research into the course of infections using a smartphone app may be performed in the future, which may shed more light on this. However, no other study has identified the use of smartphones for infection symptom scores, so our findings could not be confirmed. However, the similarities between our outcomes and those of studies with paper diaries are encouraging. In particular, for trials where consent will be required anyway, smartphone diaries may be considered in the future, which could significantly reduce the energy and time spent to collect outcomes after a patient leaves the practice.

Conclusions

Smartphone diaries for symptom scores over the course of infections are an efficient and acceptable means of collecting data in research.

Acknowledgments

Funding was obtained as part of the SATIN (Symptomatic Versus Antibiotics Treatment of Urinary Tract Infections in Women) which was a work package of the Irish Primary Care Clinical Trials Award from the Health Research Board, Ireland (CTN-2014-011). The authors thank the members of the SATIN steering committee and the Clinical Research Facility Galway for their input in the early development of the smartphone app. The authors would like to thank the GP practitioners and the patients who participated in the study.

Authors' Contributions

AV designed, managed, and supervised the study; performed the statistical analyses and interpretation; and wrote the manuscript. KF and RF organized GP and patient enrollment; collection of smartphone data; and follow-up phone calls. DH and USF provided the microbiological information. MC provided support during the design of the study, helped to interpret the results, and corrected the manuscript. All authors read the drafts of the manuscript and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Electronic patient-reported outcome (ePRO) systems for symptom monitoring in patients with cancer have shown quality of life and survival benefits in controlled trials. They are beginning to be used in routine oncology practice. Many software developers provide software solutions for clinicians, but how should clinicians decide which system to use? We propose a synthesis of the main questions regarding the effectiveness, safety, and functionality of an ePRO system that a clinician should ask software providers to assist in the selection of a software product in order to obtain the best value tools for their patients and their practice.

(J Med Internet Res 2021;23(9):e30549) doi:10.2196/30549

KEYWORDS

ePRO; cancer; remote monitoring; quality; effectiveness; security; digital monitoring; digital health; cancer patients; patients with cancer; oncology

Background

Electronic patient-reported outcome (ePRO) systems for symptom monitoring of patients with cancer have had demonstrated quality of life and survival benefits in controlled trials (Table 1). They also result in a reduction of emergency hospitalization and have favorable cost-effectiveness and clinical utility; in addition, users have good perceptions of ePRO systems [1-9].

The practical integration of these ePRO systems into patient care is increasing and the positive results of trials have contributed to their increased use. The organization of medical teams is challenging because it requires the presence of a nurse dedicated to initial alert management and a dedicated time for the physician to respond to the alert.

It is challenging for clinicians and patients to identify systems that will add value to patient care in real life because the number of ePRO tools available is rapidly increasing, making it difficult for physicians to choose just one.

Table 1. Randomized studies of remote monitoring of patients with cancer by electronic patient-reported outcome systems.

Authors	Number of patients	Indications	Questionnaires used	Multicentric trial	Type of cancer	Improved outcome
Basch, 2017 [1] and 2016 [9]	766	Toxicity monitoring	NCI-CTCAE[a]	No	All	Quality of life, survival, reduced emergency use
Mir, 2020 [2]	609	Toxicity monitoring	PRO-CTCAE[b]	No	All	Dose intensity
Basch, 2020 [3]	1191	Toxicity monitoring, follow-up, supportive care	PRO-CTCAE	Yes	All	Quality of life, symptom control
Absolom, 2021 [4]	508	Toxicity monitoring	NCI-CTCAE	No	All	Quality of life, symptom control

[b]PRO-CTCAE: Patient-Reported Outcomes version of the Common Terminology Criteria for Adverse Events.

[c]SDS-15: Symptom Distress Scale-15.

[d]ESAS: Edmonton Symptom Assessment System.

Many criteria can be used to select ePRO systems, although there is little scientific literature focused on ePRO systems in oncology. However, some criteria on effectiveness, security, and functionality are usually included in telehealth or digital therapeutics assessments [10-12].

In general, ePRO systems must meet specific criteria for both the patient's and clinician's benefit. Here, we propose some questions that physicians may direct toward system providers to help them choose a relevant ePRO software.

Effectiveness Criteria

1. Notifications must be sent to the medical team. This factor appears to be more important than sending a notification to the patient on their smartphone and allowing them to call the medical center. This was included in randomized studies of ePRO systems for patients with cancer [1-9].
2. The solution must be a medical device with quality marking such as a Class II CE mark [13-15]. This ensures that the product complies with the essential requirements of the relevant European Union legislation in which all devices must be evaluated for clinical efficacy and any side effects, if applicable, by means of preclinical and clinical evaluation. As ePRO systems are Class IIa medical devices, manufacturers must provide full quality assurance such as product and postmarket surveillance (materiovigilance) to obtain conformity. The management of materiovigilance is included in Class IIa CE marking and is mandatory.
3. The solution must use validated algorithms. This validation aims to assess reliability and the performance of algorithms in detecting events; algorithms' performance should be published in journals [1-9,16,17].
4. The solution should contain algorithms that allow adverse events monitoring of the main drugs used in oncology (ie, chemotherapy, immunotherapy, hormonotherapy, targeted therapy, radiotherapy) [1-6,8,16,17].
5. As early supportive care improves survival in oncology, the solution should contain algorithms to detect symptoms that make a patient eligible for early supportive care [3,5,6,18].
6. The solution should allow for follow-up of the patient to detect complications or symptomatic relapse early, which improves clinical utility and patient outcomes [3,7].
7. Clinicians should use solutions with up-to-date algorithms, especially for patients receiving therapies such as maintenance or long-course treatment. As the main new drugs (eg, immunotherapy or targeted therapies) have only been widely used for fewer than 5 years, solutions using algorithms older than this should be avoided. This is mandatory for Class IIa CE marking of medical devices [13-15].
8. Validated questionnaires such as the Patient-Reported Outcomes version of the Common Terminology Criteria for Adverse Events (PRO-CTCAE) items from the National Cancer Institute or the Edmonton Symptom Assessment System (ESAS) should be used in the patient questionnaire. The PRO-CTCAE measurement system was developed to capture symptomatic adverse events in patients in cancer clinical trials and is now recommended for ePRO remote monitoring of symptoms because it evaluates the symptom attributes of frequency, severity, and interference. It has also been linguistically validated in more than 30 languages [3,19]. ESAS is one of the most used patient-reported outcome scales for symptom assessment in palliative care and oncology in the past 25 years. Although it only uses unidimensional scales to assess symptom intensity, ESAS has been psychometrically validated, has been translated into numerous languages, and is freely available. A change

of one point was found to be the optimal cutoff for both improvement and deterioration for all 10 symptoms included in ESAS using a sensitivity-specificity approach. As it enables rapid, pragmatic assessment of multiple symptoms simultaneously, ESAS is used extensively in the clinical setting for symptom screening and monitoring worldwide. However, it cannot be used to monitor all treatment toxicities because only 10 symptoms are assessed; the ESAS does not include digestive symptoms (eg, vomiting, diarrhea), cutaneous symptoms, fluid retention (eg, edema), or sepsis. However, its routine use was associated with a 6% increase in 1-year overall survival in a retrospective matched cohort study of 128,893 patients [20-22].

Safety Criteria

1. A real-life study assessment of the solution should be done to confirm that performance and compliance are in line with that reported in premarket studies and to assess the postmarket security of the solution. It is especially important to assess the satisfaction of patients in a real-life study [13].
2. In Europe, the solution must comply with the General Data Protection Regulation (GDPR) that protects and secures patient data. Data protection regulations strengthened the management of alerts and the security of data transmitted to the medical team [23].
3. Oncologists should avoid a solution that allows clinicians to set alert thresholds themselves because the lack of data about the safety and reliability of modified thresholds can result in physician responsibility if a patient experiences an adverse event (eg, following a false negative event).
4. Solutions that allow the creation of "homemade" algorithms should be avoided for the same reasons as described in the previous point.
5. Oncologists should avoid solutions developed by software providers about which a critical security alert was issued by health authorities (eg, risk of a serious adverse event due to critical software dysfunction). Many countries are already publishing these notifications on their health agency's portal (eg, the French national health security agency [24]).

Functionality

1. As not all patients have smartphones, the software should allow for the sending of forms by mail or SMS text message to patients [3].
2. The software must allow different health professionals (physicians and nurses and their colleagues) to manage notifications [3].
3. There should be one software for all major cancers, covering the entire course of treatment (active treatment and surveillance) to avoid the use of multiple software for one patient. This would reduce the technical burden placed on professionals and result in higher levels of satisfaction among patients and health professionals in routine use [3].
4. A single software containing an all-in-one algorithm enabling the detection of toxicities, follow-up management, and supportive care should be prioritized to avoid the use of multiple software with different algorithms. Too many different rules triggering notifications to physicians reduce understandability among users [3].
5. A free-text window triggering notifications when used should be integrated into the patient form to improve communication of other symptoms that are not present on the form or to allow patients to ask health professionals questions [3,7].
6. A software that allows the integration of patient reports into the electronic health record of the health center would be useful to improve the care team's management of notifications [4].
7. A software that contains cancer patient education modules would assist in optimizing treatment tolerance and compliance [25].

These criteria are summarized in Figure 1.

As ePRO systems will become a standard of quality of care for patients with cancer, the use of these solutions will increase, but their efficacy, security, and functionality should be warranted by the software providers to give the same benefit to real-life patients to allow reimbursement for these tools by health authorities.

Figure 1. Criteria synthesis of ePRO systems for remote monitoring of patients with cancer by oncologists. EMR: electronic medical record; ePRO: electronic patient-reported outcome; ESAS: Edmonton Symptom Assessment System; PRO-CTCAE: Patient-Reported Outcomes version of the Common Terminology Criteria for Adverse Events.

Must have	To be privileged if has	Better if has	Avoid if
Validated algorithms in published trial	All-in-one algorithms (toxicities, follow-up, and supportive care algorithms)	Cancer patient education module	Oncologists can personally set alert thresholds
Class IIa CE marking	One software for all cancers, encompassing the full course of treatment (active treatment and surveillance)	EMR integration	Software developer had a critical security alert issued by health authorities in the past 3 years (eg, serious adverse event due to software dysfunction)
Notification management for physicians and nurses	Adverse events monitoring algorithms for main therapies		Algorithms >5 years without update
Complies with General Data Protection Regulation	PRO-CTCAE / ESAS items		"homemade" algorithms
A single instrument for all types of cancer	Free-text window triggering notification when used		
	Follow-up algorithms		
	Supportive care algorithms		
	Real-life study validation		
	Option to send patient form via mail or SMS text message		

Acknowledgments

No one received compensation for their contribution. We thank Professor Claire Snyder, PhD (Johns Hopkins School of Medicine) and Professor Ethan Basch, MD, MSc (The University of North Carolina at Chapel Hill) for their relevant suggestions.

Authors' Contributions

All authors contributed to the critical revision of the manuscript.

Conflicts of Interest

Abstract

Background: Research on the integration of artificial intelligence (AI) into community-based primary health care (CBPHC) has highlighted several advantages and disadvantages in practice regarding, for example, facilitating diagnosis and disease management, as well as doubts concerning the unintended harmful effects of this integration. However, there is a lack of evidence about a comprehensive knowledge synthesis that could shed light on AI systems tested or implemented in CBPHC.

Objective: We intended to identify and evaluate published studies that have tested or implemented AI in CBPHC settings.

Methods: We conducted a systematic scoping review informed by an earlier study and the Joanna Briggs Institute (JBI) scoping review framework and reported the findings according to PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analysis-Scoping Reviews) reporting guidelines. An information specialist performed a comprehensive search from the date of inception until February 2020, in seven bibliographic databases: Cochrane Library, MEDLINE, EMBASE, Web of Science, Cumulative Index to Nursing and Allied Health Literature (CINAHL), ScienceDirect, and IEEE Xplore. The selected studies considered all populations who provide and receive care in CBPHC settings, AI interventions that had been implemented, tested, or both, and assessed outcomes related to patients, health care providers, or CBPHC systems. Risk of bias was assessed using the Prediction Model Risk of Bias Assessment Tool (PROBAST). Two authors independently screened the titles and abstracts of the identified records, read the selected full texts, and extracted data from the included studies using a validated extraction

form. Disagreements were resolved by consensus, and if this was not possible, the opinion of a third reviewer was sought. A third reviewer also validated all the extracted data.

Results: We retrieved 22,113 documents. After the removal of duplicates, 16,870 documents were screened, and 90 peer-reviewed publications met our inclusion criteria. Machine learning (ML) (41/90, 45%), natural language processing (NLP) (24/90, 27%), and expert systems (17/90, 19%) were the most commonly studied AI interventions. These were primarily implemented for diagnosis, detection, or surveillance purposes. Neural networks (ie, convolutional neural networks and abductive networks) demonstrated the highest accuracy, considering the given database for the given clinical task. The risk of bias in diagnosis or prognosis studies was the lowest in the participant category (4/49, 4%) and the highest in the outcome category (22/49, 45%).

Conclusions: We observed variabilities in reporting the participants, types of AI methods, analyses, and outcomes, and highlighted the large gap in the effective development and implementation of AI in CBPHC. Further studies are needed to efficiently guide the development and implementation of AI interventions in CBPHC settings.

KEYWORDS

artificial intelligence; machine learning; community-based primary health care; systematic scoping review

Introduction

The use of artificial intelligence (AI) in primary health care has been widely recommended [1]. AI systems have been increasingly used in health care, in general [2], given the hope that such systems may help develop and augment the capacity of humans in such areas as diagnostics, therapeutics, and management of patient-care and health care systems [2]. AI systems have the capability to transform primary health care by, for example, improving risk prediction, supporting clinical decision making, increasing the accuracy and timeliness of diagnosis, facilitating chart review and documentation, augmenting patient–physician relationships, and optimizing operations and resource allocation [3].

Community-based primary health care (CBPHC) is a society-wide approach to primary health care that involves a broad range of prevention measures and care services within communities, including health promotion, disease prevention and management, home care, and end-of-life care [4]. CBPHC incorporates health service delivery from personal to community levels and is the first and most frequent point of contact for the patients with health care systems for patients in many countries, including Canada [4]. In addition to providing comprehensive health care and its importance within healthcare systems, CBPHC has also been identified as essential in formulating evidence-informed public health policies [5]. Given the growing role of primary health care and CBPHC in our society [6], it is important to develop strategies that address the limitations of the existing health care system and enhance the overall quality of care delivered alongside all other aspects of CBPHC. This includes efforts for reducing the growing health care burden of CBPHC providers as well as the burden of chronic diseases, decreasing rates of misclassification and misdiagnosis, reducing cases of mismanaged diseases, and increasing accessibility to care [7-17].

Indeed, integration of AI into CBPHC could help in a variety of ways, including identifying patterns, optimizing operations, and gaining insights from clinical big data and community-level data that are beyond the capabilities of humans. Over time, using AI in CBPHC could lessen the excessive workload for health care providers by integrating large quantities of data and knowledge into clinical practice and analyzing these data in ways humans cannot, thus yielding insights that could not otherwise be obtained. This will allow health care providers to devote their time and energy to the more human aspects of health care [18]. Several studies have reported early successes of AI systems for facilitating diagnosis and disease management in different fields, including radiology [19], ophthalmology [20], cardiology [21], orthopedics [22], and pathology [23]. However, the literature also raises doubts about using and implementing AI in health care [24,25]. Aspects including privacy and consent, explainability of the algorithms, workflow disruption, and the “Frame Problem” that is defined as unintended harmful effects from issues not directly addressed for patient care [26].

Despite the potential advantages, disadvantages, and doubts, there is no comprehensive knowledge synthesis that clearly identifies and evaluates AI systems that have been tested or implemented in CBPHC. Thus, we performed a systematic scoping review aiming to (1) summarize existing studies that have tested or implemented AI methods in CBPHC; (2) report evidence regarding the effects of different AI systems’ outcomes on patients, health care providers, or health care systems, and (3) critically evaluate current studies and provide future directions for AI-CBPHC researchers.

Methods

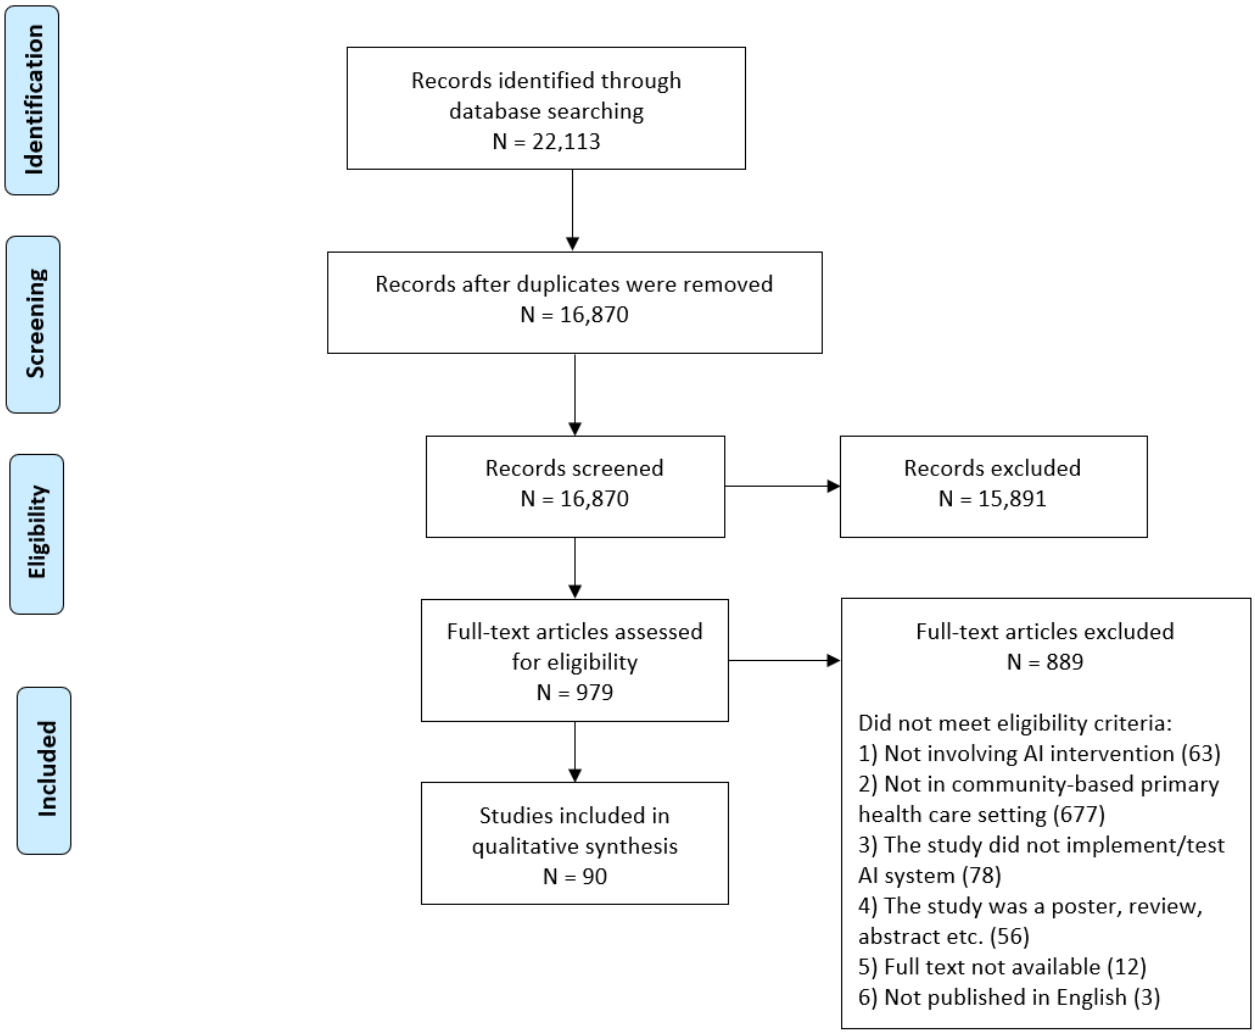
Study Design

Based on the scoping review methodological framework proposed by Levac et al [27], and the Joanna Briggs Institute (JBI) methodological guidance for scoping reviews [28], we developed a protocol with the following steps: (1) clarifying the purpose of the review and linking it to a research question, (2) identifying relevant studies and balancing feasibility with breadth and comprehensiveness, (3) working in a team to iteratively select studies and extract their data, (4) charting the extracted data, incorporating a numerical summary, (5) collating, summarizing, and reporting the results, and (6) consulting the results regularly with stakeholders throughout regarding emerging and final results. This protocol is registered and

available on the JBI website and the Open Science Framework (OSF) websites. We completed this review as per the published protocol.

We formed a multidisciplinary committee of experts in public health, primary health care, AI and data science, knowledge translation, and implementation science, as well as a patient partner and an industry partner (with expertise in the AI-health domain) with whom we consulted during all the steps of the scoping review. This helped us to interpret the results. The screening process is shown in Figure 1. Our review is reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analysis-Scoping Reviews) reporting guideline for reporting the study [29] (see Multimedia Appendix 1). Studies that did not report their study design are categorized by methodology according to the classification outlined by the National Institute for Health and Care Excellence [30].

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the selection procedure. AI: artificial intelligence.



We used the Prediction Model Risk of Bias Assessment Tool (PROBAST) tool for assessing the risk of bias, which includes 20 signaling questions to facilitate structured judgment of risk of bias organized in four domains of potential biases related to the following: (1) participants (covers potential sources of bias related to participant selection methods and data sources); (2) predictor variables (covers potential sources of bias related to the definition and measurement of predictors evaluated for inclusion in the model); (3) outcomes (covers potential sources of bias related to the definition and measurement of the outcomes predicted by the model); and (4) analyses (covers potential sources of bias in the statistical analysis methods) [31]. Risk of bias was judged as low, high, or unclear. If one or more domains were judged as having high risk of bias, the overall judgment was "high risk" [31].

Eligibility Criteria

We defined our bibliographic database search strategy for peer-reviewed publications in English or French using the Population, Intervention, Comparison, Outcomes, Setting and Study (PICOS) design components [32].

Population

Studies about any population that provides health care services, including nurses, social workers, pharmacists, dietitians, public health practitioners, physicians, and community-based workers (an unregulated type of provider) were included, as were those

about any populations who receive CBPHC services. We adhered to the definition of CBPHC provided by the Canadian Institutes of Health Research (CIHR) (ie, the broad range of primary prevention measures including public health, and primary care services within the community, including health promotion and disease prevention; the diagnosis, treatment, and management of chronic and episodic illness; rehabilitation support; and end-of-life care) [4]. Studies that took place in any CBPHC points of care, including community health centers, primary care networks, clinics, and outpatient departments of hospitals, were also included. Studies conducted in emergency departments were excluded.

Intervention

Only studies that "tested" or "implemented" or "tested and implemented" AI methods, such as computer heuristics, expert systems, fuzzy logic, knowledge representation, automated reasoning, data mining, and machine learning (eg, support vector machines, neural networks, and Bayesian networks) were included. Studies related to robot-assisted care were excluded.

Comparison

No inclusion or exclusion criteria were considered.

Outcomes

The primary outcomes of interest were those related to individuals receiving care (eg, cognitive outcomes, health outcomes, behavioral outcomes), providers of care (eg, cognitive outcomes, health outcomes, behavioral outcomes), and health care systems (eg, process outcomes). Moreover, we analyzed the outcomes of the AI systems for their accuracy and impact on the outcomes of care.

Analysis Methods

All study designs using qualitative, quantitative, or mixed methods were eligible for inclusion. In particular, we included experimental and quasi-experimental studies (randomized controlled trials, quasi-randomized controlled trials, nonrandomized clinical trials, interrupted time series, and controlled before-and-after studies), and observational (cohort, case control, cross- sectional, and case series), qualitative (ethnography, narrative, phenomenological, grounded theory, and case studies), and mixed methods studies (sequential, convergent).

Information Sources and Search Criteria

An information specialist with an epidemiologist, an AI-healthcare researcher, and a family doctor developed a comprehensive search strategy and Medical Subject Headings (MeSH) mediated by the National Library of Medicine. The systematic search was conducted from inception until February 2020 in seven bibliographic databases: Cochrane Library, MEDLINE, EMBASE, Web of Science, Cumulative Index to Nursing and Allied Health Literature (CINAHL), ScienceDirect, and IEEE Xplore. Retrieved records were managed with EndNote X9.2 (Clarivate) and imported into the DistillerSR review software (Evidence Partners, Ottawa, ON) to facilitate the selection process (see Multimedia Appendix 2 for the search strategies used on each database).

Study Selection Process

Title and Abstract Screening (Level 1)

Using DistillerSR, two independent reviewers conducted a pilot screening session using a questionnaire based on our eligibility criteria to test the screening tool and to reach a common understanding. Then, the two reviewers independently screened the titles and abstracts of the remaining records. A third reviewer resolved disagreements between the two reviewers.

Full-Text Screening (Level 2)

Using DistillerSR and the abovementioned questionnaire, the same two reviewers independently assessed the full texts selected at level 1 for their eligibility to be included in the review. A third reviewer resolved conflicting decisions. For those references for which we did not have full-text access, we attempted to obtain access through the interlibrary loan mechanism at the McGill University Library. Studies that met the eligibly criteria were included for full data extraction.

Data Collection

We used a data extraction form, approved by our consultative committee, that we designed based on the Cochrane Effective Practice and Organisation of Care Review Group (EPOC) data collection checklist [33]. Specifically, we extracted study characteristics (eg, design and country of the corresponding author); population characteristics (eg, number of participants and type of disease or treatment); intervention characteristics (eg, AI methods used); and outcome characteristics, including outcomes related to the patients (eg, cognitive outcomes, health outcomes, behavioral outcomes), providers of care (eg, cognitive outcomes, health outcomes, behavioral outcomes), and health care systems (eg, process outcomes).

Assessment of Risk of Bias in the Included Studies

Two reviewers independently appraised the included studies using the criteria outlined in PROBAST to evaluate the risk of bias in each included study that was eligible for evaluation using PROBAST [31]. A third reviewer verified their appraisals.

Synthesis

We performed a descriptive synthesis [34] to describe the studies in terms of their population (patient, primary care providers), interventions (AI systems, evaluated parameters), and outcomes. The results were arranged according to the PICOS format. The tools and techniques for developing a preliminary synthesis included textual descriptions of the studies, grouping and clustering, and tabulation.

Consultation

Throughout the steps of the review, we regularly updated all members of the research team and requested their feedback. We also presented our preliminary results during a workshop at Université Laval, Québec, Canada, with a multidisciplinary group of experts (in public health, primary care, AI and data science, knowledge translation, implementation science, as well as a patient partner, and an industry partner) and collected their comments and feedback.

Patient Involvement

Using a patient-centered approach, our team co-developed the protocol, conducted the review, and reported the results of this study. We integrated patients' priorities within our research questions, search strategy terms, and outcomes of interest. Our patient partner was involved in each step of the research process, including the definition of the objectives, main analysis, descriptive synthesis, interpretation of preliminary and final results, and dissemination of the results obtained in this study.

Results

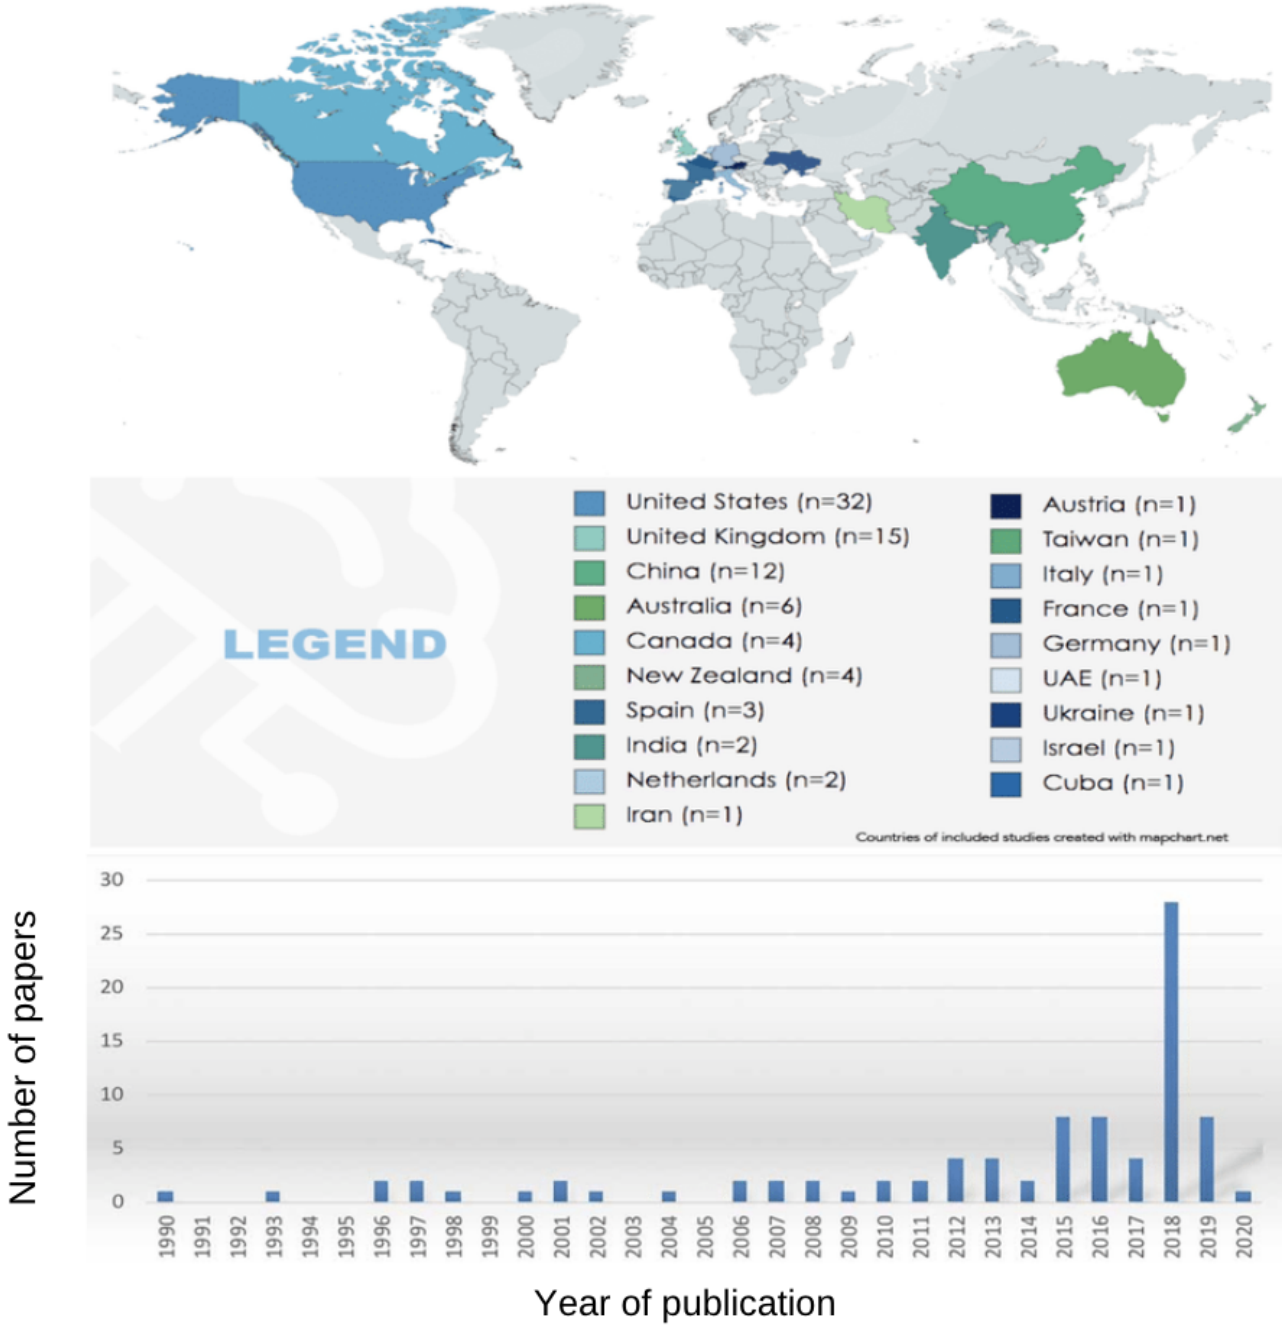
We identified 16,870 unique records. After screening their titles and abstracts, 979 studies remained for full-text review. Ultimately, 90 studies met our inclusion criteria (Figure 1).

Study Characteristics

Countries and Publication Dates

The number of studies published annually has increased gradually since 1990, especially since 2015. Figure 2 shows the timeline of the AI-based studies. Moreover, the four countries publishing a high number of studies are the United States (32/90, 36%), the United Kingdom (15/90, 17%), China (12/90, 13%), and Australia (6/90, 7%). The remaining are New Zealand (4/90, 5%), Canada (4/90, 5%), Spain (3/90, 3%), India (2/90, 2%), and the Netherlands (2/90, 2%), followed by Iran, Austria, Taiwan, Italy, France, Germany, the United Arab Emirates, Ukraine, Israel, and Cuba publishing 1 study each (1%). North America accounts for the highest number of studies (37/90, 41%) followed by Europe (25/90, 28%), Asia (18/90, 20%), and Oceania (10/90, 11%).

Figure 2. Distribution and timeline showing the publication of studies based on artificial intelligence.



Aims of the Included Studies

The included studies sought to describe and test or implement either a novel AI model in CBPHC (16/90, 18%) or an off-the-shelf AI model, which is a modified or improved version of existing AI models in CBPHC (74/90, 82%).

Conceptual Frameworks

Among the 90 studies, 2 (2%) reported using a sociocognitive theoretical framework [35,36]. One of these used the I-change model [35], a model that evolved from several cognitive models, explores the process of behavioral change and the determinants that relate to the change, and focuses on individuals' intentions for adopting innovations [35,37]. In the first study [35] using the I-change model, the authors investigated the cognitive determinants associated with Dutch general practitioners' intention to adopt a smoking cessation expert AI system in their respective practices and found that workload and time constraints are important barriers.

The second study used a continuing medical education framework [38] and compared traditional expert-led training (control group) with an online multimedia-based training activity supplemented with an AI-driven simulation feedback system (treatment group) [36]. Diagnosis accuracy significantly improved in the treatment group when compared to the control group, providing evidence supporting the efficacy of AI medical training methods.

Time Frame of the Collected Data Sets

Among the included studies, 25% (23/90) used data collected over a period of 1 year or less, 20% (17/90) used data collected over a period between 1 and 5 years, 12% (11/20) used data collected over a period between 5 and 10 years, and 9% (8/90) used data collected during more than a 10-year period. One study (1%) used three data sets, collected data from three different sites with over three different time periods (<1 year, 1-5 years, >10 years) [39]. The remaining studies (30/90, 33%) did not specify the time frames of their data set collections.

Population Characteristics

Patients

Sample Size

Overall, 88% (79/90) of the included studies reported their sample size. A total of 21,325,250 patients participated in the testing, training, or validation of the AI systems.

Sex, Gender, and Age

Among the 79 studies reporting their sample size, 46 (58%) reported the sex distribution and none of the studies reported on gender-relevant indicators. Further, 32 (41%) reported the participants' mean age and standard deviation. Overall, the mean age of the participants in these studies was 60.68 (±12.15) years. Age was reported as a range in 21% (17/79) of the studies reporting the sample size, and the remaining 38% (30/79) did not report the age of their participants.

Ethnicity

Among all the included studies, 22% (19/79) reported the participants' ethnic origins, which included Caucasian, Asian-Middle eastern, South Asian, African, American Indian, Alaskan Native, Hispanic, Pacific Islander, Māori, and mixed (Table 1).

Table 1. Characteristics of the participants in the included studies (N=90).

Participant characteristics	Value
Patients	
Total number	21,325,250
Female	2,087,374
Male	1,814,912
Did not report the sex	17,422,964
Age (years), mean (SD)	60.68 (12.15)
Number of studies reporting the sample size of patients (n)	79
Health care providers	
Total number	2,581
Female	467
Male	224
Did not report the sex	1,890
Age (years), mean (SD)	48.50 (7.59)
Number of studies reporting the sample size of health care providers (n)	17
Ethnicities reported for patients (number)	
Caucasian	814,467
Asian	8550
African	42,057
American Indian/Alaskan native	13
Hispanic	5066
Mixed ethnicity	11
Unknown	2,241,937
Number of studies reporting patients' ethnicities (n)	19
Number of studies reporting health care providers ethnicities (n)	0

Other Sociodemographic Information

Only 27% (25/90) of the included studies reported other sociodemographic characteristics of their participants. Socioeconomic status (ie, income level) was the most commonly reported (12/90, 13%). Other characteristics reported were educational status, marital status, area of residence, employment status, smoking status, and insurance status.

Health Care Providers

Among the 90 included studies, 55 (61%) reported the involvement of primary health care providers. Further, 41 of these 55 studies (75%), involved general practitioners, 5 (9%) included nurses, 1 (2%) involved psychiatrists, 1 (2%) involved occupational therapists, and 1 (2%) involved an integrated care specialist. Six studies (7%) involved general practitioners together with other types of health care providers, specifically nurses (3/55, 5%), physician assistants, (1/55 2%), nurses, surgeons, and non-surgeon specialists, (1/55, 2%) and respirologists (1/55; 2%).

Sample Size

Among these 55 studies, 17 (31%) reported the sample size. The data pertaining to 2581 primary health care providers were collected in these studies.

Five of these studies (29%) reported the sex distribution and none reported on gender-relevant indicators. Moreover, 2 (12%) studies reported the age of the primary health care provider participants. The mean age and SD obtained in all the studies for which we collected information is 48.50 (±7.59) years (Table 1).

Sociodemographic Information

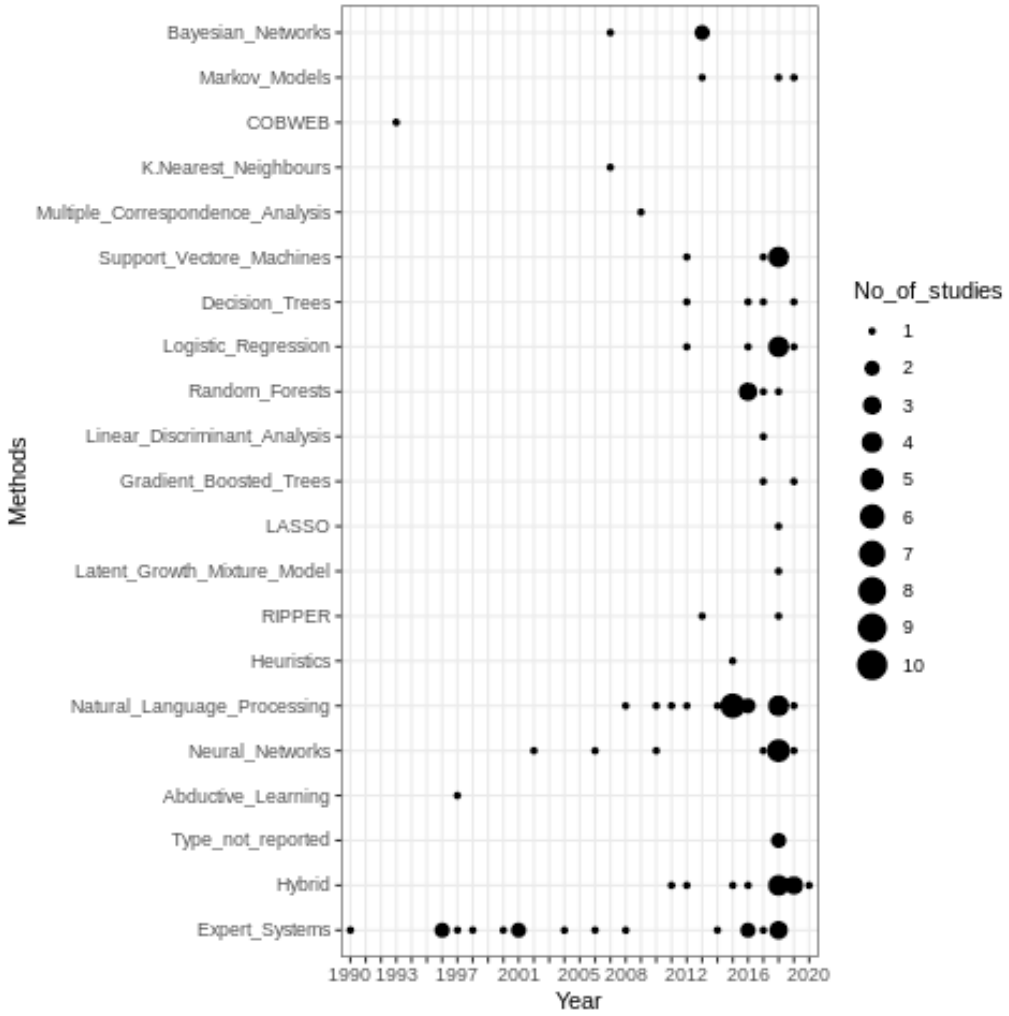
Out of 17 studies, only 1 (5%) reported the primary health care providers' locations of practice. Among the 120 providers in this study, 57 providers practiced in rural areas and 63 practiced in urban areas.

Intervention

AI Methods

Most of the included studies (78/90, 86%), used a single AI method (non-hybrid) and the remaining 14% (n=12) used hybrid AI models—meaning that they integrated multiple AI methods. The most commonly used methods were machine learning (ML) (41/90, 45%) and natural language processing (NLP), including applied ML for NLP (24/90, 27%), and expert systems (17/90, 19%). Figure 3 illustrates the number of studies published according to the type of AI method and year of publication (see Multimedia Appendices 3 and 4 for details regarding the AI methods).

Figure 3. Number of studies published according to the artificial intelligence method used and years of publication.



Performance Measures of AI Interventions

In terms of evaluating the performance of AI models, we considered the following performance metrices: True positive (TP), True negative (TN), False positive (FP), False negative (FN), sensitivity, specificity, precision, F1 score (ie, the weighted average of precision and recall, and area under the curve [AUC]). Among the 90 included studies, 31 (34%) did not report the performance of their models. Among the 59 studies that reported model performance, 13 (22%) used 2 or more performance measures and the remaining 46 (78%) used one measure (see Multimedia Appendix 4 for detailed information on studies' AI methods used in the included studies and their performance measures).

Generated Knowledge

Most of the included studies (81/90, 91%) were either diagnosis- or prognosis-related or focused on surveillance, and the remaining involved operational aspects (eg, resource allocation, system- level decisions) (see Multimedia Appendix 4 for detailed information).

Health Conditions

The majority of the 90 included studies (68/90, 76%) investigated the use of AI in relation to a specific medical condition. Conditions studied were vascular diseases including hypertension, hypercholesteremia, peripheral arterial disease, and congestive heart failure (10/90, 11%) [40-49]; infectious diseases including influenza, herpes zoster, tuberculosis, urinary tract infections, and subcutaneous infections (8/90, 9%) [50-57]; type 2 diabetes (5/90, 6%) [58-62]; respiratory disorders including chronic obstructive pulmonary disease and asthma (6/90, 8%) [63-69]; orthopedic disorders including rheumatoid arthritis, gout, and lower back pain (5/90, 5%) [36,39,70-72]; neurological disorders including stroke, Parkinson disease, Alzheimer disease [73-75], and cognitive impairments (6/90, 5%) [76,77]; cancer including colorectal cancer, and head and neck cancer (4/90, 4%) [78-81]; psychological disorders including depression and schizophrenia (3/90, 3%) [82-84]; diabetic retinopathy (3/90, 3%) [85-87]; suicidal ideations (2/90, 2%) [88,89]; tropical diseases including malaria (2/90, 2%) [90,91]; renal disorders (2/90, 2%) [92,93]; autism spectrum disorder (2/90, 2%) [94,95]; venous disorders including deep vein thrombosis and venous ulcers (2/90, 2%) [96,97]; and other health conditions (8/90, 8%) [98-105].

Data Sets (Training, Testing, and Validation)

In this section, we briefly explain the training, testing, and validation of the data sets, and then present our results. The training data set is the subset of the data that are used to fit in the initial AI model and to train it. The testing data set is the subset of the data used to evaluate the model that fits the initial training data set. The validation data set is a subset of the data used to conduct an unbiased evaluation of the model that fits the training data set, while simultaneously optimizing the model's hyperparameters, namely the parameters whose values are used to control the learning process [106]. The evaluation of these parameters is important because it provides information about the accuracy of predictions made by the AI model, and the prospective effects of hyperparameter tuning [107].

Among the 90 included studies, 9 (10%) reported on all three data sets, 33 (36%) reported on the training and testing data sets, and 36 (40%) reported on the training and validation data sets. No descriptions of these data sets were provided in 49 (54%) of the included studies.

Legal Information and Data Privacy

Legal information concerning privacy was mentioned in 4% (4/90) of the studies in our review. Although health care records were anonymized to protect participants' information in all four of these studies, only one explicitly reported ensuring data collection, storage, and sharing security. The remining studies did not report on data privacy and other legal information.

Involvement of Users

Development

Two of the 90 included studies (2%) reported about the AI developers, all of whom were engineers [60,86]. None of the studies reported the involvement of the end users, including health care providers and patients, in the development stage.

Testing and Validation

Seven out of the 90 (8%) included studies reported information about those who participated in testing or validating the AI. This included general practitioners and nurses [86], engineers [60], general practitioners [51,81], occupational therapists [74], respirologists [64], and nurses [108].

Outcomes

Extraction of the data related to the benefits for patients, primary health care providers, and the health system explained in this section was conducted according to what the authors of the included studies clearly reported as specific benefits to each of these categories.

Potential Benefits for Patients

Included studies reported the following potential benefits of implementing AI in CBPHC: improvements in treatment adherence, person-centered care, quality of life, timeliness of high-risk patient identification, screening speed and cost-effectiveness, enhanced predictability of morbidities and risk factors, benefits related to early diagnosis, as well as early prevention of diseases for the elderly, and facilitated referrals.

Potential Benefits for Primary Health Care Providers

The included studies reported the following information regarding primary health care provider-related benefits of implementing AI in CBPHC: enhanced interprofessional communication and quality of primary care delivery, reduced workload of these providers, and facilitation of referrals and patient-centered care.

Other benefits included benefits with respect to use of AI as a reminder system, application of AI tools to inform commissioning health care priorities, the benefit of an AI system as a quality improvement intervention by generating warnings in electronic medical records and analyzing clinical reports, facilitating monitoring of the diseases, and using AI to reduce health risks.

Potential Benefits for the Health Care System

Studies in our review found that AI can play a role in improving individual patient care and population-based surveillance, can be beneficial by providing predictions to inform and facilitate policy makers decisions regarding the effective management of hospitals, benefits to community-level care, cost-effectiveness, and reducing burden at the system level.

Economic Aspects

Only one study (1%) among the included 90 papers assessed the cost-effectiveness of the AI system studied. The Predicting Out-of-Office Blood Pressure in the Clinic [PROOF-BP] system that the study authors developed for the diagnosis of hypertension in primary care was found to be cost-effective compared to conventional blood pressure diagnostic options in primary care [49].

Challenges of Implementing AI in CBPHC

Our results suggest that challenges of using AI in CBPHC include complications related to the variability of patient data as well as barriers to use AI systems or to participate in AI research owing to the age or cognitive abilities of patients.

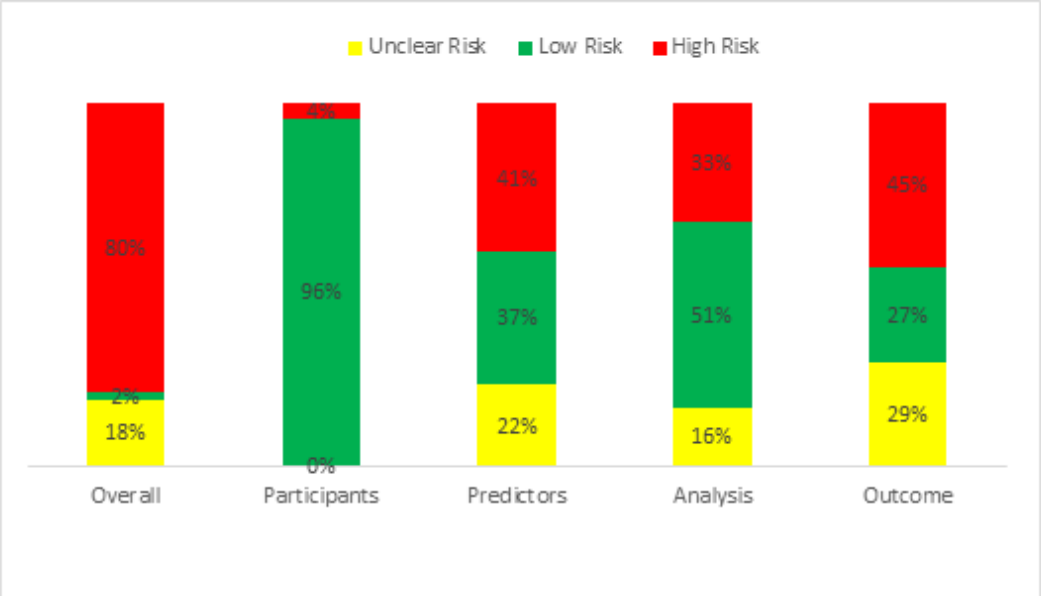
With respect to the health care system, our review found challenges related to how information is recorded (eg, the use of abbreviations in medical records), poor interprofessional communication between nurses and physicians, inconsistent medical tests, and a lack of event recording in cases of communication failures. The included studies also mentioned problems with respect to the restricted resources and administrative aspects such as legislations and administrative approvals, as well as challenges with respect to the lack of digital or computer literacy among the primary health care providers.

In the included studies, other challenges were reported at the level of the health care system such as the data available for use with AI as well as challenges at the level of AI itself (eg, complexity of the system and difficulty in interpretation). The following were identified as the main barriers regarding the data: (1) insufficient data to train, test, and validate AI systems, leading to negative impacts on the robustness of AI models and the accuracy of their predictions; (2) poor quality data, inaccuracies in the data, misclassifications, and lack of representative data; (3) deidentification of protected medical data; and (4) variability in the data sets and combining different data sets. Regarding AI, computational complexity and difficulties in interpreting or explaining some AI model compositions were among the barriers at the AI level.

Risk of Bias

We identified the studies that were eligible to be evaluated using PROBAST. Among our included studies, 54% (49/90) were eligible to be evaluaeted using the PROBAST tool and most (39/49, 80%) were at high risk of bias according to our assessment with PROBAST (Figure 4). With respect to risk of bias for each of the four domains assessed, few studies presented risks regarding participants, (2/49, 4%), whereas 45% (22/49) studies exhibited risks of bias regarding outcomes. See Multimedia Appendices 5 and 6 for details on common causes of risks in each study).

Figure 4. Risk of bias graph: assessing risk of bias in five categories namely overall, participants, predictors, analysis, and outcome (presented as percentages).



Discussion

Principal Findings

We conducted a comprehensive systematic scoping review that included 90 studies on the use of AI systems in CBPHC and provided a critical appraisal of the current studies in this area. Our results highlighted an explosion in the number of studies since 2015. We observed variabilities in reporting the participants, type of AI methods, analysis, and outcomes, and highlighted the large gap in the effective development and implementation of AI in CBPHC. Our review led us to make the following main observations.

AI Models, Their Performance, and Risk of Bias

ML, NLP, and expert systems were the most commonly used in CBPHC. Convolutional neural networks and abductive networks were the methods with the highest performance accuracy within the given data sets for the given task. We observed that a small number of studies reported on the development and testing or implementation of a new AI model in their study, and most of the included studies (74/90, 82%) reported on the usage and testing or implementation of an off-the-shelf AI model. Previous work has demonstrated how off-the-shelf models cannot be directly used in all clinical applications [109]. We observed a high risk of overall bias in the diagnosis- and prognosis-related studies. The highest risk of bias was in the outcome, predictor, and analysis categories of the included studies; validation of studies (external and internal) was poorly reported, and calibration was rarely assessed. A high risk of bias implies that the performance of these AI models in a new data set might not be as optimal as it was reported in these studies. Given the high risk of bias observed in the included studies, AI models used in other settings (ie, with other data) may not exhibit the same level of prediction accuracy as observed.

Where to Use AI?

Primary health care providers are more likely to use AI systems for system-level support in administrative or health care tasks and for operational aspects, rather than for clinical making decisions [1]. However, our results show that few AI systems have been used for these purposes in CBPHC. Rather, the existing AI systems are mostly diagnosis- or prognosis-related, and used for disease detection, risk identification, or surveillance. Further studies in this regard are needed to evaluate the reason behind this tendency in addition to studies for proving the efficiency and accuracy of AI models for assisting in clinical decision making within CBPHC settings. In our review, we found that only 2 of the 90 studies used a (sociocognitive) theoretical framework. Future research needs to use knowledge, attitudes, and behavior theories to expand AI usage for clinical decision making, and more efforts are required to develop and validate frameworks guiding effective development and implementation of AI in CBPHC.

Consideration of Age, Sex, and Gender

Our results show that AI-CBPHC research rarely considers sex, gender, age, and ethnicity. In general, the effect of age is rarely investigated in the AI field and ageism is often ignored in the analysis of discrimination. In health research, AI studies that have evaluated facial and expression recognition methods identified bias toward older adults [109]. This bias could negatively affect the accuracy of the predictions made by AI systems that are commonly used by health care providers.

Furthermore, sex and gender are sources of variations in clinical conditions, affecting different aspects including prognosis, symptomatology manifestation, and treatment effectiveness, among others [110,111]. Despite this importance, big data analytics research focusing on health through the sex and gender lens has shown that current data sets are biased given they are incomplete with respect to gender-relevant indicators with sex-disaggregated data. Indeed, less than 35% of the indicators in international databases have full disaggregation with respect to sex [112]. Our results are consistent with this observation, as we found just half of the AI-CBPHC research with patient participants and nearly one-third with health care provider participants described the sex distribution. Moreover, no AI-CBPHC research has reported on gender-relevant indicators. These are important aspects that need to be considered in the future AI-based CBPHC studies to avoid potential biases in the AI systems.

Consideration of Ethnicity and Geographical Location

Less than one quarter of included studies have reported patient participants' ethnicities, with no discussion on the ethnicities of participating health care providers. Moreover, for those studies that reported patient ethnicity, we observed that the collected data were related to causation populations, thus raising questions regarding the representativeness of the data set, leading to biases. Such biases could result in the AI system making predictions that discriminate against marginalized and vulnerable patient populations, ultimately leading to undesirable patient outcomes.

According to our results, most of the AI research in CBPHC has taken place in North American and Europe-centric settings. Several factors contribute to ethnoracial biases when using AI, including not accounting for ethnoracial information, thereby ignoring the different effects illnesses can have on different populations [113]. Consequently, studies can yield results with historical biases as well as biases related to over- or under-representation of population characteristics in data sets and in the knowledge, bases used to build AI systems. In turn, stereotypes and undesirable outcomes may be amplified. Ensuring ethnic diversity in study populations and accounting for this diversity in analyses is an imperative for developing AI systems that result in equitable CBPHC.

Involvement of Users

Despite the many potential benefits of AI to humans, the development of AI systems is often based on "technology-centered" design approaches instead of "human-centered" approaches [114]. Our results indicate that no AI-CBPHC study has involved any end users in the system development stage and involving primary health care professional users during the validation or testing stages has been rare. This results in AI systems that do not meet the needs of health care providers and patients; they suffer from poor usage scenarios and eventually fail during implementation in clinical practice. A recent assessment of the current user-centered design methods showed that most of the existing user-centered design methods were primarily created for non-AI systems and do not effectively address the unique issues in AI systems [115]. Further efforts are needed to include health care providers and patients as users of the developed AI systems in the design, development, validation, and implementation stages in CBPHC. Nevertheless, effectively involving these users in the development, testing, and validation of AI systems remains a challenge; further studies are required to overcome them.

Ethical and Legal Aspects

Ethical and legal challenges related to the use of AI in health care include, but are not limited to, informed consent to use AI, safety and transparency of personal data, algorithmic fairness, influenced by the aforementioned biases, liability, data protection, and data privacy. Our results indicate that ethical and legal aspects have rarely been addressed in AI-CBPHC research, except with respect to privacy and data security issues. There is a need to address all legal and ethical aspects and considerations within AI-CBPHC studies to facilitate implementation of AI in CBPHC settings. For instance, to increase the use of AI systems by CBPHC providers, clarifying scenarios in which informed consent is required could be useful, as would clarifying providers' responsibilities regarding the use of AI systems. To improve patient outcomes related to AI use in CBPHC, defining the responsibilities of providers and researchers regarding the development and implementation of AI-health literacy programs for patients may be necessary, together with gaining an understanding of how and when patients need to be informed about the results that AI systems yield.

Economic Aspects

AI systems can provide solutions to rising health care costs; however, only one (1%) AI-CBPHC study has addressed this issue by conducting a cost-effectiveness analysis of AI use. This is consistent with other study results showing that the cost-effectiveness of using AI in health care is rarely and inadequately reported [116,117]. Thus, further research analyzing cost-effectiveness is needed for identifying the economic benefits of AI in CBPHC in terms of treatment, time and resource management, and mitigation of human error; this would be valuable as it could influence decisions for or against implementing AI in CBPHC.

AI in Clinical Practice

Our results show different barriers and facilitators for implementing AI in clinical practice. Aspects related to the data were among mostly mentioned ones. For instance, the lack of high amounts of quality data, specifically when using modern AI methods (eg, deep learning), is a challenge commonly faced when developing AI systems for use in CBPHC. The promotion of AI-driven innovation in any setting, including CBPHC, is closely linked to data governance, open data directives, and other data initiatives, as they help to establish trustworthy mechanisms and services for sharing, reusing, and pooling data [118] that are required for the development of high-quality data-driven AI systems.

In addition, some data security and privacy laws can create a bottleneck, limiting the use of AI systems in CBPHC and the sharing of health care information that is required for developing high- performance AI systems. To facilitate the implementation and adoption of high-quality AI systems in CBPHC and ensuring benefits to patients, providers and the health care system, research providing insights for addressing these implementation challenges is needed.

Limitations of the Study

Our review has some limitations. Firstly, given that we used the Canadian Institute of Health Research's definition of CBPHC to determine our inclusion criteria and given that the definition of CBPHC differs from one country to another, our search strategy may not have captured all relevant records. Secondly, we excluded studies conducted in emergency care settings. In many countries, emergency departments are the points of access to community-based care. The European Commission recently released a legal framework (risk-based approach) for broad AI governance among EU member states [118] and categorized emergency care and first aid services as "high risk." Requirements of high-quality data, documentation and traceability, transparency, human oversight, and model accuracy and robustness are cited as being strictly necessary to mitigate the risks in these settings [118].

Conclusion

In this systematic scoping review, we have demonstrated the extent and variety of AI systems being tested and implemented in CBPHC, critically evaluated these AI systems, showed that this field is growing exponentially, and exposed knowledge gaps that remain and that should be prioritized in future studies.

Acknowledgments

This study was funded by Canadian Institutes of Health Research's Planning/Dissemination Grants (Principal Investigators [PIs]: SAR and FL), Québec SPOR SUPPORT Unit (PI: SAR) and start-up fund from McGill University (PI: SAR). We acknowledge the support from these institutions. SAR receives salary support from a Research Scholar Junior 1 Career Development Award from the Fonds de Recherche du Québec-Santé (FRQS), and her research program is supported by the Natural Sciences and Engineering Research Council (NSERC) Discovery (grant 2020-05246). FL is a Tier 1 Canada Research Chair in Shared Decision Making and Knowledge Translation. We thank the Québec-SPOR SUPPORT Unit for their methodological support and Paula L. Bush, PhD, for her revisions of the draft of this manuscript.

Abstract

Background: Hemodialysis (HD) therapy is an indispensable tool used in critical care management. Patients undergoing HD are at risk for intradialytic adverse events, ranging from muscle cramps to cardiac arrest. So far, there is no effective HD device–integrated algorithm to assist medical staff in response to these adverse events a step earlier during HD.

Objective: We aimed to develop machine learning algorithms to predict intradialytic adverse events in an unbiased manner.

Methods: Three-month dialysis and physiological time-series data were collected from all patients who underwent maintenance HD therapy at a tertiary care referral center. Dialysis data were collected automatically by HD devices, and physiological data were recorded by medical staff. Intradialytic adverse events were documented by medical staff according to patient complaints. Features extracted from the time series data sets by linear and differential analyses were used for machine learning to predict adverse events during HD.

Results: Time series dialysis data were collected during the 4-hour HD session in 108 patients who underwent maintenance HD therapy. There were a total of 4221 HD sessions, 406 of which involved at least one intradialytic adverse event. Models were built by classification algorithms and evaluated by four-fold cross-validation. The developed algorithm predicted overall intradialytic adverse events, with an area under the curve (AUC) of 0.83, sensitivity of 0.53, and specificity of 0.96. The algorithm also predicted muscle cramps, with an AUC of 0.85, and blood pressure elevation, with an AUC of 0.93. In addition, the model built based on ultrafiltration-unrelated features predicted all types of adverse events, with an AUC of 0.81, indicating that ultrafiltration-unrelated factors also contribute to the onset of adverse events.

Conclusions: Our results demonstrated that algorithms combining linear and differential analyses with two-class classification machine learning can predict intradialytic adverse events in quasi-real time with high AUCs. Such a methodology implemented

with local cloud computation and real-time optimization by personalized HD data could warn clinicians to take timely actions in advance.

Introduction

Hemodialysis (HD) therapy has a substantial role in critical care management [1]. Due to oliguria or even anuria, most patients with renal failure require fluid removal during HD therapy to maintain an euvolemic status. The volume-dependent component of hypertension may be corrected by fluid removal, but the ultrafiltration process exposes HD patients to the risks of hemodynamic instability, which may lead to fatal consequences such as cardiac arrest [2]. Intradialytic hypotension is the most frequent complication during HD [3-7] and has been identified as a pivotal cause of reduced HD efficacy [4,8]. Acutely, intradialytic adverse events can be fatal; chronically, frequent intradialytic adverse events increase patient morbidity and long-term all-cause mortality [3,9,10]. Therefore, it is urged to develop a solution for this unmet medical need.

The Crit-Line (Fresenius Medical Care) monitor is a device developed to assist with fluid removal during ultrafiltration by noninvasively monitoring real-time hematocrit, oxygen saturation, and intradialytic volume status, using an optical transmission method [11]. Although uncontrolled studies have suggested that this device reduced intradialytic symptoms [5,12] and assisted in the assessment of target weight [13,14], an unblinded randomized controlled trial showed a higher hospitalization rate in the Crit-Line group than in the control group [15]. Therefore, novel solutions are urged to solve this unmet medical need.

Artificial intelligence has been applied to HD patients to assist clinical practice, including prediction of urea clearance [16-19], dietary protein intake [17,20], volume status [21], erythropoiesis-stimulating agent response [22-26], iron supplement response [22,24], hemoglobin level [27], HD quality [28-31], mortality [32], etc. Although artificial intelligence has also been applied to predict intradialytic hypotension risks, previous studies lack time-series data input [17,33]. Therefore, we aimed to include time-series data in a machine learning model to predict intradialytic adverse events. Herein, we hypothesize that the machine learning method can predict intradialytic adverse events in an unbiased manner. To solve this unmet need, we conducted this study.

Methods

Study Protocol and Subjects

This was a retrospective observational study in a single institution. We reviewed the records of all patients who underwent maintenance HD therapy at Changhua Christian Hospital, a tertiary-care referral center in middle Taiwan, between August 2017 and October 2017. During this period, 129 patients were eligible for enrollment evaluation, and 108 patients completed the 3-month study. HD sessions were excluded for the following three reasons: (1) session interruption due to dialyzer exchange, (2) more than one interruption per session due to patient urination or defecation, and (3) inability of patients to freely express their discomfort during the session. Eventually, a total of 4221 HD sessions from 108 patients were used to build the model. Each patient received either 39 or 40 HD sessions during the 3-month study period.

The Institutional Review Board of our institution approved all protocols in April 2017 before the study began, and the protocols conformed to the ethical guidelines of the Helsinki declaration. The need for informed consent was waived because of the retrospective nature of the study.

Dialysis and Physiological Data Collection

Demographic information from medical records, including age, gender, and years under dialysis treatment, were included for model building. Dialysis and physiological data of the enrolled patients during the 4-hour HD session were included in the study. Physiological data were measured and recorded by medical staff every 30 to 60 minutes approximately. Dialysis data were collected from the dialysis machine automatically. Intradialytic adverse events were documented by medical staff according to physiological measurements or patient complaints, as shown in Table 1. The list of HD machine readouts is presented in Multimedia Appendix 1.

For each HD session i (i=1-4221), the data set HD_i consisted of records $\{Y_{j,k}, T_k\}$, where j (range 1-9) is the index for the dialysis and physiological measurements, and k is the index of time when a measurement is taking. $Y_{j,k}$ is the value of the measurement j at time T_k. HD_i also included additional time-invariant patient-specific information Y_j (j=10-13), including age, gender, years under dialysis treatment, and predialytic weight (Multimedia Appendix 2). According to the manufacturer default setting, the machine-derived dialysis data are recorded from the dialysis machine automatically once the value of venous pressure or transmembranous pressure alters and becomes different from the last measurement at $T=T_{k-1}$. Therefore, the time interval $T_k - T_{k-1}$ between any two consecutive records may not be equal.

Table 1. List of intradialytic adverse events.

Adverse event	Episodes, n
Muscle cramps	138
Blood pressure elevation	108
Low blood pressure	64
Miscellaneous	45
Headache	28
Lightheadedness	26
Chest tightness	23
Vascular access thrombosis	23
Cold sweating	22
Nausea/vomiting	12
Fever	10
Tachycardia	10
Dyspnea	8
Hoarseness	8
Chills	5
Leg pain	5
Low back pain	5
Shoulder pain	5
Altered mental status	4
Chest discomfort	3
Numb hands	3
Tinnitus	3
Vascular access occlusion	3
Abdominal pain	2
Hypersomnia	1
Palpitation	1
Pruritus	1

Feature Extraction

To avoid the artifacts at the beginning of the data due to the different procedures on how the dialysis was set up and started in each HD session, the first data point $Y_{j,1}$ at the beginning of each HD session was excluded if the blood flow rate varied between T_1 and T_2. We also excluded the data point $Y_{j,k}$ when the blood flow rate was equal to or below zero due to dialysis interruption (dialyzer exchange or patient urination/defecation). An entire HD session was excluded from the analysis if the session was interrupted more than once.

In our main analysis, the whole data set $\{Y_{j,k}, T_k\}$ of an HD session was included for feature extraction if no adverse event was registered for the session. On the other hand, for the HD session with adverse events, only data preceding the first adverse event were included for feature extraction, meaning the length of HD was less than 4 hours. Because the time interval between two adjacent records and the length of HD sessions vary, regression analysis is challenging, and we need to include the temporal features of the measured variables in the analyses for classification. To this end, we derived the mean, standard deviation of the mean, and coefficient of variance, as well as the slope and R square of linear regression from the dialysis and physiological measurements $\{Y_{j,k}, T_k\}$. We also derived the maximum, minimum, and mean of change rate (the first-order derivative), as well as the second-order derivative of venous pressure and transmembranous pressure as features for analysis. A total of 84 features $\{X_h\}$ (h=1-84), including those from the raw measurements $\{Y_{j,k}, T_k\}$ and those derived from the temporal aspect of the data as described above, were extracted for each HD session (Multimedia Appendix 3). Feature extraction of data sets was performed using the AWK program (source code available in the format of .awk; Multimedia Appendix 4).

As aforementioned, the dialysis data set $\{Y_{j,k}, T_k\}$ is recorded once the values of venous pressure or transmembranous pressure

change. Therefore, the value of any measurement at the time T_p between two measured time stamps, T_k and T_{k-1}, can be assigned as $\{Y_{j,k}, T_p\} = \{Y_{j,k}, T_{k-1}\}$. Thus, feature extraction of the data in an HD session could be terminated at an arbitrary time (T_p).

Outcome Labeling for Model Building

For outcome labeling, the HD sessions with one or more than one adverse event were labeled as 1, and HD sessions with no adverse event were labeled as 0. We also randomly relabeled 4221 HD sessions regardless of their true outcome as a negative control set while kept the same 0 to 1 ratio as the experimental set. A two-class classification model was built and evaluated by four-fold cross-validation using Azure (Microsoft Inc). At least three repeats were performed by introducing different random numbers for each model building.

Selection for Top Performance Features

To pinpoint which features are more important than others in predicting HD adverse events, we also selected and used key features for model building and compared the results with that by a total of 84 features. The selection of key features was performed using MATLAB (MATrixLABoratory, MathWorks Inc) (source code available in the format of .m; Multimedia Appendix 5). A two-class classification model was built using ensemble random undersampling boosted trees by four-fold cross-validation. The score was given by summing up the percentages of true positives and true negatives.

The key feature selection process started with selecting the top feature according to the scores obtained from the model using a single feature from the 84 features once at a time. Next, the top two-feature combinations were selected from the two-feature combination pool, which was established by combining the top feature from the last step with each of the remaining 83 features. The two-feature combinations that resulted in scores higher than that of the top feature from the last step were kept for the next step. Likewise, the top three-feature combinations could be selected from the pool established by combining the top two-feature combinations with each of the remaining 82 features when the three-feature combinations scored higher than the two-feature combinations. We repeated this procedure until the top 20-feature combinations were selected. Features that most frequently appeared in these 20-feature combinations were defined as key features.

Ethics Approval and Consent to Participate

This study was approved by the Institutional Review Board of National Yang-Ming University (N_105_0132) and the Institutional Review Board of Changhua Christian Hospital (CCH IRB No. 161005).

Results

Demographic Characteristics of the Study Participants

As of November 2017, we enrolled 108 patients. Multimedia Appendix 6 shows the baseline characteristics of the 108 patients at the beginning of the study. The mean age was 63.6 years, 60 (56%) patients were male, and the mean duration on dialysis was 7.7 years. A total of 47 (44%) patients had diabetes mellitus, 69 (64%) patients had hypertension, 11 (10%) patients had coronary artery disease, 12 (11%) patients had congestive heart failure, 7 (7%) patients had a history of stroke, and 2 (2%) patients had malignancy.

The list of intradialytic adverse events and the number of occurrences are shown in Table 1. Four HD sessions had more than three intradialytic adverse events, 19 HD sessions had three adverse events, 106 HD sessions had two adverse events, and 276 HD sessions had a single adverse event. Altogether, there were 406 HD sessions with adverse events out of 4221 total HD sessions (Multimedia Appendix 7).

Performance of the Model for Prediction

To increase the outcome 1 to 0 ratios, wherein the session with an adverse event is labeled as 1 and the session without an adverse event is labeled as 0, we categorized the 27 adverse events listed in Table 1 into three groups. The first group was total events but excluded events of blood pressure elevation, vascular access occlusion, and vascular access thrombosis. A total of 323 HD sessions belonged to adverse event group 1. The second group included muscle cramps, and there were 138 HD sessions in this group. The third group included blood pressure elevation, and there were 108 HD sessions in this group.

Group 1: All Events Except Blood Pressure Elevation

A two-class averaged perceptron was used for model building with a learning rate of 20 and maximal iterations of 20. For the 84-feature model, the mean area under the curve (AUC) was 0.83 (SD 0.03), with an F1 score of 0.53, sensitivity of 0.53, and specificity of 0.96 (Figure 1A and 1B curve a). Compared with the negative control, (mean AUC=0.50, SD 0.04; F1=0.15; Figure 1A curve b), the 84-feature model of the two-class averaged perceptron could predict adverse events plausibly. Other algorithms were also tested for the prediction. The mean AUC obtained by two-class support vector machines (SVM) was 0.83 (SD 0.02), with an F1 score of 0.55, sensitivity of 0.53, and specificity of 0.96. The results were similar to those obtained by the averaged perceptron. Compared to averaged perceptron and SVM algorithms, two-class logistic regression and decision forest did not predict the adverse events well. The mean AUC obtained by logistic regression was 0.82 (SD 0.02), with an F1 score of 0.48, and the mean AUC obtained by decision forest was 0.83 (SD 0.02), with an F1 score of 0.46. Additionally, intrapatient partition and interpatient partition for sampling did not show significant difference in prediction (mean AUC=0.83, SD 0.03; mean F1=0.53, SD 0.02 vs mean AUC=0.82, SD 0.04; mean F1=0.50, SD 0.06).

Figure 1. Prediction of all intradialytic adverse events except blood pressure elevation. (A) Machine learning performance represented by receiver operating characteristic (ROC) curves from 84 features (curve a, red), the top 21 features (curve c, green), all features but excluding ultrafiltration-related features (curve d, blue), and the negative control (curve b, black). Each ROC curve shown here is the average of 12 simulated ROC curves. (B). Machine learning performance represented by ROC curves is obtained from ultrafiltration-related features (curves e, f, g, h, i, j, and k) and from 84 features (curve a, black). (C) Area under the curve (AUC) and F1 scores from different feature combinations for predicting all intradialytic adverse events. UF: ultrafiltration.

	All features	All with out-come randomly labeled	Top features without UF related features	All without UF related features	UF related features	UF volume related features	UF rate related features	Two UF related features	Single UF related feature		
Feature included	1 - 84	1- 84	2,5,6,8,11,14,17,20 ,21,26,29,31,36,47-49, 50-52, 57,59	1-69, 84	70-83	78-83	70-77	72,82	76	77	78
Number of features used	84	84	21	70	14	6	8	2	1		
AUC	0.83	0.50	0.82	0.81	0.83	0.82	0.75	0.65	0.69	0.70	0.48
F1 score	0.53	0.15	0.45	0.45	0.52	0.46	0.36	0.22	0.25	0.28	0.15

Ultrafiltration rate and ultrafiltration volume are important parameters for HD. However, our models indicated that employing a single feature, such as the maximal value of ultrafiltration volume (feature 78) or the mean value of ultrafiltration rate changes (feature 77), cannot predict adverse events properly (Figure 1B curves j and k). The model built by the maximal value of ultrafiltration volume, defined as the ultrafiltration volume recorded at the last time point, had an AUC of 0.48 and F1 score of 0.15, which were similar to the results of the negative control. On the other hand, the model built by the mean value of ultrafiltration rate changes during HD sessions had an AUC of 0.70 and F1 score of 0.28. Combining two ultrafiltration-related features also failed to predict adverse events (Figure 1B curve h). After up to six ultrafiltration volume-related features (features 78-83) were used for prediction, the AUC increased from 0.48 to 0.82, and the F1 score increased from 0.15 to 0.46 (Figure 1B curve f). The model with 14 ultrafiltration features (features 70-83) had an AUC of 0.83 and F1 score of 0.52 (Figure 1B curve e).

Next, the 21 features that most frequently appeared in the 20-feature combinations were selected for the evaluation. The two-class averaged perceptron model based on these top 21 performance features but skipping ultrafiltration-related features showed a mean AUC of 0.82 (SD 0.02) and F1 score of 0.45 (Figure 1A curve c). The increase of one or two features did not enhance the prediction significantly (23 top features model: mean AUC=0.82, SD 0.02; F1=0.46). Compared with the model based on all features but excluding ultrafiltration-related features (AUC=0.81; F1=0.45; Figure 1A curve d; 70 features), the results of the 21 top features model (without ultrafiltration-related features) demonstrated that a quarter of the total 84 features was sufficient to predict adverse events.

The 21 features were age, maximum transmembranous pressure, minimum systolic blood pressure (SBP), minimum diastolic blood pressure (DBP), minimum pulse pressure, minimum blood flow rate, mean SBP, mean venous pressure, mean transmembranous pressure, slope of linear regression of SBP, slope of linear regression of DBP, slope of linear regression of pulse pressure, slope of linear regression of pulse rate, slope of linear regression of transmembranous pressure, standard deviation of the mean of blood flow rate, R-squared of linear regression of pulse pressure, and related parameters to the second-order derivative of venous pressure (features 2, 5, 6, 8, 11, 14, 17, 20, 21, 26, 29, 31, 36, 47-52, 57, and 59) (Multimedia Appendix 3).

Group 2: Muscle Cramps

The model, which was based on 14 ultrafiltration-related features, had a mean AUC of 0.85 (SD 0.04) and F1 score of 0.45 (Figure 2 curve d) for predicting the occurrence of muscle cramps, and the result is similar to that of the 84-feature model (mean AUC=0.83, SD 0.04; F1=0.42; Figure 2 curve a) and

better than that of the model built based on all features but excluding ultrafiltration-related features (mean AUC=0.79, SD 0.04; F1=0.30; Figure 2 curve c). However, a single ultrafiltration-related feature cannot predict cramps properly (Figure 2 curves i and k). The combination of two ultrafiltration-related features also failed to predict muscle cramps (AUC=0.79 and F1=0.29 for features 70 and 77; AUC=0.84 and F1=0.37 for features 78 and 83). Our results demonstrated that ultrafiltration-related features contribute more than other features to the prediction of muscle cramps.

Figure 2. Prediction of a specific intradialytic adverse event: muscle cramps. (A) Machine learning performance is represented by receiver operating characteristic (ROC) curves from 84 features (curve a, red), all features but excluding ultrafiltration-related features (curve c, orange dot), ultrafiltration-related features (curves d, e, f, i, k), and the negative control (curve b, black). F1 score	0.42	0.07	0.30	0.45	0.37	0.29	0.22	0.16	0.08

Group 3: Blood Pressure Elevation

The model, which was based on a total of 84 features, had a mean AUC of 0.93 (SD 0.02) and F1 score of 0.41 for predicting the occurrence of hypertension (Figure 3 curve a). Compared with the model built based on 14 ultrafiltration-related features (AUC=0.72; F1=0.22; Figure 3 curve c), our results demonstrated that ultrafiltration parameters did not play important roles in predicting intradialytic hypertension. Even though the model based on 24 blood pressure–related features had an AUC higher than 0.9 (AUC=0.92, SD 0.03; F1=0.38; Figure 3 curve d), features other than blood pressure can further contribute to an additional improvement in the F1 score.

Figure 3. Prediction of a specific intradialytic adverse event: blood pressure elevation. Consistency of the Predicted Probabilities of Adverse Events Over Time

As shown in Figure 1, the time series features were collected throughout the HD session, from the beginning of HD to the time point right before the index adverse event or right before the end of the HD session, which has no adverse event. In this case, we defined the end of feature collection as 0 minutes if this ending time point was right before the occurrence of the index adverse event. In addition to 0 minutes, we also set the cutoff ending time points of feature collection as 5, 10, 15, 20, and 60 minutes before the occurrence of the adverse event to evaluate the prediction accuracy. Machine learning for predicting all intradialytic adverse events, except blood pressure elevation, showed that features of the 0-minute cutoff led to the best AUC and F1 score (AUC=0.83; F1=0.53) compared to those learned from the features of earlier cutoff time points (Figure 4A and 4B), even though AUC scores from the features of the cutoff ending time points 5, 10, 15, and 20 minutes before the index adverse event or before the end of HD sessions without an adverse event were about 0.80 and their F1 scores were all lower than 0.5. The results suggest that while the information embedded in the 20-minute time window before the index adverse event is valuable, the information embedded in the 5-minute time window before the index adverse event is more influential for event prediction.

To further understand the cutoff ending time point dependence of prediction accuracy, 500 HD sessions were randomly selected to compare the prediction probabilities of adverse events obtained from 84 features with cutoff ending time points of 0, 5, 10, 15, and 20 minutes before the index adverse event. As shown in Figure 4C (red circles), five HD sessions possessed strong consistency in the predicted probabilities of adverse events using extracted features based on different cutoff ending time points, and adverse events indeed occurred in these five HD sessions. Since there should be approximately 40 HD sessions developing adverse events among 500 randomly selected HD sessions, the results suggest that at least one-tenth of HD sessions with adverse events can be sighted as early as 20 minutes in advance and can be further confirmed by real-time machine learning using features from subsequent cutoff ending time points (Figure 4C).

Even though none of the 84 features contained explicit time series information, the linear and differential analyses that feature extraction employed may be affected by the length of HD sessions. Therefore, we truncated the HD sessions with no adverse events (negative ones) and compared the prediction results with those from the untruncated ones. Since the average length of HD sessions with adverse events (positive ones) was 3.3 hours, negative HD sessions were truncated and randomly assigned endpoints (T_{end}) between 3 and 3.5 hours, yet the endpoints of positive ones remained unchanged. The data set $\{Y_{j,k}, T_k\}$ at endpoint T_{end} was defined according to the same method used for $\{Y_{j,k}, T_k\}$ at arbitrary time T_p. Regarding the results, the mean AUC was 0.89 (SD 0.019), F1 score was 0.55, sensitivity was 0.52, and specificity was 0.97. Alternately, the AUC was 0.86 with an F1 score of 0.55 when the endpoints were assigned exactly at 3.3 hours. Compared to the original results obtained from the untruncated negative HD sessions with a duration of about 4 hours (AUC=0.83, F1=0.53, sensitivity=0.53, and specificity=0.96), the prediction results were better when the endpoints were set earlier. Indeed, the AUC was 0.92, with an F1 score of 0.62, sensitivity of 0.61, and specificity of 0.98, when the endpoints were randomly assigned between 2.5 and 3.5 hours for negative HD sessions.

Figure 4. Prediction performance for group 1 intradialytic adverse events using the features of different cutoff ending time points. (A) Machine learning performance represented by receiver operating characteristic (ROC) curves from 84 features extracted from [Yj, Tk]HD terminated at different cutoff ending time points as follows: one time point before an adverse event (noted as 0 minutes), and 5, 10, 15, 20, and 60 minutes before an adverse event or before the end of the hemodialysis (HD) session if no adverse event. (B) Area under the curve (AUC) and F1 scores. (C) Probability of adverse event occurrence in 500 randomly selected HD sessions. The red circle indicates the HD session with adverse events, and the predicted probabilities of adverse events are all higher than 0.8 independent of the cutoff ending time point.

Discussion

Contributions and Principal Findings

Our findings indicate that algorithms combining linear and differential analyses with two-class classification machine learning predict intradialytic adverse events with high AUCs. We attempted to identify features that contribute the most to predicting all adverse events, except hypertension, (group 1) from a total of 84 features extracted from $[Y_j, T_k]_{HD}$. Among the top 23 features, only feature 76 and feature 82 were related to ultrafiltration (the number of times that the ultrafiltration rate changes and the linear regression slope of ultrafiltration volume). After excluding these two ultrafiltration-related features, we found that the remaining 21 features were sufficient for accurate prediction with good discriminating power, with a slight reduction in the AUC from 0.83 (84 features) to 0.82 (21 features). The model built by 14 ultrafiltration-related features also had a good AUC of 0.83. Therefore, instead of including all 84 features for model building, selecting the top 21 ultrafiltration-unrelated features or integrating a total of 14 ultrafiltration-related features can reduce computing load. Our results also suggest that these two clusters of features (Figure 1A curve c and Figure 1B curve e) may embed similar factors contributing to the onset of adverse events.

In our study, muscle cramp was an adverse event that occurred most frequently during HD treatment. A muscle cramp is a common adverse event that happens during HD therapy, with a prevalence of 28% among all HD sessions [5,34]. Muscle cramps result from ischemia of the skeletal muscle tissue, indicating an early sign of hypotension, and it may lead to premature discontinuation of HD sessions [35,36]. Tissue ischemia during HD is positively related to the ultrafiltration rate [5,37,38]. Indeed, the model built by 14 ultrafiltration-related features had an AUC of 0.85 for predicting the occurrence of muscle cramps in this study. We excluded all ultrafiltration-related features to test the prediction accuracy, including ultrafiltration rate and ultrafiltration volume, and the AUC reduced from 0.82 (84 features) to 0.79 (70 features), indicating that ultrafiltration-related features are important but not necessarily required to predict muscle cramps. The results from machine learning revealed that ultrafiltration-independent features contribute to predicting intradialytic muscle cramps as well.

In general, symptomatic hypotension occurs in 20% to 30% of dialysis sessions [6,39-43]. There are two major pathophysiological mechanisms of intradialytic hypotension. First, when plasma fluid removal through ultrafiltration exceeds the rate of plasma refilling into the blood vessels, blood volume reduces [5]. In the meantime, if the cardiovascular and neurohormone systems fail to compensate for the acute vascular volume depletion during ultrafiltration, hypotension occurs [3,44-47]. Frequent episodes of intradialytic hypotension may cause reduced ultrafiltration, inadequate “dry weight,” increased preload, and impaired heart function that eventually leads to more episodes of hypotension, thus creating a vicious cycle. Meanwhile, frequent intradialytic hypotension disrupts dialysis efficiency and efficacy. It is associated with higher morbidity

and mortality [48-51], which partly contributes to the fact that cardiovascular disease is the leading cause of morbidity and mortality in HD patients [52]. Lin et al recently developed an intelligent system to predict intradialytic hypotension [53]. However, our prediction models not only further precluded ultrafiltration-related features but also examined overall intradialytic adverse events instead of only focusing on the hypotensive episode.

As shown in Multimedia Appendix 8, the top 16 features that majorly contributed to predicting muscle cramps included patient characteristics, venous pressure, transmembranous pressure, ultrafiltration, blood flow rate, and pulse pressure. The minimal value of venous pressure and the mean value of transmembranous pressure were features that had the most hits (20 and 17 hits, respectively). These top two features for predicting muscle cramps were derived from dialysis machine output parameters, indicating that there is a potential to integrate our algorithm into the dialysis machine software to alert clinicians and to adjust dialysis machine settings in advance. Nevertheless, unlike prediction of all adverse events, for which only two out of the top 23 features were related to ultrafiltration, eight out of the top 16 features were related to ultrafiltration in terms of predicting muscle cramps, indicating that ultrafiltration-related parameters are important factors of muscle cramps.

Compared with several two-class classification modules, such as Bayes point machine, boosted decision tree, and SVM, models built by two-class average perceptron had the best AUC and F1 score. We also built models by deep learning (data not shown), but the results from deep learning did not show a good AUC and F1 score, possibly due to the limited number of our HD data sets. As clinicians are now facing the new era of artificial intelligence [54], the integration of computer science and dialysis medicine could be regarded as the first step to improve HD patients' care quality comprehensively. Our study demonstrated the feasibility of this integration. Even though the limited number of data sets and imbalanced data outcomes in our research hinder better prediction accuracy, it is anticipated that increased data sets will further improve the AUC and F1 score. Moreover, integrating machine learning with the dialysis machine and modifying algorithms in real-time by cloud computing with accumulation of data sets could enhance prediction performance.

Several questions may be answered if the size of the HD data set is expanded in future studies. First, how early can we predict adverse events? The consistency in the predicted probabilities of adverse events using features based on different cutoff ending time points could detect about one-tenth of HD sessions with adverse events (Figure 4). We anticipate that an increase in the number of HD sessions with adverse events for model training can improve imbalanced data and possibly bring forward the timing for the alert. Second, since most of the adverse events took place in second-half HD sessions, whether the data sets of second-half HD sessions are sufficient for prediction can be further studied. Finally, if more HD sessions with adverse events are recruited, we can build models for different adverse events instead of grouping the events to reduce imbalanced data outcomes.

Conclusion

In this study, a model of two-class classification was established to predict intradialytic adverse events in quasi-real time, with AUCs higher than 0.8. The consistency in the predicted probabilities of adverse events obtained from the features extracted in the ongoing HD process in real time could have the HD session tagged for forthcoming adverse events. Such a methodology implemented with local cloud computation could warn clinicians to take necessary actions and adjust the HD machine settings in advance.

Abstract

Background: In-hospital cardiac arrest (IHCA) is associated with high mortality and health care costs in the recovery phase. Predicting adverse outcome events, including readmission, improves the chance for appropriate interventions and reduces health care costs. However, studies related to the early prediction of adverse events of IHCA survivors are rare. Therefore, we used a deep learning model for prediction in this study.

Objective: This study aimed to demonstrate that with the proper data set and learning strategies, we can predict the 30-day mortality and readmission of IHCA survivors based on their historical claims.

Methods: National Health Insurance Research Database claims data, including 168,693 patients who had experienced IHCA at least once and 1,569,478 clinical records, were obtained to generate a data set for outcome prediction. We predicted the 30-day mortality/readmission after each current record (ALL-mortality/ALL-readmission) and 30-day mortality/readmission after IHCA (cardiac arrest [CA]-mortality/CA-readmission). We developed a hierarchical vectorizer (HVec) deep learning model to extract patients' information and predict mortality and readmission. To embed the textual medical concepts of the clinical records into our deep learning model, we used Text2Node to compute the distributed representations of all medical concept codes as a 128-dimensional vector. Along with the patient's demographic information, our novel HVec model generated embedding vectors to hierarchically describe the health status at the record-level and patient-level. Multitask learning involving two main tasks and auxiliary tasks was proposed. As CA-mortality and CA-readmission were rare, person upsampling of patients with CA and weighting of CA records were used to improve prediction performance.

Results: With the multitask learning setting in the model learning process, we achieved an area under the receiver operating characteristic of 0.752 for CA-mortality, 0.711 for ALL-mortality, 0.852 for CA-readmission, and 0.889 for ALL-readmission. The area under the receiver operating characteristic was improved to 0.808 for CA-mortality and 0.862 for CA-readmission after solving the extremely imbalanced issue for CA-mortality/CA-readmission by upsampling and weighting.

Conclusions: This study demonstrated the potential of predicting future outcomes for IHCA survivors by machine learning. The results showed that our proposed approach could effectively alleviate data imbalance problems and train a better model for outcome prediction.

KEYWORDS

in-hospital cardiac arrest; 30-day mortality; 30-day readmission; machine learning; imbalanced dataset

Introduction

Background

In the United States, approximately 209,000 patients experience in-hospital cardiac arrest (IHCA) each year [1]. The rate of survival to hospital discharge is around 14%, and only 7% of IHCA patients could regain an independent life or a partially independent life [2]. In order to reduce the severe effect of IHCA on personal life or society, identifying measures to improve IHCA outcomes is crucial.

Prior Work

Prognostic factors and prediction tools for survivors of IHCA and their neurologic outcomes have been identified in previous studies [3-8]. However, the evidence of an early warning system for predicting the mortality of IHCA survivors is limited. Current early warning scoring systems using physiologic track-and-trigger systems (TTSs) have been developed for identifying patients at risk for IHCA or other serious outcomes including mortality [9-11]. Most of TTSs rely on the routine observations of vital signs carried out by ward staff. Although many patients could be monitored with this approach, the quality of evidence underpinning the use of TTSs is poor. Specifically, most TTSs have low sensitivity, low positive predictive values, and high specificity [12,13]. In addition to the high mortality after IHCA, readmission after IHCA has a significant cost burden and is associated with comorbidities. Predicting readmission events provides the chance for appropriate interventions and reducing health care costs, including further readmission [14,15].

Our Study

Here, we first extracted the IHCA cohort from the National Health Insurance Research Database (NHIRD). We assessed their risk based on historical electronic health records (EHRs) in the NHIRD. To provide a long enough window for clinical intervention, we used the 30-day mortality and readmission after IHCA as our prediction targets. In contrast to TTSs, EHRs are prepared by physicians, and they contain several important medical information, including the diagnosis and management of patients. To achieve a better performance, we developed a novel deep learning model, hierarchical vectorizer (HVec), to analyze the patients' historical EHRs and predict mortality and readmission. This study aimed to demonstrate that with the proper data set and learning strategies, we can predict the outcome of IHCA patients based on their historical claims and help clinicians design more effective intervention programs.

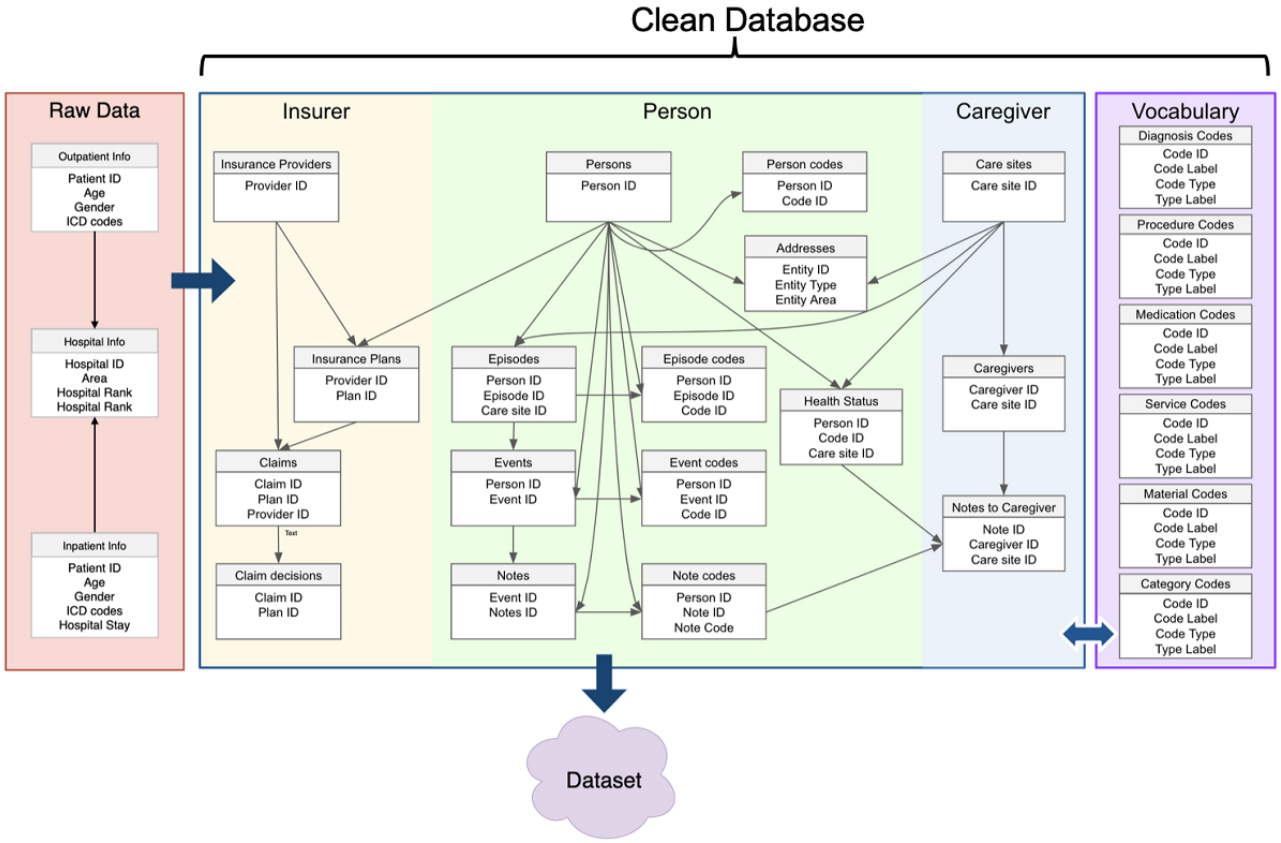
Methods

Data Collection

This study was approved by the Institutional Review Board of National Taiwan University Medical College. The IHCA cohort extracted from the NHIRD consisted of 168,693 patients who had at least one IHCA event over 9 years (between January 1, 2002, and December 31, 2010). The Taiwan National Health Insurance program is the only health insurance scheme in Taiwan and covers up to 99.99% of Taiwan's population [16]. The NHIRD contains all health records in inpatient and outpatient settings (clinic or emergency department); however, the records cannot be specifically linked to each patient. International Classification of Disease, 9th Revision (ICD-9) was used during the study period for diagnosis and medical procedures. The NHIRD contains medical information, including gender, age, diagnosis, medical procedure, operation, medication, laboratory test, care site, discharge status, and cost of each hospital visit. Laboratory test results and bedside information, including vital signs, blood pressure, and physical examination, are not included in the NHIRD.

The IHCA population was defined by inpatient records with the ICD-9 procedure codes 99.60 (cardiopulmonary resuscitation, not otherwise specified) and 99.63 (closed-chest cardiac massage) [17]. We used the extract, transform, and load (ETL, see Figure 1) procedure to process raw data into a clean database by eliminating records with missing or invalid information. Raw data in the cleaned database were re-grouped into three major categories (insurer, person, and caregiver) to improve data organization. In addition, vocabulary tables were constructed based on extracted concepts that were used in the raw data.

Figure 1. ETL process for converting raw NHIRD data into the data set. The raw data are extracted, transformed, and loaded into the cleaned database after cohort selection and eliminating the invalid data. ETL: extract, transform, load; ICD: International Classification of Disease; NHIRD: National Health Insurance Research Database.



Experimental Data Set

The 168,693 patients in the data set were split into three data sets: train, validation, and test. The training data set (70% of the data set) was used to train each model. The remaining 30% of patients were split between the validation and test data set evenly to tune the hyperparameters (Table 1) and evaluate model performance, respectively.

For comparison, we trained two single-task models for both mortality and readmission. Person upsampling and event weighting were only performed on the training data set so as not to affect the distribution of the validation and test data set. The F1 score and area under the receiver operating characteristic (AUROC) were our main evaluation metrics.

Input Features

In the retrospective review of the data set, each person may have multiple clinical records (inpatient/outpatient visit) to the hospital within a 9-year period. Each clinical record was set as a unit of analysis. For each clinical record, information was extracted and grouped into input and target features (see Tables 2 and 3). The input features consisted of five major groups described as follows:

1. Medical records consisted of five types of codes, and all codes in the clinical records were mapped to over 400,000 clinical concepts. The health status of the patient in the current record can be determined from this group.

2. Demographics included the age, gender, and information of the targeted patients.
3. Care site information included information of the clinical institution where the patient received treatment.
4. Record statistics provided information on the length (by day) of the record, the number of codes in each International Classification of Disease (ICD) code category, and the total monetary cost involved. This could help the model estimate the severity of the patient's disease at the record level.
5. Historical information described previous hospital stays and admissions. It was used to estimate the overall health status of the patient in our model.

Table 2. Summary of the input features of the model.

Group and feature name	Feature description	Dimension
Medical records		
Diagnosis	Diagnosis codes from the health record	128
Procedures	Procedure codes from the health record	128
Meds	Medication codes from the health record	128
Tests	Lab test codes from the health record	128
Other	Other codes from the health record	128
Demographics		
Claim type	Inpatient or outpatient	2
Age	Age at the event	1
Gender	Male or female	2
Care site information		
Care site type	Type of site (public, corporate, or private)	21
Care site specialization	Medical center, community hospital, district hospital, regional hospital, or clinic	5
Care site rank	Rank of the care site	17
Record statistics		
Hospital stay	Duration of current hospital stay	1
Total cost	Monetary cost of each of the five ICD[a] codes	5
Total count	Counts of each of the five ICD codes	5
Historical information		
Past hospitalization duration	The number of days a person spends in the hospital within 3, 6, 12, and 24 months	4
Past admission count	The number of times a person is admitted to the hospital within 3, 6, 12, and 24 months	4

Table 3. Summary of the prediction targets.

Group and feature name	Feature description	Dimension
Main target		
Mortality	Whether this event would lead to another mortality event in (within 1 to 30) days	1
Readmission	Whether this event would lead to another readmission event in (within 1 to 30) days	1

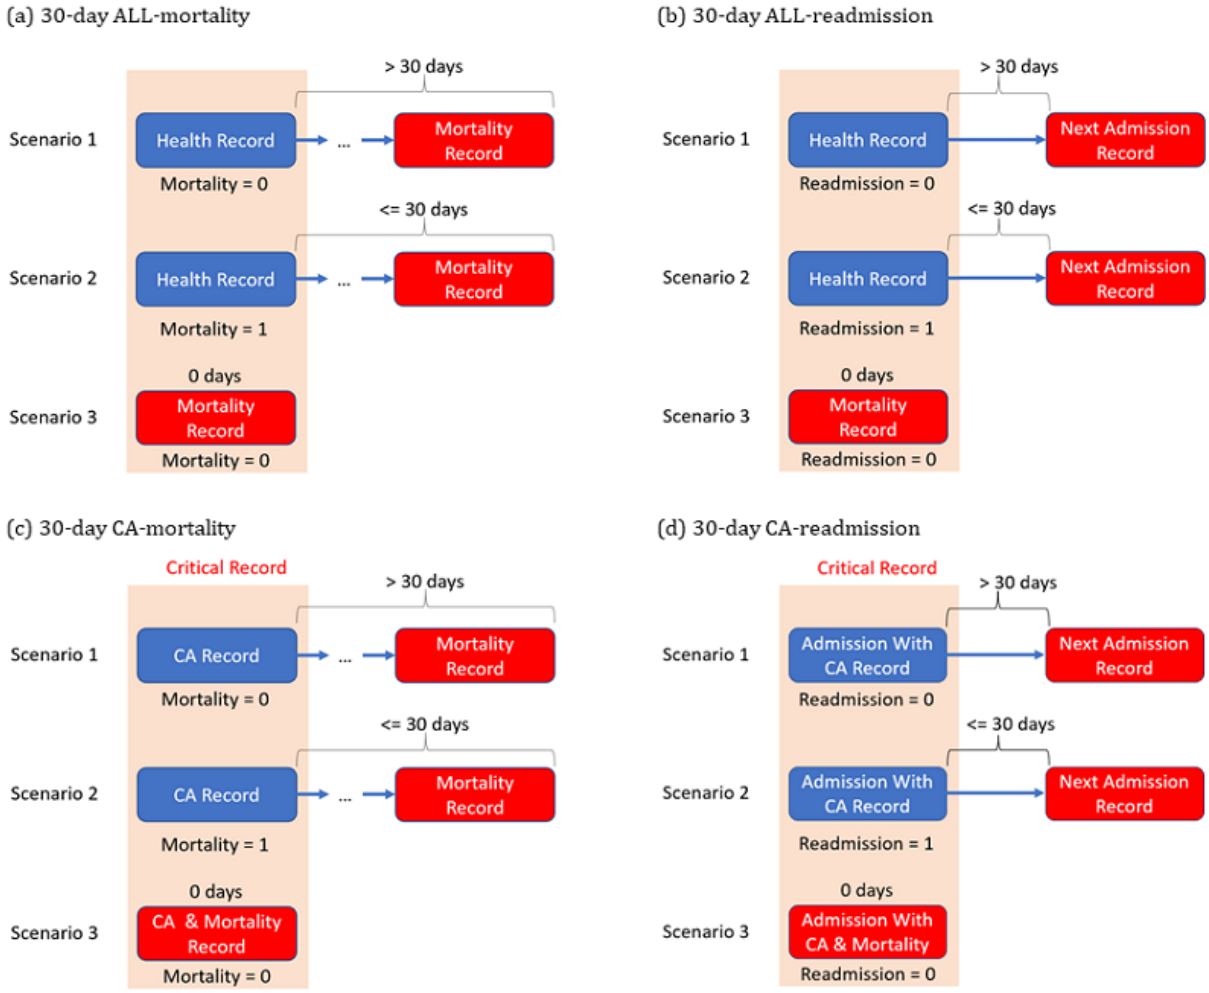
Targets

A threshold of 30 days was set to predict whether a person would die or readmit within 30 days. Mortality was defined when the patient had an inpatient or outpatient record of mortality or was discharged under critical condition following IHCA. For readmission, whether the patient is readmitted within 1 to 30 days from hospital discharge was predicted. In contrast to other mortality studies, records with mortality (0-day mortality record) were excluded in our study. The main purpose of this strategy was to reduce the "leakage" of features in these records. Our initial results showed that the features of mortality records usually contain information (eg, respiratory failure) explicitly indicating patient mortality. Indeed, these features are significant factors for predicting mortality. However, such cases are not beneficial to our model as the severe condition of these patients makes it hard to treat them with any intervention. Moreover, the high degree of correlation of these features and mortality would cause the model to rely on them and underestimate other potential predictive factors. In order to avoid leakage and let the model focus on other predictive factors,

mortality records were set as the negative class, and previous records of mortality (within 30 days) were the positive class.

In clinical practice, the 30-day outcomes of patients after IHCA and discharge from hospitalization are of great interest. The 30-day mortality or readmission after cardiac arrest (CA; CA-mortality/CA-readmission) is a subset of 30-day mortality or readmission. In the rest of the paper, ALL-mortality/ALL-readmission will be used to represent the 30-day mortality or readmission for all records. CA-mortality/CA-readmission refers to the 30-day mortality or readmission following CA (Figure 2).

Figure 2. ALL/CA-mortality and ALL/CA-readmission. 3 scenarios of 30-days mortality & readmission after cardiac arrest. Events in red are the outcomes we want to predict. ALL-mortality: 30-day mortality after all records; ALL-readmission: 30-day readmission after all records; CA: cardiac arrest; CA-mortality: 30-day mortality after cardiac arrest records; CA-readmission: 30-day readmission after cardiac arrest records.

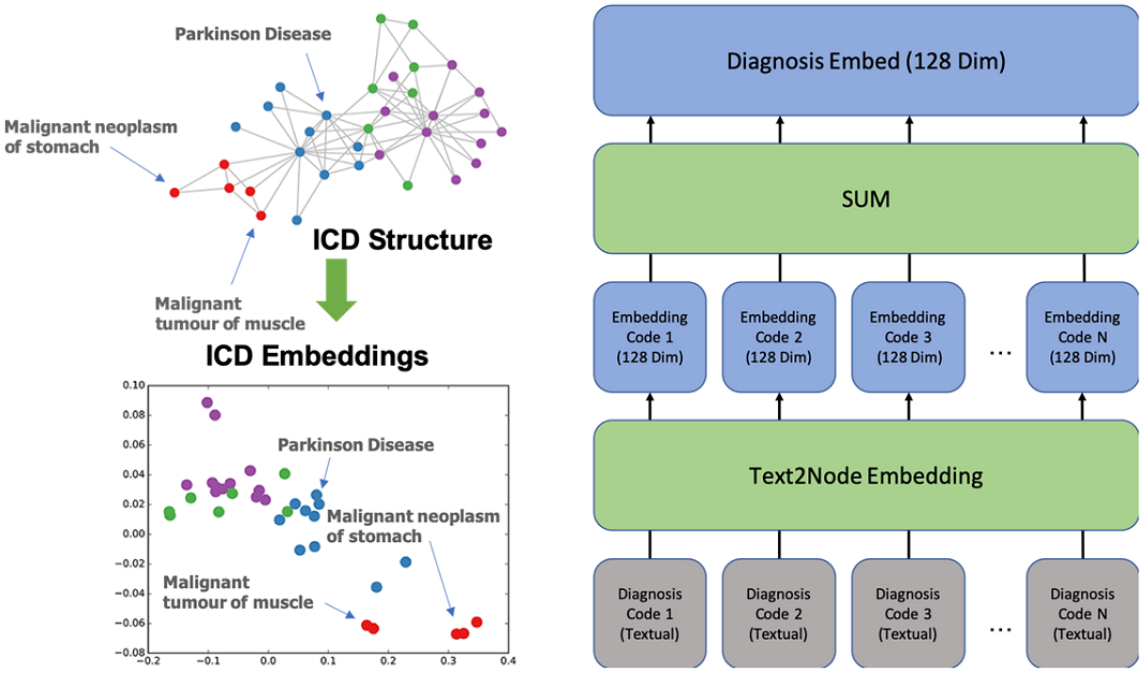


ALL-mortality/ALL-readmission is more common than CA-mortality/CA-readmission as most people would not survive after the first CA event. This means that when we want to predict the future outcome of a recovered CA patient, we do not have enough positive cases for analysis.

Hierarchical Vectorizer (HVec)

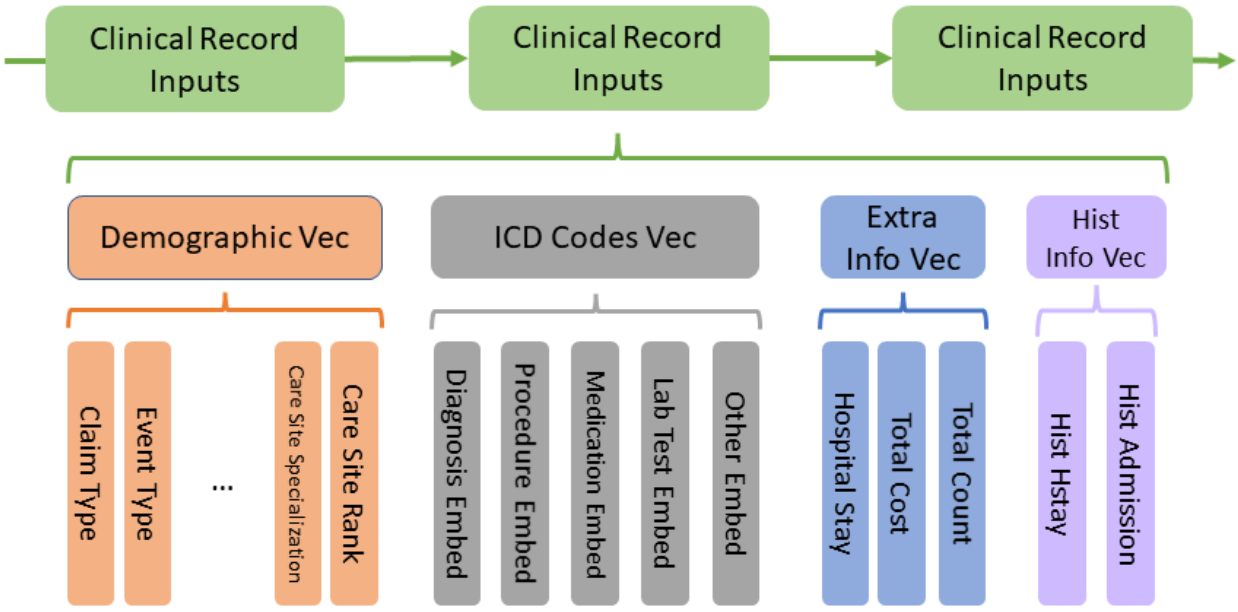
Each record was constructed into a 707-dimension vector for further training. Based on Table 1, all features except for ICD code features (textual features) can be vectorized with one-hot encoding. The features of ICD codes were extracted directly from the health record. A medical knowledge embedding system called Text2Node was used to embed the textual features into vectors [18]. Each of the five categories of ICD codes could contain many ICD codes from a single record, and all codes were added together as a single code for a given category (see Figure 3 as an example). Trained from a substantial medical knowledge database, Text2Node can effectively transform the textual medical concepts into a latent space while preserving the relationship of similar concepts.

Figure 3. Example of Text2Node embedding [18] and code embedding for diagnosis codes in a clinical record. Dim: dimension; ICD: International Classification of Disease.



For each clinical record, by concatenating all feature vectors into group vectors hierarchically (see Figure 4), the clinical record vector was obtained. After sorting each clinical record vector according to the date, time series techniques were used to train a model to predict the outcomes of each record.

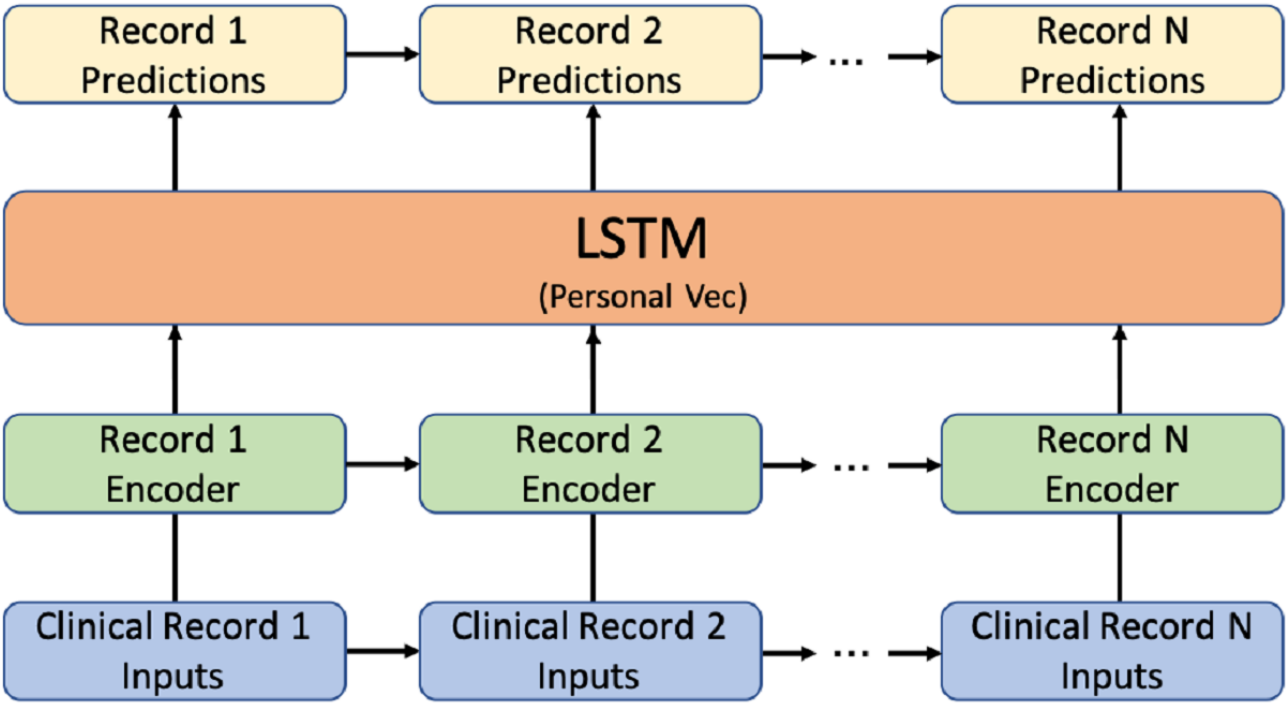
Figure 4. Feature concatenation to generate clinical record vectors for time series analysis. ICD: International Classification of Disease; Vec: vector.



Model Architecture

Deep recurrent neural networks (RNNs) have been proven to be a powerful tool for predicting time series data. In clinical research, the use of RNNs, especially long short-term memory (LSTM), for clinical prediction has been widely investigated [19-21]. Inspired by Choi's work [19], we proposed an HVec model using LSTM networks (Figure 5). In this framework, the record encoder was a fully-connected layer that generated the record embedding for each clinical record independently. The record embedding was a latent vector that contained all the information representing the current clinical record. This latent vector was used as the input of the LSTM to update the person vector (ie, patient status). This person vector was then used to predict our targets.

Figure 5. HVec model using LSTM networks. HVec: hierarchical vectorizer; LSTM: long short-term memory; Vec: vector.



However, most previous studies were based on a relatively balanced data set. As we pointed out earlier, the distribution of CA-mortality/CA-readmission is extremely imbalanced. Training LSTM networks with an extremely imbalanced data set is always challenging because, without a carefully designed training strategy, the model could be biased (ie, predicting the negative class for all records). In order to address this problem, two different training strategies have been proposed to alleviate model bias during the training step:

1. The multitask learning framework was introduced to combine several related learning tasks to regularize the gradient and alleviate data imbalance problems during training.
2. At the person level, CA-mortality/CA-readmission records were upsampled, and at the record level, higher weights were assigned to CA records.

Multitask Learning

The multitask learning framework was proposed, and several auxiliary related tasks were added to the HVec outputs (Figure 6). In this framework, the main functions were mortality and readmission. Here, instead of dividing each main task output into ALL-mortality/ALL-readmission and CA-mortality/CA-readmission independently, an output was considered to cover both because the latter is a subset of the former. Although the distribution was different, they still can be achieved simultaneously with the proposed person upsampling and CA record weighting (described in the next section). Inspired by a previous study [22], three auxiliary autoencoder tasks were introduced to help the model learn the embeddings (Figure 6). Two self-supervised regression tasks were also introduced to allow the embedding to "memorize" the current cost and predict the future cost. Furthermore, another classification task was implemented to predict whether a record is an IHCA record considering that we observed the correlation of IHCA to mortality in the previous analysis.

To monitor the gradients of different tasks and regularize the learning process with auxiliary tasks, Theorem 1 was adopted from Du et al [23].

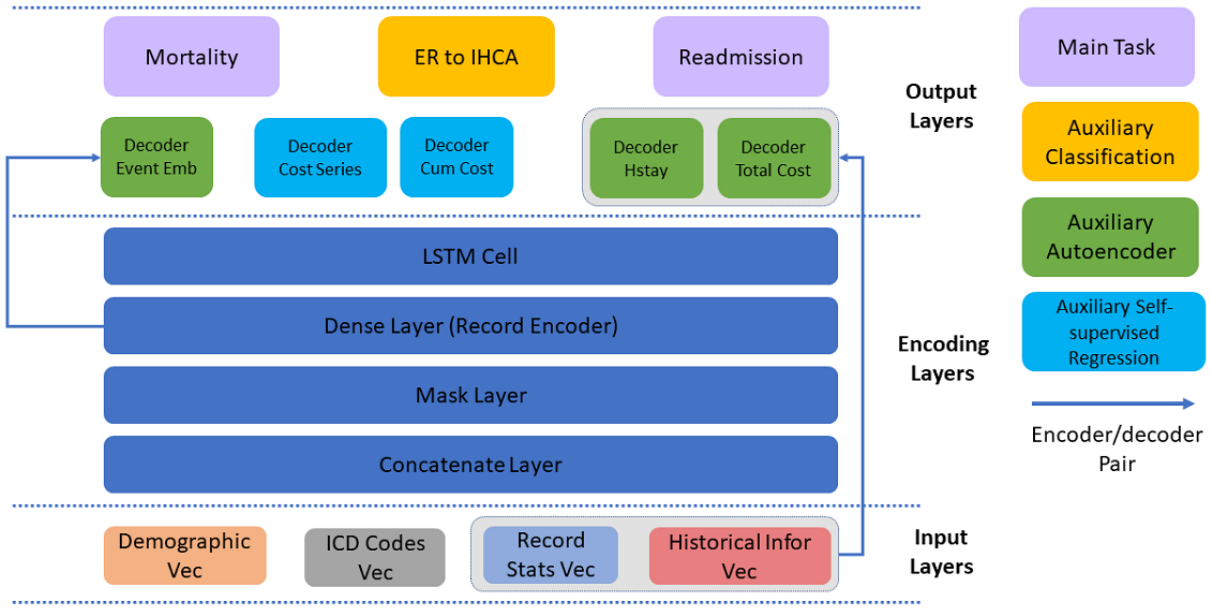
Theorem 1 given any gradient vector field $G(\theta^{(t)}) = \nabla_{\theta}$ (θ) (1) to denote the main task and an arbitrary vector field $V(\theta^{(t)})$ to denote the gradient from another auxiliary task, the update strategy using:

$$\theta^{(t+1)} := \theta^{(t)} - \alpha^{(t)} (G(\theta^{(t)}) + V(\theta^{(t)}) + \max (0, \cos(G(\theta^{(t)}), V(\theta^{(t)}))) \textbf{ (2)}$$

with a proper can coverage to a local minimum.

Following this theorem, HVec can learn and converge with a large data set.

Figure 6. Multiple outputs for multitask learning. Cum: cumulative; Emb: embedding; ER: emergency room; Hstay: hospital staying; ICD: International Classification of Disease; IHCA: in-hospital cardiac arrest; Infor: information; LSTM: long short-term memory; Stats: statistics; Vec: vector.



Person Upsampling and CA Record Weighting

Although the gradients from different tasks can be monitored in multitask learning, with a heavily imbalanced data set (eg, CA-mortality), the auxiliary tasks may fail to regularize the main task. When we trained the HVec model, all records of a person were treated as a single sequential record and fed together into the model. Therefore, in each batch, the batch size was equal to the number of people in the batch. Compared with the number of all records, the number of CA records for each person was relatively rare. CA-mortality and CA-readmission were rare compared with ALL-mortality and ALL-readmission.

The weighting strategy [24] was proposed to solve this problem from two perspectives: at the person level, patients with CA-mortality/CA-readmission records were upsampled per batch (see Figure 7); at the record level, a higher weight was assigned to CA records to make the objective function more sensitive to CA-mortality/CA-readmission records. The upsampling of patients with CA-mortality/CA-readmission records can guarantee that at the person level, there are more CA-mortality/CA-readmission records [25].

Assigning a higher weight to CA records could also emphasize the CA records during training by modifying the loss functions accordingly. Considering N-loss functions $\{L_1,\ldots,L_N\}$ corresponding to auxiliary tasks, the loss function can be written as (3).

Where (4) is a function that equals 1 if the statement in the bracket is true and otherwise 0; w_{pos} and w_{neg} are the positive and negative class weight, respectively. Combined with the gradient update strategy in equation 1, the HVec can learn from the extremely imbalanced data set effectively.

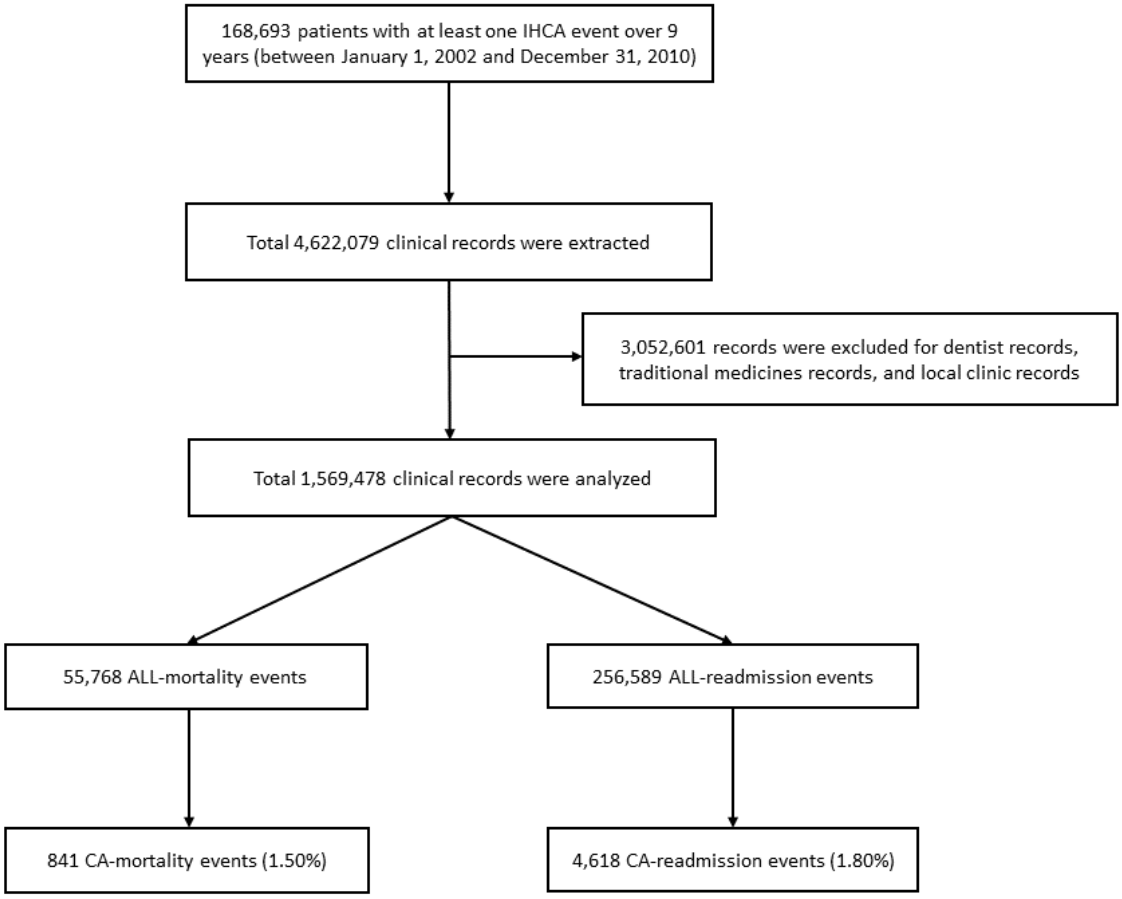
Results

Overview

A total of 168,693 patients and 4,622,079 clinical records were extracted from the NHIRD over 9 years, and 3,052,601 records (dentist records, traditional medicine records, or local clinic records) were excluded because these records were concentrated with repetitive conditions and mainly added noise to the machine learning models (Figure 8).

Figure 8. CONSORT diagram of the study cohort. ALL-mortality: 30-day mortality after all records; ALL-readmission: 30-day readmission after all records; CA: cardiac arrest; CA-mortality: 30-day mortality after CA records; CA-readmission: 30-day readmission after CA records; IHCA: in-hospital cardiac arrest.



There were 1,569,478 clinical records in the cleaned database, including both inpatient and outpatient records, from 168,693 patients (mean number of records per person: 9.30, SD 10.90) who have experienced at least one IHCA event. The results indicate an imbalanced data set, where the most imbalanced task was CA-mortality with a ratio of 0.53%. The characteristics of the study population are summarized in Table 4. There were 173,345 IHCA records (11.04% of the total clinical records), and on average, there were 1.02 IHCA records for each person.

The age of the patients in the data set ranged from 0 (newborn) to 118 years (mean age 68.66, SD 18.96 years), including 104,691 females and 64,002 males. Overall, 164,322 patients (97.4%) had CA only once, 4,174 patients (2.4%) had CA twice, and only 197 patients (0.2%) had CA more than twice. Death was recorded for 87,311 patients (51.75% mortality rate). Of these 87,311 patients, 82,225 patients died during their first hospitalization for CA (94.17%; Figure 9).

Table 4. Characteristics of the study population.[a]

Characteristics	Study population (N=168,693)
Age (years), mean (SD)	68.66 (18.96)
Gender (male), n (%)	64,002 (37.9)
Record number per person, mean (SD)	9.30 (10.90)
Cardiac arrest frequency, n (%)	
1	164,322 (97.4)
2	4174 (2.4)
≥3	197 (0.2)
Mortality, n (%)	87,311 (51.75)

Experiment 1: Single-Task Learning Versus Multitask Learning

In this experiment, person upsampling and event weighting were not applied. The model performance is summarized in Tables 5 and 6.

As shown in Table 5, multitask learning could improve the model performance for ALL-mortality and CA-mortality in terms of the AUROC and F1 scores. Based on single-task and multitask results, there was a relatively high improvement in performance for the extremely imbalanced CA-mortality task compared with the ALL-mortality task. However, the precision was relatively low due to the imbalance ratio, which also affected the F1 score. Moreover, the F1 score of CA-mortality was too low for real-life applications.

Table 5. Single-task and multitask learning performance for CA-mortality and ALL-mortality.[a]

Mortality	CA-mortality				ALL-mortality			
	AUROC[b]	F1	Precision	Recall	AUROC	F1	Precision	Recall
Single-task learning	0.658	0.014	0.010	0.024	0.663	0.130	0.101	0.180
Multitask learning	0.752	0.049	0.041	0.060	0.711	0.147	0.093	0.349

[a]CA-mortality: cardiac arrest mortality (30-day mortality after CA records); ALL-mortality: 30-day mortality after all records.

[b]AUROC: area under the receiver operating characteristic.

As shown in Table 6, the improvement in multitask learning for readmission prediction was not as significant as that for mortality prediction. Furthermore, in CA-readmission prediction, the F1 score and precision were decreased.

Table 6. Single-task and multitask learning performance for CA-readmission and ALL-readmission.[a]

Readmission	CA-readmission				ALL-readmission			
	AUROC[b]	F1	Precision	Recall	AUROC	F1	Precision	Recall
Single-task learning	0.847	0.214	0.162	0.315	0.872	0.554	0.424	0.801
Multitask learning	0.852	0.209	0.152	0.335	0.889	0.562	0.430	0.811

[a]CA-readmission: cardiac arrest readmission (30-day readmission after CA records); ALL-readmission: 30-day readmission after all records.

[b]AUROC: area under the receiver operating characteristic.

In this experiment, compared with single-task learning, multitask learning could achieve a better performance for ALL-mortality and ALL-readmission. However, multitask learning could not solve the extremely imbalanced data set.

Experiment 2: Improving CA Prediction Performance

Experiment 1 showed that models had difficulties making good predictions based on the CA-mortality and CA-readmission data due to the extremely imbalanced data set. In this experiment, we demonstrated that by applying person upsampling and event weighting, we could further improve the performance for CA-mortality and CA-readmission without considerably affecting ALL-mortality and ALL-readmission. In our experiment, the upsampling rate indicates how many times upsampling was performed for the positive class (patients with CA-mortality or CA-readmission) in a batch, and an upsampling rate of 1 means we did not perform upsampling. The CA event weight indicates the loss weight w_{pos} in equation 3, and we always set w_{neg}=1. We used different upsampling rates and event weights in our experiments. Our results are

summarized in Tables 7 and 8, including the previous results on single-task model performance (first row of each table).

Overall, compared with the 30-day mortality task, the imbalanced 30-day mortality task showed a larger increase in performance when applying balancing techniques. As shown in Table 7, after upsampling and event weighting, the models demonstrated improved performance for both ALL-mortality and CA-mortality. For CA-mortality, the F1 score was increased by 36.7% (from 0.049 to 0.067).

Table 7. Mortality models with their respective hyperparameter configuration and their performance in predicting both CA-mortality and ALL-mortality.[a]

Mortality			CA-mortality		ALL-mortality	
Upsampling rate	Event weight	Multitask	AUROC[b]	F1	AUROC	F1
1	1	No	0.658	0.014	0.663	0.130
1	1	Yes	0.752	0.049	0.711	0.147
10	1	Yes	0.808	0.064	0.728	0.155
10	5	Yes	0.802	0.067	0.726	0.158

[a]CA-mortality: cardiac arrest mortality (30-day mortality after CA records); ALL-mortality: 30-day mortality after all records.

[b]AUROC: area under the receiver operating characteristic.

Similar to ALL-mortality and CA-mortality, the AUROC and F1 score were increased for both ALL-readmission and CA-readmission by applying the two techniques. Based on the results in Table 8, a minor but consistent increase was achieved in CA-readmission prediction. However, there was no significant improvement in ALL-readmission prediction. This is because upsampling and event weighting would not greatly affect the learning process for a more balanced data set.

Table 8. Readmission models with their respective hyperparameter configuration and their performance in predicting CA-readmission and ALL-readmission.[a]

Readmission			CA-readmission		ALL-readmission	
Upsampling rate	Event weight	Multitask	AUROC[b]	F1	AUROC	F1
1	1	No	0.847	0.214	0.872	0.554
1	1	Yes	0.852	0.209	0.889	0.562
5	1	Yes	0.861	0.230	0.884	0.555
5	5	Yes	0.862	0.237	0.884	0.555

[a]CA-readmission: cardiac arrest readmission (30-day readmission after CA records); ALL-readmission: 30-day readmission after all records.

[b]AUROC: area under the receiver operating characteristic.

In summary, the results indicated that multitask learning, upsampling, and event weighting could effectively improve the model prediction performance for an imbalanced data set. We also showed that these techniques could be collectively used to achieve better results for an extremely imbalanced data set.

Discussion

In this study, we constructed a large patient database that includes 9 years of EHRs for over 168,000 IHCA patients, which can be used for future IHCA-related research. In addition, we developed an HVec model (LSTM model) that uses a multitask learning strategy to predict the 30-day mortality and readmission.

The results showed that our model could successfully predict future mortality and readmission using EHR data for IHCA patients. We proposed the person upsampling and record weighting strategies to handle the extremely imbalanced data problem in this study. After applying these techniques, some improvements were achieved in CA-mortality and CA-admission prediction.

In contrast to other studies using deep learning models to predict another IHCA event after CA [26], our study focused on predicting the future outcomes of IHCA patients after discharge. To the best of our knowledge, this is the first study to predict mortality and readmission after IHCA events by machine learning. The model may serve as a surveillance system for those who experienced IHCA. Patients with a high risk of mortality or readmission in the near future could be identified and re-evaluated before discharge. This study also demonstrated the potential of another model for predicting future mortality and readmission after each record using previous EHRs (ALL-mortality/ALL-readmission). The model might help identify those with a high risk in inpatient and outpatient situations. However, mortality and readmission rates are different in the general population compared with the patients selected in this study. Using hospital EHRs with patients' information in the NHIRD, we can construct a real-time alert system based on machine learning methods to predict the adverse events of IHCA survivors and improve their outcomes. Further prospective studies are needed to verify the utility of this system in the general population.

Several studies have reported models for predicting the outcomes of CA patients [8]. In a systematic review of current prediction models, the median AUROC value was 0.84 with an IQR of 0.80 to 0.89 [8]. For IHCA survivors, Chan et al. reported that the cardiac arrest survival post-resuscitation in-hospital (CASPRI) score could be used to predict favorable neurologic outcomes after discharge [3]. The AUROC of the CASPRI score was 0.80. Nanayakkara et al used deep learning models to predict the IHCA events of CA survivors, and the AUROC was 0.87 [26]. In our study, we encountered the difficulty of imbalanced data. Using proper learning strategies, we achieved comparable AUROC values (0.808 for CA-mortality and 0.862 for CA-readmission). However, the recall and precision rates were low in our study due to imbalanced data. This is a challenge we aim to resolve. When using historical medical records to predict outcomes, in many cases, the records contain information that may indicate the outcomes. For example, critical diagnosis and rescue medication are often associated with mortality. Including these types of information can facilitate training and give a high AUROC and F1; however, the model itself is of limited use. Mortality records were set as the negative class in our study to avoid overfitting. In further studies, the model may be improved by adjusting the threshold to optimize the trade-off between specificity and sensitivity.

In our HVec framework, we encoded each person's EHRs in two levels of latent vectors (record-level and person-level) and ensured that the model learns both simultaneously using the unsupervised autoencoder strategy. The predictive results were promising with these latent vectors. The latent vectors in these two levels may be further explored to facilitate clinicians' decision-making and provide better clinical interventions. In addition, the person vector may be used as a biomarker to evaluate the overall health status of a person beyond the health care setting. Along with some recently developed models such as Deep Patient [22] and MixEHR [27], we showed that the use of deep neural networks to extract information from EHRs might solve complex clinical research problems.

An imbalanced data distribution is common in clinical research, especially for disease-related predictions. In comparison with common diseases, many important diseases lack positive cases, making it difficult to train a good model. In a previous study [19], the authors attempted to address this problem by using a balanced, distributed data set and train a deep learning model with the balanced data set. Similarly, in this study involving CA-mortality and CA-readmission, we demonstrated that by carefully designing model learning strategies (eg, multitask learning and upsampling), some common problems in clinical research could be solved effectively with machine learning models.

This study has some limitations. First, the IHCA cohort was retrospectively extracted from the NHIRD. Further studies are needed to evaluate the efficacy of this model as an early warning system and determine how this system affects patients' outcomes. Second, as our model was developed based on the NHIRD, the generalization of this model to other health insurance data sets is not proven. Third, each patient's vital signs and laboratory data were not included in the analysis due to the study design. A combination of EHRs and patients' clinical data may further improve model performance. Fourth, traditional machine learning methods have the limitation of interpretability. Specific risk factors for 30-day mortality/readmission were unknown in this study. In future studies, we plan to develop an explainable model and investigate specific predictive factors in the model.

In summary, our model showed good performance in predicting 30-day mortality and readmission after IHCA, which can help clinicians monitor CA patients' status better. We aim to provide more insights to clinicians with proactive intervention recommendations. Nevertheless, a challenge remains in the interpretative ability of the deep learning model. Our future work will mainly focus on the interpretative power of the model trained using EHRs.

Acknowledgments

This study was supported by the Ministry of Science and Technology, Taiwan (project: 109-2634-F-002-031). CYC, YLH, and CHH were involved in data collection. SA, AW, KCF, and JX were involved in constructing the deep learning model. CYC and SA contributed equally to this paper and drafted the article. Finally, YLH, CHH, and RS made the final revision. YLH, CHH, and RS contributed equally as corresponding authors. All authors approved the final version of the article.

Abstract

Background: Skin and subcutaneous disease is the fourth-leading cause of the nonfatal disease burden worldwide and constitutes one of the most common burdens in primary care. However, there is a severe lack of dermatologists, particularly in rural Chinese areas. Furthermore, although artificial intelligence (AI) tools can assist in diagnosing skin disorders from images, the database for the Chinese population is limited.

Objective: This study aims to establish a database for AI based on the Chinese population and presents an initial study on six common skin diseases.

Methods: Each image was captured with either a digital camera or a smartphone, verified by at least three experienced dermatologists and corresponding pathology information, and finally added to the Xiangya-Derm database. Based on this database, we conducted AI-assisted classification research on six common skin diseases and then proposed a network called Xy-SkinNet. Xy-SkinNet applies a two-step strategy to identify skin diseases. First, given an input image, we segmented the regions of the skin lesion. Second, we introduced an information fusion block to combine the output of all segmented regions. We compared the performance with 31 dermatologists of varied experiences.

Results: Xiangya-Derm, as a new database that consists of over 150,000 clinical images of 571 different skin diseases in the Chinese population, is the largest and most diverse dermatological data set of the Chinese population. The AI-based six-category classification achieved a top 3 accuracy of 84.77%, which exceeded the average accuracy of dermatologists (78.15%).

Conclusions: Xiangya-Derm, the largest database for the Chinese population, was created. The classification of six common skin conditions was conducted based on Xiangya-Derm to lay a foundation for product research.

Introduction

Skin conditions affect 1.9 billion people [1] and are the fourth-leading cause of the nonfatal disease burden across 188 low- and high-income countries [2-4]. Patients with skin diseases usually account for 10% of the number of outpatients in Chinese general hospitals and are also among the most common patients in primary care. However, there is a severe lack of dermatologists, particularly in rural Chinese areas. Based on incomplete statistics from the Chinese Society of Dermatology and Sexually Transmitted Diseases, there are approximately 30,000 dermatologists in China, accounting for 0.0016% of the total number of people with skin diseases.

The total number of dermatologists in China is less than 30,000, which results in a large gap between the supply and demand of dermatological resources, especially in primary care hospitals. In addition, some long-standing problems in the Chinese medical industry still exist, such as the uneven distribution of high-quality doctor resources, primary care hospital doctors prone to misdiagnosing patients, missed diagnoses, and insufficient knowledge of rare diseases [5,6]. Addressing these problems necessitates the use of artificial intelligence (AI) in Chinese dermatology. AI has transformed health care [7] and has become one of the most trending research topics. Deep learning algorithms, powered by advances in computation and the creation of large databases, have recently been shown to outperform humans in visual tasks [8]. Recent studies in the medical field, such as those on automatic lesion segmentation and intelligent disease recognition, have successfully used AI to identify skin diseases based on image data [9]. The use of AI in Chinese dermatology started later than in some high-income countries but has been developing rapidly; it could be a solution to the problems that exist in dermatology.

Using deep learning methods for skin disease identification requires a large amount of data. Skin images from the Chinese population are limited. Most public databases on skin diseases are from the US or European Union (EU) population, with a relatively small size and without corresponding pathology information to support their validity [9,10]. The images in the ISIC database, for example, come mainly from light-skinned populations in the United States, Europe, and Australia [11]. Other researchers prefer to use data sets established based on their own patients. These data sets contain information about limited types of skin diseases, include a smaller sample size, or have decreased reliability [12,13]. These problems hinder the use of Chinese AI products, because the systems developed based on these data sets are unreliable for automatically diagnosing members of the Chinese population. Therefore, it is necessary to build a data set with skin images from the Chinese population that would enable successful diagnosis of skin diseases for Chinese patients.

In this paper, we aim to build a database consisting of skin images based on the Chinese population and present an AI-based method for classifying six common skin diseases to lay a foundation for further product research.

Methods

Construction of Xiangya-Derm

As approved by the ethics committee of Central South University, we captured each image with either a digital camera or a smartphone in the Dermatology Outpatient Department, which relies on the Xiangya Big Data Collection Platform. The images were collected according to uniform standards from many cooperating hospitals in Nanjing, Guangzhou, Wuhan, Changsha (cities in China), etc. Most of these images have corresponding pathology information to ensure the accuracy of diagnosis information. For the other common and easy-to-diagnose skin diseases, images were verified by at least three experienced dermatologists. Meanwhile, the dermatologists were asked to annotate the specific location of the skin lesions in each image using an open source software called LabelImg [14]. Finally, the images with a clear diagnosis were added to Xiangya-Derm, a Chinese database. We classified the existing data into six types of skin diseases (malignant tumor, benign tumor, erythema papule scale, bullous, allergic, and connective tissue) based on the classification of common skin diseases and the amount of existing data.

Study of Six Common Skin Diseases

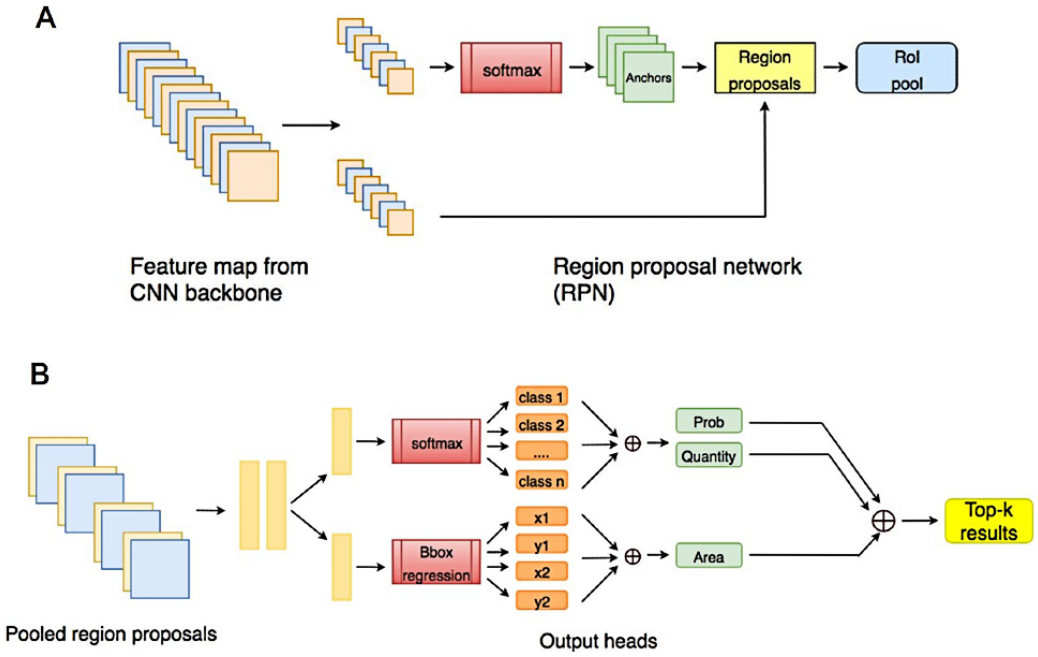
After the construction of Xiangya-Derm, we conducted research on the classification of some common skin diseases from the Xiangya-Derm database using a convolutional neural network (CNN). First, six different subtypes of common dermatoses with additional data magnitudes and common outpatients (psoriasis, basal cell carcinoma, seborrheic keratosis, pemphigus, eczema, and lupus erythematosus) were selected, and a data set consisting of 5660 clinical images was constructed. These six subtypes of skin diseases were selected because they are the most common and representative skin diseases in primary care hospitals in China and because more data were available for these diseases than for any other. This data set contained common skin disease types, such as skin tumors, erythema, and scaling disease. In this data set, the image numbers of psoriasis and other diseases were unbalanced. If the data set had been used directly to classify each type of disease separately, it would have created a severe bias in the network against psoriasis. Therefore, we downsampled psoriasis samples to balance the number of samples among different categories. Moreover, we

re-established a database containing six types of diseases, totaling approximately 3000 images, which ensured that the number of samples in different categories was within a reasonable range. In this range, the disease with the largest number of samples had over 1000 images, while the disease with the fewest samples had fewer than 200 images.

Based on a balanced number of samples in different categories, we proposed a network, called Xy-SkinNet, that was trained to be a six-category model for these six common types of diseases. Before we constructed the model, images in the database for modeling were checked. We found that the background of the clinical images in our database was complex and the size of lesions was relatively small. To overcome these problems and improve the classification performance, the model was designed to first detect the regions of interest that contained lesions. A specially designed information fusion block was then used to output the result by considering all the regions. The network used modified ResNet (M-ResNET) as the backbone network and Faster R-CNN [15], a two-stage object detection method, as the basic structure. Regarding the training and testing data set size, we trained our model with 2400 images and tested it with the remaining 600 images (training size:testing size=4:1) in the database.

Faster R-CNN is an improved version of R-CNN [16] and Fast R-CNN [17]. As a two-stage method, Faster R-CNN comprises two parts. The first part is a region proposal network (RPN), which generates several candidate regions on the entire image according to some preset box (anchor) and keeps only the foreground regions. The second part classifies and locates each remaining region in a fine-grained manner. These two parts share some network parameters. The structure of the model is shown in Figure 1. Based on the basic structure of the method, we improved it by adding an information fusion block for dermatosis characteristics.

Figure 1. Structure of Xy-SkinNet. CNN: convolutional neural network.



Human Versus Computer Competition

To evaluate the performance of Xy-SkinNet and validate its effectiveness in a clinical situation, we conducted a contrast experiment with 31 dermatologists of different seniority levels, including professors, senior attending doctors, young attending doctors, and medical students of dermatology. In our contrast experiment, Xy-SkinNet and all dermatologists had to identify the type of disease from a set of 100 clinical images without a time limit. Their performances were evaluated using accuracy as the metric. To ensure the fairness and validity of the comparison, all the images used contained only one type of skin disease and had been previously verified using corresponding histopathological information. Histopathological examination was the golden standard for diagnoses of these six types of skin diseases. Compared with other diagnostic technologies, histopathological examination was more accurate and objective. If there were some cases whose histopathological features were atypical, we let another three specialists (who did not take part in human vs. computer competition) determine a final diagnosis. Images for this contrast experiment were selected by dermatologists who did not participate in the experiment, and the images were not included in the training or testing data sets used in the process of building of our model.

Results

Xiangya-Derm, a Chinese Dermatological Database

Xiangya-Derm, as a new Chinese database, contains nearly 20 years of data from 15 hospitals, including Xiangya Hospital Central South University, the Third Hospital of Central South University, and Henan Provincial People's Hospital. Most images were matched with pathology information to ensure the accuracy of the image diagnostic information. Other common skin diseases that are easily recognized by the naked eye were independently confirmed by three dermatologists. Each patient's clinical history was recorded on the Xiangya Big Data Collection Platform. It is worth mentioning that most of the data in the

Xiangya-Derm database have been labeled with bounding boxes by skin experts (Figure 2).

There are over 150,000 images in the Xiangya-Derm database, including 571 different skin diseases. Approximately, 60,000 images have been assigned annotations of skin type and lesion location. Common skin diseases, such as benign and malignant skin tumors, erythema papule scales, allergic skin diseases, and bullous skin diseases, are included (Figure 3). Of the total images in the database, 14,063 images are of skin tumors, including 5356 images of malignant tumors and 8707 images of benign tumors.

For common skin diseases, the diagnosis was independently made by three dermatologists based on history, clinical images, and dermoscopic features (Figure 2A). For rare skin diseases and skin tumors, the diagnosis was made based on history, clinical images, dermoscopic features, and histopathological features (Figure 2B). All the information about the patients and their diseases was collected in our database.

The database mainly consists of six types of skin diseases: malignant tumor, benign tumor, erythema papule scale, connective tissues, allergic, and bullous (Figure 3A). Representative examples in the Xiangya-Derm database are presented in Figure 3B, including psoriasis, melanoma, and dermatofibrosarcoma protuberans (an extremely rare disease). In addition to clinical images, dermascopic images, medical imaging information (eg, B-scan ultrasonography, positron emission tomography–computed tomography [PET-CT]) and history were included.

Figure 2. Pattern of the Xiangya Big Data Collection Platform.

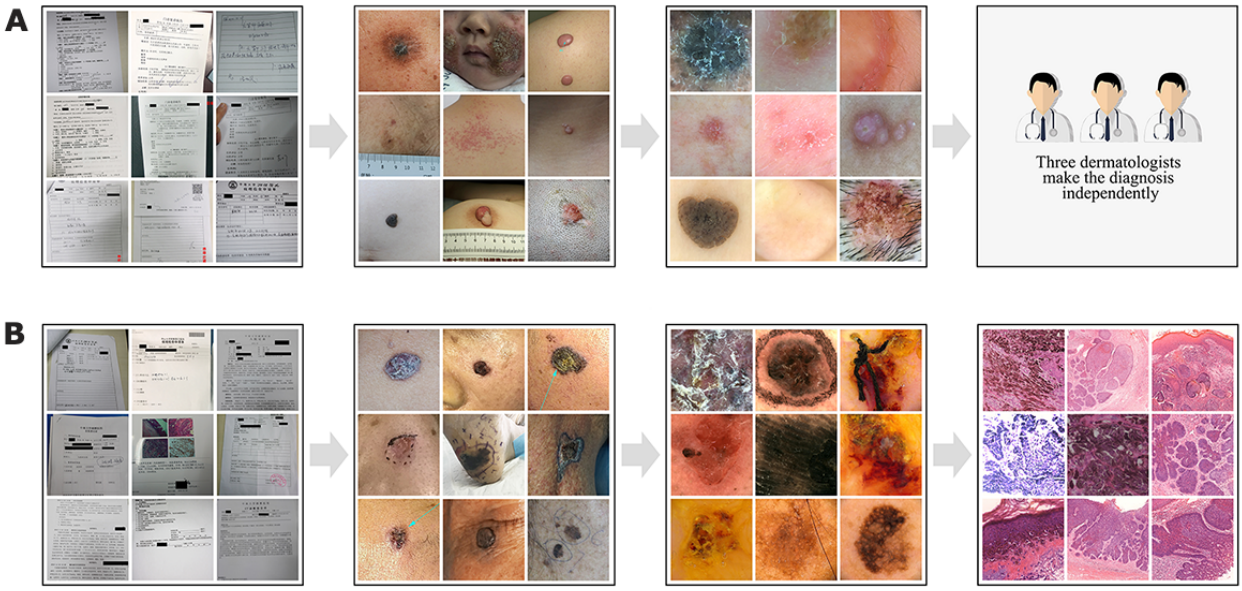


Figure 3. Branching tree diagram of the Xiangya-Derm database.

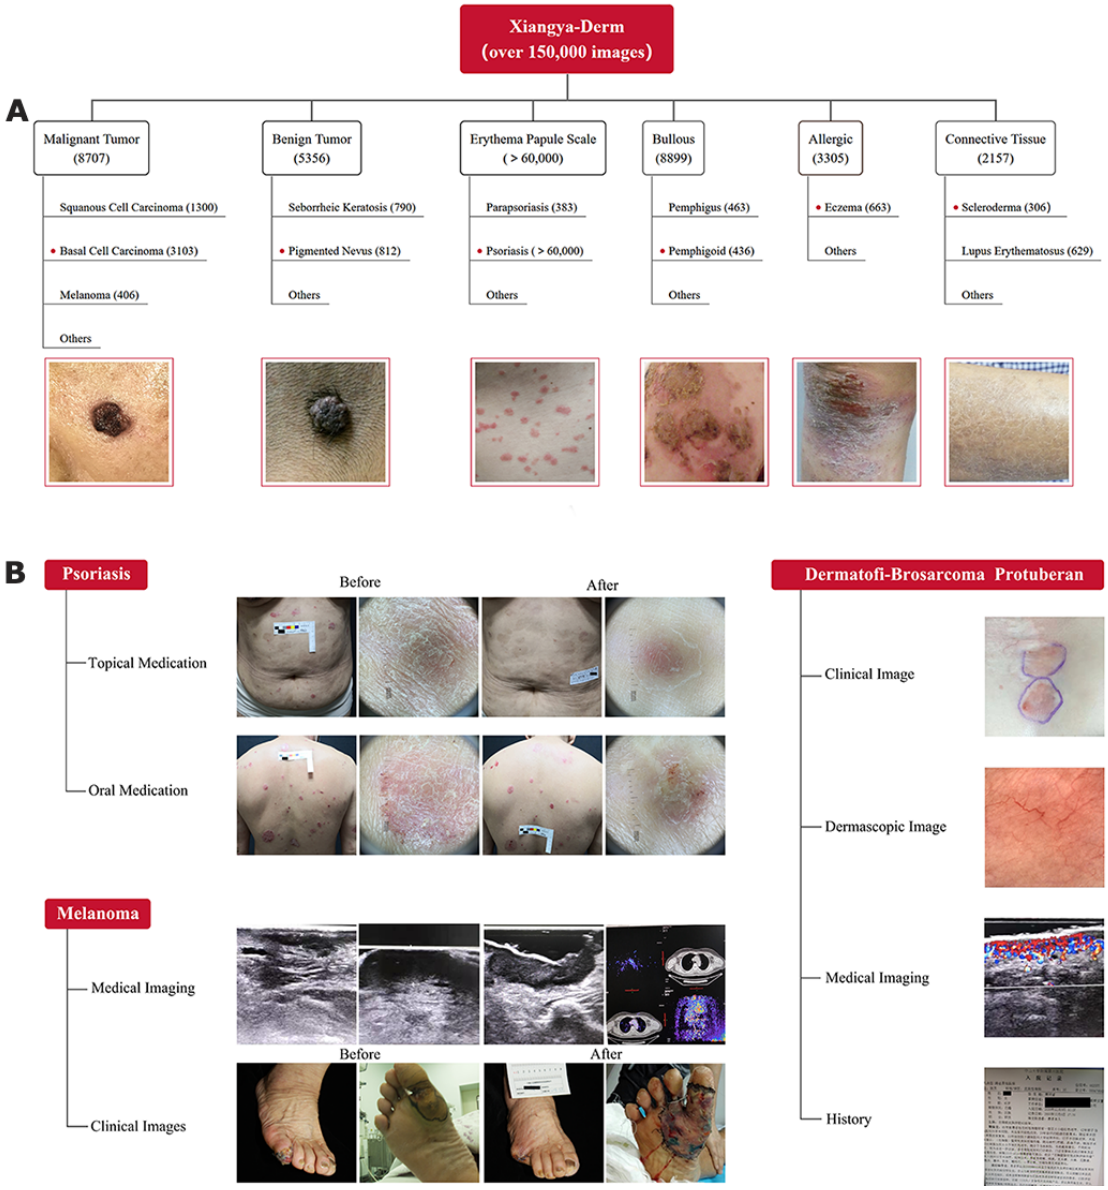

Xy-SkinNet Performance on Six Common Skin Diseases

The performance when using different CNN structures as the backbone model on the testing data set is shown in Table 1. The ResNet-152 model showed better performance than others in terms of top 1 and top 3 mean accuracies (61.48% and 77.38%, respectively). Xy-SkinNet's top differential diagnosis was for pemphigus and had a top 1 accuracy of 80.0%. When Xy-SkinNet was allowed three diagnoses, its top 3 accuracy rose to 90.0%. We also found that the performance of the ResNet-101 model was similar to that of the ResNet-152 model for certain diseases, such as seborrheic keratosis, pemphigus, and lupus erythematosus. However, the ResNet-101 model was better than the ResNet-152 model in terms of the top 1 accuracy on eczema (59.1% vs 54.5%) and the top 3 accuracies on lupus erythematosus (70.0% vs 60.0%).

The comparison between the experimental results of Xy-SkinNet and the average performance of dermatologists is shown in Table 2. The receiver operating characteristic (ROC) curve of the model for six types of diseases is shown in Figure 4, in which the performance of each dermatologist is also plotted. As the results showed (Table 2), Xy-SkinNet achieved a top 1 accuracy of 64.75%, while the average performance of the dermatologists was 62.13%. Moreover, Xy-SkinNet outperformed the dermatologists in terms of the top 3 accuracy, where Xy-SkinNet achieved an accuracy of 84.77%, while the dermatologists achieved an accuracy of 78.15%. As shown in Figure 4, for Xy-SkinNet, the area under the curve (AUC) values for the six types of diseases were 0.81, 0.85, 0.90, 0.96, 0.79, and 0.76, respectively, which were higher than the corresponding values of the average performance level of the dermatologists.

Moreover, we recorded the time costs for Xy-SkinNet and each dermatologist in our experiments. The results showed that Xy-SkinNet takes only 10 seconds to identify all 100 clinical images, while some dermatologists took over 2500 seconds or over 25 seconds for a single image. Even dermatologists with minimal time costs took up to 1216 seconds to classify the images. These results showed that the method adopted in this paper can achieve comparable performance in terms of accuracy

to that of dermatologists and outperform dermatologists in terms of time costs.

The comparison of accuracies (%) on six different skin diseases between Xy-SkinNet and the average of dermatologists with different levels in the external data set provided by dermatologists are shown in Table 2. Xy-SkinNet achieved a top 1 accuracy of 64.75%, while the average performance of the dermatologists was 62.13%. Moreover, Xy-SkinNet outperformed the dermatologists in terms of the top 3 accuracy, where Xy-SkinNet obtained an accuracy of 84.77%, while the average performance of the dermatologists was 78.15%.

Table 1. Classification accuracies (%) of Xy-SkinNet.[a]

Backbone	PSO[b] (%)	BCC[c] (%)	SEK[d] (%)	PEM[e] (%)	ECZ[f] (%)	LUE[g] (%)	Mean (%)

ResNet-50	61.9	20.0	60.0	70.0	45.5	40.0	49.57
ResNet-101	54.8	20.0	70.0	80.0	59.1	50.0	55.65
ResNet-152	69.4	40.0	75.0	80.0	54.5	50.0	61.48
Xy-SkinNet	64.1	50.0	70.0	75.0	83.9	45.5	64.75
Top 3							
ResNet-50	66.7	70.0	75.0	90.0	68.2	60.0	71.65
ResNet-101	61.9	40.0	80.0	90.0	72.7	70.0	69.10
ResNet-152	71.6	80.0	90.0	90.0	72.7	60.0	77.38
Xy-SkinNet	67.7	70.0	90.0	90.0	100.0	90.9	84.77

[a]The classification accuracies (%) of Xy-SkinNet on six different skin diseases using different backbone networks as the feature extractor are shown. The ResNet-152 model showed better performance than the ResNet-50 and ResNet-101 models in terms of top 1 and top 3 mean accuracies. However, our original algorithm performed better than the others, especially in terms of the top 3 accuracies.

[b]PSO: psoriasis.

[c]BCC: basal cell carcinoma.

[d]SEK: seborrheic keratosis.

[e]PEM: pemphigus.

[f]ECZ: eczema.

[g]LUE: lupus erythematosus.

Table 2. Comparison of accuracy (%) between Xy-SkinNet and the average of dermatologists.

Class	Sample size	Top 1 (computer; %)	Top 1 (dermatologists; %)	Top 3 (computer; %)	Top 3 (dermatologists; %)
LUE[a]	11	45.5	60.6	90.9	70.0
ECZ[b]	31	83.9	47.5	100.0	76.9
SEK[c]	10	70.0	60.8	90.0	77.9
PSO[d]	93	64.1	75.7	67.7	87.2
BCC[e]	10	50.0	67.4	70.0	84.9
PEM[f]	20	75.0	60.8	90.0	72.0
All	175	64.75	62.13	84.77	78.15

[a]LUE: lupus erythematosus.

[b]ECZ: eczema.

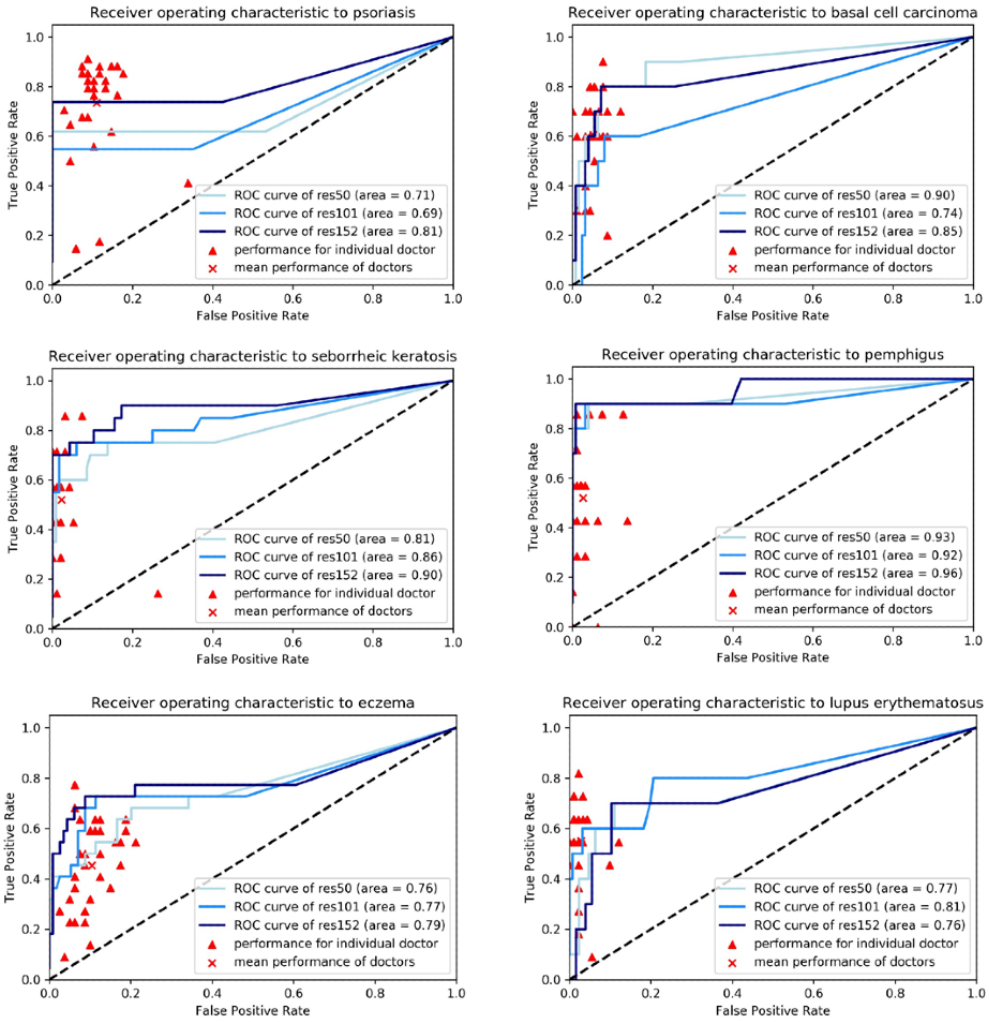
[c]SEK: seborrheic keratosis.

[d]PSO: psoriasis.

[e]BCC: basal cell carcinoma.

[f]PEM: pemphigus.

Figure 4. ROC curve of the six-category classification model. The three blue lines represent the mean ROC curves over the ResNet50, ResNet101, and ResNet152 runs. Each triangular point represents the results of one dermatologist. Results suggested that the mean performance of the dermatologists was lower than that of the models for most diseases. ROC: receiver operating characteristic.



Discussion

Principal Results

In this study, we established a new database, Xiangya-Derm, which consists of over 150,000 clinical images of 571 different skin diseases in the Chinese population. Xiang-Derm is the first integrated, normative database based on skin conditions in the Chinese population. Based on this database, we selected six common skin diseases and proposed an AI network, Xy-SkinNet. The top 1 and top 3 diagnostic accuracies of Xy-SkinNet were higher than those of dermatologists from the Department of Dermatology. This study was an attempt at exploring AI products and services and has successfully set the stage for future development. An increasing number of studies are incorporating clinical images [18-21].

There are already some open databases, such as AtlasDerm, Derm101, and Dermnet. Considering differences in skin color, Xiangya-Derm can provide data for realizing AI diagnosis of skin diseases among the Chinese population. Many existing databases lack medical history information, especially information about pathological diagnosis, and, potentially, contain some misdiagnosed photos. Notably, one of the greatest advantages of Xiangya-Derm is that most images contain corresponding skin pathology results, providing the category annotation of a gold standard, which can be most effectively applied to various research studies and in the development of AI. This feature ensures that the diagnostic information about pictures used for deep learning is accurate and reduces the diagnostic errors caused by misdiagnosis. Of course, there are also a small number of unmatched pictures in our database, which is correlated with the lack of corresponding dermoscopic images.

In addition, XiangyaDerm provides image data with the location for all skin lesions, thus enabling researchers to apply object detection algorithms in computer vision for the automatic diagnosis of skin diseases. Moreover, each image has a full set of clinical information about the patient, including demographic information, complaints, current medical history, past medical history, and family history. Given the complete set of big data, conducting further research on AI diagnosis using multimodal data, which is more coincident with the real-world diagnosis process and more intuitive for both doctors and patients, is achievable.

Comparison With Prior Work

Many attempts have been made in the field of automatic diagnosis of dermatosis. For example, Alćonet et al [22] proposed a system that consisted of a feature extractor and a classifier. This system is capable of adapting its decision-making process based on patient information. Blum et al [23] performed digital image analysis using 64 different analytical parameters based on 837 cases of melanocyte lesions to establish a computer algorithm for diagnosing melanocyte lesions. The diagnostic accuracies of the algorithm for complete and partial imaging were 82% and 84%, respectively. Another study used multiple databases to perform dermoscopic and digital dermoscopic examinations of cutaneous melanoma and compared the diagnostic accuracies of different dermal algorithms and digital dermatoscopy joint intelligence [24].

CNNs have presented varying results in medical fields when using an improved algorithm [8,25,26]. Pal et al [10] designed and produced a psoriasis skin biopsy image data set of 90 images and attempted to segment the images using several different neural network models. Their results were superior to the manual extraction features. Sun et al [9] attempted to classify dermatological images using CNNs as feature extraction methods. They used a data set that included 198 types of diseases and 6584 images. However, despite using a large data set, the final result was inferior to that obtained by the use of AI extraction features. Han et al [27] used a deep learning algorithm to classify clinical images of 12 dermatoses, with performance comparable to that of 16 dermatologists. Tschandl et al [28] showed that computers can achieve an accuracy similar to that of medical students by using a CNN-based method to diagnose skin diseases on an image. In our study, the AI-based six-category classification outperformed the dermatologists. Patients' multimodal data were used to create a simulated clinical setting for AI. Thus, the comparison between AI and the dermatologists is fair as the diagnosis made by dermatologists in real clinical practice partially depends on history and other nonimage information.

Relevant research reports also increasingly support that deep learning systems can help improve the accuracy of nondermatologists or clinicians with a lack of experience, especially in primary care [1]. AI can also foster and improve the confidence of doctors. In China, 95% of dermatologists are concentrated in tertiary hospitals, and the number of dermatologists at county hospitals, especially township hospitals, is less than 5% of the total number. In addition, numerous county and township hospitals have a limited number of dermatologists. The proportion of doctors and patients is unbalanced, and the level of doctors is uneven, causing delayed diagnosis for many patients, poor prognosis, aggravation of the family economic burden, etc [29]. In our research, we selected six skin diseases: psoriasis, basal cell carcinoma, seborrheic keratosis, pemphigus, eczema, and lupus erythematosus. Our research may satisfy the needs of primary doctors, as these six conditions are common in primary care and outpatient work. In the future, we intend to explore an auxiliary diagnosis system that can provide dermatologists with three possible diagnoses, ranked by accuracy, for one lesion. The risk of misdiagnosis is likely to decline for primary diagnoses when combining AI and manual correction.

Because there are few dermatologists in China's rural areas, we plan to build a multidimensional AI platform that assists Chinese primary dermatologists in diagnosing skin diseases through deep learning and the construction of Xiangya-Derm. In light of the lack of criteria for skin disease data sets, we would like to encourage the establishment of standards in the future. It would be beneficial to create a new data set or improve the existing data sets with multimodal clinical information.

Limitations

Although we included six types of skin diseases in our data set, a large number of skin diseases were not considered. One of the reasons for this is that these six diseases cover most of the skin conditions in clinical practice. With this database and the development of AI products, new data for rare skin diseases can be collected at the same time as the diagnosis of common skin diseases. In addition, the quality of health services has improved in China, and some skin diseases, such as bacterial and parasitic skin diseases, are rarely seen. Thus, it is difficult to collect data on these diseases. Moreover, the clinical images in our database were collected from the Chinese population, making the database ineffective for training an intelligent global skin disease diagnosis system.

Conclusions

Xiangya-Derm, the largest database for skin diseases in the Chinese population, was created, and six common skin conditions were classified based on Xiangya-Derm to lay a foundation for product research.

Abstract

Background: Recently, the analysis of endolymphatic hydropses (EHs) via inner ear magnetic resonance imaging (MRI) for patients with Ménière disease has been attempted in various studies. In addition, artificial intelligence has rapidly been incorporated into the medical field. In our previous studies, an automated algorithm for EH analysis was developed by using a convolutional neural network. However, several limitations existed, and further studies were conducted to compensate for these limitations.

Objective: The aim of this study is to develop a fully automated analytic system for measuring EH ratios that enhances EH analysis accuracy and clinical usability when studying Ménière disease via MRI.

Methods: We proposed the 3into3Inception and 3intoUNet networks. Their network architectures were based on those of the Inception-v3 and U-Net networks, respectively. The developed networks were trained for inner ear segmentation by using the magnetic resonance images of 124 people and were embedded in a new, automated EH analysis system—inner-ear hydrops estimation via artificial intelligence (INHEARIT)-version 2 (INHEARIT-v2). After fivefold cross-validation, an additional test was performed by using 60 new, unseen magnetic resonance images to evaluate the performance of our system. The INHEARIT-v2 system has a new function that automatically selects representative images from a full MRI stack.

Results: The average segmentation performance of the fivefold cross-validation was measured via the intersection of union method, resulting in performance values of 0.743 (SD 0.030) for the 3into3Inception network and 0.811 (SD 0.032) for the 3intoUNet network. The representative magnetic resonance slices (ie, from a data set of unseen magnetic resonance images) that were automatically selected by the INHEARIT-v2 system only differed from a maximum of 2 expert-selected slices. After comparing the ratios calculated by experienced physicians and those calculated by the INHEARIT-v2 system, we found that the average intraclass correlation coefficient for all cases was 0.941; the average intraclass correlation coefficient of the vestibules

was 0.968, and that of the cochleae was 0.914. The time required for the fully automated system to accurately analyze EH ratios based on a patient's MRI stack was approximately 3.5 seconds.

Conclusions: In this study, a fully automated full-stack magnetic resonance analysis system for measuring EH ratios was developed (named INHEARIT-v2), and the results showed that there was a high correlation between the expert-calculated EH ratio values and those calculated by the INHEARIT-v2 system. The system is an upgraded version of the INHEARIT system; it has higher segmentation performance and automatically selects representative images from an MRI stack. The new model can help clinicians by providing objective analysis results and reducing the workload for interpreting magnetic resonance images.

Introduction

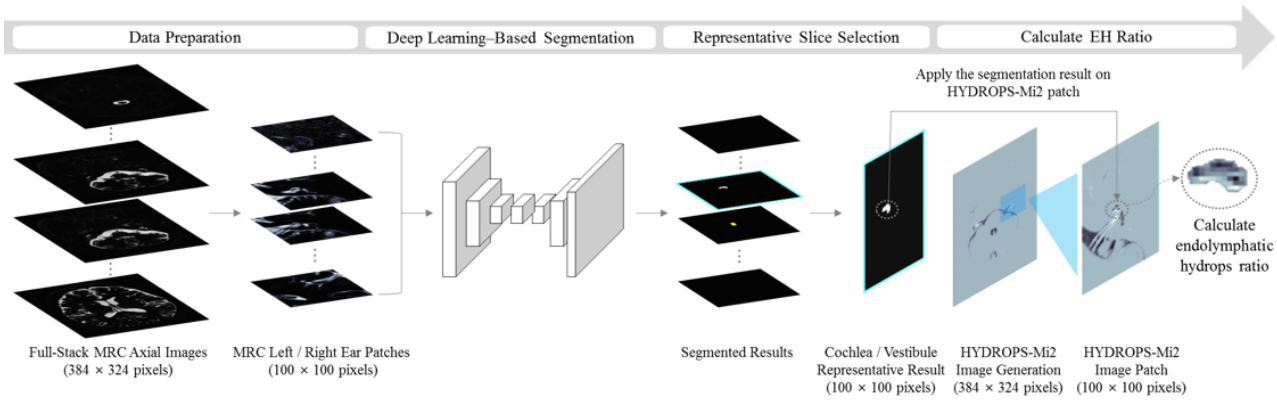
Although many medical fields have been developed over the past few decades, medical imaging techniques, such as computed tomography and magnetic resonance imaging (MRI), have advanced greatly [1]. Experienced radiologists and physicians typically interpret such images in the clinical field. However, in recent years, due to the remarkable development of machine learning, the situation is changing [2]. Artificial intelligence, including machine learning, is widely used in various fields of medical science, and image analysis via a convolutional neural network is developing rapidly [3].

Ménière disease is a multifactorial disorder with typical symptoms, such as recurrent vertigo attacks, fluctuating hearing loss, tinnitus, and sensations of ear fullness. The prevalence of Ménière disease varies by region and study, but the estimated prevalence ranges from 30 to 150 patients per 100,000 people [4]. In particular, it is known that this prevalence is higher within White and female populations and increases with age [5]. Endolymphatic hydrops (EH) is a histologic hallmark of Ménière disease in which the endolymphatic spaces in the cochlea and the inner ear vestibule are distended [6]. According to current diagnostic criteria, pure tone audiometry is the only objective test for the diagnosis of definite or probable Ménière disease. Further, electrocochleography is a common test for estimating EH ratios [7]. However, electrocochleography is used only as a reference examination for diagnosing Ménière disease because it does not directly show the endolymphatic space. Similarly, Ménière disease is challenging to diagnose objectively, and efforts have been made in recent years to directly measure EH ratios by using MRI [8-10].

A protocol for image-based EH analysis was suggested in a previous study [11]; it required specific image viewer software to generate a hybrid image of signals (ie, a hybrid of the reversed image of the positive endolymph signal and native image of the positive perilymph signal [HYDROPS] or a HYDROPS image multiplied by T_2-weighted magnetic resonance cisternography [HYDROPS-Mi2]). This process involves the manual contouring of inner ear organs for boundary segmentation, which is mostly performed by medical experts.

The need for automated analyses has emerged because conventional quantitative analyses require more time and effort than typical image interpretation processes. The automatic measurement of EH ratios via MRI was proposed based on the deep learning approach in our previous study [12]. Our research showed that the convolutional neural network–based deep learning model—the inner-ear hydrops estimation via artificial intelligence (INHEARIT) system—could efficiently segment cochleae and vestibules in magnetic resonance images and calculate the EH ratios of the segmented regions [12]. However, our study had a few limitations. First, full-stack image validation was not conducted in our previous study. Thus, medical experts were needed to manually select representative image slices of cochleae and vestibules from the full magnetic resonance image stack and load them into the system, and this human user process was time consuming. Second, validation with an isolated data set was not performed, which made it difficult to verify the robustness of the system. Lastly, various deep learning models were not used, except for the Visual Geometry Group (VGG) network architecture—a VGG-19–based network [13]. To compensate for these limitations, we developed a fully automated analytic system for calculating EH ratios by using deep learning and MRI—the INHEARIT-version 2 (INHEARIT-v2) system. The entire framework for this analytic system is depicted in Figure 1.

Figure 1. The proposed inner-ear hydrops estimation via artificial intelligence-version 2 (INHEARIT-v2) framework. EH: endolymphatic hydrops; HYDROPS-Mi2: hybrid of the reversed image of the positive endolymph signal and native image of the positive perilymph signal image multiplied by T_2-weighted magnetic resonance cisternography; MRC: magnetic resonance cisternography.



Methods

Study Participants

Two data sets were used in this study—one for the deep learning–based training models and another for validation. For the training models, the magnetic resonance images of 124 patients (males: n=57; females: n=67; age: mean 49.3 years, SD 16.02 years; range 17-76 years) who participated in our previous INHEARIT study were used [12]. For the additional test, 60 new participants were recruited from Samsung Medical Center from February 2018 to September 2019. Written informed consent was obtained from all participants. This study was approved by the Institutional Review Board of Samsung Medical Center (approval number: 2020-06-046).

Data Set for Analysis

We scanned all patients' inner ears with a 3.0-T MRI device (MAGNETOM Skyra; Siemens Medical Solutions). Gadobutrol (gadolinium-DO3A-butriol; Gadovist 1.0), which was used as the contrast agent, was intravenously administered to patients before MRI. Different magnetic resonance scans were made by using heavily T_2-weighted magnetic resonance cisternography (MRC) to distinguish the outlines of organs. Positive perilymph images (PPIs) and positive endolymph images (PEIs) were used to evaluate EHs. The HYDROPS images were obtained by subtracting the number of PEIs from the number of PPIs. MRC images, PPIs, and PEIs had identical fields of view, matrix sizes, and slice thicknesses [8,14].

Data Annotation by Physicians

One neuroradiologist and one neuro-otologist independently evaluated the MRC images. Representative slices of 4 classes—the left cochlea and vestibule and the right cochlea and vestibule—were selected, and their contours were annotated manually. The main slices of a cochlea or vestibule and their regions of interest (ROIs) were chosen based on the following criteria. For the cochlear ROI, among all MRI slices in which the basal, middle, and apical views of organs were visible, the slice with the largest modiolus height was chosen. For the vestibular ROI, the lowest slice, in which the lateral semicircular canal ring was obvious in images that were rotated by more than 240°, was chosen, and images of the ampulla were excluded [12]. Each physician drew contours of the ROIs on MRC images, and the contours were compared to determine a point of agreement.

Deep Learning Training Models for Inner Ear Segmentation

To segment the ROIs, 2 deep learning models were developed based on the architectures of the Inception-v3 [15] and U-Net [16] networks. The models were named 3into3Inception and 3intoUNet. For segmentation via the Inception-v3 network, deconvolutional layers were added after the conventional feature extraction of convolutional layers, and skip connections were included between convolutional and corresponding deconvolutional layers, as we did in our previous study [12]. The purpose of the U-Net network is to conduct segmentation; this network consists of feature contraction and feature expansion parts that function as encoders and decoders, respectively. In this network, a portion of contracted information is copied and concatenated to the corresponding expansion part, thereby reducing the amount of information that is lost during the segmentation process.

The physician-selected main slice image and the previous and next images were loaded simultaneously from full-stack MRC images for model training. The cross-sectional area of target inner ear structures is relatively small in a whole-brain image. Since this can cause a class imbalance problem, image patches of 100×100 pixels were acquired from each left and right reference point. This process is shown with the 3intoUNet network in Multimedia Appendix 1; 3 sequential MRC image patches were independently fed into each of the networks, and features were summated before the addition of deconvolutional layers. The green dotted boxes represent parts of the network that perform the same function (ie, the contraction of features in each input image). This sequential 3-input approach has been shown to yield high performance in terms of medical image segmentation [12]. The implementation and analyses of these models were performed via the Python 3.5 (Python Software Foundation) environment. The NumPy library was used for arithmetic calculation, the sklearn and ImageIO libraries were used for image preprocessing, and the TensorFlow library was used for model training.

The developed models were trained with a selectively annotated data set of 124 subjects. Afterward, the models were fine-tuned with both the selectively annotated and fully annotated data sets, per the optimum curriculum learning strategy for the segmentation of weakly annotated data [12]. Although we analyzed 4 target organs (the left cochlea, left vestibule, right cochlea, and right vestibule), the number of representative image slices per subject varied between 2 and 4 because a cochlea and a vestibule from each side could have been in the same image slice depending on the anatomical structure of the person. First, we trained a model with the selectively annotated data set and conducted moderate augmentation (1584 times). Afterward, we fine-tuned the model with both the fully annotated and selectively annotated data sets and conducted high augmentation (14,544 times). Therefore, the original 262 slices from the selectively annotated data set were augmented to 412,008 slices, and the initial 372 slices from the fully annotated and selectively annotated data sets were augmented to 5,410,368 slices for training. For augmentation, image patches were randomly flipped along the horizontal direction, cropped via random shifting (ie, from a reference point), and had their pixel intensity changed. There was a wide range of variation between the augmented images and the original image (eg, differences in intensity, shifted cropping areas, etc), and the physicians agreed to use the augmented images as training inputs.

Fivefold cross-validation was conducted, and segmentation performance was evaluated by measuring the intersection over union (IoU) between the ground truth areas (clinician-annotated region) and prediction areas (model-based, automatically determined region). The IoU was calculated as follows:

$$\text{IoU} = \text{area of overlap/area of union} = A_{overlap}/(A_{GT} + A_{pred} - A_{overlap}) \quad \textbf{(1)}$$

In equation 1, A_{GT} is the ground truth area, A_{pred} is the prediction area, and $A_{overlap}$ is the intersection between A_{GT} and A_{pred}. The model was trained on graphical processing units (NVIDIA GTX 1080Ti; Nvidia Corporation). The parameters were determined via grid searching and optimized to a learning rate of $1e^{-5}$ with the Adam optimizer [17]; a dropout rate [18] of 0.4 and batch size of 4 were used. Batch normalization and mean subtractions were performed to prevent internal covariate shifts.

Full-Stack Image Segmentation of an Additional Test Data Set

Once model training was completed, the model was tested with an additional data set of unseen magnetic resonance images. As shown in Figure 1, the full-stack MRC images of a patient were fed into a deep learning network. Slice indices that represented cochleae and vestibules were selected from a stack of segmentation results. The selected results were applied to HYDROPS-Mi2 patches as masks, and EH ratios were calculated for segmented regions.

Figure 2 shows the process of conducting a full-stack magnetic resonance image segmentation analysis by using the test data set. A subject's full-stack images were given an index number that ranged from 1 to the total number of slices (N). Figure 2 shows a subject's full-stack MRC image patches for the left and right ears and their corresponding segmentation results. The INHEARIT-v2 platform–selected representative slice for each class was indicated by a cyan-colored slice boundary. Figure 2 also shows the segmentation results and the MRC patches for a selected index number and the ground truths of each class. In this example, the selected index number was identical to the ground truths of all classes. The system chose the representative slices for each class—the left cochlea, left vestibule, right cochlea, and right vestibule—based on the size of the segmented area in each class. The representative key slice selection process was formulated as follows:

In equation 2, i is a slice index, N is the total number of segmented images of a subject, s^i_c represents a segmented area in the *ith* slice in class C, I_C is the key slice index of class C, and S_c is the segmented region in the key slice in class C. Thus, the key slices with the largest segmented areas for each class were selected. The slices chosen by the INHEARIT-v2 system and human experts were compared, and the index distance between the slices was calculated. The chosen segmentation results were used as masks for EH ratio calculation in the next step.

The EH ratio was estimated by using a HYDROPS-Mi2 image, which is an image that is generated via the pixel-wise multiplication of HYDROPS and MRC image signals [11] for a given index slice. The EH ratio is defined as follows [12]:

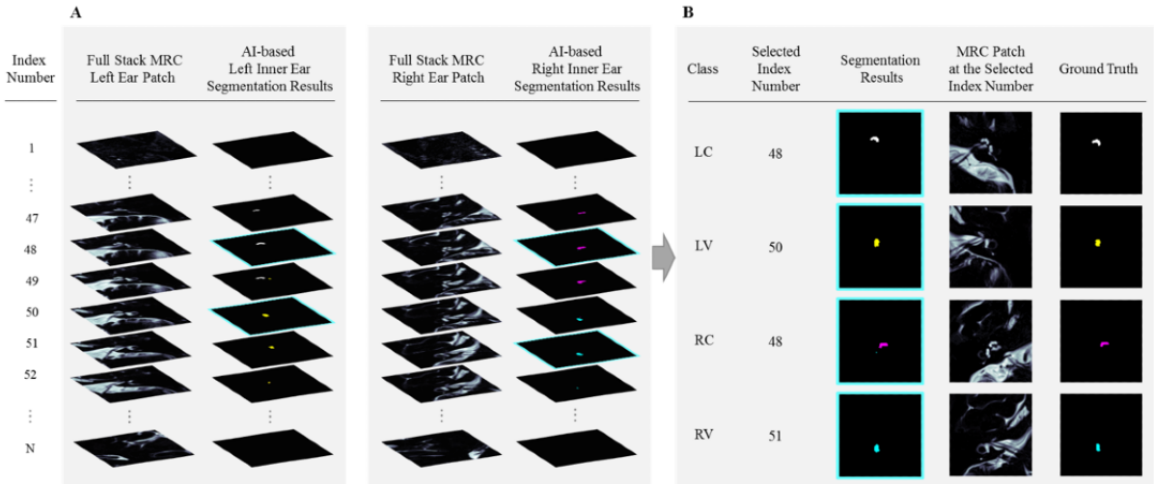
$$\text{EH ratio} = \text{Total number of pixels with a negative value in the segmentation area/total number of pixels in the segmentation area} \quad \textbf{(3)}$$

The above equation (equation 3) can be restated as follows:

$$\text{EH ratio} = (P_C^{Seg} \cap P_C^{Neg})/P_C^{Seg} \quad \textbf{(4)}$$

In equation 4, P_C^{Seg} denotes the total number of pixels in the segmented area in class C, and P_C^{Neg} denotes the total number of pixels with negative values in class C.

Figure 2. The full-stack magnetic resonance image segmentation analysis process for the test data set. A: A full stack of MRC images and their segmentation results. B: Representative slices and the segmentation results of each class. AI: artificial intelligence; MRC: magnetic resonance cisternography.



Statistical Analysis

The agreement between the values calculated by experts (the neuroradiologist and the neuro-otologist) and the INHEARIT-v2–predicted values was measured by using a single-score intraclass correlation coefficient (ICC), which was based on a two-way model and Pearson correlation coefficient. The analyses were performed by using R software (The R Foundation) [19].

Results

Model Experiments

Table 1 shows the segmentation performance of the developed artificial intelligence–based models—the 3into3VGG, 3into3Inception, and 3intoUNet networks. Average performance values were represented as the average IoU values from the fivefold cross-validation with SDs, which were 0.761 (SD 0.036) for 3into3VGG, 0.784 (0.025) for 3into3Inception, and 0.811 (0.032) for 3intoUNet. The U-Net–based model, 3intoUNet, had the highest mean area under the receiver operating characteristic curve. Therefore, the 3intoUNet model was used for the additional test.

Table 1. The segmentation performance of the proposed networks—3into3VGG, 3into3Inception, and 3intoUNet. These networks were based on the Visual Geometry Group-19, Inception-v3, and U-Net networks, respectively. The results are represented as the average intersection over union values from the fivefold cross-validation with SDs.

Networks	IoU,[a] mean (SD)
3into3VGG	0.761 (0.036)
3into3Inception	0.784 (0.025)
3intoUNet	0.811 (0.032)

[a]IoU: intersection over union.

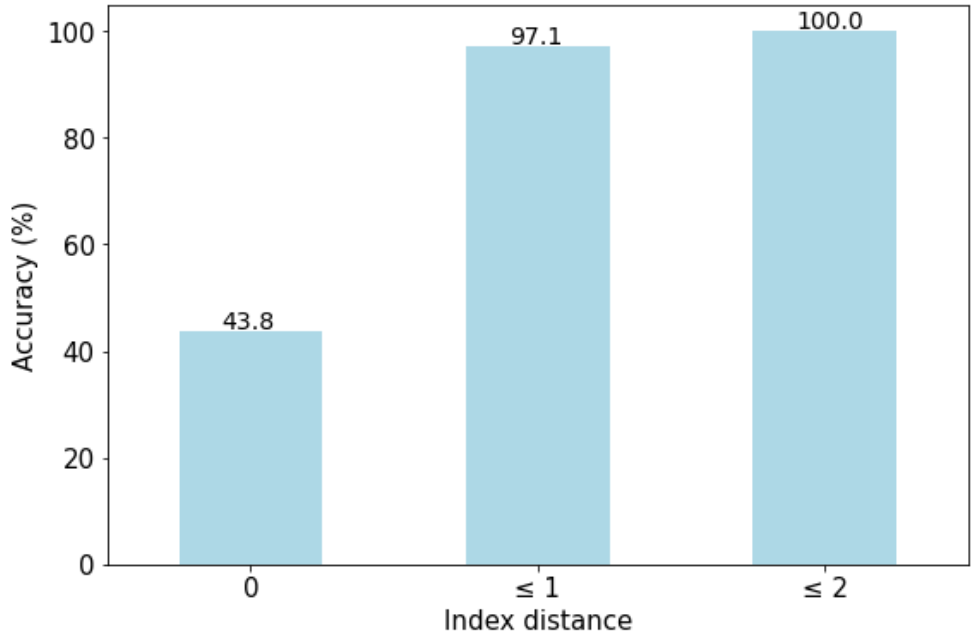
Additional Test With the Full-Stack Image Data Set

The data set of magnetic resonance images that were collected from 60 new participants (males: n=19; females: n=41; age: mean, 47.1 years, SD 15.27 years; range 21-68 years) for an additional test consisted of 33 subjects with definite Ménière disease (unilateral or bilateral), 17 subjects with sensorineural hearing loss and vertigo, and 10 normal subjects without any symptoms.

System validation was performed on the full-stack images of the subjects. Each image consisted of 104 MRC axial-view image slices, and 3 sequential slices—the main axial-view image slices and the previous and next slices—were fed into the trained model as an input. The model automatically segmented the organs by simultaneously analyzing the three input images and generated a segmentation result as an output. A total of 102 segmented output images were acquired from a subject's stack, and 1 image from each class was selected as a representative result.

With regard to the total 240 image slices of the target organs of 60 subjects, the distance (ie, the number of slice indices) between the manually selected image slices and system-selected image slices was 0 for 105 cases (43.8%), 1 in 233 cases (97.1%), and 2 in 240 cases (100%), as shown by the graph in Figure 3. This means that the representative magnetic resonance slices (ie, from a data set of unseen magnetic resonance images) that were automatically selected by the INHEARIT-v2 system only differed from a maximum of 2 expert-selected slices.

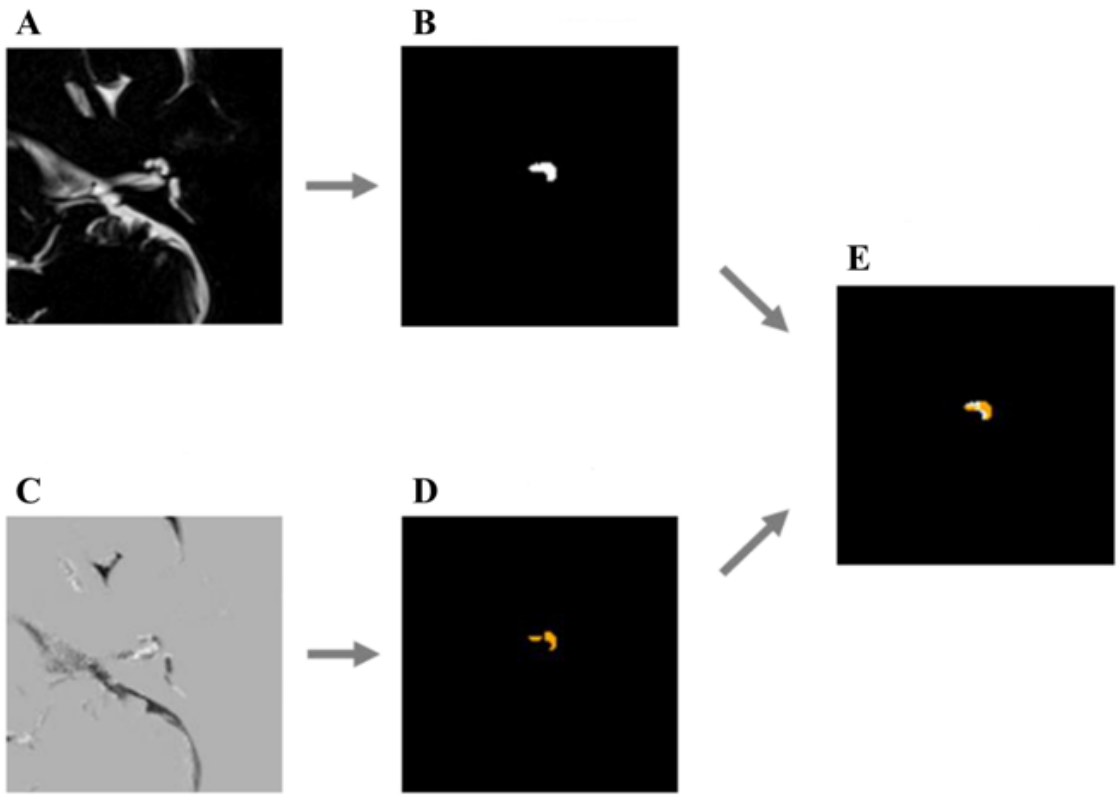
Figure 3. Performance of the inner-ear hydrops estimation via artificial intelligence-version 2 (INHEARIT-v2) system in finding the representative slice index in the magnetic resonance image stacks of 240 target organs of 60 subjects.



Agreement Analysis of EH Ratios That Were Calculated by Using the Test Data Set

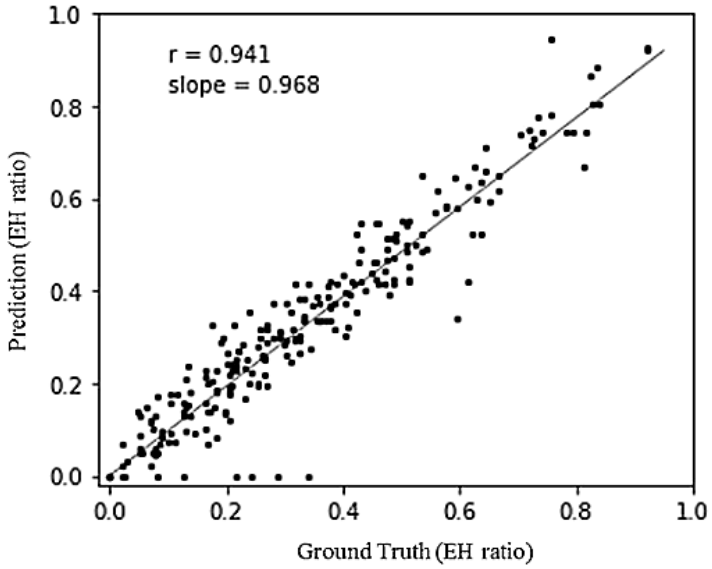
HYDROPS-Mi2 images were generated at the selected slice index, and EH ratios were calculated for all additional test cases. A case example of segmentation and EH visualization is represented in Figure 4; an MRC patch for a left ear was segmented, and the EH of the left cochlea (as seen in the HYDROPS-Mi2 patch) is shown in orange. The segmented result was used as a mask. A hydrops was overlaid on the segmented result, and the calculated EH ratio was 0.633.

Figure 4. Visualization of an endolymphatic hydrops in a left cochlea. A: Magnetic resonance cisternography patch (left ear). B: Left cochlea segmentation result. C: HYDROPS-Mi2 patch (left ear). D: Endolymphatic hydrops. E: Endolymphatic hydrops in the left cochlea. HYDROPS-Mi2: hybrid of the reversed image of the positive endolymph signal and native image of the positive perilymph signal image multiplied by T_2-weighted magnetic resonance cisternography.



The agreement between the physician-calculated and INHEARIT-v2–estimated EH ratios was calculated. The average ICC value for all cases was 0.941; the average ICC of the vestibules was 0.968, and that of cochleae was 0.914 (Figure 5). The average INHEARIT-v2–based calculation time was 3.585 seconds (SD 0.642 seconds) per subject.

Figure 5. The correlation between physician-calculated (ground truth) EH ratios and those predicted by the proposed platform (based on the segmentation area). EH: endolymphatic hydrops.



Discussion

Principal Findings

Due to the development of MRI machines, data and image processing technology, big data, and cloud systems, the role of artificial intelligence in the medical field will likely increase with time. Recently, algorithms have begun to help clinicians in real-world clinics and have been used to predict clinical outcomes that are useful for health care systems [3]. We developed a fully automated analytic system—the INHEARIT-v2 system—for calculating EH ratios by using deep learning and MRI. The INHEARIT-v2 system automatically segmented cochleae and vestibules in brain MRC images and detected representative slices for these organs. The system estimated the EH ratios of segmented regions in key image slices, and the results had a high correlation with those that were manually calculated by experts during an additional test.

Since the mid-2000s, the analysis of EHs by using 3T MRI has been widely accepted as a useful method for the diagnosis of Ménière disease among various groups [10,20]. In particular, injecting contrast media through an intravenous route is a widely used MRI method for patients with Ménière disease because it is less invasive, results in shorter waiting times for patients, and allows physicians to observe both ears simultaneously [11]. Recently, hydropses have been evaluated in several studies either by precisely dividing each area of the cochlea and vestibule or by using a 3D model to measure the whole volume of the endolymphatic space based on magnetic resonance images [21,22].

Recent medical image studies have reported the development of fully automated analytic systems. The implemented tools were designed to provide end-to-end workflows to minimize the amount of human intervention during analysis [23,24]. Several recent studies used deep learning techniques to segment inner ears and related organs in medical images. Some studies were conducted on computed tomography images to segment other organs, such as the sigmoid sinus, facial nerves, or temporal bones [25,26]. Another study analyzed magnetic resonance images for labyrinth segmentation [27]. These studies analyzed various ear-related organs in 3D space, but the main purpose of segmentation was primarily anatomical visualization for surgical planning. However, our study is different because the objective of segmentation was to calculate EH ratios in patients with Ménière disease by conjoining different magnetic resonance image modalities.

The results of our study substantially complemented the limitations of our previous study [12]. Although our former results laid the foundation for conducting EH analyses with deep learning technology, in this study, the improvements allowed for immediate clinical diagnosis and follow-up. Consequently, the accuracy of the EH analysis increased, and even if a human expert did not choose a representative image slice, the representative section was automatically extracted from the magnetic resonance image stack and analyzed successfully.

Another technical improvement over our previous study is that in this study, various deep learning models, such as the U-Net and Inception-v3 networks, were used as a base architecture. We developed a better performing model that effectively segmented inner ears. Furthermore, an additional test was performed to prove the robustness of the system. By developing the INHEARIT-v2 system, expert interpretation became much easier and faster, and more objective analyses were possible.

The best performance, which was based on the mean area under the receiver operating characteristic curve from the fivefold cross-validation, was achieved by the 3intoUNet network, which was based on the U-Net architecture. The U-Net network is designed for medical image segmentation [16]. As such, it is distinguishable from other deep learning models, such as VGG-19 and Inception-v3. Further, it was initially developed for the classification of raw images, such as those of a car, building, or human [13,15]. The 3intoUNet network allows for the analysis of consecutive images, similar to how medical experts browse an MRI stack to identify the location of a target organ. This serial-image training approach was suggested in our previous study on using a VGG-19–based model, which proved to be effective in a medical image segmentation task [12]. The same approach was successful for both the U-Net–based and Inception-v3–based networks. Since inner ears occupy only a small portion of the area (<60 pixels) in whole-brain images (384×324 pixels), the 3intoUNet network has a generalizable architecture for analyzing full-stack magnetic resonance images.

With regard to the performance of the system in automatic representative slice selection, when compared to physicians' choices, the system's choices had a gap distance of ≤2 for 100% (240/240) of the test data set. The physicians' goal was to select a key slice of an organ based on the organ's anatomical relationship with other organs [12], whereas the system's goal was to locate the slice with the largest segmented area for each organ. Despite the possible minimal misalignment between the automatically selected and manually selected key slices, the correlation between the INHEARIT-v2–calculated and physician-calculated EH ratio values was high, indicating that the amount of misalignment did not substantially affect the EH ratio calculation. Based on our results, measuring the entire hydrops volume of the cochlea and vestibule for diagnosis is unnecessary.

Several concerns might arise when artificial intelligence systems are used in real clinical settings. In this study, we found that using such artificial intelligence systems could be an alternative to manually measuring hydrops ratios in real settings. However, this does not mean that Ménière disease can only be diagnosed by this system. The cutoff value for the EH ratio was not clearly defined during the diagnosis of definite Ménière disease. Future studies for estimating the EH ratio cutoff value in the diagnosis of definite Ménière disease are still needed. In addition, HYDROPS-Mi2 images were used to analyze EH ratios. However, these images were acquired via software modification, and hydropses in modified images can be more exaggerated compared to those in original images. The final concern is that Ménière disease is a multifactorial disease, which means that making an accurate diagnosis is typically a very complex process. Other diseases that mimic the symptoms of Ménière disease should be ruled out in clinical settings. The main purpose of hydrops measurement via artificial intelligence is to provide clinical support, which can be helpful for medical professionals when making a final clinical diagnosis.

Future studies can include additional normal control subjects to determine the optimal EH ratio threshold by comparing individuals with Ménière disease and healthy individuals without the disease. However, the association between clinical symptoms and EHs is not uniform from patient to patient; thus, such analyses require a clinician's comprehensive judgment [28]. To improve these analyses, in addition to magnetic resonance images, a model for analyzing heterogeneous data, such as the clinical variables used for diagnosis, can be applied to the deep learning algorithm. In addition, because the cause and mechanism of Ménière disease have not been fully elucidated, such technology can be widely used for the differential diagnosis of other conditions that are thought to be associated with EHs [29].

Notably, we fully automated the calculation of EH ratios by developing an analytic system—the INHEARIT-v2 system—by using MRI and deep learning, which have important clinical implications. Although several aspects should be further investigated, this framework will be a helpful tool for clinicians who adopt an MRI analysis approach for diagnosing patients with Ménière disease.

Conclusion

We developed a fully automated system—the INHEARIT-v2 system—for calculating EH ratios by using deep learning and MRI. The proposed system can quickly and accurately analyze EHs without the intervention of an expert of various inner ear diseases, including Ménière disease experts. This automatic system can perform objective and time-saving analyses for assessing the EH ratios in the inner ear magnetic resonance images of patients with Ménière disease.

Acknowledgments

This work was supported by National Research Foundation of Korea grants, which are funded by the Korean government (the Ministry of Science and ICT; grants NRF-2020R1F1A1073904 and NRF-2021M3E5D2A01022399), and the Future Medicine 20*30 Project of the Samsung Medical Center (grant SMX1210791).

Authors' Contributions

BHC, WHC, and JWK designed the research. WHC and YSC collected the data. CJP, YKK, and KK analyzed the data. CJP and YSC wrote the main paper. BHC, WHC, and HJK provided critical revisions, discussed the results and implications, and commented on the manuscript at all stages.

Abstract

Background: Recently, artificial intelligence technologies and machine learning methods have offered attractive prospects to design and manage crisis response processes, especially in suicide crisis management. In other domains, most algorithms are based on big data to help diagnose and suggest rational treatment options in medicine. But data in psychiatry are related to behavior and clinical evaluation. They are more heterogeneous, less objective, and incomplete compared to other fields of medicine. Consequently, the use of psychiatric clinical data may lead to less accurate and sometimes impossible-to-build algorithms and provide inefficient digital tools. In this case, the Bayesian network (BN) might be helpful and accurate when constructed from expert knowledge. Medical Companion is a government-funded smartphone application based on repeated questions posed to the subject and algorithm-matched advice to prevent relapse of suicide attempts within several months.

Objective: Our paper aims to present our development of a BN algorithm as a medical device in accordance with the American Psychiatric Association digital healthcare guidelines and to provide results from a preclinical phase.

Methods: The experts are psychiatrists working in university hospitals who are experienced and trained in managing suicidal crises. As recommended when building a BN, we divided the process into 2 tasks. Task 1 is structure determination, representing the qualitative part of the BN. The factors were chosen for their known and demonstrated link with suicidal risk in the literature (clinical, behavioral, and psychometrics) and therapeutic accuracy (advice). Task 2 is parameter elicitation, with the conditional probabilities corresponding to the quantitative part. The 4-step simulation (use case) process allowed us to ensure that the advice was adapted to the clinical states of patients and the context.

Results: For task 1, in this formative part, we defined clinical questions related to the mental state of the patients, and we proposed specific factors related to the questions. Subsequently, we suggested specific advice related to the patient's state. We obtained a structure for the BN with a graphical representation of causal relations between variables. For task 2, several runs of simulations confirmed the a priori model of experts regarding mental state, refining the precision of our model. Moreover, we noticed that the advice had the same distribution as the previous state and was clinically relevant. After 2 rounds of simulation, the experts found the exact match.

Conclusions: BN is an efficient methodology to build an algorithm for a digital assistant dedicated to suicidal crisis management. Digital psychiatry is an emerging field, but it needs validation and testing before being used with patients. Similar to psychotropics,

any medical device requires a phase II (preclinical) trial. With this method, we propose another step to respond to the American Psychiatric Association guidelines.

Introduction

The recent adoption of smartphone health applications that collect data (weight, exercises, etc) and allow the consumer to see graphs and diagrams illustrates the sociological and psychological power of digital self-care and self-management. This phenomenon is of particular importance for adolescents and young adults. However, asking patients to fill in scales or questionnaires on their smartphone instead of on a computer or a paper is not new. This is called ecological momentary assessment (EMA), a naturalistic method to access clinical data [1]. However, to be useful for users, there is a need for advice, therapeutic care, or at least personalized feedback related to the answers provided, which could be the field of ecological momentary intervention (EMI).

With the development of machine learning, it is obvious that EMI will have significant implications in the future. There are only a few experiences in psychiatry with EMI, but recent reviews suggest that results are very promising in mood disorders, anxiety, and schizophrenia [2-5]. However, those apps have different approaches. Some of them focus on providing in-app therapy, such as iBobbly [6], SuperBetter [7], Get Happy [8], or ACT Smart [9]. Few of them provide a more personalized therapy according to EMA answers from a medical team (connected device) such as MONARCA (monitoring treatment and prediction of bipolar disorder episodes) [10] or more automated like PRISM (the person real-time intervention for stabilizing mood) [11]. Except for Mindstrong [12], which uses digital phenotype (ie, no psychological data but only digital use skills such as typing or screen scrolling), none of them are using in-app artificial intelligence (AI) based on EMA data. Interestingly, and somehow counterintuitively, the efficacy of these apps for depression and anxiety is better when they are not part of a program with human interactions [2,13]. This could be an argument for more intuitive and personalized apps capable of being independent of direct care. We also know that the fill rate is higher when patients have more severe symptoms [14].

Suicide attempts (SAs) are a major health care issue and could be an interesting focus for add-on smartphone app care. Suicide is a highly challenging multifactor process encompassing genetics, psychological, social, cultural, and life-experienced trauma influences [15]. More than 25 million people worldwide attempt suicide each year, and around 800,000 people die from suicide [16]. Repeated epidemiological studies show that SA history is one of the major risks of suicide. Within a year of the SA, the repetition rate in adolescent and young adult populations ranges from 15% to 28% [17]. Rates of repetition are higher within 6 months of the previous SA [18]. To date, no suicide prevention program is better than others, and all of them require the active participation of health care professionals (eg, training, calls, interviews, etc) [19]. However, studies have shown that personalized brief contact interventions reduce recurrence after an SA [20]. A specific and personalized app could optimize these strategies.

Therefore, to prevent a patient's SA and suicide, we have created an EMA plus EMI new approach based on a mobile health care application. Our application, which is not connected to the medical team via the internet, will collect data from the patient twice a day regarding anxiety, mood, and sleep disorders, with decreasing frequency during 1 year. The data entries by the patient will be made via analogic visual scales and drop-down lists. Then, algorithm-based feedback enhanced with AI will proactively inform the patient with comments and advice based on the World Health Organization's recommendations or associated self-coping or mindfulness practices.

The aim is to position our smartphone application like a health care partner, which is why we named it "Medical Companion." However, to be relevant, our app needs to encompass AI.

Many specialists are convinced that AI and machine learning will be major breakthroughs in medicine and psychiatry [21-23] and could disrupt the practices [24]. Machine learning is a computational strategy that automatically determines (learns) methods and parameters to find the best solution for a problem rather than provide a previously set solution programmed a priori by a human. The strength of machine learning is its ability to explore multiple patterns in complex data. The algorithms used in machine learning can categorize, cluster, and predict by using supervised and unsupervised techniques. The most used algorithm is the support vector machine, a multivariate supervised learning technique that classifies subjects into groups within a margin-based statistical framework.

Promising achievements have been reached by this kind of bottom-up analysis with machine learning. For example, in medical imaging, researchers used more than 1000 anonymous patient X-rays to train a naïve Bayesian network (BN) to detect tuberculosis [25]. The algorithm had close to a 100% accuracy rate. There are several recent reviews and perspectives in this field [22,26-28].

The same approach has been used in psychiatry, with a research focus on diagnosis, treatment effect prediction, and outcome prediction. Authors used physiological markers [29], neuroimaging data [30] or clinical specific scales [31] with up to 75% accuracy [30,32].

However, for optimal accuracy, machine learning needs a substantial amount of data. Contrary to biological or imaging data, clinical psychiatry produces heterogenic data often

associated with poor availability and management [21,33]. Moreover, this prediction bias increases with large samples when calculated with probabilistic statistics [21,33,34]. Therefore, some authors suggest the use of more expert-based algorithms using BN [35,36]. Our goal is to create an algorithm that selects different types of pre-established advice based on each individual's limited data.

Our algorithm, developed with this expert BN technique, will achieve a high level of personalized advice and comments based on individual answers to our in-app questions.

This paper describes the method to build the algorithm. It is part of a large trial, oriented on clinical efficiency and designed per recent American Psychiatric Association (APA) guidelines for digital devices [37]. We are currently working on the smartphone application by itself, and we will run a clinical trial to evaluate its feasibility, efficacy, and use (clinical trial NCT03975881) in real life.

Methods

Theoretical Background of BN

Pearl [38] defines a BN as a probabilistic graphical model that allows the representation of a set of variables and their probabilistic relationships using a directed acyclic graph (DAG). By connecting the cause to the effect with an arrow, we obtain the most intuitive graphical representation of the influence of one event, one act, or one variable on another. It models the causal relationships well. Interestingly, BNs are knowledge representation models that can be built from expert experiences. Furthermore, a BN can learn from data, updating knowledge of the status of a subset of variables when other variables (the evidence variables) are observed and perform inferences by an incremental process.

A BN is an annotated DAG that encodes a joint distribution for a random set of variables X. Formally, a BN for X is a pair: $B = [G,\Theta]$. For a summary of notations used in the text, see Textbox 1.

The first component $G = (X, U)$ is determined by a set of variables $X = \{X_1, X_2...X_n\}$ whose elements are called vertices or nodes and a set $U = \{u_1, u_2,..., u_m\}$ of the Cartesian product $X \times X$ whose elements are called arcs or edges, which represent the direct dependencies between the variables. For an arc $u = (X_i, X_j)$, x_i is the initial end (origin), X_j is the final end (destination). An arc u is directed, starting from X_i and arriving at X_j. Above all, the graph G encodes independence assumptions to satisfy the local Markov property—each variable X_i is independent of its nondescendants given its parents in G.

The second component of the pair, namely Θ, represents the set of parameters that quantify the network. It contains a set of conditional probability distributions (CPD) $\Theta_i = P_B (X_i|In\Pi_i)$ for each variable X_i, where Π_i denotes the set of parents of X_i in G.

Textbox 1. Notations used in the text and their meaning.

- *B:* Bayesian network
- *G:* Graph
- Θ*:* Set of parameters that quantifies the network
- *X:* Node variable in the model
- Π_i: Set of parents of X_i
- *U:* Set of edges
- *u:* An arc

The BN defines a unique joint probability distribution over X given by:

In BNs, conditional probability tables (CPTs) associated with each node should be defined to measure the relationships between variables. However, it has been pointed out that it is usually difficult to quantify the CPTs due to the complexity of the BN, which is defined by its dimension (ie, the number of independent parameters used to describe its CPD).

where r_i is the cardinality of X_i and  is the number of configurations of the parents of X_i. If X_i has no parents, q_i=1.

So, if a binary variable has n binary parents, the corresponding contribution q_i of its CPD to the model complexity is exponential and equals 2^n, since each r_j=2. Specifically, the elicitation of all BN probabilities is a complex and time-consuming task. To simplify a CPT, we can use a noisy-or model (NOM) where the number of probability values to estimate is now proportional to the number n of parents. Thus, it allows for simplifying the CPD [38].

Building a BN From Expertise

The knowledge bases are built to formalize our knowledge in specific domains and support our reasoning on events and decisions in a structured way. A BN is a declarative ("knowing what") knowledge-representation formalism constructed from expertise. Due to its probabilistic content, it allows for exploiting more efficiently the structure of the knowledge bases.

Constructing a BN from expertise is based on several steps. For this purpose, Kjaerulff and Madsen [39] divide the process into 2 tasks: (1) structure determination, representing the qualitative part of the BN, and (2) parameter elicitation, with the conditional probabilities, corresponding to the quantitative part.

Determining the structure requires skills, inventiveness, close communication with experts, and a high level of expertise. This process needs to address 2 main tasks: (1) identification of the relevant variables and (2) identification of the links between the variables.

The parameter elicitation makes the tacit knowledge as explicit as possible (and therefore easier to convey) and formalizes the expert's reasoning in an inference engine. It aims at eliciting subjective conditional probabilities from expertise to artificially reproduce the analysis of the situation and the decision-making of the expert. Finally, expert domain knowledge can be handled as prior distribution, but it is not certain that the expert has the experience to formulate valid probability judgments naturally. Authors point out that the experts must be assisted by an experienced probabilistic facilitator who will provide feedback to the experts, for example, by using simulations [40]. Inconsistencies will be discussed and will allow the model to be adjusted. Inversely, the facilitator needs a clear understanding of the decision problem for which an elicited probability distribution is required.

Many elicitation methods exist, but the most popular is the roulette method (or the "chips and bins method" or histogram method) [41]. It is prized by the experts because it provides visual feedback in the form of histograms.

Building Our BN

Our project (clinical trial NCT03975881) is an innovative approach to prevent the relapse of SAs and suicides in patients with a previous SA. It is the core of our healthcare smartphone application. The program is an add-on to the usual care process and is built to work autonomously. The BN will help to:

1. Estimate actual psychiatric and behavioral state based on users' answers to in-app questions.
2. Match the estimated state with appropriate and accurate preexisting advice and care provided by the smartphone app.

Variables Determination for Estimating Behavioral and Psychiatric State

At first, we have identified contextual variables that are mandatory data in any clinical study (ie, age, gender, type of SA, date, and localization). Only age and gender will be exploited in the algorithm to reduce the required amount of expert estimation. Then we defined clinical questions related to the mental state of the patients. All questions (Q) have been provided by experts in the form of a single choice and are related to specifics factors. The elicitation of each clinical dimension corresponds to a set of questions $Q = \{Q_1 \ldots Q_m\}$.

The clinical dimensions were chosen for their known and demonstrated link with the suicidal risk in the literature [42,43]. Some are clinical markers related to depression (mood, cognitive retardation, sleep or appetite disorders, and physical pain) or anxiety, as well as a measure of the presence and the severity of suicidal ideation. The intensity measures of suicidal thoughts were adapted from specific psychometric scales (ie, the Columbia-Suicide Severity Rating Scale) [44]. Others are behavioral markers that can be disturbed if the patient's clinical condition changes (eg, the use of video games) or may promote suicidal ideation (eg, substance use disorder).

We had 9 clinical dimensions, 23 questions, and 10 pieces of advice. All questions were linked according to clinical knowledge and translated into the BN model. Categories were anxiety, sleep, appetite, physical complaints (eg, headache, stomach pain, etc), cognitive impairment (concentration and memory), mood, suicidal thought and behavior, and addictive behavior (eg, alcohol, tobacco, screens, and games, etc).

To simplify and fit a four-level Likert scale, an expert group created the questions to approach the mental state category. For example, "How anxious are you?", "How much were you able to cope with your anxiety?" and "How long were you anxious during the last day?" For the last question, instead of "absent," "low," "medium," or "high," we opted for "none," "less than 1 hour," "from 1 to 3 hours," and "almost all day." All questions were a priori scored by an expert according to the BN structure.

All patient answers were made of visual analog scales (VASs). The formulated questions were slightly modified every day (and twice a day during the first weeks) to avoid a perception of a process that seems too "automatic."

More precisely, the discussions between the experts led us to identify 3 variables for each factor, described as follows:

1. Immediate value of factor (IF) corresponds to the measure in percentage extracted from the questions for the VAS at instant *t*.
2. Cumulated value of factor (CF) is the mean of time-repeated immediate value. If we consider that the weight given to each datum is equivalent, the more the data increases, the lower the weight of each datum, which will decrease the responsiveness of the system (ie, the anxiety experienced several weeks ago might not have the same impact for calculating an estimated state than a few hours ago). To address this issue, we have introduced a forgetting factor α to reduce the weight of older data as follows:
   - $CF_{new} = (1-\alpha) \times IF + \alpha \times CFold$
   - If $\alpha=0$, no aggregation, CF=IF; if $\alpha=1$, no update, the CF remains unchanged.
3. Contextual severity (CS) corresponds to a discrete variable with a domain (high, medium, low, absent) that describes the seriousness of one given dimension with respect to one given context (which is the CF describing the user characteristic). For instance, for some dimensions, a high IF is "severe" when the CF for this dimension is also high, but it is less serious when the CF is low (ie, if a patient anxiety state is "none," a single high anxiety score stays relatively low compared to a patient who is repeatedly anxious, independent of their level of immediate anxiety).

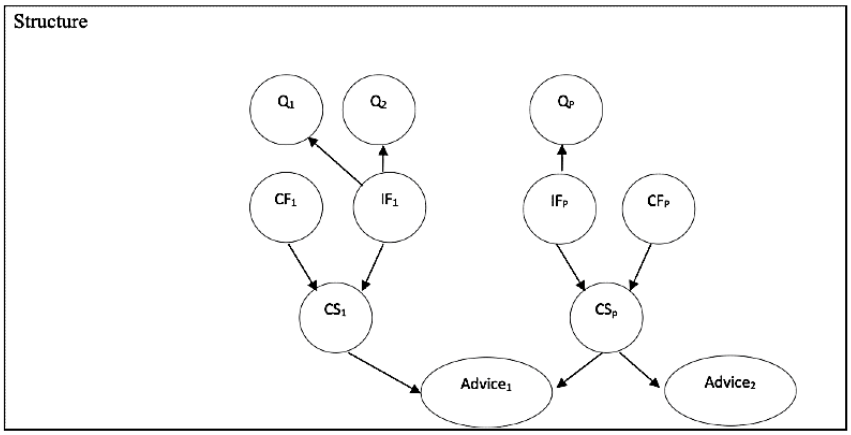
Structure Determination of the BN

The BN structure (Figure 1) models the expert way such as:

1. The state regarding one dimension can vary according to the patient context, but as contextual variables, only age and gender are included in the model.
2. The patient will not answer a question regarding his state similarly for the corresponding dimension (eg, answers concerning anxiety will be different if he is usually very anxious vs not anxious).
3. The severity of one specific dimension depends on a "comparison" between its IF and CF, confronting temporal aspects of states.
4. Each advice depends on the severity of potentially several dimensions because it could be triggered by one or many dimensions.

The CS of a specific dimension depends on both IF and CF. The combination of different CS from a selected set of dimensions gives the most efficient advice related to those dimensions. Nodes are represented as circles and edges as arrows. Responses to each question (Q) associated to each dimension depend on the IF of the dimension, and they become independent of each other if we know the value of IF.

Figure 1. Bayesian Network Structure. CF: cumulated value of factor; CS: contextual severity; IF: immediate value of factor; Q: question.



Parameters Elicitation

According to the 2-task process described by Kjaerulff and Madsen [45], we identified from the previous structure the following parameters (ie, CPD) to validate the work of our experts. Due to the high number of dimensions used in this work and the large volume of data, we chose to illustrate this part only with a selected factor, anxiety, because it is a dimension whose severity can change very acutely. Therefore, we can illustrate the model's reactivity to an acute change of clinical state. The same has been applied to each dimension.

For each dimension *I*, we defined an a priori probability as follows: $P(IF_i=high)$, $P(IF_i=medium$, $P(IF_i=low)$, and $P(IF_i=absent)$ so that a "random" patient will be associated with this dimension to the corresponding level (high, medium, low, and absent) regarding his context (age and gender). $P(CF_i)$ will be initialized to $P(IF_i)$.

For each question related to its dimension, $P(Q = j/IF_i = k)$ is the probability that the answer of this question Q will be the *j*th *one*, given that the patient IF is in its *k*th level.

The main issue is to estimate how a specific individual with specific clinical characteristics may answer a question about his specific state with sufficient accuracy. However, there are no epidemiological or clinical works available with such a level of detail regarding the studied population. Thus, it is impossible to refer to scientific data for the percentage of patients with a medium level of anxiety answering low anxiety to a question asked. Through their knowledge and experience, experts may be able to provide accurate answers. To estimate the value in the domains (absent, low, medium, and high), we use probability calculations as follows:

- $P(CS_i/IF_i,CF_i)$: Defined the severity given the dimensions' IF and CF.
- $P(advice/CS_1...CS_p)$: The scoring depends on all the dimensions' severity, specifically, CS, and as previously described in the theoretical background section of BN, a NOM distribution is used to simplify this dependency.

Experts also offered advice addressing many efficient actions for suicidal crisis management such as lifestyle, sleep, relaxation or mindfulness exercises, management of social rhythms, physical activity, and emergency solutions (ie, calling person in the patient's pre-established circle of confidence, exercising with abdominal breathing, practicing mindfulness or relaxation, and calling emergency services) [44].

Each piece of advice might be useful for every factor but at different levels of accuracy. Therefore, the advice must have a good sensitivity (ie, if it is essential, the system must not omit it). Similarly, if it is not essential given the patient's state, it should not be triggered in excess, so it must have good specificity. For this purpose, experts have estimated the a priori probability $P(advice/ CS_1...CS_p)$ of advice efficiency due to the intensity of each factor.

Algorithm Accuracy Testing by Simulation

Step 1

Building the algorithm is a multistep process. First, we perform a simulation of the first data set for mental state provided by the expert (Table 1) using the BN simulation model. Our model generates three distributions of factors: (a) a priori, (b) when all answers associated with the factor are the highest and have very severe scoring P(++), and (c) when all answers associated

with the factor are the lowest and have less severe scoring P(--). Simulations are made for each category of mental state.

Table 1. Expert-based Bayesian network construct regarding anxiety.

What is your level of anxiety?	Distribution for 100 subjects with no (absent) anxiety	Distribution for 100 subjects with low level of anxiety	Distribution for 100 subjects with medium level of anxiety	Distribution for 100 subjects with high level of anxiety
No anxiety	100	5	0	0
Low anxiety	0	90	15	5
Medium anxiety	0	5	80	15
High anxiety	0	0	5	80
Total	100	100	100	100

Step 2

Return to the expert with simulation results. If simulations are accurate regarding medical expert knowledge, step 3 is possible. If not, experts provide a new data set, and we rerun step 1.

Step 3

Next, we perform a simulation of the first data set for the advice provided by experts using the BN simulation model (Table 2). Our model generates incremental updates (1 to 15 successive scorings by patients) of (a) IF in a specific pattern of the first 9 successive scorings at the lowest score, (b) CS values (based on CF) in a specific pattern of the first 9 successive scorings at lowest score then, IF in a progressive increasing severity pattern from scoring 10 to 15, (c) CS values (based on CF) in a progressive increasing severity pattern from scoring 10 to 15 then, IF for an immediate highest severity scoring starting at answer 10 lasting until answer 15, (d) CS values (based on cumulated severity) for an immediate highest severity scoring starting at answer 10 lasting until answer 15, and (d) for each of the 1 to 15 scorings in both patterns (ie, immediate or progressive), our algorithm will generate the advice and recommendations.

Table 2. Conditional probability of contextual severity as a function of the immediate value and cumulated value of a given factor.

CF[a] and IF[b]	Contextual severity function of CF and IF			
	High	Medium	Low	Absent
High				
Medium	0.98	0.02	0	0
High	0.99	0.01	0	0
Low	0.9	0.1	0	0
Absent	0.85	0.15	0	0
Medium				
High	0.19	0.8	0.01	0
Medium	0	0.99	0.01	0
Low	0	0.71	0.28	0.01
Absent	0	0.66	0.3	0.04
Low				
High	0.11	0.23	0.65	0.01
Medium	0	0.19	0.8	0.01
Low	0	0.01	0.98	0.01
Absent	0	0.01	0.7	0.29
Absent				
High	0.05	0.15	0.3	0.5
Medium	0	0.12	0.23	0.65
Low	0	0.01	0.19	0.8
Absent	0	0	0.01	0.99

[a]CF: cumulated value of factor.

[b]IF: immediate value of factor.

Step 4

Different values and their distribution along the train of different pre-established scoring are presented to experts for review. They are asked to examine the accuracy and consistency of the advice proposed compared to their clinical expertise and knowledge. Then, if necessary, changes are made in the model, and the simulation is rerun beginning with step 3. Reviews and reruns are made as many times as necessary to achieve our goal. Expert opinion is a qualitative variable (yes or no).

Results

Simulations were done according to our 4-step methodology. For each run, experts provided estimations regarding the distribution of answers in specific populations (Table 1). Experts are asked to estimate for 100 subjects with a specific state regarding anxiety (absence, low, medium, or high) how they should answer, and what would be the distribution of answers (no, low, medium, or high) because not all highly anxious patients will submit a high anxiety rating. This corresponds to $P(answer(Q)/IF_i)$.

At each run, we calculated the conditional probability of CS as a function of the IF and CF of a given factor (Table 2). For example, if the IF and CF are high, the probability that CS will be high is 0.99 (expressing few changes). But if IF is low, with a high CF, the probability that the CF remains high is 0.9 and zero for low and absent anxiety, respectively.

The distribution of dimensions can be seen in Figure 2. After two simulation runs, the experts found that the advice proposals were accurate. The a priori status is a distribution of all 4 severity levels (absent, low, medium, and high) as proposed by the experts. In the two extreme conditions (lowest and highest severity), the experts are far less heterogeneous and become more accurate regarding clinical knowledge. Priori denotes the expert estimated distribution of answers by severity in our population of patients with previous SAs (absent in blue, low in green, moderate in orange, and severe in red). A P(++) rating of users' scores illustrates a severe rating for all questions related to anxiety, and we calculated the algorithm-generated score for each related category of mental state. A P(--) rating of users' score demonstrates the lowest rating for all questions related to anxiety, and we calculated the algorithm-generated score for each related category of mental state.

In the second phase, the main goal was to achieve an accurate match between all scoring by categories and the advice. The experts did provide a priori distribution of answers according to the BN structures (Table 3). For example, the first line means "what is the a priori probability that the immediate state is high, medium, low, and absent knowing that the person is a man aged above 18 years.

The final simulations of matching answers and advice for anxiety are provided in Figure 3 and Figure 4, and an example of an expert-based BN construct is shown in Table 4. Figure 3 represents the final run simulation of the probability of advice proposal during incremental updates of 15 successive scorings by virtual patients according to an immediate worsening after 9 successive lowest scores. In Figure 3a, for each dimension, ordinate scores above zero correspond to IF and below zero CS values (based on CF). Moreover, in Figure 3b, the normalized score of the 10 pieces of advice related to anxiety are represented over the 15 steps of the simulation. Figures 4a and b show the final run simulation of the probability of advice proposal during incremental updates according to a progressive worsening after 9 successive lowest scores. Table 4 demonstrates an expert's BN construct regarding the "call friends" advice and their accuracy in categorizing patients with various anxiety levels. For example, this specific advice might be relevant for 50 out of 100 patients with low anxiety level and 99 out of 100 with high anxiety level. This corresponds to P(advice = call friend/$CS_{anxiety}$). This construction has been made for each piece of advice.

Figure 2. Distribution of probabilities for each dimension, for a priori status (P), high scoring P(++), and absent scoring status P(--).

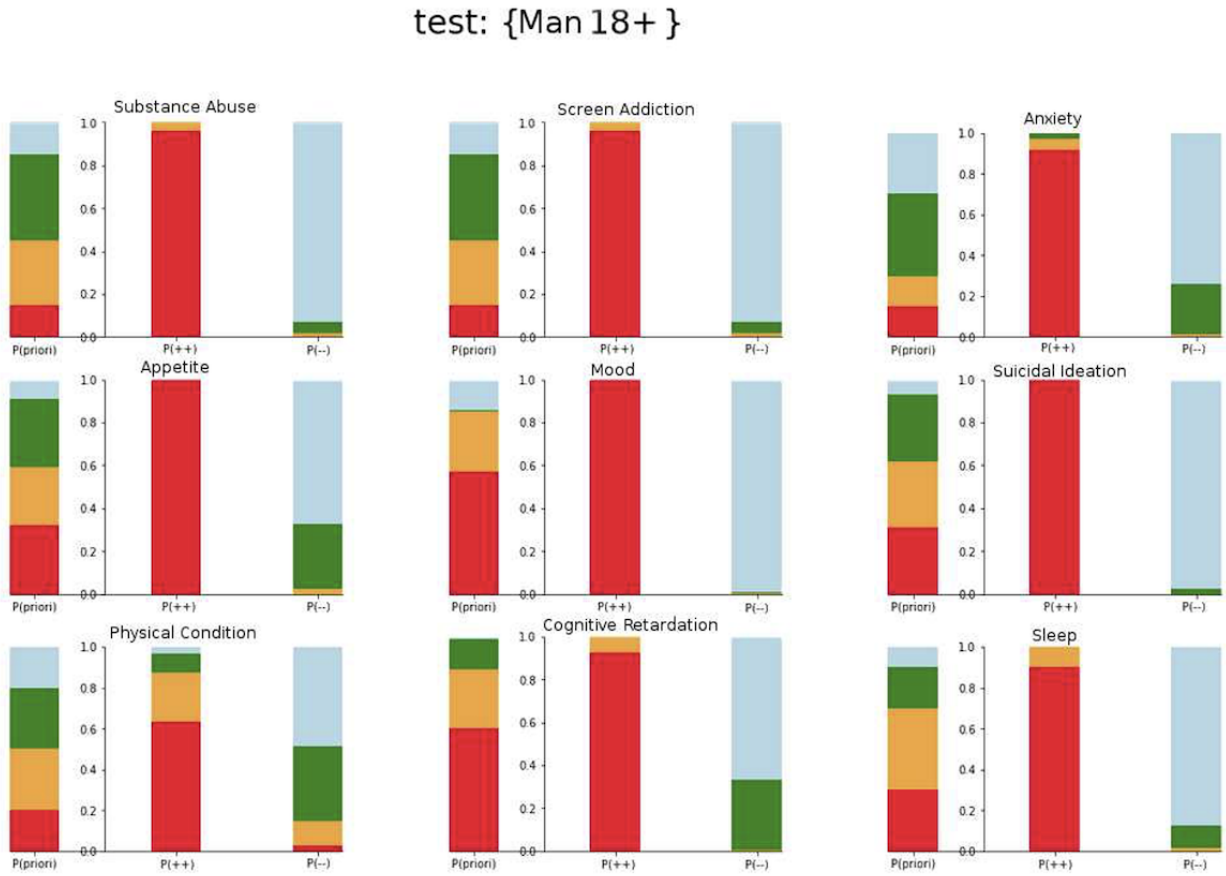


Table 3. Probability distribution for anxiety of the immediate value and cumulated value a priori based on age and gender.

	High	Medium	Low	Absent
Men, age (years)				
>18	0.15	0.15	0.4	0.3
<18	0.2	0.2	0.35	0.25
Women, age (years)				
>18	0.28	0.28	0.22	0.22
<18	0.3	0.3	0.2	0.2

In the first part of each figure (Figure 3a and Figure 4a), IF and CS for each dimension are represented. Above zero is the a priori distribution of IF; below zero reflects the progressive increase of knowledge (learning ability) represented as CS becoming progressively the mirror of IF over time.

In the second part of each figure (Figure 3b and Figure 4b), advice suggestion probabilities are initially fixed in the proportions of a general population of patients that committed SA independent of their clinical state. By increasing the knowledge of the specific clinical state of a given patient (ie, with a low and constant level of anxiety), the advice is adapting and stabilizing. When anxiety IF scoring becomes suddenly (3) or progressively (4) severe, some of them are rising (eg, emergencies and calls to referent psychiatrist or the person of trust), and others are decreasing, finally stabilizing again in another configuration.

The simulation stops when the advice has the same distribution as the a priori state and the advice is clinically relevant. After two simulation runs, experts found accurate matching.

Figure 3. Final run simulation of the probability of advice proposal during incremental updates (immediate worsening after 9 successive lowest scores). IPSRT: interpersonal and social rhythm therapy.

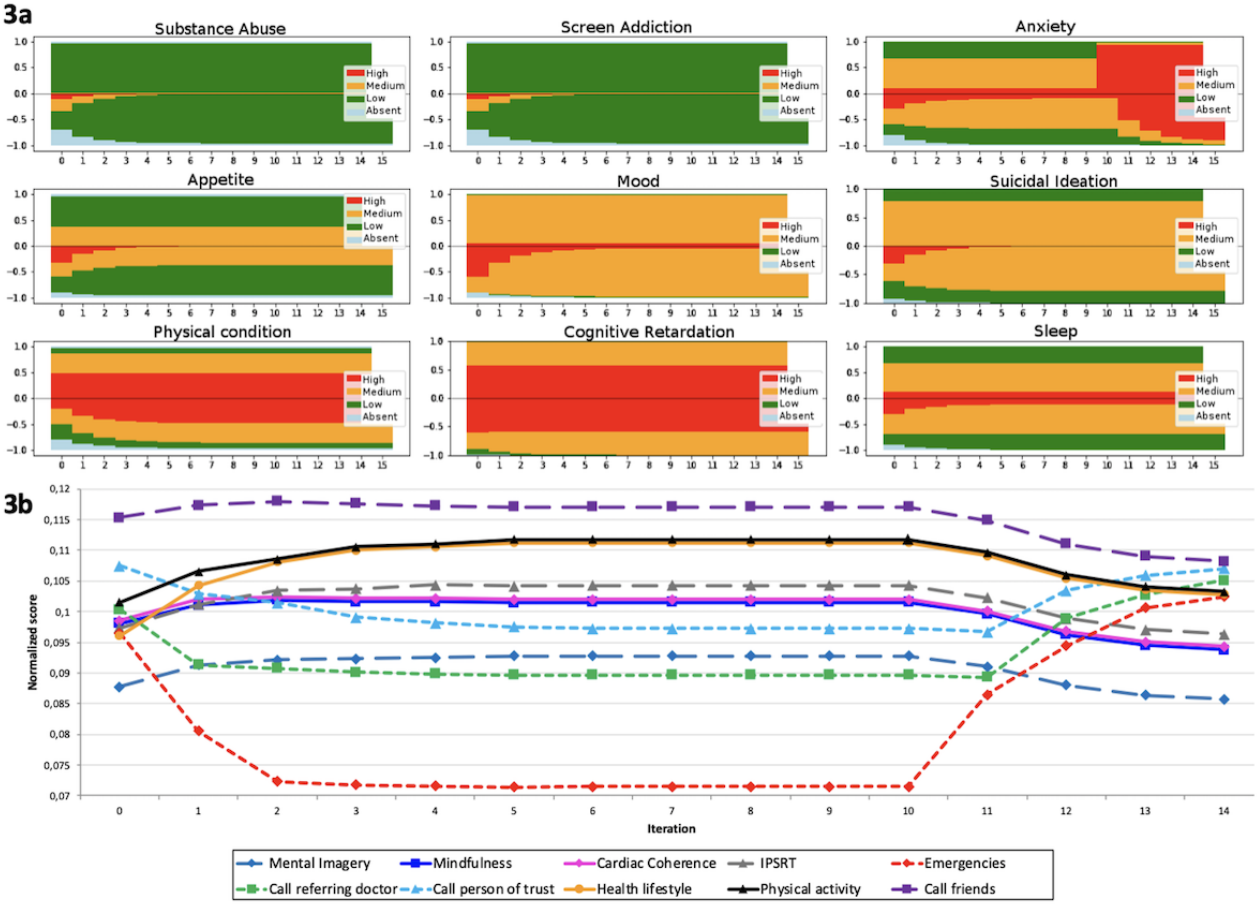

Figure 4. Final run simulation of the probability of advice proposal during incremental updates (immediate worsening after 9 successive lowest scores). IPSRT: interpersonal and social rhythm therapy.

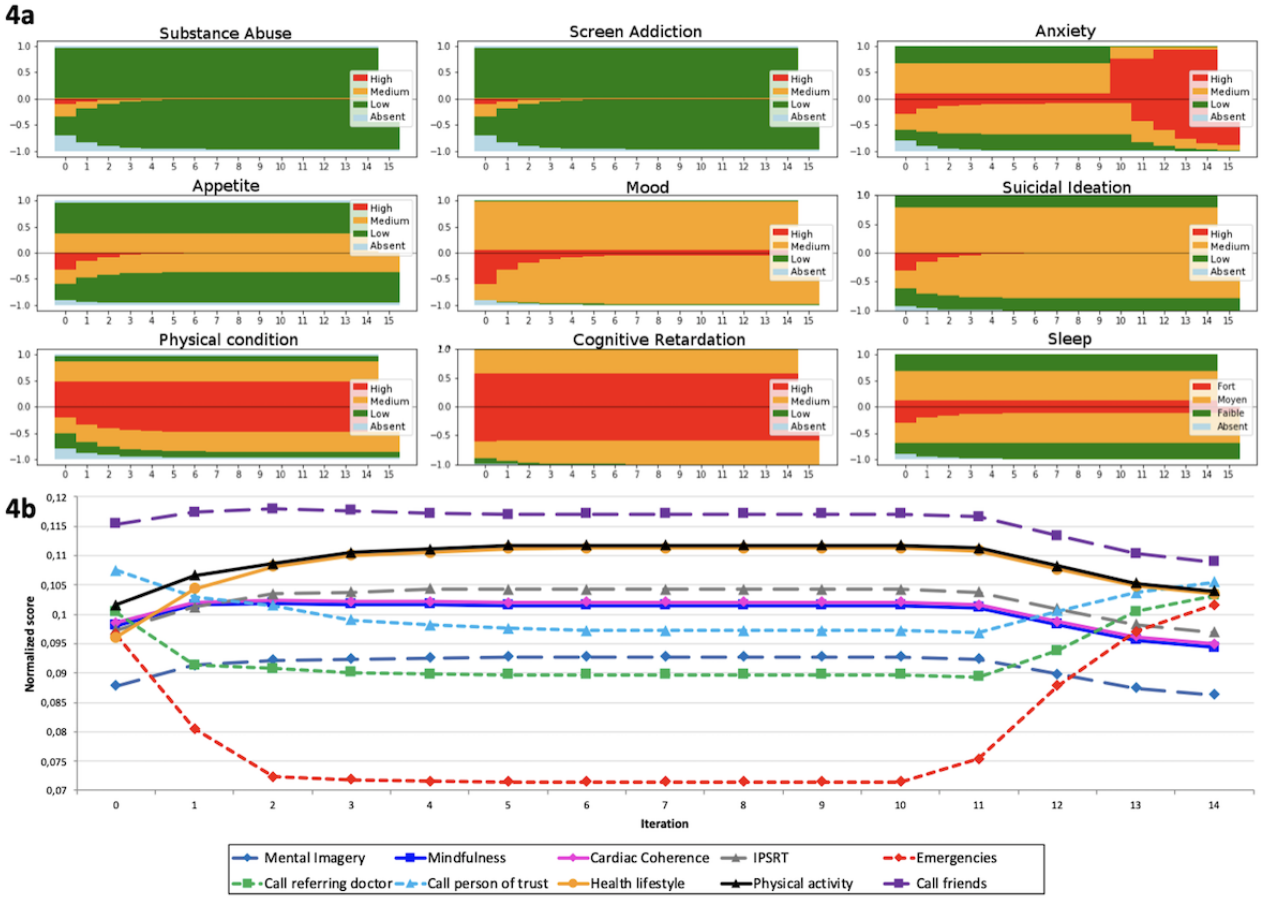

Table 4. Expert-based Bayesian network construct regarding "call friends" advice.

Contextual severity: call friends, social contacts (circle of proximity)	Anxiety		
	High	Medium	Low
Yes	99	80	50
No	1	20	50

Discussion

Principal Findings

Our results are consistent with our hypothesis and strongly suggest that BNs are an interesting model for developing algorithms in highly expert professional fields, especially when data are unavailable.

Our model showed that depending on the clinical dimensions of a patient with a stable clinical state, it will rapidly converge (in three iterations) to a pattern of pertinent advice. In the example described in Figure 3 and Figure 4 for a patient with a constant and low level of anxiety, the pattern of advice converges to a solution that inputs priority advice without caregivers' interventions. Indeed, going to the emergency and calling the referent psychiatrist or a person of trust are not pertinent advice for this level of severity. When the clinical state worsens, the model still demonstrates a rapid adaptation and stabilization to this event. The advice pattern reorders itself pertinently by prioritizing emergencies and caregiver intervention, and other forms of advice such as mindfulness or therapy become less pertinent. These less pertinent types of advice decrease over time when the clinical state worsens (Figure 3 and Figure 4). They are not directly dependent on the severity of anxiety, and their absolute probability stays constant. However, their relative probability (ie, the scores after normalization across every form of advice) decreases over time.

We also see that the weight of some advice, such as mindfulness and cardiac coherence, are the same. This might be explained by the fact that only the weight linked to cognitive retardation is different. Cognitive retardation does not play a role in a scenario on anxiety (Figure 3 and Figure 4), showing that its level of contextual severity stays the same over time and is independent of the level of anxiety.

As we expect, such an a priori expert model is valuable to test preclinical situations, and the results of our simulation with various patient profiles allow us to build a valid BN. The APA points out that application developers often make many claims, while the level of scientific evidence that accompanies these

apps is often quite low [37,46]. In a recent study [47], the authors analyzed the claims of 73 mental health applications (the top-ranked applications from the two largest app stores) for acceptability and efficiency. There was a difference between positive statements about their effectiveness and acceptability. They found that less than 53% of these claims were associated with evidence in the scientific literature, and 33% referred to techniques for which no evidence could be found.

For this purpose, the APA proposes a hierarchical framework of 5 levels to evaluate apps [39]. The first level of the model aims to evaluate the quality of the information referenced by the application to decide if we can consider using the app. Scientific data is very important in this step. Levels 2 and 3 constitute the basic medical decision-making process centered on nonmaleficence. As in any therapeutic intervention or evaluation, apps induce risks that must be scientifically evaluated but are often overlooked; that is the goal of the second level. Level 3 aims to evaluate the necessary scientific evidence, providing us reasons for potential use. Level 4 evaluates the usability of the apps and level 5 tests interoperability.

This framework highlights the need for the scientific development of applications that correspond to the standards of therapeutic research. For this reason, we consider that a preclinical phase is essential before continuing to the clinical phase.

During the design phase of the device, the preclinical step makes it possible to check its performance and safety and will help us evaluate its later acceptability for the patient. By comparison, when it comes to the development of a drug, this phase makes it possible to evaluate a molecule in cultured cells (in vitro) and in animals (in vivo), but in our case, we can talk about evaluation in silico that is often used in recent pharmacological studies [48].

With our Bayesian approach, we can make simulations of patients, considering these to be preclinical tests as recommended by good practices in clinical therapeutic research, and we can increase its scientific validity. Nevertheless, it still is a simple model with only 9 clinical dimensions and 10 types of advice driven by 23 questions. In developing preclinical tests in the future, models will have to be improved with more variables.

There are numerous healthcare apps in mobile app stores. At the moment, very few provide academic validation with state-of-the-art clinical trials. To date, there are only 2 FDA (Food and Drug Administration)-approved or CE (Conformitè Europëenne)-approved apps (reSET@ and Flow) in psychiatry [49]. One provides digitalized depression prevention treatment [50], and the other is for opioid addiction management [51].

Our project is one of the first attempts to build autonomous care support for suicide prevention in a specific at-risk population of patients with previous SA with a methodology in accordance with APA guidelines.

From a larger point of view, the main idea driving this project is that it is possible to build an app that mimics a doctor's care enough to be a valuable (and efficient) add-on. The empowerment of patients is a vital topic, and economic issues are also important.

But most importantly, we are showing that algorithms for clinical and behavioral disturbance in psychiatry might be a crucial field for BN, particularly when there is not enough available data to build such algorithms. For example, there is important scientific literature for anxiety in patients with depression, suicidal ideation, or SA; however, the data are not specific enough to answer very specific questions regarding sleep disturbance according to the level of anxiety in a patient 3 months after SAs. Therefore, expert opinion is crucial.

Such an algorithm, embedded in smartphone apps, could be used by many patients and consequently produce a large amount of new specific data. This data will eventually help us improve our model by incrementally updating the parameters (ie, all the probability distributions) to recognize one given factor better or associate one advice type better to some situations.

Since we will have a lot of usage data, it is important to determine if the recommendations are followed by action and if this type of algorithm increases their relevance. This could be of particular interest for therapeutic compliance or even access to emergency care. The clinical stage of our research, associated with our application's usage data, will allow us to study this question.

Conclusion

We are convinced that using digital devices with efficient algorithms is crucial for medical treatment in terms of reliability and safety. However, to date, very few devices meet accurate methodological requirements. Our work is a proof of concept that emphasizes the need for preclinical trials by algorithm development. Additionally, it shows that BN is an accurate and very efficient branch of AI in psychiatry and clinical psychology.

However, building the application and randomized controlled clinical trials are necessary to confirm our choices and the overall efficacy of our device.

Abstract

Background: An artificial intelligence (AI)–assisted contouring system benefits radiation oncologists by saving time and improving treatment accuracy. Yet, there is much hope and fear surrounding such technologies, and this fear can manifest as resistance from health care professionals, which can lead to the failure of AI projects.

Objective: The objective of this study was to develop and test a model for investigating the factors that drive radiation oncologists' acceptance of AI contouring technology in a Chinese context.

Methods: A model of AI-assisted contouring technology acceptance was developed based on the Unified Theory of Acceptance and Use of Technology (UTAUT) model by adding the variables of perceived risk and resistance that were proposed in this study. The model included 8 constructs with 29 questionnaire items. A total of 307 respondents completed the questionnaires. Structural equation modeling was conducted to evaluate the model's path effects, significance, and fitness.

Results: The overall fitness indices for the model were evaluated and showed that the model was a good fit to the data. Behavioral intention was significantly affected by performance expectancy (β=.155; *P*=.01), social influence (β=.365; *P*<.001), and facilitating conditions (β=.459; *P*<.001). Effort expectancy (β=.055; *P*=.45), perceived risk (β=−.048; *P*=.35), and resistance bias (β=−.020; *P*=.63) did not significantly affect behavioral intention.

Conclusions: The physicians' overall perceptions of an AI-assisted technology for radiation contouring were high. Technology resistance among Chinese radiation oncologists was low and not related to behavioral intention. Not all of the factors in the Venkatesh UTAUT model applied to AI technology adoption among physicians in a Chinese context.

Introduction

Background

The artificial intelligence (AI) race has long since begun; its silicone roots date back to 1956 [1]. In China's "Development Plan for The New Generation of Artificial Intelligence," the goal was to synchronize China's overall technology and AI applications with the world's advanced level of technology by 2020. The total value of China's AI industry market is expected to reach US $127 billion by 2025 [2], and the medical AI industry is forecasted to account for one-fifth of the overall AI market [3]. In the health care industry, AI has been developed for administrative assistance, clinical decision-making support, patient monitoring, and robotic surgeries [4]. In clinical decision-making support, computer software is used to analyze clinical data and assist medical professionals in making more precise decisions on disease diagnoses and treatments [5]. Sketching tumors is one such subfield.

Delineating tumors is tricky and requires much education, guidance, and expertise. For radiation oncologists, the tumor target contouring process for precision head and neck radiation therapy is time consuming. It requires, on average, 180 minutes of intense work for each patient, and contouring areas that are created by different radiation oncologists for the same tumor can be highly variable [6]. Moreover, contouring accuracy is key for achieving successful treatment outcomes. Suboptimal tumor coverage and poor-quality radiation therapy plans are major factors of disease relapse and inferior survival [7]. An AI contouring tool that automates the primary gross tumor volume contouring process for patients with cancer was developed at Sun Yat-sen University Cancer Center, wherein it has been applied clinically since 2019; over 12,500 cases of radiation planning have been carried out with the tool's assistance. The contouring system has a high level of accuracy (ie, when compared with the manual contouring accuracy of radiation oncologists). Although oncologists still need to edit automated contours by making minor adjustments, the system substantially saves time by up to 39.4%, and intraobserver and interobserver variations have been reduced by 36.4% and 54.5%, respectively [8].

Although the benefits of AI assistance appear to be obvious, like all forms of change, the adoption of AI technology might be met with resistance, especially within health care settings; it has been said that the only constant is change [9]. There is much hope and fear surrounding such technologies, and this fear can manifest as resistance from both health care professionals and patients [10]. One particular fear that may promote resistance is the fear that AI tools will replace workers (even skilled workers like doctors)—the much discredited, but still prevalent, Luddite fallacy [11]. In a *British Medical Journal* head-to-head debate, the topic was as follows: "Could machines using artificial intelligence make doctors obsolete?" Dr Jörg Goldhahn said "yes" and foreboded that humans simply cannot keep up with the data crunching advantage that computers have over humans [12]. Further, Vanessa Ramptom and Professor Giatgen Spinas claimed that the role of doctors will not become obsolete; instead, these roles will change to specifically focus on treating a patient as a whole [12]. These perspectives encompass part of the larger narratives that describe AI technology as either utopian or dystopian.

There are also claims that doctors are slow to uptake new technologies. In 2004, there was evidence of resistance across the United States against using a computerized order entry system to overcome issues, such as doctors' illegible handwriting, and reduce the number of incorrect prescriptions. The Cedars-Sinai Medical Center notably forced the withdrawal of the system, which was installed in two-thirds of the 870-bed hospital [13]. Similarly, in 2006, Bhattacherjee and Hikmet [14,15] found that physicians were resistant to adopting administrative health care information technologies, and more recently, in 2014, Hsieh [16] discovered 5 factors (attitude, subjective norm, perceived behavior control, institutional trust, and perceived risk) that influenced the adoption of such technologies. Notably, these studies all concerned administrative technologies. There is, however, also evidence of doctors resisting AI technology for other uses, such as patient diagnosis and treatment plan development.

Even though the National Institute of Health claims that AI technology is trending in cancer care [17], a number of notable AI projects have failed in the United States. The MD Anderson Cancer Center, one of the top cancer centers in the world, cancelled a project that involved IBM Corporation's oncology expert advisor tool, Watson, in 2016 after spending US $62 million [18]. In February 2021, IBM Corporation also tried to sell their Watson Health business, as it was not profitable [19].

In this study, we assessed whether there has been any resistance to the uptake of an AI contouring system in China and examined the system's pros and cons. Few prior studies have focused on the technology acceptance of AI tools that provide clinical decision-making support in cancer care from physicians' perspectives. AI health care researchers have primarily analyzed technical innovation and clinical results but have seldom considered the human contexts that are invariably involved in use behavior. Social and implemental issues need to be addressed when an AI tool is introduced in hospitals. Further, it is especially important to examine the extent of perceived risks and technology resistance bias.

Objective

The objective of this study was to develop and test a model for investigating the factors that drive Chinese radiation oncologists' acceptance of an AI contouring tool for automating the primary gross tumor volume and normal tissue contouring process. This study analyzes how expectancy, social influence, facilitating conditions, perceived risk, and resistance bias contribute to the Technology Acceptance Model (TAM).

Theoretical Background and Hypothesis Development

The theoretical models in this study included the TAM and the Unified Theory of Acceptance and Use of Technology (UTAUT) model. The perceived risk and status quo bias theory variables were added to the UTAUT model.

The first TAM was developed by Fred D Davis in 1989, and it was based on the theory of reasoned action. The TAM was used to analyze consumers' behaviors in the context of health information technology based on the following two major variables: perceived usefulness and perceived ease of use [20]. Later, in 2000, Venkatesh and Davis [21] developed the TAM2, which also addressed perceived usefulness and use intentions in terms of social influence and cognitive instrumental processes. They added the subjective norm, voluntariness, image, job relevance, output quality, and result demonstrability constructs, which significantly influenced user acceptance. The evolution of the TAM3 came next; the TAM3 was a comprehensive nomological network (ie, an integrated model) for evaluating individual-level (information technology) adoption and use [22].

In 2003, Venkatesh et al [23] also created a UTAUT model, which is an integrated tool based on 8 original models that were published in major information systems journals from a range of disciplines. These models included the theory of reasoned action model, the TAM, the motivation model, the theory of planned behavior model, a combination of the TAM and the theory of planned behavior model, the model of PC utilization, the innovation diffusion theory model, and the social cognitive theory model. The UTAUT originally explained technology acceptance among employees, and in 2012, a UTAUT2 model was developed, which focused on consumer technologies [24]. As AI-assisted contouring technology has been developed for medical staff in hospitals, hedonic motivation and price value, which were explored in the UTAUT2 model, were considered inapplicable to explaining oncologists' acceptance behaviors in this study. Therefore, we used the original UTAUT model in this study. The original model and its various modifications have been popularly used in studies of technology adoption in the health care industry over the past 5 years [25-28].

The UTAUT model revealed the following four variables: performance expectancy, effort expectancy, social influence (which is used to evaluate the behavioral intention to use a new technology), and facilitating conditions (which are used to evaluate use behavior). Most research has proven that these four constructs positively affect potential users' behavioral intentions [29,30]. Performance expectancy is defined as "the degree to which an individual believes that using a new technology will help him or her to attain gains in job performance." This construct was integrated from a similar concept in the TAM—perceived usefulness [31]. Effort expectancy is defined as "the degree of ease of use associated with IT" [23]. This concept is similar to the perceived ease of use construct in the TAM and innovation diffusion theory and the complexity of technology construct in the model of PC utilization. Social influence is defined as "the degree to which an individual perceives the importance of how others believe that he or she should use new IT." This concept was developed based on the notion that "an individual's behavior is influenced by the way in which one believes others will view him/her as a result of having used health IT" [23]. The Venkatesh model integrated subjective norms from the theory of reasoned action, the TAM2, and the theory of planned behavior; social factors from the model of PC utilization; and the image construct from the innovation diffusion theory into the social influence construct. The facilitating conditions construct is defined as "the degree to which an individual believes that an organizational and technical infrastructure exists to support the use of the system" [23]. The UTAUT's facilitating conditions concept contains the perceived behavior control concept from the theory of planned behavior and the combined TAM and theory of planned behavior model, the facilitating conditions concept from the model of PC utilization, and the compatibility construct from the innovation diffusion theory [23]. Lastly, the intention-usage behavior relationship has long been discussed in many studies of technology acceptance, and we expected that behavioral intentions to use AI-assisted technology would have a significant influence on use behavior. Based on these variables, we proposed the following hypotheses:

- Hypothesis 1: Performance expectancy positively affects oncologists' behavioral intentions to use an AI contouring tool for developing radiation therapy plans.
- Hypothesis 2: Effort expectancy positively affects oncologists' behavioral intentions to use an AI contouring tool for developing radiation therapy plans.
- Hypothesis 3: Social influence positively affects oncologists' behavioral intentions to use an AI contouring tool for developing radiation therapy plans.
- Hypothesis 4: Oncologists' behavioral intentions positively affect their use behaviors when using an AI contouring tool for developing radiation therapy plans.
- Hypothesis 5A: Facilitating conditions positively affect oncologists' use behavior when using an AI contouring tool for developing radiation therapy plans.
- Hypothesis 5B: Facilitating conditions positively affect oncologists' behavioral intentions to use an AI contouring tool for developing radiation therapy plans.

Perceived risk has long been discussed as a negative factor in health care information technology adoption studies [10,16], and it refers to the combination of uncertainty and the seriousness of an outcome [32]. Featherman and Pavlou [33] identified the following seven facets of e-service–related perceived risk: performance risk, financial risk, time risk, physiological risk, social risk, privacy risk, and overall risk. In this study, we addressed perceived risk based on the following four aspects: (1) performance risk, which we defined as the probability of malfunction and performance failure and whether the AI contouring tool could mislead physicians with inaccurate contouring; (2) time risk, which we defined as the probability of physicians needing more time to correct errors caused by the AI system; (3) psychological risk, which we analyzed in terms of whether using the AI contouring tool may cause psychological discomfort due to having a negative effect on clinicians' self-perceptions of the treatment plan; and (4) privacy risk, which we defined as a potential loss of the confidential patient data in the AI-assisted system. As the AI systems were

purchased by public hospitals without input from individual physicians, no financial or social risk assessment was required.

Resistance to change refers to people's attempts to maintain previous behaviors or habits that are connected to their past experiences when facing changes [15,34,35], and this has been discussed as a major barrier to health care information technology adoption [15,36]. The fear of job loss has also been discussed as a factor of the slow adoption of new information technologies [37]. We suggest that radiation oncologists might believe that AI-assisted technologies might replace them and that the adoption of such technologies will lead to an increase in unemployment rates. Thus, we included these two factors in the resistance bias construct, which we defined as people's resistance to using a new technology resulting from their resistance to change and concerns about unemployment. Therefore, we proposed the following hypotheses:

- Hypothesis 6: Perceived risk negatively affects oncologists' behavioral intentions to use an AI contouring tool for developing radiation therapy plans.
- Hypothesis 7: Resistance bias negatively affects oncologists' behavioral intentions to use an AI contouring tool for developing radiation therapy plans.

Methods

Participants and Sampling

The majority of participants were radiation oncologists (227/307, 73.9%) and medical students (80/307, 26.1%) from the Department of Radiation Oncology at Sun Yat-sen University Cancer Center who had clinical experience in using the computational system for contouring. The sample pool also included radiation oncologists from other hospitals in China. Participants were recruited between July 2020 and November 2020. A convenience sampling method was used in this study, as only a few hospitals in China have AI-assisted contouring systems. As our survey had 29 items, the required number of participants was more than 290. The questionnaire was conducted by sending direct website links via email or WeChat (a social media platform developed by Tencent Holding Limited). Questionnaires were only considered valid if (1) an account responded only once and (2) the total response time for completing the questionnaire was more than 60 seconds. In total, 322 radiation oncologists replied to the web-based survey. After filtering out the invalid responses, 307 responses—176 from Sun Yat-sen University Cancer Center and 131 from other hospitals—were deemed valid for data analysis.

Measurements

Our model included 8 constructs with 29 questionnaire items. Each item assessed 1 construct and was sourced from relevant literature related to new technology acceptance research. Some changes were made to fit the AI-assisted contouring system context (Table 1). After we developed a list of questions, a team discussion was held to reach a consensus. Afterward, we asked a group of 10 oncologists with experience in working with the AI system to answer the questions and provide comments for system improvement. A 7-point Likert scale, which ranged from 1 (strongly disagree) to 7 (strongly agree), was used to assess the items for all constructs except those for the use behavior construct, in which the answers were "yes" or "no."

The first page of the questionnaire provided an overview of this study's background, purpose, voluntary nature, and anonymity and an introduction of the AI-assisted tumor volume contouring system, which included information on its general functions and operating procedures and images of the system to help the participants gain a clear understanding. We developed 2 questionnaires to assess oncologists' perceptions. All participants first answered the following question: "Have you used the AI-assisted contouring system?" If the answer was "yes," then they were directed to answer the questions for those who have already used the system (Table 1); if the answer was "no," then they were directed to answer the questions for those who have not used the system. The questionnaires were identical apart from the usage of verb tenses. The questions were translated from English to Mandarin Chinese for the survey. Ethical approval was obtained from the Ethics Committee of the Department of Anthropology at Sun Yat-sen University.

Table 1. Questionnaire items related to the research model constructs.

Variables and items	Questionnaire items	Sources
PE[a,b]		
PE1	• I find the automated contouring system useful in my job.[c] • I think the automated contouring system will be useful in my job.[d]	Venkatesh et al [23] and Kijsanayotin et al [25]
PE2	• Using the automated contouring system enables me to accomplish tasks quicker.[c] • I think using the automated contouring system will enable me to accomplish tasks quicker.[d]	Venkatesh et al [23] and Kijsanayotin et al [25]
PE3	• Using the automated contouring system increases my productivity.[c] • I think using the automated contouring system will increase my productivity.[d]	Venkatesh et al [23] and Kijsanayotin et al [25]
PE4	• Using the automated contouring system improves the outcomes of my work.[c] • I think using the automated contouring system will improve the outcomes of my work.[d]	Venkatesh et al [23] and Kijsanayotin et al [25]
EE[a,e]		
EE1	• The automated contouring system is clear and understandable to me.[c] • I think the automated contouring system will be clear and understandable to me.[d]	Venkatesh et al [23] and Kijsanayotin et al [25]
EE2	• It was easy for me to become skillful at using the automated contouring system.[c] • I think it will be easy for me to become skillful at using the automated contouring system.[d]	Venkatesh et al [23] and Kijsanayotin et al [25]
EE3	• I find the automated contouring system easy to use.[c] • I think the automated contouring system will be easy to use.[d]	Venkatesh et al [23] and Kijsanayotin et al [25]
EE4	• Learning to operate the automated contouring system is easy for me.[c] • I think learning to operate the automated contouring system will be easy for me.[d]	Venkatesh et al [23] and Kijsanayotin et al [25]
SI[a,f]		
SI1	• People (eg, colleagues and friends) who influence my behavior think that I should use the automated contouring system.[c,d]	Venkatesh et al [23] and Kijsanayotin et al [25]
SI2	• People who are important to me (eg, department heads, tutors, superiors, and hospital leaders) think that I should use the automated contouring system.[c,d]	Venkatesh et al [23] and Kijsanayotin et al [25]
SI3	• Social propaganda has been helpful in the use of the automated contouring system.[c,d]	Venkatesh et al [23] and Kijsanayotin et al [25]
SI4	• In general, my hospital and my department have supported the use of the automated contouring system.[c,d]	Venkatesh et al [23] and Kijsanayotin et al [25]
FC[a,g]		
FC1	• I have the resources (devices, support from colleagues, etc) necessary to use the automated contouring system.[c,d]	Venkatesh et al [23] and Kijsanayotin et al [25]
FC2	• I have the knowledge (the clinical and computer skills) necessary to use the automated contouring system.[c,d]	Venkatesh et al [23] and Kijsanayotin et al [25]
FC3	• Health and information technology personnel in the hospital are available to assist with system difficulties.[c,d]	Venkatesh et al [23] and Kijsanayotin et al [25]
FC4	• I have adequate knowledge resources (eg, books, documents, and consultants) to help me learn about the automated contouring system.[c,d]	Venkatesh et al [23] and Kijsanayotin et al [25]

Variables and items	Questionnaire items	Sources
BI[a,h]		
BI1	• I intend to use the automated contouring system in the next 2 months.[c,d]	Venkatesh et al [23] and Kijsanayotin et al [25]
BI2	• I will use the automated contouring system in the next 2 months.[c,d]	Venkatesh et al [23] and Kijsanayotin et al [25]
BI3	• I plan to use the automated contouring system in the next 2 months.[c,d]	Venkatesh et al [23] and Kijsanayotin et al [25]
PR[a,i]		
PR1	• There is a possibility of malfunction and performance failure, so the system might fail to deliver accurate contouring areas and could mislead my work with inaccurate contouring.[c,d]	Ye et al [10], Bhattacherjee and Hikmet [15], and Andrews et al [38]
PR2	• There is a probability that I need more time to fix the errors and nuances of the artificial intelligence system.[c,d]	Ye et al [10], Bhattacherjee and Hikmet [15], and Andrews et al [38]
PR3	• I think using the automated contouring system may cause psychological distress, as it could have a negative effect on my self-perception of the treatment plan.[c,d]	Ye et al [10], Bhattacherjee and Hikmet [15], and Andrews et al [38]
PR4	• I am concerned that my patients' personal information and health details are/would be insecure and could be accessed by stakeholders or unauthorized persons, leading to lawsuits for physicians and the hospital.[c,d]	Ye et al [10], Bhattacherjee and Hikmet [15], and Andrews et al [38]
RB[a,j]		
RB1	• I do not want the automated contouring system to change how I develop my treatment plan for manual contouring because the new system is unfamiliar to me.[c,d]	Bhattacherjee and Hikmet [15] and Dou et al [34]
RB2	• I do not want to use the automated contouring system because of past experience; these new high-tech products always fall flat during practical application.[c,d]	Bhattacherjee and Hikmet [15] and Dou et al [34]
RB3	• I do not want to use the automated contouring system because there is a possibility of losing my job, as artificial intelligence–assisted technology may do my work better than me.[c,d]	Raza et al [37]
UB[k,l]		

Variables and items	Questionnaire items	Sources
UB1	• I have already used the automated contouring system.[c] • I am preparing to use the automated contouring system.[d]	Venkatesh et al [23]
UB2	• I recommend that others should use the automated contouring system.[c,d]	Venkatesh et al [23]
UB3	• Have you ever overridden the contouring system after using it for some time?[c] • Would you ever override the contouring system?[b]	Venkatesh et al [23]

[a]7-point scale (1=strongly disagree; 2=quite disagree; 3=slightly disagree; 4=neither agree or disagree; 5=slightly agree; 6=quite agree; 7=strongly agree).

[b]PE: performance expectancy.

[c]Questions for those who have already used the system.

[d]Questions for those who have not used the system.

[g]FC: facilitating conditions.

[h]BI: behavioral intention.

[i]PR: perceived risk.

[j]RB: resistance bias.

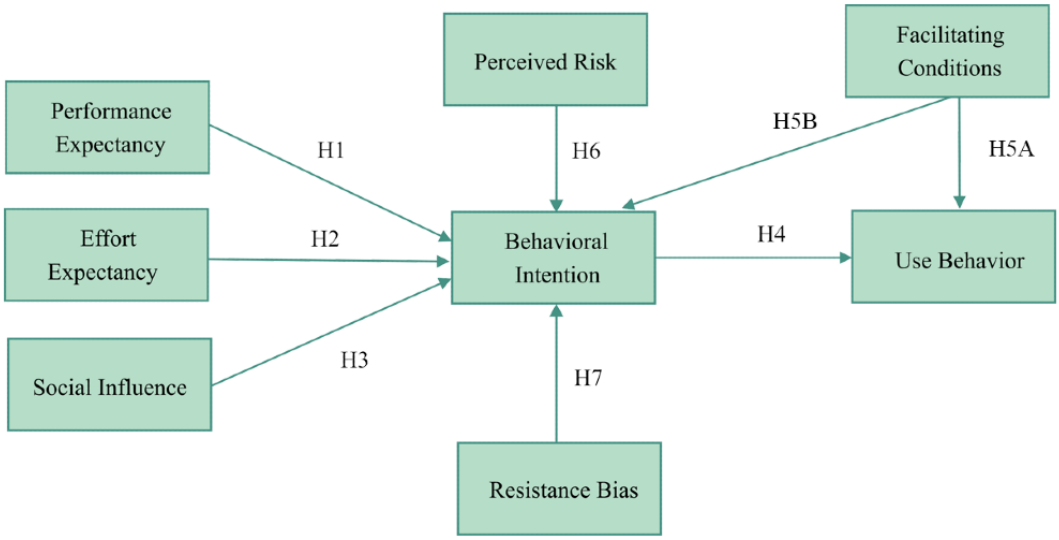
[k]2-point scale (1=yes; 2=no).

[l]UB: use behavior.

Data Analysis

Structural equation modeling analysis was conducted by using IBM SPSS Amos 21.0 (IBM Corporation), and this was a 2-step analysis [39]. First, items and constructs were evaluated for reliability and validity via a confirmatory factor analysis of the measurement model. Second, the structural model's path effects, significance, and goodness of fit and mediation effects were evaluated. More specifically, the path analysis was performed by conducting a series of multiple regression analyses to derive the standardized regression coefficients (ie, β) for all proposed paths. Figure 1 shows the conceptual model for the analysis; the arrows with solid lines are the paths indicating the relationships among the specified concepts in the hypothesis. IBM SPSS Version 25.0 (IBM Corporation) was used for the descriptive statistics analysis.

Figure 1. The development of our model for investigating radiation oncologists' acceptance of an artificial intelligence–assisted contouring system. H: hypothesis.



Results

Demographic Results

The demographic characteristics of the 307 participants are shown in Table 2. About an equal number of men (151/307, 49.2%) and women (156/307, 50.8%) participated in this study. The majority (269/307, 87.6%) of the participants' ages ranged between 18 and 40 years, and all of the participants had at least a bachelor's degree. In China, radiation oncologists who work on contouring are often aged under 40 years, as senior oncologists mainly focus on checking the accuracy of contouring based on the treatment plans, which are mostly developed by

junior oncologists. Thus, it was unsurprising that we had more participants aged under 40 years. In our study, 185 participants had at least 4 years of experience in radiation oncology, 123 participants had already used the AI-assisted contouring technology, and 184 had not yet used it.

Table 2. Demographic characteristics (N=307).

Characteristics	Participants, n (%)
Sex	
Male	151 (49.2)
Female	156 (50.8)
Age (years)	
18-25	121 (39.4)
26-30	67 (21.8)
31-40	81 (26.4)
41-50	30 (9.8)
>50	8 (2.6)
Education	
Bachelor's degree	137 (44.6)
Master's degree or doctoral degree	170 (55.4)
Experience in radiation oncology (years)	
≤3	122 (39.7)
4-6	61 (19.9)
7-10	23 (7.5)
>10	101 (32.9)
Artificial intelligence–assisted contouring technology usage	
Yes	123 (40.1)
No	184 (59.9)

Measurement Model

To test the reliability and validity of this study, we examined common method bias, as all items in our survey were collected from the same questionnaire. We connected all of the items to a common latent factor and used a confirmatory factor analysis to conduct a single-factor test [40]. The results showed that the fit of the single-factor model was poor (χ^2_{377}=4294.616; χ^2/df=11.392; adjusted goodness of fit index=0.354; comparative fit index=0.628; Tucker–Lewis index=0.599; root mean square error of approximation=0.184), indicating that common method bias was insignificant in this study.

We also conducted some tests to examine the constructs' reliability, and the results are summarized in Table 3. The Cronbach α and composite reliability values were higher than the threshold of 0.7 [41], which indicated good construct reliability. For convergent validity, all item loadings ranged from 0.633 to 0.980, and good composite reliability (>0.7) was achieved [42].

Convergent validity was assessed with average variance extracted (AVE) values; all construct AVE values were greater than 0.5 [43] and thus showed good convergent validity. In Table 4, the square roots of the AVE values were higher than the numbers in the off-diagonal direction (correlations between a particular construct in the same column and other constructs in different rows) in the corresponding columns, indicating the good discrimination validity of all constructs. The results of a single-factor analysis of variance showed that the main effect that experience had on behavioral intention was not significant ($F_{3,303}$=2.587; P=.053).

The mean scores for behavioral intention (5.484 out of 7.0) and use behavior (1.713 out of 2.0) were high, which showed that the participants had high intentions to use the AI-assisted contouring system. However, even though the total degree of resistance was low, 17.6% (54/307) of the respondents showed a degree of resistance (ranked as an average score of ≥5 for resistance bias). Specifically, 13 out of the 123 (10.6%) participants who had accessed the AI system showed a degree of resistance, and 41 out of the 184 (22.3%) participants who had not accessed the AI system also showed a degree of resistance.

[b]Not applicable.

Structural Model Analysis

The fitness of the model was evaluated with the following criteria: (1) the standardized root mean square residual (0.0317) had to be smaller than 0.08, (2) the comparative fit index (0.968) had to be greater than 0.90, and (3) the root mean square error of approximation (0.056) had to also be smaller than 0.08. As shown in Table 5, most of the indicators satisfied the criteria and the combination rule [44], which demonstrated that the hypothesized model was a good fit to the data.

Figure 2 shows a graphic description of the regression analysis, and Table 6 shows the numerical results of the path coefficient analysis. Standardized factor loadings (ie, β) were the standardized regression coefficients for each proposed path, which indicated the relationships among the variables in this study. *P* values were the parameters used to determine the results of the hypothesis test [45]. Behavioral intention was positively affected by performance expectancy (β=.155; *P*=.014), social influence (β=.365; *P*<.001), and facilitating conditions (β=.459; *P*<.001), and use behavior was significantly affected by behavioral intention (β=.235; *P*<.001). Effort expectancy (β=.055; *P*=.450), perceived risk (β=−.048; *P*=.348), and resistance bias (β=−.020; *P*=.634) did not significantly affect behavioral intention, and facilitating conditions (β=.004; *P*=.845) did not significantly affect use behavior. Behavioral intention also moderated the effects that social influence (*P*=.001) and facilitating conditions (*P*<.001) had on use behavior. R^2 values were calculated to assess the validity of the research model; 78.1% of the effects of behavioral intention could be explained by perceived risk, effort expectancy, social influence, facilitating conditions, performance expectancy, and resistance bias, and 75.3% of the effects of use behavior could be explained by behavioral intention and facilitating conditions (Figure 2).

Table 5. Research model fit.

Model fit indices	Criteria	Research model fit values
Chi-square value	The smaller the better	692.543
Degrees of freedom	The larger the better	354
Normed chi-square value (χ^2/df)	1<χ^2/df<3	1.956
Root mean square error of approximation	<0.08	0.056
Standardized root mean square residual	<0.08	0.0317
Comparative fit index	>0.9	0.968

Figure 2. Estimates from the regression analysis. H: hypothesis.

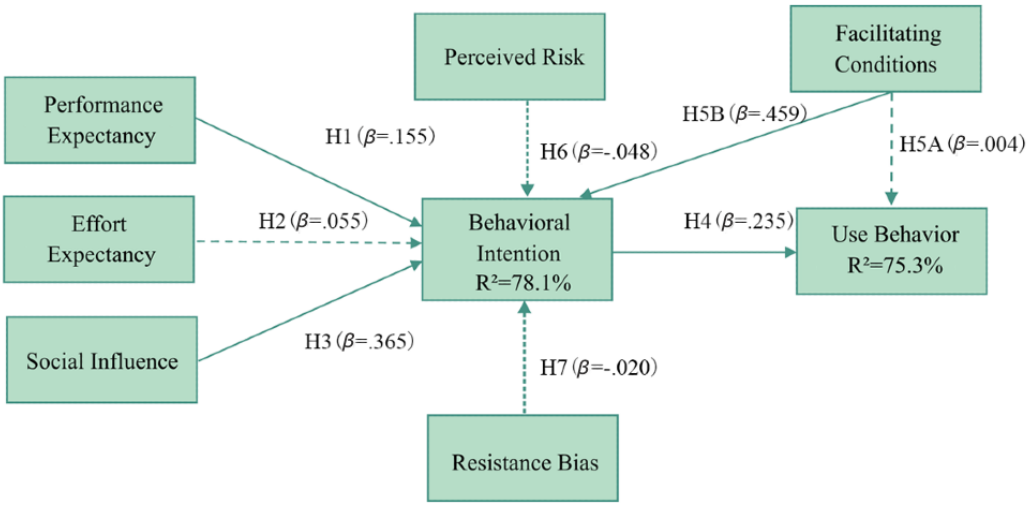

Table 6. Summary of support for the hypotheses.

Variables and hypotheses	Standardized factor loadings (SE)	Critical ratio (T value)	*P* value	Results
Hypothesis 1: Behavioral intention is affected by performance expectancy.	0.155 (0.063)	2.464	.01	Supported
Hypothesis 2: Behavioral intention is affected by effort expectancy.	0.055 (0.073)	0.755	.45	Not supported
Hypothesis 3: Behavioral intention is affected by social influence.	0.365 (0.076)	4.795	<.001	Supported
Hypothesis 4: Use behavior is affected by behavioral intention.	0.235 (0.024)	9.778	<.001	Supported
Hypothesis 5A: Use behavior is affected by facilitating conditions.	0.004 (0.022)	0.195	.85	Not supported
Hypothesis 5B: Behavioral intention is affected by facilitating conditions.	0.459 (0.061)	7.561	<.001	Supported
Hypothesis 6: Behavioral intention is affected by perceived risk.	−0.048 (0.051)	−0.939	.35	Not supported
Hypothesis 7: Behavioral intention is affected by resistance bias.	−0.020 (0.042)	−0.476	.63	Not supported

Discussion

Principal Findings

In this study, we investigated factors that may affect the adoption of an AI-assisted technology for developing treatment plans for cancer radiation therapy patients. The constructs of the research model were developed based on the UTAUT model, and perceived risk and resistance bias were added as potential barriers to new technology adoption. There were 3 principal findings, as follows: (1) the physicians' overall perceptions of the AI-assisted technology for radiation contouring were high; (2) social influence and facilitating conditions played a much more important role in AI adoption among radiation oncologists than performance expectancy, but effort expectancy was not significantly related to behavioral intention (*P*=.45); and (3) perceived risk (*P*=.35) and resistance bias (*P*=.63) were not significantly related to behavioral intention.

The Physicians' Overall Perceptions of the AI-Assisted Technology for Radiation Contouring Were High

Participants had high behavioral intentions (score: mean 5.484 out of 7.0) to use the new AI-assisted contouring technology; 90.9% (279/307) of the total sample gave scores of 4 or above, meaning that they were planning to use the system within 1 year. This result nearly matched those of a survey conducted in 2019, in which 84.62% of the participating medical departments planned to try the AI-assisted contouring system; 10.26% of these departments were in the process of purchasing the system, and 46.15% had purchased plans [46].

Participants' performance expectancy and effort expectancy were high, as they believed that the AI technology could improve their work performance and efficiency. This is similar to the perceptions of Canadian radiation oncologists, who believe that AI could save time and deliver better results to benefit patients [47].

The Relationship Among Performance Expectancy, Social Influence, and Facilitating Conditions Affected Behavioral Intention

Many studies have proven that performance expectancy, effort expectancy, social influence, and facilitating conditions have positive effects on use behavior [8,11,20,48]. For example, in a study of health care robot adoption, these four constructs significantly predicted the usage and uptake of robots [30]. In our study, performance expectancy (*P*=.01), social influence (*P*<.001), and facilitating conditions (*P*<.001) were significantly related to behavioral intention, while effort expectancy did not significantly affect behavioral intention (*P*=.45). Social influence

and facilitating conditions affected behavioral intention much more strongly than performance expectancy. These results indicate that in China, when physicians encounter AI-assisted technology for treatment plans, their opinions are more likely to be driven by people with which they have a close relationship (ie, the items of the social influence construct), such as friends and colleagues, department heads, tutors, superiors, and hospital leaders. This phenomenon reflects the culture of vertical collectivism, which is aligned with the ideology of "utilitarian Guanxi"—a Chinese philosophy that combines the pursuit of profit with objective goals [49]. Further, social propaganda, such as news stories about successfully using AI technology from professionals in the health care industry, likely influences physicians' perceptions toward using such technology.

Facilitating conditions did not have a direct effect on use behavior. However, this construct was the most important factor that affected behavioral intention. As shown by our results, behavioral intention moderates the effect that facilitating conditions have on use behavior (P<.001), indicating that providing support, such as support from the information technology team in a hospital, and having the knowledge and skills needed for using new technology were necessarily important and influenced radiation oncologists' use intentions. On the other hand, most researchers that use the UTAUT model agree that effort expectancy has a significant effect on behavioral intention. However, there have been some exceptions. For example, perceived ease of use did not have an effect on attitudes related to health care professionals' decisions to accept telemedicine technology [50]. In our study, effort expectancy did not affect use intention. In China, physicians in level 3 public hospitals (the highest standard in China) usually have heavy workloads. For example, at Sun Yat-sen University Cancer Center, the Department of Radiation Oncology works on approximately 1200 cases each day. The participants claimed that they did not mind putting in more effort and spending more time on learning about the new technology in order to later reduce their workloads. Determining whether this approach reduces or redistributes workloads is an area worthy of future investigation. Additionally, the AI technology was developed based on participants' previously used software. As a result, they found it easier to gain fluency with the system.

Perceived Risk and Resistance Bias Were Not Significantly Related to Behavioral Intention

In most research on new technology adoption, perceived risk has negatively affected the public's behavioral intentions [11,29]. However, in our study, perceived risk did not affect radiation oncologists' behavioral intentions. Even though they perceived risks (score: mean 4.418 out of 7.0) such as the possibility of being misled with inaccurate contouring and privacy issues, oncologists still had the intention to use the system, as did others (colleagues and superiors). The main reason for this was that it could effectively reduce their heavy workloads. In interviews with some of the participants, physicians explained that they could manually fix the errors in the contouring area because the amount of patient case data has increased and machine learning has made the AI-assisted contouring system more and more accurate; therefore, more time will be saved in the future.

As discussed in a study by Ye et al [10], resistance bias has had a negative impact on the technological acceptance of AI ophthalmic devices. However, different from the general public's perceptions, the low score for resistance bias (score: mean 3.528 out of 7.0) in our study showed that radiation oncologists were not likely to reject AI-assisted contouring technology, regardless of their unfamiliarity with the technology, their past experiences with the failure of new technology products, or the possibility of AI replacing and displacing jobs.

Our study demonstrated that resistance to using an AI-based contouring system to improve patient outcomes and work efficiency was low. There was little to no apprehension among users to learn about and implement this new technology. In previous studies of technology acceptance, resistance bias was observed among medical staff when the benefits of technology were not clear or immediate [36,51,52]. In past research on health care robot adoption, resistance bias did not have a direct negative effect on medical staff's behavioral intentions, as the health care robots were convenient to use and provided significantly better results than those provided by traditional methods [30]. In our study, the AI platform was developed by using the previous software that the oncologists used for work. This resulted in immediate benefits for improving contouring results and saving time. Therefore, negative perceptions surrounding new technologies with clear and immediate benefits, particularly fear and apprehension toward using such technologies (regardless of the degree of these perceptions), may not be prevalent in China. On the other hand, the AI contouring system in our study is used as an assistance tool for providing image contouring results as part of the process for developing a radiation therapy plan. In our case, oncologists still have to work on modifying the contouring areas and deciding on the amounts of radiation for each area. Wong et al [47] conducted a study among Canadian radiation oncologists that showed similar results; 77% of the participants agreed that human oversight was necessary for optimizing the planning process and delivering better quality care.

In China, using AI-assisted technology to relieve physicians' workloads will be a major trend in the future, as such technology tries to fill the gap between the public's demands and the limited amount of medical resources. Chinese hospitals have the need and motivation to adopt AI to improve efficiency, solve the health care professional shortage problem, and reduce patient waiting times. At Sun Yat-sen University Cancer Center, a breakthrough point for the AI product was the potential research opportunities with the AI development company for improving treatment planning accuracy, as the AI product not only helps oncologists improve their work efficiency but also serves as a valuable tool for scientific research.

Hospitals in China, like those in other Asian countries such as India, South Korea, and Thailand, have also proudly indicated their usage and acceptance of AI technology in their marketing campaigns, which have expounded to patients how much their medical services are improved by such technologies [18]. However, anecdotal reports on AI products in cancer care developed by IBM Corporation, one of the largest AI technology providers in the industry, have shown that the company has had trouble with finding customers in the United States [53] and

that technology resistance exists among oncologists who claim that they trust their own judgment over that of software [18]. We suggest that cultural differences may result in different perceptions on AI adoption in Western and Asian countries. Asian physicians may be more likely to accept the idea that AI technology is an assistant that performs certain routine tasks and more likely to reject AI doctors. In this case, the perception is that the AI system will not displace or replace the clinical practitioner; instead, the system will get rid of routine tasks and thus allow for more time to focus on patient care.

Implications for Practice

This study provides 3 suggestions for health care AI developers and hospitals that are planning to introduce AI for clinical decision-making. First, when a hospital introduces a new AI-assisted technology for clinical decision-making in China, the leadership should consider a top-down management process. Hospital leaders and department heads should demonstrate how a new technology works, advocate for the new technology, and encourage subordinate physicians to use the new technology. The hospital could also share AI success stories to influence public opinions on the use of the new technology and highlight the benefits of the system. At Sun Yat-sen University Cancer Center, breakthrough news stories about AI clinical research have been shown not only on social media platforms and local news programs but also at special events such as AI versus human competitions, which have been held at a number of academic conferences, to prove the accuracy of their AI system to both the public and experts. Second, the user interface of the new AI-assisted system should be as consistent as possible with the previously used interface to reduce the time required for users to adapt to the new technology. The hospital information technology center should also work closely with AI technology companies to provide technical support and data security for the use of the new AI platform. Third, per the lesson learned from IBM Corporation's failure in the United States, AI technology development (ie, progressing from perceptual intelligence to cognitive intelligence) should be a step-by-step process. IBM Corporation's oncology expert advisor project used natural language processing to provide treatment recommendations. However, the ambitions of such project were, in hindsight, a step too far. Instead of installing an AI doctor, Chinese hospitals first created an AI technology to act as an assistant tool for medical imaging to free physicians from routine work. When a clear application scenario for medical AI is imagined and created, people are more likely to realize the value of such technology.

Limitations and Future Research

This study has some limitations. Our results might be biased due to the age of participants, as 87.6% (269/307) of the participants were aged under 40 years. The majority of the participants (176/307, 57.3%) were also from Sun Yat-sen University Cancer Center, where medical capacity is high. Additionally, there might be elements of sampling bias, as convenience sampling was used. Further research needs to be carried out among medical professionals in other countries for comparisons of AI technology acceptance in health care services in different cultural contexts.

Conclusion

In this study, technology resistance among Chinese radiation oncologists was low and not related to behavioral intention. Negative perceptions of new technologies with clear and immediate benefits, such as fear and apprehension toward using such technologies (regardless of the degree of these perceptions), may not be prevalent in China. Further, not all of the factors in the Venkatesh UTAUT model applied to AI technology adoption among physicians in a Chinese context. Oncologists' opinions are more likely to be driven by people with which they have a close relationship (the items of the SI construct), such as friends and colleagues, department heads, tutors, superiors, and hospital leaders, and be based on receiving technology support from information technology departments and companies.

Acknowledgments

This study was supported by the National Key Research and Development Program of China (grants 2020YFC1316900 and 2020YFC1316904), the Young Creative Talent Program of Sun Yat-sen University Cancer Center (grant PT21100201), the PhD Start-up Fund of the Natural Science Foundation of the Guangdong Province of China (grant 2018A030310005), the China Postdoctoral Science Foundation (grant 2019M663348), and the National Natural Science Foundation of China (grants 72102238, 71572207, 71832015, and 72072191). The authors would like to thank Ms Wanfei Xie and Ms Le Xia from Sun Yat-sen University Cancer Center for their help with questionnaire collection.

Abstract

There is an unprecedented demand for infodemic management due to rapidly evolving information about the novel COVID-19 pandemic. This viewpoint paper details the evolution of a Canadian digital information tool, *Chloe* for COVID-19, based on incremental leveraging of artificial intelligence techniques. By providing an accessible summary of *Chloe's* development, we show how proactive cooperation between health, technology, and corporate sectors can lead to a rapidly scalable, safe, and secure virtual chatbot to assist public health efforts in keeping Canadians informed. We then highlight *Chloe's* strengths, the challenges we faced during the development process, and future directions for the role of chatbots in infodemic management. The information presented here may guide future collaborative efforts in health technology in order to enhance access to accurate and timely health information to the public.

KEYWORDS

chatbot; COVID-19; conversational agents; public health; artificial intelligence; infodemic; infodemiology; misinformation; digital health; virtual care

Introduction

In the early stages of a global health crisis caused by a novel disease such as COVID-19, misinformation tends to propagate rapidly due to the absence of easily accessible and reliable information from authoritative sources [1]. According to the World Health Organization, controlling the circulation of information about a novel disease requires infodemic management, defined as the application of "evidence-based interventions that bring understandable, localized, evidence-based information to citizens and drive positive health-seeking behaviour" [2]. At the onset of the COVID-19 pandemic in Canada, however, public health hotlines were overwhelmed with calls, impeding the infodemic management process. For example, on March 11, 2020, Quebec's provincial health information 811 phone line received 16,840 calls compared to an average of 6000 calls managed on a typical day [3].

In recent years, chatbots have emerged as a promising means to support public health efforts by easily increasing access to accurate, tailored, and free information to millions of people at once [4]. Leveraged with artificial intelligence (AI) tools, chatbots are intelligent conversational agents that result from the application of natural language processing techniques to analyze speech combined with an engine that is trained to provide human-like responses [5].

The recent surge in chatbot use across industries and business functions such as customer service, sales, marketing, and automation of internal processes stems from an evolution in the way humans communicate [6]. The current digital age, in which most individuals have access to a mobile phone and are accustomed to holding multiple conversations at once through short online interactions, represents an ideal environment for chatbot development [6]. Since the onset of the COVID-19 pandemic, chatbots are increasingly being developed to

efficiently deliver evidence-based information about COVID-19 to the public [4]. Despite these advances, the possibility of chatbots causing harm by communicating inaccurate information to users warrants ongoing monitoring of chatbot quality and safety [7].

The development of Dialogue Health Technologies Inc's chatbot *Chloe* represents a successful Canadian cooperation among health, technology, and corporate sectors, in order to assist the public during the pandemic by addressing their questions and concerns about COVID-19 [8]. Founded in 2016, Dialogue is a leading provider of virtual health care in Canada, offering its services exclusively to Canadian organizations through an online care platform using technologies developed in-house. This care platform consists of an interface in both desktop and mobile application formats that connects members to a care team consisting of health providers and coordinators. Our experience with chatbots in health care includes the design of various AI-enhanced bots used to collect and intuitively interpret patient information in order to determine urgency, appropriateness for virtual care, and the type of provider required. These chatbots were built by combining medical knowledge with state-of the art algorithms and are continuously monitored, updated, and trained to enhance their effectiveness and efficiency, including bot-to-human handoff when required [9].

Chloe was initially conceived to integrate within the Dialogue care platform as a way to help manage questions about COVID-19 from our clients but was quickly converted into a stand-alone digital application in order to be deployed as a free tool for the general public. After Health Canada confirmed the first Canadian case of COVID-19 on January 27, 2020, our medical operations and customer success teams noted an increased flow of questions from members and organizations across the country about this novel disease, looking to us as a health care company for guidance. The urgent need to slow the spread of the virus and provide large-scale access to free information about COVID-19 from authoritative sources, as well as the desire to assist flooded provincial health information phone lines in answering common questions from Canadians, prompted us to pursue an AI approach.

We launched the chatbot *Chloe*, named after Dialogue's first nurse, on March 9, 2020. *Chloe* was designed to provide free, up-to-date information to all Canadians on COVID-19 from trusted Canadian authorities, following federal, provincial, and territorial regulations based on each user's location. To ensure transparency of our technological approach, we rendered the online service and content management system open-source. *Chloe* was designed following best dialogue management principles [10] and built with Rasa, a state-of-the-art open-source framework [11].

This report first outlines the development of *Chloe*, an information and self-assessment tool to respond to a rapidly evolving health crisis. This was achieved by incrementally leveraging AI tools in order to address the challenges associated with the volume of demands and constantly changing information during the early phases of the COVID-19 pandemic. This paper then highlights *Chloe*'s strengths, the challenges we faced, and future directions for chatbot development to support infodemic management.

We wish to note that *Chloe* was designed and launched in an emergency effort to support public health authorities in keeping Canadians informed during the first wave of the COVID-19 pandemic before any governmental information tools had been deployed. Following the rollout of official and local public health online self-assessment tools providing features similar to ours, *Chloe* stopped being regularly updated.

Chloe's Development: From a Frequently Asked Questions Page to an Intelligent Chatbot

Increased uncertainty surrounding the previously unknown virus and disease resulted in a deluge of questions not only for our own care team but also for the entire Canadian health care system. In response to this surge, our Clinical Quality Committee led efforts to provide official answers to the most frequently asked questions (FAQs) from members on our care platform. This led to the release of the first version of our FAQ section on our website on March 5, 2020.

An FAQ section addresses predictable queries, but the constant flow of new information associated with the COVID-19 pandemic required a dynamic tool. In response to this challenge, we designed a self-assessment flow based on official available medical information surveyed by our care team. This allowed us to efficiently sort through and respond to the diverse concerns our members and clients had about COVID-19. We then created a smart virtual medical assistant that we named *Chloe for COVID-19* that was released publicly for all Canadians on March 9, 2020. In accordance with Dialogue's rigorous data security and privacy policies, every effort was made to ensure that Canadians could use *Chloe* in an anonymous and secure fashion. To that effect, no information that could help identify the user (including but not limited to IP addresses and approximate location) was collected by default.

Chloe would ask a user about their symptoms, location, travel history, and recent contacts. This assessment resulted in a personalized recommendation including links to local resources such as the user's provincial government's COVID-19 guidelines. Figure 1 presents one example of the start of the assessment flow for a user in Quebec.

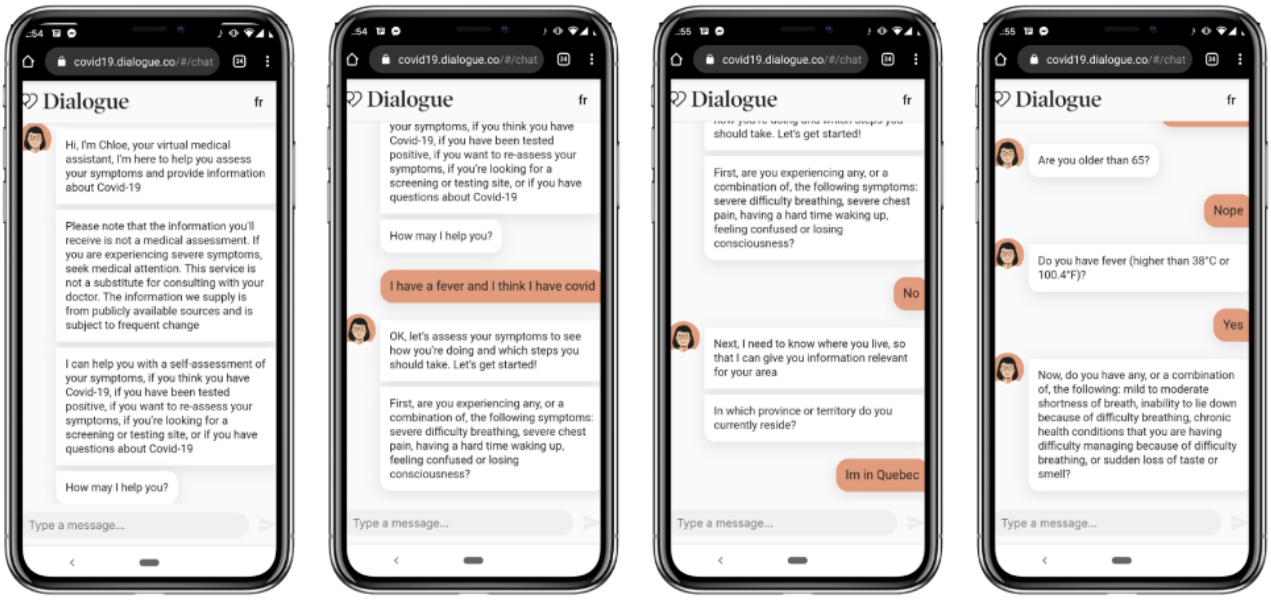
When provincial online self-assessment tools were later deployed, we integrated this information into *Chloe*. Our self-assessment tool saw the highest traffic on March 15, 2020, with 5945 new users accessing the tool, coinciding with the overflow of public health information phone lines. By April 18, 2020, it had been used 73,000 times, further indicating *Chloe's* contribution to overall public health efforts in keeping Canadians informed.

In order to keep up with constantly evolving information spanning multiple Canadian jurisdictions and to discriminate between official information and disinformation, we designed and built a web scraper. This automated service was programmed to extract the latest data from reliable sources

identified by our medical team. During the peak of the first wave, it ran every hour. When the flow of new information later slowed, it was then activated every 4 hours to ensure *Chloe* as well as our online FAQ still offered the most up-to-date information to Canadians.

In addition to the self-assessment tool and FAQ, we developed a question and answer (Q&A) model within *Chloe* to further meet the information needs of Canadians regarding COVID-19.

Figure 1. Example of self-assessment flow for a user in Quebec.



Given the time-consuming nature of this process and the need to gain a better understanding of what questions were most commonly asked, we used clustering to divide the approximately 4000 questions into 40 groups of similar questions. Clustering is a form of unsupervised machine learning, which aims to segregate groups with similar traits and assign them into clusters. The clustering algorithm used word embeddings to represent each of the questions in a multidimensional way. We were then able to accurately measure the similarity among the questions and split them into groups accordingly. For instance, all questions asking about how long the coronavirus could survive on surfaces, one of our most commonly asked questions, were grouped into one cluster.

On April 28, 2020, we released our first interactive Q&A model, marking our transition from an FAQ system to a customized conversational experience. As a first iteration of a natural language Q&A model, we implemented a distance-computing, similarity-matching algorithm. In this model, all clustered questions were embedded in a multidimensional space. Figure 2 represents this step of the process, in which each colored circle is a question and its position is determined by the attributes computed by the algorithm. Averaging techniques were used to obtain the center of each cluster. This identified the average features of the questions within the same cluster.

For example, it was determined that the average question regarding the coronavirus on surfaces holds a combination of the word "surface" or "object" and a declension of the word "time." Next, we embedded the user's question using the same pretrained model, to have it in the same multidimensional space as the cluster averages. The distance between a user's question and the clusters could be computed mathematically. The closest cluster could then be identified and the question categorized.

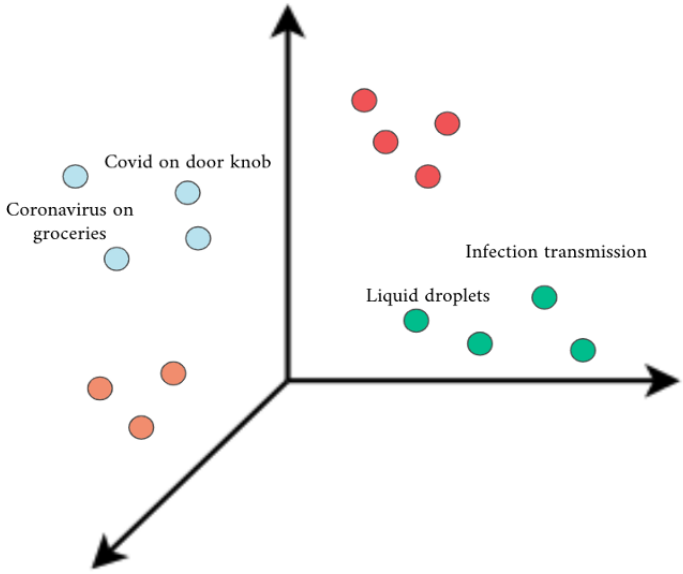
For users' questions that matched a related cluster, we could then return the associated Q&A. For instance, the question "How long does it take for coronavirus to vanish from doorknobs?" was matched to the cluster that dealt with the virus on surfaces. We could then return the associated question-answer pair that would look like this:

> *How long can coronavirus stay on surfaces? It has been demonstrated that it can last for X hours on Y surface.*

If the distance between the user's question and each of the cluster's centers was too great, however, the question would not be categorized, and an answer was not returned. In such cases, the user would be offered a link to our FAQ page, and *Chloe* would ask the user if they had another question. Our monitoring team also took note of these situations to further train *Chloe* to be able to answer an increasing number of user questions. This was achieved by having our team analyze these additional questions and add them to the set of questions used to retrain the clustering algorithm.

The up-to-date COVID-19 information identified by our web scraper was used to refine the Q&A model, which was then further optimized using machine learning techniques. Our team of applied researchers developed a machine learning model that would find the correct answer to a given question about COVID-19 by feeding it approximately 4000 questions acquired through crowdsourcing and several thousand more from data collection tools offered by Amazon Web Services [12].

Figure 2. Representation of questions in a multidimensional space.



Canada being a bilingual country, we also needed this model to accurately return question-answer pairs to all Canadians in both English and French. We therefore followed the aforementioned process twice in order to cover questions in both languages.

While developing the previously described similarity model, we also worked on a more advanced model consisting of 2 main components: a Bidirectional Encoder Representations from Transformers (BERT) model [13] that ranked all COVID-19 FAQ questions from trusted sources according to their relevance with a user's question and an out-of-distribution (OOD) detector using a Local Outlier Factor algorithm [14]. The purpose of this OOD detector was to eliminate questions that could not be answered with the available information from the vetted sources the chatbot used. This improved the number of questions answered and the accuracy of the answers provided while minimizing manual updating work from our care team. Figure 3 presents a general diagram of the model architecture.

Figure 3. Diagram of the final question & answer (Q&A) model architecture using the example of a question about the symptoms of COVID-19. BERT: Bidirectional Encoder Representations from Transformers; FAQ: frequently asked question; OOD: out-of-distribution.

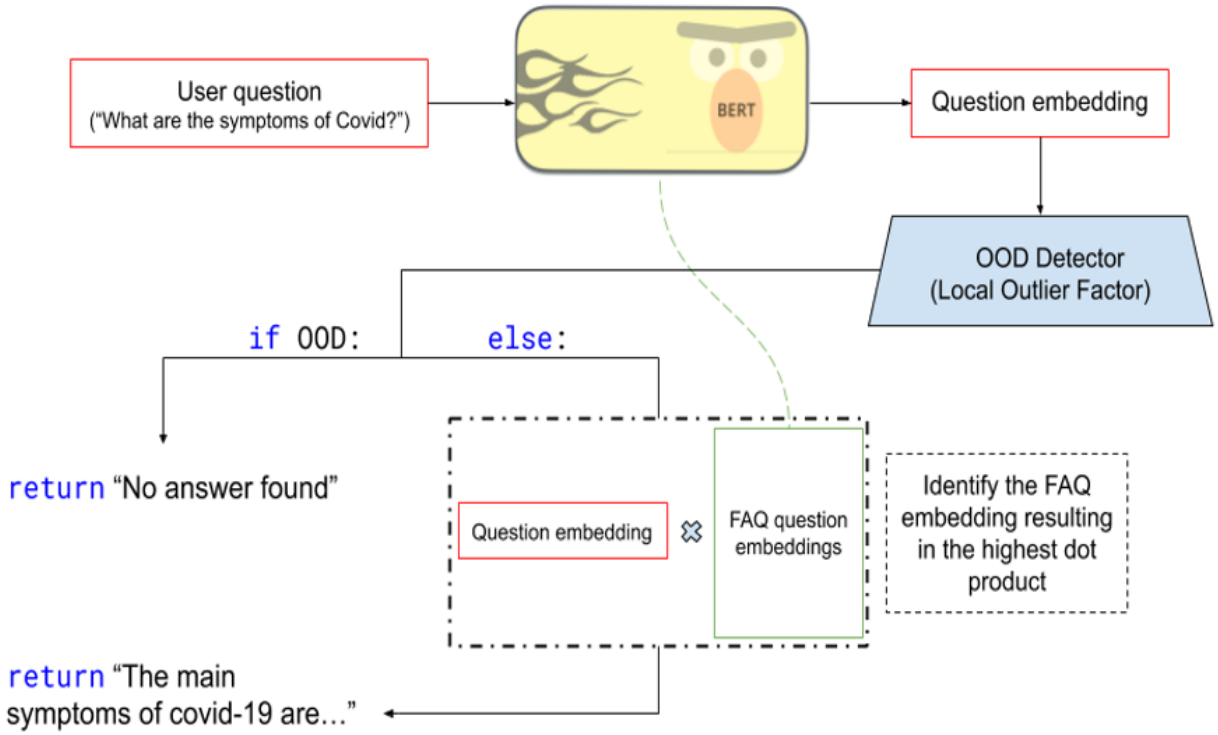


Table 1 describes the results obtained from this final Q&A model's accuracy. Overall accuracy represents the model's ability to give a correct answer to the user's question, and OOD accuracy represents its ability to detect situations in which the question asked has no answer in our data sources. The BERT pretrained model we used has a better performance in English, which explains the discrepancy between the English and French results. Although higher metrics can be obtained from Q&A models, we believe that these results are reasonable given time and data constraints. These results were also deemed acceptable because our Q&A model sought to provide answers to commonly asked questions and not directly inform patient care.

Table 1. Overall and out-of-distribution (OOD) accuracies of the final question & answer (Q&A) model in English and in French.

Language	Overall accuracy, %	OOD accuracy, %
English	81.83	90.48
French	71.32	70.60

We nevertheless addressed the error rates of our model to the best of our abilities by consistently displaying the question and answer as a pair when responding to the user. For example, if the user asked about coronavirus and pets and *Chloe* replied with information about the coronavirus and surfaces, the user would know that the model was responding about surfaces and not pets. This ensured the user would not be misled by false information. Lastly, the model was validated using a standard process [15]. The dataset was divided into training, validation, and test sets, followed by an evaluation of how the test set (not previously seen by the model) performed. Further details about the Q&A model are detailed in a poster presented at the Montreal AI Symposium 2020 [16].

Two other important features were implemented to increase *Chloe's* ability to meet the evolving needs of Canadians: a daily self-health assessment and COVID-19 testing navigation. The self-health check feature was added to the assessment flow at the end of May 2020. Users choosing to enroll in this feature received a daily SMS message with a link to their self-health check-in and had the choice to opt out at any time. Anyone using this self-health assessment service had their first name and phone numbers securely stored on our data servers located in Canada. Having regular contact with users helped tailor the assessment to the user's particular situation and needs. When starting the assessment flow, users' previously reported symptoms and concerns helped the chatbot identify relevant questions to be asked and offer appropriate recommendations. For example, if the user reported a fever the day before, the chatbot might ask if it was still present and if it had gotten better or worse.

The testing navigation feature was added on June 2, 2020 to the assessment flow to support public health officials and public health information phone lines. This feature was built in partnership with Clinia [17], a technology company enabling health care resource navigation. By integrating Clinia's application programming interface into *Chloe*, any user whose self-assessment resulted in a recommendation to get COVID-19 testing would be prompted with the option to search for testing sites. Once the user entered their desired location to get tested, they would receive a list of sites offering COVID-19 testing, their opening hours, special instructions, as well as a link to obtain directions to the sites. Figure 4 presents an example of local testing sites offered to a user in Quebec seeking navigation assistance.

To make the conversation feel as natural as possible for users, we leveraged a machine-learning technology called natural language understanding (NLU), a subtopic of natural language processing, which converts human-readable text inputs into machine language that can be processed to extract an understanding. In our particular case, we extracted intents, which represent the user's query, and entities, which represent key categorized values. For example, if a user said, "I want to find a test site close to Montreal," NLU would help us map the user's intent to something like "find_test_site" and extract the entity "Montreal," which we know is a city. Test sites in Montreal could then easily be suggested to the user. The use of NLU allowed for more open-ended questions akin to normal conversations and minimized clicking. As of June 29, 2020, *Chloe* could ask users: "How may I help you?" NLU components were associated with each possible question, providing a natural conversational experience with an intelligent chatbot. In terms of dialogue management strategies, we used a combination of NLU and static flows defined by a multidisciplinary team of medical experts, software and machine learning engineers, and conversational designers. Figure 5 presents what the latest version of *Chloe* looks like to users upon first connecting with the chatbot. In response to *Chloe*'s initial "How may I help you?", if a user's response falls outside the clusters of questions known to *Chloe*, the chatbot presents 5 clear clickable options from which the user can choose. Figure 6 shows *Chloe's* main features as presented to users.

Figure 4. Example of test navigation results for a user in Quebec.

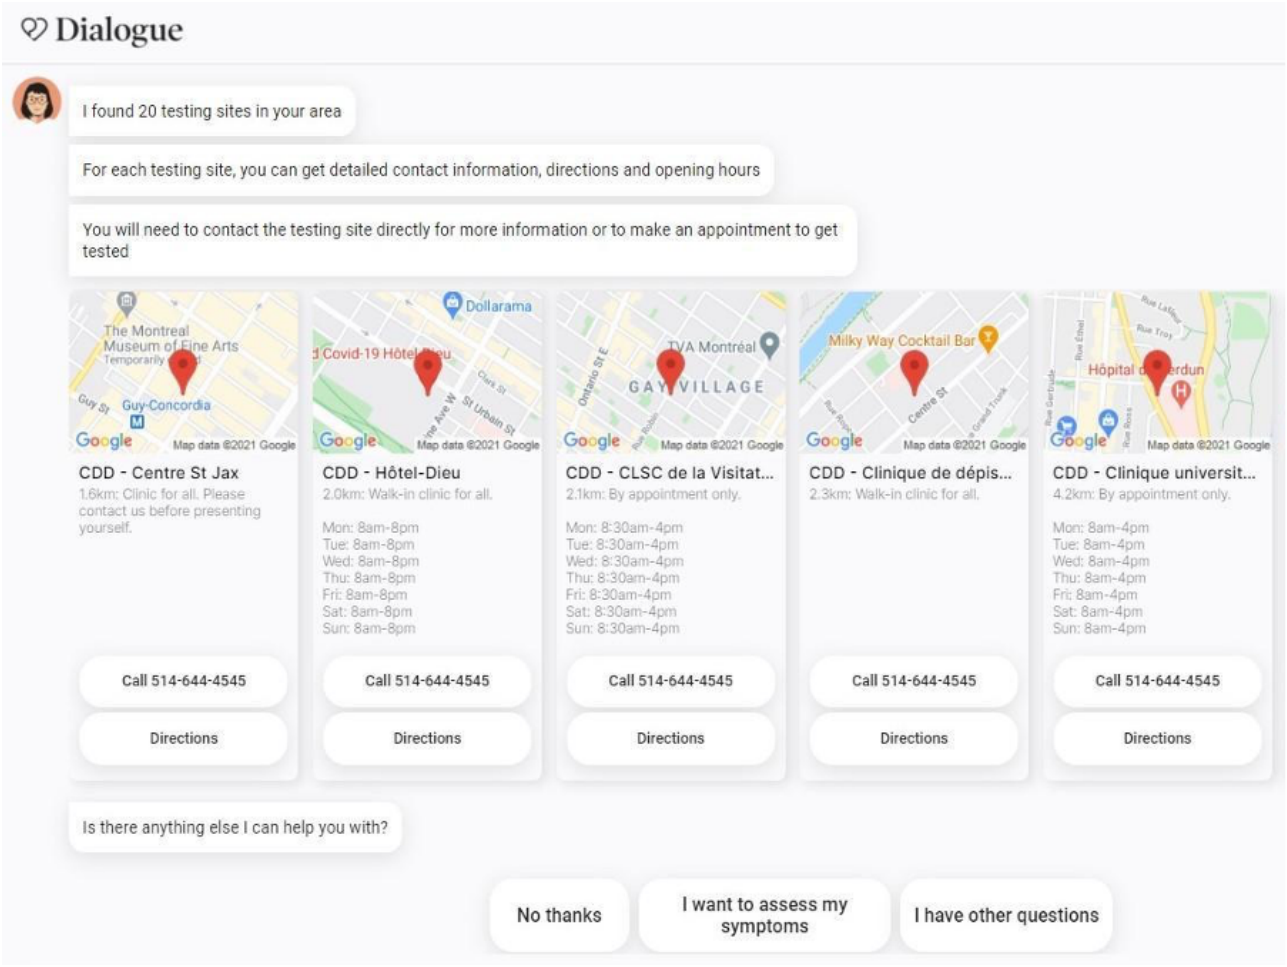

Figure 5. *Chloe's* welcome message to users explaining their options.

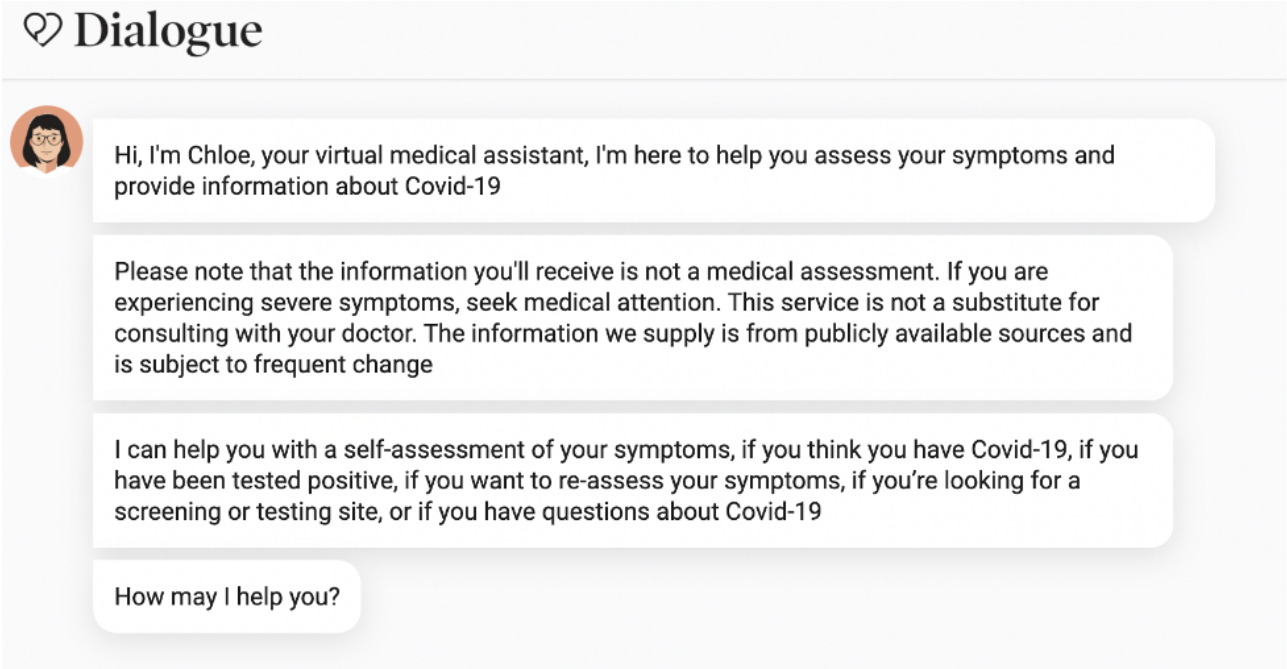

Figure 6. Display of *Chloe's* features available to users.

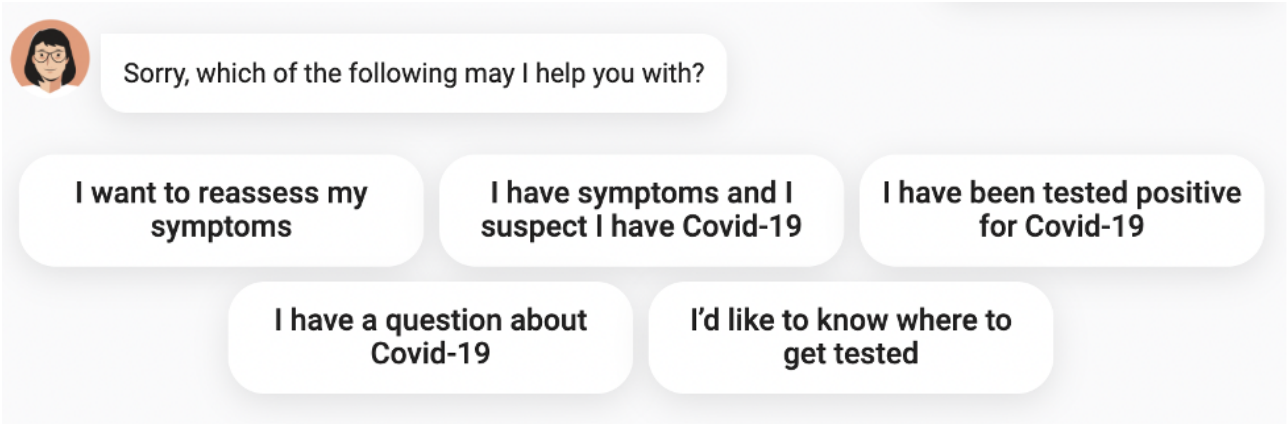

Strengths, Challenges, and Future Directions

To our knowledge, at the onset of the COVID-19 pandemic, there were no other accessible chatbots that provided free, local, up-to-date information on COVID-19 in both English and French to the Canadian public. As of early March 2020, *Chloe for COVID-19* filled this important gap by supporting efforts in keeping Canadians informed when public health hotlines were most overwhelmed. *Chloe* underwent rigorous training by a dedicated team of medical and technology experts who were involved from inception to deployment. This team continually monitored the chatbot using analytics data, making adjustments and updates when needed. Informal user testing was conducted each time a major update was introduced. This involved approximately 10 individuals recruited internally who tested out the different available flows and provided feedback.

As the pandemic unfolded and more information emerged about COVID-19, *Chloe* adapted to address evolving questions from the public. In her most advanced version in June 2020, *Chloe* uniquely integrated 5 features into 1 bilingual chatbot: a self-assessment tool, resources for users who tested positive for COVID-19, answers to common questions about COVID-19, testing navigation, and a daily self-health check-in.

Despite *Chloe's* success in providing tailored information to the Canadian public early on in the pandemic, we encountered several challenges during *Chloe's* development and after *Chloe's* launch, of which the most notable were keeping up with the increasingly vast and rapidly changing information available on COVID-19 as well as time and data constraints within an emergency health crisis context.

Rapidly changing information on COVID-19 (eg, how the disease presents in individuals, how the SARS-CoV-2 virus is transmitted, and when individuals should get tested), complicated by Canada's multijurisdictional landscape with guidelines changing from one region to another, required constant monitoring from our team to ensure accurate information was provided to users across the country. Furthermore, as mentioned earlier in this report, chatbots have the potential to address the questions of millions of people at once [4], but the risk of amplifying misinformation and the lack of research on chatbot effectiveness present significant challenges, particularly in a pandemic context [7]. By reinforcing local provincial and territorial guidelines, we ensured that *Chloe's* messaging to users aligned with the most up-to-date public health information tailored to each user's location and health situation. We learned that having a multidisciplinary team of technology, nursing, physician, customer success, and clinical quality experts, assisted by AI tools, was the best approach to quickly mobilize all necessary information and make any required adjustments to *Chloe* as the pandemic situation evolved.

Given that we developed *Chloe* as an informational tool in an emergency effort to support overwhelmed public health hotlines, we lacked the time and resources needed to rigorously evaluate *Chloe*'s implementation and measure *Chloe's* impact on users. In a noncrisis context, it would have been ideal to set and track specific implementation metrics other than general chatbot traffic to improve *Chloe* more systematically. In this instance, we prioritized the need to act quickly in assisting public health efforts at the height of a health crisis. We also considered that implementation metrics are particularly important for chatbots that directly inform patient care, such as those that refer users to consultations with health professionals. Those chatbots require closer monitoring than chatbots such as *Chloe*, whose main goal was to reliably answer the public's questions about COVID-19 and to redirect individuals to testing services and local public health guidelines when needed.

Moreover, we were unable to precisely measure *Chloe's* acceptability, but we acknowledge the importance of evaluating this metric [18]. Current metrics used to determine the acceptability of AI chatbots in health care include trustworthiness of the information provided as well as a user experience that is perceived as empathetic to the patient [19]. Despite not formally evaluating *Chloe's* acceptability, *Chloe* was designed to be trustworthy, by offering up-to-date official information from public health sources, and empathetic, by leveraging AI techniques to make the conversation feel as natural as possible with users. We also knew from prior experience designing and implementing health technology tools for the Dialogue platform, as well as extensive member feedback, that chatbots are an acceptable and easy-to-use tool for collecting, assessing, and sharing health information. That being said, rigorous user testing combined with the systematic collection of user feedback, for instance through the integration

of a permanent feedback link in the user interface of a chatbot as done by Herriman et al [4], may have allowed us to better understand user needs and make quicker improvements to *Chloe's* features.

In further building on *Chloe's* development and envisioning the future of chatbots, we would also prioritize evaluating the impact of chatbots on how well individuals feel informed. In a scoping review of the technical metrics used to evaluate healthcare chatbots, Abd-Alrazaq et al [20] found that most chatbots were assessed according to 27 different metrics, with global usability and survey designs as the most commonly used metrics. Although chatbots like *Chloe* are not "healthcare chatbots" in that they do not deliver healthcare services, the evaluation of their usability and performance is warranted in order to improve their ability to provide the right information to users at the right time.

In summary, we believe *Chloe's* development is useful in illustrating the potential for rapid collaboration among health, technology, and corporate sectors to assist public health efforts in keeping individuals informed at the height of a health crisis. Addressing the public's need for accurate health information will remain important within the current pandemic context and during any future health crises. As COVID-19 vaccination campaigns continue to target the general public, intelligent conversational agents have the potential to play a critical role in debunking misinformation surrounding vaccines and directing individuals to public health resources [21,22]. One study in the preprint stage, which examined a chatbot designed to address arguments against the COVID-19 vaccine, promisingly showed that individuals' attitudes towards vaccination became more positive after receiving information from this chatbot [23]. Moreover, in a recent Nature survey of infectious disease researchers, virologists, and immunologists in 23 countries, the majority of respondents predicted that the SARS-CoV-2 virus will likely become endemic over time, with its future closely depending on virus mutations and the type of immunity individuals will acquire [24]. In anticipation of the upcoming waves of uncertainty regarding this virus in the coming years, we envision an ongoing and growing role for chatbots in supporting public health efforts in infodemic management in order to keep the public safe and informed.

Conclusion

The devastating and widespread health consequences of the still ongoing COVID-19 pandemic and continued uncertainty surrounding this novel disease are unprecedented challenges to public health. Since the start of the pandemic, managing the ensuing deluge of both information and misinformation about COVID-19 has also required unparalleled efforts from health authorities.

In detailing the development of *Chloe for COVID-19*, we provide an encouraging example of collaboration leading to a rapidly scalable, safe, secure, and useful human-enhanced digital tool to address the information needs of Canadians during this pandemic. Continuing to leverage the potential of such chatbots to become trusted public health allies will support ongoing infodemic management strategies. As research on the safety and acceptability of these tools advances, we anticipate a growing role for chatbots, both standalone and integrated with human-provided care, in the current pandemic, in particular with vaccination rollout and ongoing efforts to combat misinformation.

Acknowledgments

The authors wish to acknowledge NuEcho and Clinia for their collaboration and their important contribution to *Chloe's* development. Financial support for this project was received from ScaleAI and Mitacs.

Conflicts of Interest

All four authors of this paper work at Dialogue Health Technologies Inc. but do not have any personal financial interests related to the contents of this paper.

Abstract

Background: Digital health agents — embodied conversational agents designed specifically for health interventions — provide a promising alternative or supplement to behavioral health services by reducing barriers to access to care.

Objective: Our goals were to (1) develop an expressive, speech-enabled digital health agent operating in a 3-dimensional virtual environment to deliver a brief behavioral health intervention over the internet to reduce alcohol use and to (2) understand its acceptability, feasibility, and utility with its end users.

Methods: We developed an expressive, speech-enabled digital health agent with facial expressions and body gestures operating in a 3-dimensional virtual office and able to deliver a brief behavioral health intervention over the internet to reduce alcohol use. We then asked 51 alcohol users to report on the digital health agent acceptability, feasibility, and utility.

Results: The developed digital health agent uses speech recognition and a model of empathetic verbal and nonverbal behaviors to engage the user, and its performance enabled it to successfully deliver a brief behavioral health intervention over the internet to reduce alcohol use. Descriptive statistics indicated that participants had overwhelmingly positive experiences with the digital health agent, including engagement with the technology, acceptance, perceived utility, and intent to use the technology. Illustrative qualitative quotes provided further insight about the potential reach and impact of digital health agents in behavioral health care.

Conclusions: Web-delivered interventions delivered by expressive, speech-enabled digital health agents may provide an exciting complement or alternative to traditional one-on-one treatment. They may be especially helpful for hard-to-reach communities with behavioral workforce shortages.

Introduction

Background

Alcohol use disorder (AUD) affects 10%-20% of men and 5%-10% of women over their lifetime, and 26.4% of adults engage in binge drinking. AUD is the third leading preventable cause of death [1], with driving under the influence accounting for 31% of driving fatalities. In addition to personal costs associated with AUD, alcohol abuse costs the US economy an average of $249 billion per year. Motivational interviewing (MI) [2] is an effective and scalable intervention for AUD [3].

It is a client-centered counseling style that is directive and elicits behavior change by helping clients explore ambivalence and resolve it in order to develop *intrinsic* motivation to change. Adaptations of MI have bourgeoned to meet the need for motivational interventions that are brief and thus compatible within primary care settings [4]. Brief motivational interviewing (BMI) interventions include MI's style of communication (communicating empathy, increasing discrepancy, rolling with resistance, and supporting self-efficacy) with the common underlying elements of effective brief interventions (eg, feedback, menus of options for changing respectful of current readiness to change, supportive advice). BMI can be delivered in multiple settings, as both a standalone intervention and in combination with other strategies for substance use disorders, such as cognitive-behavioral therapy, and has been found to be effective across meta-analyses [3-5]. Despite the high rates of alcohol use and availability of these effective interventions, only 1 in 10 individuals with AUD receive care [6,7].

Barriers to Care

A number of barriers prevent individuals from accessing the treatment they need, including acknowledging the need for treatment [8], availability of trained providers [9], proximity of providers, access to transportation, affordability, insurance coverage, scheduling, and stigma [10]. Individuals living in rural settings or in poverty — where alcohol abuse is more prominent — are disproportionately impacted by these barriers [9]. In rural settings in particular, anonymity is more difficult [11] and increases stigma around help-seeking. Lack of flexible scheduling options for individuals who work full time further exacerbate barriers to treatment [9]. Finally, when individuals do access treatment, it is not always an evidence-based treatment — further complicating issues around access to quality care.

Digital Health Interventions

Digital health interventions (DHIs) are interventions that are delivered via digital platforms (eg, applications, websites, mobile devices). Unlike telehealth (where a live provider meets with a consumer via a video chat), DHIs do not rely on a human provider to deliver services. As such, they have the potential to reduce a number of barriers associated with location (can be accessed from anywhere), scheduling (can be accessed at any time), stigma (can be accessed anonymously from the privacy of one's home), and cost (most are affordable or free). Past research indicates that consumers tend to be more truthful when disclosing possibly stigmatizing information such as a drug or alcohol disorder to a computer versus a human [12-16] — providing another advantage to DHIs as they can be more informed about consumers' at-risk behaviors than a human provider.

A review of DHIs [17] indicates that these interventions range from brief screening tools to several months of structured activities. Content includes screening and self-monitoring, personalized normative feedback, goal-setting activities, and interactive journaling. Benefits include reductions in alcohol consumption and consequences of heavy drinking. Despite all the benefits associated with DHIs, they are associated with high dropout rates [18]. For instance, a systematic review of the use of mental health support smartphone applications indicates that only 4% of users engage daily with the applications [19]. Researchers suggest that the use of a DHI without the support or recommendation of a mental health professional may limit its use [19,20]. Mohr et al [21] pointed out that improvement in mental health conditions tends to require continued behavior change over many weeks or months, yet mental health technologies are mainly didactic, thereby not ideal for supporting engagement and behavior change. Most behavioral health technologies require some human backing from a mental health professional to sustain engagement. Qualitative studies point to lack of motivation due to frustrating technology, inadequate content, competing priorities, and lack of face-to-face encounters [22,23]. This limits the promise of DHIs as a scalable solution to increase access to care, which our approach aims to improve.

A review of DHIs designed specifically for MI [24] further points out that, given the important emphasis on the interpersonal therapeutic communication style that is a core aspect of MI, delivering MI through these different modalities is difficult. For instance, can the "MI spirit," or relational aspects, happen digitally? Therefore, comprehending the type of technology used to deliver relationally focused treatments provides an understanding of how technology may be used to replace face-to-face contact. The study found that DHIs for MI vary greatly in terms of technology and richness of the media used, ranging from text-only to audio files, video files, and interactive animated characters, and that the most common feature of these technologies was personalized feedback to the participant based on their input. Only a subset of a few programs used videos (eg, a "video-doctor" actor playing a doctor's responses in MI style) or animations (eg, a robot's head with facial expressions supporting participants during the intervention). These media were always developed with the aim to mirror interpersonal communication. Our current focus on developing and evaluating 3D virtual characters able to deliver a BMI, with appropriate facial expressions, body gestures, speech synthesis, and speech recognition in real time, aims at providing awareness into how technology may be used to replace face-to-face contact.

The review by Shingleton and Palfai [24] also found that, while surveyed articles explained methods for some aspects (eg, automatic computer prompts, chat rooms, emails, videos, animated characters) to deliver MI, most articles did not explain how they translated MI principles into the DHI nor whether or how the relational components were resolved. Translating aspects that require the MI spirit such as "expressing empathy" or "collaboration" to technology — versus consolidating commitment to change and developing discrepancy, on which most studies focused — is particularly difficult to implement in a piece of software. One conclusion was that future researchers need to detail both, not only how the technical aspects (eg, chat rooms, emails) are delivered but also how the relational aspects (eg, emoticons, videos of talking narrators) are delivered in order to increase the human-like discourse with the DHI. Asking questions to help understand how participants felt about and during the interaction were also encouraged as important "soft" outcomes to uncover ways to increase the "spirit" of MI within technology. As highlighted by Mohr et al [21], while usability testing has increased in recent years, the

design of DHIs has generally not included input from end users. Our focus on technology outcomes in this article aimed at providing insight into these "soft" outcomes, by explicitly asking users of our DHI-specific survey questions about their experience with an expressive, animated embodied conversational agent (ECA) in order to inform the impact of our DHI current design, our future redesigns, and other researchers' DHIs.

Embodied Conversational Agents

ECAs (also known as virtual intelligent agents or virtual humans) are simulated human characters that may have the potential to increase consumer engagement in DHIs [25]. Unlike avatars — which are virtual entities that represent and are controlled by the user (popular in video gaming) — ECAs are virtual entities of their own that interact with a consumer autonomously and anonymously. They are developed with the aim to look, sound, and behave as closely to humans as possible. Their ability to hold conversations is still limited [26] but advancements in natural language processing and artificial intelligence (AI) hold promise in the future of ECAs as an alternative solution to traditional therapy for mental health and substance abuse concerns [27]. ECAs have the ability to use sophisticated multimodal communication to build rapport [28-41], communicate empathically [32-35,38], and engage in social talk [42-46]. Despite the promise of ECAs, research around the acceptability, feasibility, and utility of such technology by consumers of behavioral health interventions is limited. Exceptions can be found in a few studies using 3D ECAs with realistic animated facial expressions and mirroring of the users' facial expressions [25], a study including an ECA with a dialog management system allowing users to answer freely to the ECA (albeit without full robustness for broad dissemination without synchronous human support) [26], and a few others using simple ECAs [43,47-50].

In spite of their success, however, ECA development did not scale with the now abundant internet devices (smartphones, laptops) and the latest progress in 3D graphics. Some attempts have been made to build web-based, 3D ECAs [51-53]. However, their implementation is still very basic, and they do not offer an integrated framework for web-based ECA development, including the ability to recognize and synthesize social cues in real time during spoken dialog, which is a significant technical challenge and which our ECA provides.

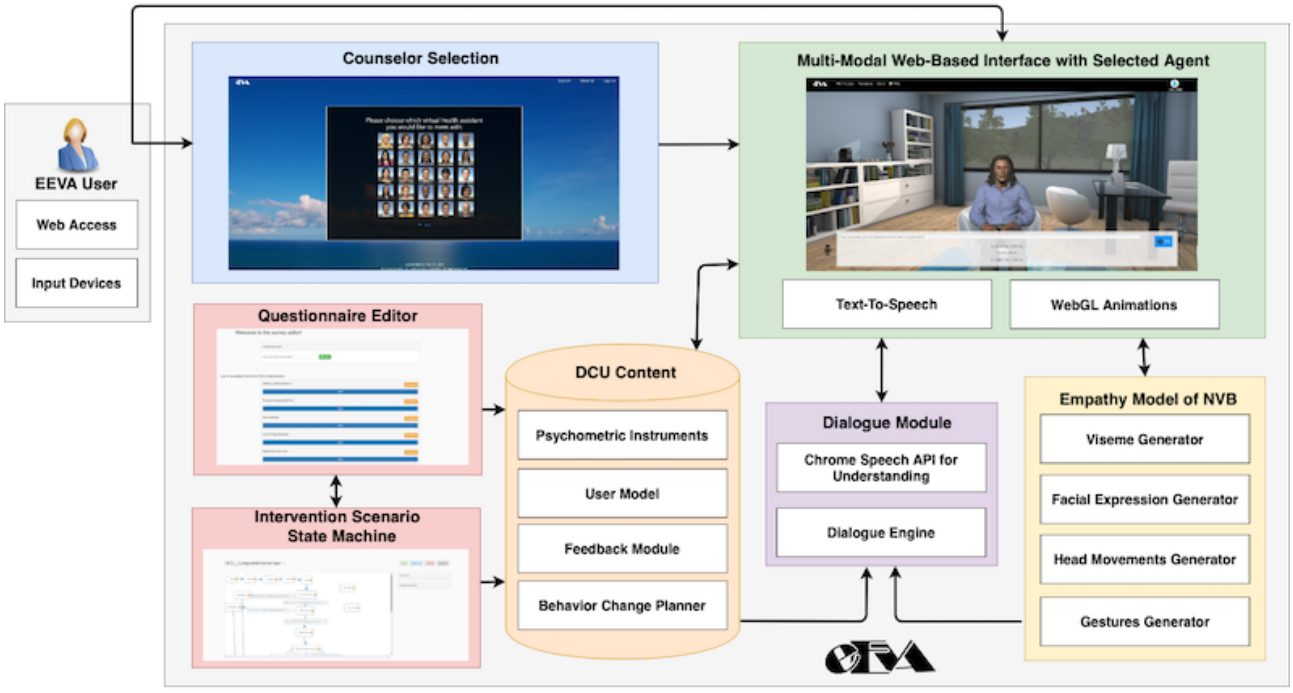
Current Study

This study aimed to fill the gap in knowledge of using ECAs in behavioral health contexts by establishing the acceptability, feasibility, and utility of using ECAs by consumers undergoing a BMI intervention for alcohol abuse. BMIs are highly structured (*assessment* of, followed by normative *feedback*, then *menu* of change options), making them amenable to delivery via DHI [22], particularly if the "MI spirit," or relational components, can be captured without face-to-face contact. One such BMI, namely the Drinker's Check-Up (DCU) [2] is the intervention used for this work. DCU has been computerized as a menu-based, text-only program delivered online that targets alcohol abuse, reducing drinking by an average of 50% at a 12-month follow-up [50]. The DCU is one of the 2 English-language, web-based DHIs designed for the public that have been tested in randomized controlled trials (RCTs) [7]. We therefore chose to study how the delivery of the DCU by an ECA will be perceived by its users, given that its nonverbal and other media features aim to address the observed limitations of the use of avatars in DHIs for MI that do not strengthen the social relationship with the user [50].

Using the technology acceptance model (TAM) [54,55] to guide our work, this study enabled us to determine if the ECA designed by our team using the empathic embodied virtual agent (eEVA; see Figure 1 and Figure 2) framework for building digital health agents [56] has enough personal characteristics and social abilities (eg, open-minded, supportive, respectful, friendly) to give users a positive experience (acceptability). The TAM stipulates that user acceptance can be predicted by the perceived usefulness (utility) and perceived ease of use (feasibility) of the technology. As such, we were interested in learning more about consumers' perceived positive experience (acceptability), usefulness of eEVA (utility), and ease of use (feasibility) to better understand acceptability and potential for adoption of the technology. Having technology that consumers like and find easy to use and helpful increases the potential for adoption, which, in turn, increases access to care. Increases in access to care have the potential to improve health outcomes for alcohol users. Prior studies have found that MI for alcohol use (including online delivery via textual interface) improves health outcomes [57].

Figure 1. Our empathic embodied virtual agent (eEVA) delivering a brief motivational interviewing behavior change session.

Figure 2. Empathic embodied virtual agent (eEVA) system overview. API: application programming interface; DCU: Drinker's Check-Up; NVB: nonverbal behavior.



Methods

Intervention

DCU

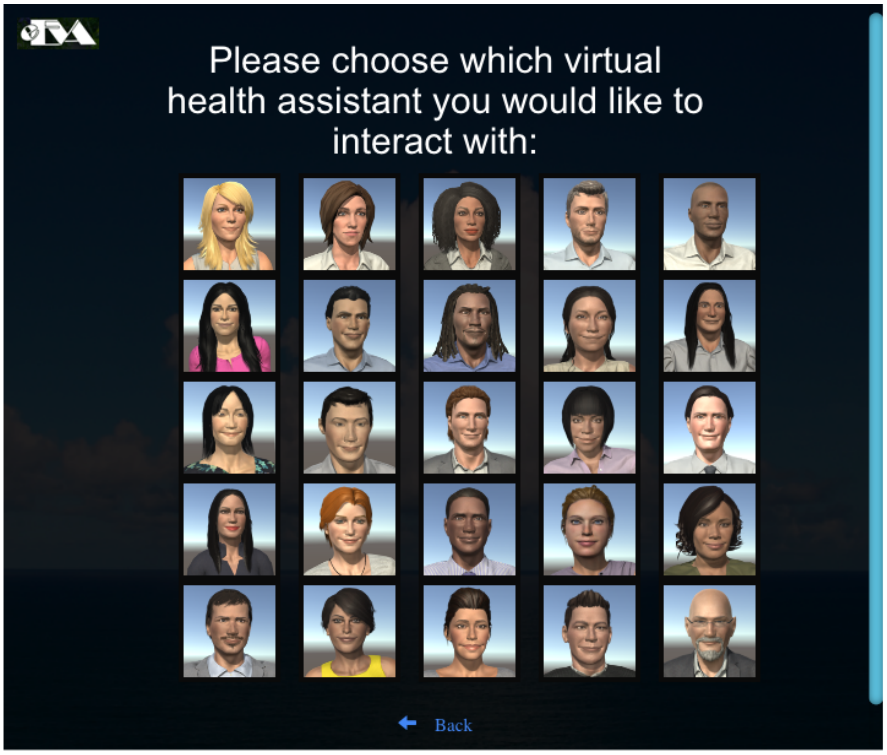
The intervention is based on DCU — an evidence-based intervention that uses strategies from MI [57]. First, users provide detailed information about their drinking (eg, own drinking patterns or issues, family history of alcohol use). Next, they receive individualized feedback about their drinking habits, including information about risk factors and consequences [58]. Finally, they resolve their ambivalence about whether to change their drinking, plan for a change, and set goals for change. The intervention provides resources to help users with changing their drinking [59]. However, the DCU does not tell the clients what to do or not to do — it is up to the user whether they want to change their alcohol use. The DCU has been studied extensively and led to reductions in the quantity and frequency of drinking by 50% throughout a 12-month follow-up period, when compared to a waitlist control group [57]. The DCU is 1 of the 2 web-based DHIs that have the strongest evidence supporting their efficacy based on RCTs [7].

In this study, the DCU was delivered via an ECA (namely eEVA) rather than via its traditional textual interface. As a BMI, the eEVA intervention combines MI style of communication with the common underlying elements of effective brief interventions characterized by the acronym FRAMES [2]: *Feedback* about client's individual status is personalized and stored in a user model database, keeping a record of users' answers for the next session(s); *Responsibility* for changing is left with the individual, and the language used throughout the intervention reflects this (eg, "I will not pressure you in any way"); *Advice* is provided in a supportive manner, with empathic choice of words and supportive body gestures (eg, leaning forward, head nodding); *Menus* of different options for changing that respect an individual's readiness to change are offered; *Empathic* style of communication is central to the individual-clinician relationship, and it is conveyed by the ECA's verbal utterances (eg, spoken reflections), nonverbal behavior (NVB; eg, smiling facial expressions, lean forwards, hand flips, nodding at appropriate times), and empathic choice of wording (eg, "It might be surprising to you to know that you are in the top percentile in drinking compared to people of your gender and age; you might want to review your answers again …"); and *Self-efficacy* is nurtured and emphasized throughout, including with choice of words and positive facial expressions (eg, various head nods and smiling facial expressions).

Technical Implementation of the Intervention

Our eEVA framework (shown in Figure 2) provides (1) a realistic 3D WebGL graphics virtual environment with a realistic virtual office environment that can be "inhabited" by 1 of the 25 available racially diverse ECAs (shown in Figure 3), each with physiologically realistic Facial Action Coding System–validated facial expression animations and full body animations; (2) real-time speech recognition of the user's answers; (3) text and multiple choice input; (4) voice synthesis for the ECA's spoken utterances; (5) ECA's lip synchronization between phonemes and visemes; (6) ECA's adaptive nonverbal responses such as head nods or leaning forward depending upon the utterance dialog act; (7) configurable dialogue content; and (8) ability to capture and process users' social cues such as facial expression recognition (which will be enabled in a future study).

Figure 3. Menu of diverse empathic embodied virtual agent (eEVA) embodied conversational agents consumers can select.



Technically speaking, the framework consists of 3 main components. First, the application layer consists of a modular client-side JavaScript mainframe that controls the multimodal user interface, audio and video input, graphical user interface (GUI) interaction, and services such as speech recognition and speech synthesis. Second, the JavaScript mainframe handles execution of a scenario (the content of the DCU in this study) — a collection of state machines that are created by developers. Third, the scenario states can be constructed to pull information (eg, the ECA's speech, graphics to show) from the data layer — a database of content.

The backbone of the client-side application is a JavaScript framework that handles the formation of a group of modules and the communication between them. Each module then implements various functionalities, including gaining feedback from the user (eg, asking to access microphone and camera) and processing input information (eg, analyzing users' responses, extracting facial expressions if desired); determining how to answer the user (eg, words agent should say, NVBs); and answering the user through a multimodal 3D-embodied ECA, with speech synthesis, NVBs, and multimedia content (eg, text, images, and videos).

This results in an interactive online application that can run on numerous platforms such as desktop, cell phone, autonomous robotic agent, and potentially smartwatch integrations (Figure 4). In addition, the user can also choose between a collection of 3D virtual characters to interact with — of different genders, races, and appearances. To personalize the eEVA system further, favorite chosen characters are remembered and displayed after login during the next interaction with the system. Distributing the framework core (eg, 3D character, perception, behavior) to consumer devices makes this technology scalable, with little to no overhead with additional users. Computer-intensive functionality such as speech and face recognition is asynchronous via web services or with built-in functionalities in the browser.

Figure 4. Empathic embodied virtual agent (eEVA) running on different platforms: (a) desktop, (b) mobile phone, (c) autonomous robot, (d) smartwatch concept.

Unlike traditional ECAs, the eEVA design follows common modularity patterns found in robotics platforms such as ROS [60], allowing us to generate collections of modules to cover a diversity of application use cases, such as various browsers, many internet bandwidth limitations, and interaction capabilities. For instance, when using speech recognition, to provide the transcript of the user's spoken utterances to be used by the ECA application, based on browser capabilities, a specialized module can be used to either interface with the Web Speech API or to use another service such as Watson Speech to Text. The advantage of this design is the seamless passing from one module implementation to another, including at runtime, without affecting the rest of the application.

To model social interaction, 3 main categories of module functionality are necessary, namely input/sensing modules (for perceiving social cues from the user in real time); social interaction decision-making modules, including an ECA behavior module, vocal command interpretation, and the scenario controller; and output/actuator modules for actually expressing verbal and nonverbal cues to the user. The functionalities of the main modules used in the current version of eEVA are listed in Table 1. Most modules have simple functions to retrieve or display information from and to the user or call functions from libraries (third-party or in-house) or services.

Table 1. Listing of the most significant modules and their function descriptions used in the empathic embodied virtual agent (eEVA) for our health agent.

Module	Function description
Input/Sensing Module	• User microphone interface using WebRTC application programming interface (API) • Speech recognition using Google Chrome API • Interface with CoreNLP • Graphic user interface (GUI) for direct user input (text, buttons)
Social Interaction Decision-Making Modules	• Vocal command interpretation • Embodied conversational agent's (ECA) behavior (gesture and facial animations) • Scenario controller (state machine execution)
Output/Actuator Modules	• Speech synthesis • 25 webGL 3D eEVA ethnically diverse characters

We tested 2 types of network connections: broadband and 4G mobile data. The majority of the launch time consists of loading the 3D character and surrounding virtual environment, which takes about 30 seconds and 25 seconds on 4G and broadband, respectively. The experiments (Table 2) showed that the main distributed functionalities of the eEVA framework allow real-time interaction and adequate loading times. This was echoed by users, as discussed in our Results section.

Table 2. Average response time and standard deviation analysis for the empathic embodied virtual agent (eEVA) using 4G or broadband connections over the internet between North America and Europe, with caching disabled (first run).

Functionality	Time on 4G mobile data (milliseconds)	Time on broadband internet (milliseconds)
Unity 3D character, mean (SD)	30018 (663)	24626 (1910)
TTS[a] (sentence), mean (SD)	939 (381)	551 (141)
TTS (word), mean (SD)	72 (40)	44 (23)
Speech recognition	~30 (offline processing)	N/A[b]
Entire HTTP request, mean (SD)	1124 (166)	784 (66)
DOM[c] loading, mean (SD)	2313 (80)	1635 (224)

[a]TTS: text to speech.

[b]N/A: not applicable.

[c]DOM: Document Object Model.

Model of Empathic Verbal and Nonverbal Behavior

To simulate some of the communication psycholinguistic signals of a counselor delivering a BMI, we first videotaped BMI sessions between a live licensed counselor and a client. Then, a clinical expert reviewed the videotapes to code verbal reflections and NVB. From these, the expert generated a set of rules for basal behaviors of the health agents. Based on the codes of verbal and NVBs, eEVA was implemented with the following verbal reflections: "Ah." "Alright." "Okay." "Good." "Sounds Good." "Oh, okay." "Great!" "Thanks for letting me know." "Oh, I see." "Okay, thanks!"

In addition, the following NVB animations were synthesized on the agent's face: smile, facial expressions, hand gestures (typing on a computer at a desk, hands resting on the agents' legs, formless flick, two-handed flip, two-handed contrast gesture), body leans (forward), head gestures (nod, shake, nonshake), and eyebrow movements (up, neutral, and down), which our results (discussed later) showed are conducive of a positive experience for the user with the agent in the given health care context.

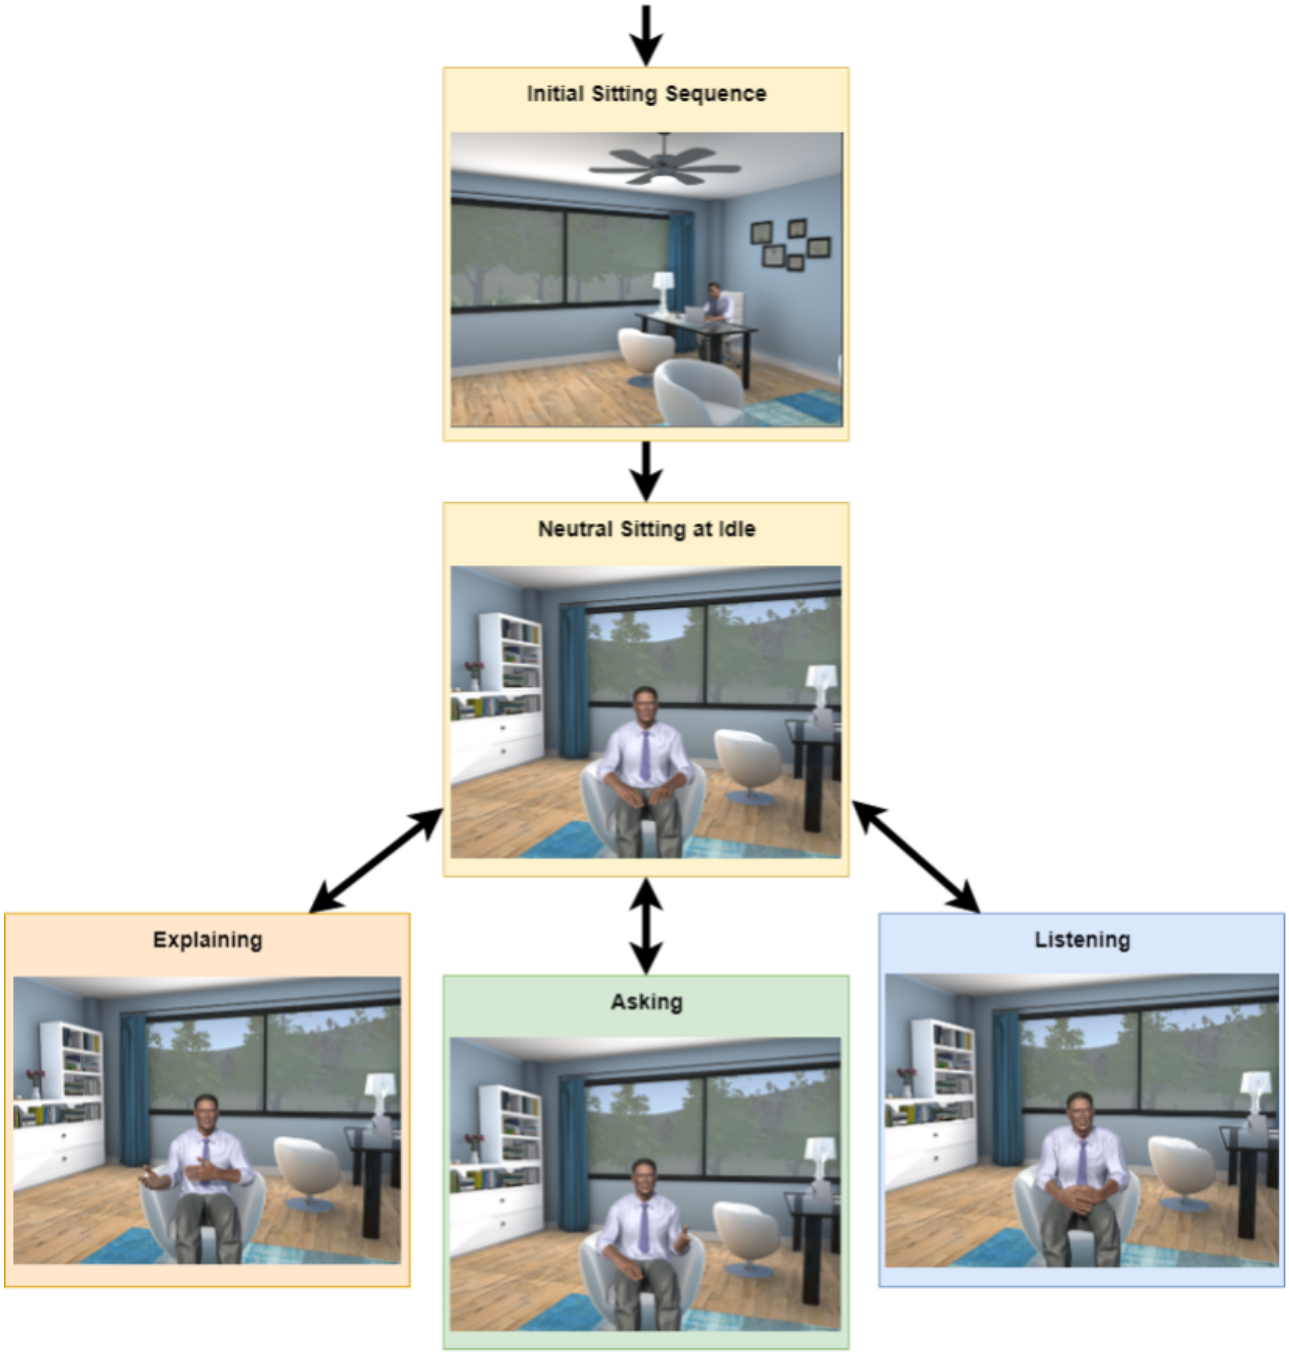
Since it was determined that head nods are critical to portraying (some level of) active listening, we sought to offer 3 variants depending on the user's chosen responses. We created a set of nods using established emotional expressions governed by activation of specific individual facial movement animations. All 3 of the head nods included activation of head down and eyes down. However, depending on the type of reaction required, these also included facial expressions (eg, smile, mild concern).

The patterns observed in the videotapes of the counselor-client session also directed us towards creating rules about when certain statements should be made, to ensure the counselor did not appear judgmental and to make the interaction appear more natural. In all scenarios, the counselor began seated at the desk while typing on the computer, then looked up and moved to the chair closer to where the user perceives they are sitting during an initial greeting. Once seated, the counselor began with a greeting introduction and then moved on to delivering the DCU. Verbal responses to user responses were applied based on the "score" of each question to provide nonjudgmental reactions for higher scores that might indicate a problem and positive reactions for scores that might suggest healthy consumption

levels. For example, “Sounds good” was used in response to a user mentioning that they wanted to change.

In parallel, NVBs were applied using a set of states that were determined as appropriate given the context of the interaction as shown in Figure 5: Neutral, Explaining, Asking, and Listening. In the *Neutral* state, the counselor spoke and used a smile, a gaze, facial expressions, head gestures, or eyebrow movements. In the *Explaining* state, which was activated during long periods of speaking, the two-handed flip and two-handed contrast gesture were applied. When the counselor posited a question to the user, the *Asking* state was initiated, which included a single hand formless flick. While the counselor waited for the user to respond to a question, the *Listening* mode was initiated, which included a leaning forward gesture. The leaning gesture remained in effect until a choice was made, at which point the body resumed an upright sitting position.

Figure 5. Defining nonverbal behaviors for virtual health agents. All undergo the initial sitting sequences and then assume a neural sitting at idle position. From here, the agent can enter either the be explaining, asking, or listening loop.



Participants

Participants were alcohol users aged 21 to 55 years and recruited online to participate in the intervention. Participants had to have engaged in heavy drinking (consumed 5 drinks in one sitting at least once in the past year), not currently be receiving treatment for their AUD, and not have a medical condition for which alcohol use would be contraindicated. Users were also screened for severe mental illness. We recruited 51 participants as part of a larger RCT of the effectiveness of this program in reducing

alcohol abuse. Participants were 62% (32/51) male, were 32% (19/51) female, and had a mean age of 28 (SD 15.8) years. Participants reported their race as White (21/51, 42%), Black (12/51, 24%), Asian (3/51, 7%), Other (2/51, 3%), and no response (12/51, 24%). Participants reported their ethnicity as non-Hispanic (43/51, 84%), Hispanic (8/51, 15%), and no response (2/51, 1%). Marital status was reported as married (23/51, 46%), single (17/51, 34%), divorced (3/51, 7%), widowed (1/51, 1%), or no response (6/51, 12%). Their education level was reported as high school (7/51, 14%), some college (13/51, 25%), Associate's degree (10/51, 19%), Bachelor's degree (18/51, 36%), and Graduate degree (3/51, 6%).

Procedures

Participants were recruited online via targeted advertising on Facebook, offering free treatment for alcohol users and compensation for research participation. When users clicked on the ad, they were redirected to an online screener (on Qualtrics) to ensure they were eligible for the study. If they were eligible, users were randomly assigned to receive the same DCU MI intervention delivered online either by an ECA (eEVA) or a textual interface. Participants in this study were those who were assigned to eEVA, since the control group assigned to the text-only interface could not comment on the ECA's social features that they did not see. Once randomized, participants were provided with a username and password to enter the DHI platform eEVA. Participants had to log on, enter demographic information, and begin the intervention. After completing the intervention (participants were given 1 week to complete), they were redirected to an online survey on Qualtrics to provide feedback about their experience with the intervention.

Measures

After completing the intervention, participants were asked to provide feedback on the feasibility, acceptability, and utility of the technology. Specifically, we sought feedback regarding their engagement (acceptability), perceived utility, and intent to use the technology (feasibility). Participants completed a questionnaire developed for this study. Since there does not exist, to date, a standardized instrument to evaluate interaction with ECAs of various levels of complexities, we used and adapted relevant existing questionnaires commonly used for the evaluation of human interaction with technologies involving some social cues, whether embodied with graphics or with robot technologies. Questions were based on a combination of the engagement model by O'Brien and Toms [61], Almere model by Heerink et al [62], and "Godspeed questionnaire" by Bartneck et al [63], which has been widely used to evaluate human-technology interactions using 5 key concepts — anthropomorphism, animacy, likability, perceived intelligence, and safety — that have been found useful for interacting with either ECAs or robots. All responses were on a 7-point Likert scale (1=Strongly Agree; 7=Strongly Disagree), with lower scores indicating more desirable findings. There was no cut-off as the measures were combined for the purpose of this study and were meant to provide descriptive feedback. In addition, each question included a blank space with a prompt of "Comments" for participants to provide optional qualitative feedback to each question.

The engagement model by O'Brien and Toms [61] explores acceptability of the ECA via constructs of user engagement with technology. Six attributes of a technology make it more likely that a user will engage with it (challenge using the technology, interest, motivation to use the technology, and appeal of the technology [eg, "I found the health assistant interesting"]). Responses were on a 7-point Likert scale (1=Strongly agree; 7=Strongly disagree).

The Almere model evaluates the user's acceptance of the digital health agent by relying on constructs from the Unified Theory of Acceptance and Use of Technology [12]. Users replied to 13 statements (eg, "I enjoyed participating in this session with the health assistant") that map to constructs that predict intent to use the technology and perceived usefulness of the technology. Responses were on a 7-point Likert scale (1=Strongly agree; 7=Strongly disagree).

The Godspeed questionnaire consists of 12 questions that capture 5 constructs that measure human-like traits of robots, which we adapted for ECA (eg, "The health agent seemed warm"): (1) anthropomorphism (eg, moving rigidly or moving elegantly), (2) animacy (eg, mechanical or organic), (3) likeability (eg, unfriendly or friendly), (4) perceived intelligence (eg, incompetent or competent), and (5) perceived safety (eg, anxious or calm). Each trait could be rated as being very human-like to very unhuman-like on a 7-point scale.

All questions included a fill-in option for participants to expand on their numerical responses with qualitative feedback if they wanted to. We highlight some of those comments in the Results section.

Results

Acceptability and Utility

Participants reported high acceptability and utility of the technology, as indicated by their scores on the Almere model questions (mean 2.31, SD 1.05). Most participants reported enjoying their interaction with the agent (44/51, 86%) stating "The questions she asked me, no one had asked me before and helped recognize my drinking problem." They thought the agent was both physically appealing (38/51, 74%) and had a pleasant voice (42/51, 82%), stating:

> *He is neat, he has a good haircut, he is well dressed.*
>
> *He appears wise, intelligent, and healthy.*
>
> *The voice was adequate, calm, and confident.*

Furthermore, participants indicated that they found it easy to interact with the health agent (45/51, 89%) and they learned to do so quickly (45/51, 89%), stating:

> *I just followed the instructions and voila!*
>
> *I just waited and followed his instructions; it was easy.*

Participants had more difficulty with the voice feature of the technology, with only 69% (35/51) reporting that they felt like the agent understood them when they spoke into the microphone.

Based on the qualitative feedback, this may have been due to issues with participants' microphone setting rather than the technology itself:

> *I set my microphone up, but it seems there is a problem with it.*
>
> *I tried to speak my answers, but it never worked so I ended up typing them.*

Those who were able to get their microphones to work seemed to have no difficulty speaking to the agent as echoed by their qualitative feedback (eg, "I don't even repeat my answers; the agent understands me very well."). Despite some difficulties with the microphone, 78% (40/51) felt like they could have a conversation with the agent, stating "I felt that he knows me, knows what I want" and reported that they sometimes felt like they were talking to a real person (36/51, 71%), stating that:

> *…his voice sounded quite real…*
>
> *…the gestures he made, way he moved around…*
>
> *he answered me like a real person…*

Participants further reported that the health assistant was friendly (45/51, 89%) and they found it to be useful (44/51, 88%) because:

> *…he explained things that I did not know…*
>
> *…it helped me recognize that I have a problem…*
>
> *I learned a lot.*

Participants reported that they were comfortable disclosing information about their drinking to their digital health assistant (48/51, 93%), with 83% (41/51) reporting that they were *more* comfortable disclosing their drinking to the digital health assistant over their medical doctor. Indeed, participants highlighted:

> *The assistant gives me a level of trust that I don't have with other humans.*
>
> *It is more easy talking to (the health agent) than to a real person.*
>
> *I don't feel like they are judging me.*

Finally, participants reported trusting the advice the health agent gave them (43/51, 85%) and that they planned on following that advice (44/51, 86%), stating:

> *I think she is sincere and wants to help me with my problems.*
>
> *…because it is based on facts and studies and that is real and valid information for me.*

One participant noted "I didn't feel like I was given advice, more like information to be able to make my own decision. I was the one with the power to give myself advice." — perfectly capturing the intent of MI.

Engagement

Participants were highly engaged with the DHI, as indicated by their score on the engagement questions (mean 2.86, SD –0.96), indicating that the majority of participants agreed with statements around how engaged they were. Specifically, 69% (35/51) were not worried about making mistakes while using the technology, stating:

> *At first, it was a little bit intimidating, but then I felt confident.*
>
> *The assistant feels understanding, attentive, very friendly.*

A majority (44/51, 86%) thought it was a good idea to use the health assistant, reporting:

> *He is kind of like a home counselor who works with reliable information and statistics.*
>
> *It is practical, easy to use, and guides the person on what to do without forcing us to make a final decision.*

Participants felt that the system could be adaptive to their needs (46/51, 90%), stating that "it could be adapted to other health problems like smoking."

Finally, 88% (45/51) found the health assistant to be interesting, indicating "I was impressed by the way it converts my answers into figures and important information for my health" and said they would interact with the agent again (43/51, 85%):

> *Setting a new exchange with the health assistant would help me to reach my goal.*

Impressions of the Digital Health Agent

Participants reported a high number of human-like traits on the Godspeed questions (mean 2.07, SD 0.89). Participants reported that the agent moved appropriately (43/51, 85%) and seemed warm (46/51, 90%), responsive (45/51, 89%), knowledgeable (47/51, 92%), relaxed (46/51, 90%), flexible (42/51, 83%), honest (46/51, 90%), respectful (46/51, 90%), confident (47/51, 92%), interested (44/51, 86%), open-minded or nonjudgmental (43/51, 84%), and supportive (45/51, 89%).

Overall, participants' responses to the questionnaires and qualitative feedback indicated that they found the delivery of an MI intervention by a digital health agent over the internet to be acceptable, be engaging, and have features that are close to human-like.

Discussion

Our goal with this study was to understand if the technology we developed was feasible (able to be implemented online), acceptable, useful, and easy to use by consumers. As such, we focused largely on the technology aspects of the intervention.

Principal Findings

This study provides an optimistic outlook for the use of digital health agents to deliver brief online interventions in the future. Consumers overwhelmingly reported positive experiences in their interactions with the agent, with many reporting that they trusted the agent and felt that they could more comfortably disclose information that they may not have disclosed to a human provider. This echoes what has been found in the literature around disclosing to computers versus humans [12,14,64,65].

Further, participants tended to attribute many human-like traits to their agent (eg, friendly, trustworthy, kind) and commented

positively on the physical appearance, voice, and physical gestures of the agent. Our team engaged in coding of verbal reflections, hand gestures, and facial expressions of a real therapist to enhance the digital agent's nonverbal communication to resemble what a therapist might do in session [66].

Implications for this work are important. Given the shortage of mental health workforces in many locations, digital health agents may provide an acceptable complement to traditional face-to-face therapy, reducing demand for higher levels of care, where a digital health agent can act as a clinician "extender" to deliver booster sessions. Similar to telehealth services, digital health agents resolve a number of barriers to care such as transportation and scheduling.

In addition, digital health agents reduce stigma around mental health care, are less costly than one-on-one therapy, and can be scaled out and disseminated. For individuals with high levels of social anxiety, digital health agents may provide them with a unique opportunity to get help. Given the digital nature of the agent, it is possible to adjust the programming to make the agent able to speak in multiple languages, reducing language barriers for minority and refugee populations. Already, consumers can pick a digital health agent from a library of diverse options of physical visual features (gender, age, race, and ethnicity; see Figure 2) and vocal features (gender). This is an exciting development given the lack of a diverse mental health workforce [67,68].

This study has provided the investigative team with valuable feedback to improve the technology, including improving the flow and tone of the voice, providing questions in text, and formatting the technology for use on mobile phones and with lower bandwidth.

Limitations

Despite these enthusiastic findings and implications, it is important to note a number of limitations. First, digital health agents cannot replace traditional therapy and certainly cannot manage crisis situations. They are well suited for brief, structured interventions, but cannot replace the complex nature of a therapeutic relationship and complex therapeutic interventions such as family therapy and emotion-focused therapy. They were considered and studied in this article as clinician "extenders." Second, this study was conducted with participants in the United States only. It is unclear if technology acceptability would be as high in other countries. Third, the impact of the DHI on actual alcohol outcomes remains unclear. A study is underway to better understand the effects of a digital health agent. Fourth, it is unclear whether ECAs are suitable for various health problems besides alcohol and for various other populations not studied here, such as the elderly or children. Finally, the access to and cost of reliable internet necessary to use ECAs may limit access to some — potentially further increasing the digital divide.

Conclusions

This type of intervention and research on digital health agents in virtual reality over the internet are still in their infancy, and there is much work to be done. For instance, the same BMI intervention delivered in this study could be adjusted to other health behaviors (eg, other substances, medication compliance, weight management). Other interventions could be delivered to screen or treat a variety of problems. Furthermore, our team is working on integrating natural language dialog management features such that the agent will respond to the consumer's answers without needing specific input from which to read. We conducted preliminary work [26] for a speech-enabled ECA for BMI interventions with promising results. However, natural language understanding is still a very open research area of computer science, and its use in DHIs is not robust enough to deploy with real users who need support and help, without the potential frustrations generated by unreliable agent's speech understanding. Our team has also worked on features based on AI that allow a PC-based agent (ie, operating on PC only and not web-based) to pick up on the consumer's facial expressions in real time (eg, if the consumer smiles, the agent smiles back), which has been shown to improve users' engagement with digital health agents [25], and we plan to add this type of feature to our web-based eEVA system.

Despite all these exciting potential developments, it is critical to evaluate DHIs with high levels of rigor before they can be deployed for the population at large. As pointed out by Carroll [7], very few of the many available internet-based interventions have been carefully evaluated in well-controlled clinical trials, and the majority of those studies have been conducted with college populations, bringing into questions the generalization of the results to broader society. The conclusions that can be drawn from many studies are constrained by high levels of dropout, high attrition, and weak control conditions (eg, waitlists). To that end, we will report on the results of the RCT we conducted to assess the efficacy of the eEVA DHI compared to a text-only version of the intervention.

We furthermore consider that these digital health agents and DHIs can only complement the unique experience of psychosocial therapy and serve as "clinician extenders" [7]. As suggested by Mohr et al [21], mental health technologies in general should be considered as sociotechnical systems (or technology-enabled services rather than mere products) that must fit within an ecosystem of mental health services (involving human support and organizational factors). Our aim is to provide relief to a clogged mental health system and provide online access to self-help to individuals who otherwise would not access traditional face-to-face care. Further research on whether DHIs increase access to care by removing the barriers identified earlier (eg, availability and proximity of trained providers, affordability, stigma) or whether they increase the digital divide is needed [21]. Digital health agents, even with integrated AI, will not replace human therapists; they should be considered therapist extenders.

Abstract

Background: Children with cancer experience a myriad of nutritional challenges that impact their nutrition status during treatment and into survivorship. Growing evidence suggests that weight at diagnosis impacts cancer outcomes, but provider guidance on nutrition and diet during treatment varies. Nutrition literacy and culinary resources may help mitigate some common nutritional problems; however, many patients may face barriers to accessing in-person classes. Along with dietitian-led clinical interventions, web-based resources such as the newly updated electronic cookbook (e-cookbook) created by The University of Texas MD Anderson Cancer Center, @TheTable, may facilitate access to nutrition and culinary education during treatment and into survivorship.

Objective: We sought to define and describe the features and content of the @TheTable e-cookbook and compare it with analogous resources for a lay audience of patients with childhood cancer and childhood cancer survivors as well as their families.

Methods: We evaluated freely available web-based resources via a popular online search engine (ie, Google). These searches yielded three web-based resources analogous to @TheTable: the American Institute for Cancer Research's Healthy Recipes, The Children's Hospital of San Antonio's Culinary Health Education for Families Recipe for Life, and Ann Ogden Gaffney and Fred Hutchinson Cancer Research Center's Cook for Your Life. These sites were analyzed for the following: number of recipes, search functionality, child or family focus, cancer focus, specific dietary guidance, videos or other media, and miscellaneous unique features.

Results: Cook for Your Life and Culinary Health Education for Families Recipe for Life were the most comparable to @TheTable with respect to cancer focus and family focus, respectively. Healthy Recipes is the least user-friendly, with few search options and no didactic videos.

Conclusions: The @TheTable e-cookbook is unique in its offering of child- and family-focused content centered on the cancer and survivorship experience.

KEYWORDS

pediatric oncology; web-based resources; oncology nutrition; culinary education; oncology; children; pediatric; nutrition; culinary; education

Introduction

An estimated 300,000 children aged 0-19 years are diagnosed with cancer each year in the United States [1]. Although the incidence of cancer in children and adolescents in the United States has risen slightly over the past few decades, the 5-year survival rate has improved from 58% to over 80% since the mid-1970s [2-4]. This significant improvement in survival rate has resulted in the need to mitigate long-term treatment-related sequelae in childhood cancer survivors (CCS), such as secondary cancers, obesity, and cardiovascular disease. Many of these late effects may be exacerbated by excess weight and poor diet, which highlights the importance of nutrition education across the cancer care continuum [5]. Despite these issues, adherence to dietary guidelines is low across the population, including among children without a history of cancer [6], CCS [7,8], and adult survivors of childhood cancer [9-11]. Specifically, the diet of CCS is lacking in fruits, vegetables, and calcium [11,12]. Resources that promote diet quality are scarce for patients with childhood cancer undergoing treatment and CCS as well as their families.

Evidence suggests that children with a BMI outside a healthy weight range at presentation (ie, <5th or >85th percentile [13,14]) have significantly poorer survival than those with a BMI within the healthy weight range [14-17]. Diet quality commonly worsens during treatment in pediatric patients [18] and into survivorship [8,19]; however, provider guidance on diet modification and nutrition adequacy is rarely offered and greatly varies. Recently diagnosed patients and their families have voiced the need to incorporate guidance on appropriate nutrition and lifestyle changes in cancer care [20]. Younger patients may be at particular risk of experiencing adverse effects due to a poor diet that was present and continued through treatment—as many dietary habits are established by the age of 3 years—or one that started during treatment [18,21].

While diet quality in pediatric patients and CCS warrants further research, practical and accessible dietary guidance is clearly needed for patients during treatment. Parents of CCS refer to digital nutrition- and cooking-related content to inform their food choices [22]. Digital information provided by authorized sources could support families of CCS by dispelling diet myths, curbing the spread of misinformation, and promoting nutrition literacy and culinary knowledge. Nutrition-focused web-based resources may help increase the frequency of homemade meals, a factor that has been positively associated with diet quality. Web-based resources focused on healthy eating are promising means to mitigate common treatment-related sequelae and late effects as well as barriers to accessing information on nutrition among CCS.

This paper describes nutrition-focused web-based resources targeted to patients with childhood cancer and CCS as well as their families. The University of Texas MD Anderson Cancer Center's (MDACC) electronic cookbook (e-cookbook), @TheTable, was developed in 2012 by a team of research dietitians, culinary specialists, and other staff [23]. Since its original dissemination, @TheTable has undergone significant design changes to improve its user-friendliness. The collection of recipes and nutrition-related content has grown substantially, and the educational nutrition information is now offered in three additional languages (Spanish, Mandarin Chinese, Arabic) that reflect well-represented populations within the institution. In this study, we compared the features and content of @TheTable with those of other freely available web-based resources and highlighted the unique aspects of this e-cookbook.

Methods

Search Strategy for the Identification of Web-Based Resources

We mirrored the methods typically used by patients, survivors, and families to acquire information and conducted multiple internet searches between 2019 and 2020 using combinations of keywords such as "tools," "cancer," "recipes," "healthy," and "eating." An MDACC research librarian independent of our research team additionally assisted in the search and found comparable results.

Resource Selection

Resources were included based on the following criteria: a substantial (>100 recipes) and searchable recipe catalogue, cost-free use of resource, and authorized source (ie, content generated or reviewed by a registered dietitian or affiliated with a major institution). From the web-based search, the two closest analogues to @TheTable were selected for in-depth analysis. The included sites were analyzed for the following: number of recipes, search functionality, child or family focus, cancer focus, specific dietary guidance, videos or other media, and miscellaneous unique features. To compensate for the uniqueness of the resources targeted to childhood cancer populations, the Culinary Health Education for Families (CHEF) Recipe for Life site created by The Children's Hospital of San Antonio was included as a web-based resource with a pediatric focus that the research team was familiar with.

Features and Content Extraction

Website features are shown in Table 1. Content extracted included number of recipes available on the site and ability to search by certain criteria (eg, texture, symptom, nutrition need, meal type). Filters and search functionality were included as key features of web-based resources, as these allow organization of larger libraries or nutrition content for browsing and also allow users with specific questions or needs to find information quickly, thus increasing usability.

Table 1. Key features of web-based cookbooks and resources for patients.

Site title	Author	Recipes, n	Search by symptom	Search by nutrition	Search by meal type	Child focus	Cancer focus	Diet tips/guides	Videos	Other features
@TheTable [24]	The University of Texas MD Anderson Cancer Center	>770	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Question submission
Healthy Recipes [25]	American Institute for Cancer Research	250-300	No	No	Yes	No	Yes	Yes	No	Physical activity guidelines
Culinary Health Education for Families Recipe for Life [26]	The Children's Hospital of San Antonio	>75	No	Yes	Yes	Yes	No	Some	Yes	Teaching kitchens; provider referrals to culinary programs; home activities; blog; community resources
Cook for Your Life [27]	Ann Ogden Gaffney; Fred Hutchinson Cancer Research Center	>500	No	No	Yes	No	Yes	Yes	Yes	Culturally adapted menus; menu collections

The presence or absence of child or family focus was also noted. A "kid-friendly" website was one that had a sensory approach to food (eg, inclusion of color, shape, texture) to facilitate accommodating child-specific preferences and aversions (related or unrelated to treatment); focused on child-specific nutritional needs related or unrelated to the cancer experience; and acknowledged the role and journey of the caretaker or parent in treatment and survivorship. Cancer focus was gauged according to whether recipes could accommodate treatment-related adverse effects; the presence or absence of symptom- or treatment-specific content or search functions largely defined this category. The availability of nutrition tips or guidelines, the presence of freely available didactic videos, and miscellaneous features unique to the web-based resource (ie, overlapping in-person classes, home activities, blogs or newsletters, cultural inclusivity) were assessed.

Results

Included Web-Based Resources

To better examine the MDACC @TheTable e-cookbook, selected web-based resources were analyzed. We identified the following: Healthy Recipes from the American Institute for Cancer Research; CHEF Recipe for Life from the Children's Hospital of San Antonio; and Cook for Your Life, created by Ann Ogden Gaffney and owned by the Fred Hutchinson Cancer Research Center.

@TheTable Resource

@TheTable is a web-based resource that may be accessed without cost or subscription. It includes over 770 recipes that are searchable by symptom, nutritional need, texture, and flavor, in addition to standard cookbook features (Table 1). Nutrition-related filters allow selection of nutritious recipes specific to certain diets such as vegan, vegetarian, and low-sodium diets (Figure 1). Figure 1A shows a screenshot of the landing page for the @TheTable e-cookbook. From this page, site visitors can access a myriad of freely available resources specifically designed for patients with cancer. The family focus of the e-cookbook aims at bolstering the nutritional habits of family units. The salient features of the e-cookbook are recipes searchable by symptom, meal type, texture, and color, as well as nutrition tip sheets and didactic videos. Most recipes are in English, and some are in Spanish. Figure 1B shows nutrition tip sheets available in this e-cookbook. Freely available tip sheets on @TheTable can additionally be accessed in Spanish, Mandarin Chinese, and Arabic. This augments accessibility, especially for bilingual households or those living outside the United States. Tip sheets cover topics such as the nutritional needs of growing girls and boys undergoing treatment for cancer, the management of symptoms such as constipation, and practical tips for the grocery store. Figure 1C shows the @TheTable nutrition guide for pediatric patients with leukemia. The nutrition booklet follows the pedagogy of MyPlate, the nutrition guide likely used by families in public schools in the United States, and builds on that knowledge. It aims to establish a common language to enhance future interactions with clinicians and dietitians caring for pediatric patients with cancer. This booklet centered around the five food groups is also available in Mandarin Chinese, Arabic, and Spanish. Symptom-related filters show recipes that accommodate common treatment-related adverse effects such as diarrhea, nausea, dysgeusia, and constipation (Figure 2). Site visitors can also use the color filter to search by phytonutrient (eg, blue/purple filter for anthocyanin-rich foods). These specific filters were designed to complement a trifold brochure distributed at weekly in-person MDACC culinary classes. The texture filter allows the user to find comfort measures for symptoms such as mouth sores or mucositis (eg, soft or smooth/creamy) or select sensory aspects (eg, crunchy, dry, chewy). Videos on @TheTable show prerecorded recipes filmed in an onsite research kitchen. These 19 instructional videos feature pediatric patients, chefs or culinary experts, and research dietitians. An additional feature of @TheTable is the nutritional guidance on various topics delivered via tip sheets and booklets (N=26; Figure 2). As Table 2 illustrates, these are also available

in Spanish (19/26, 73%), Mandarin Chinese (18/26, 69%), and Arabic (18/26, 69%) to increase usability.

Figure 1. Representative images of @TheTable features for patients with cancer and survivors.

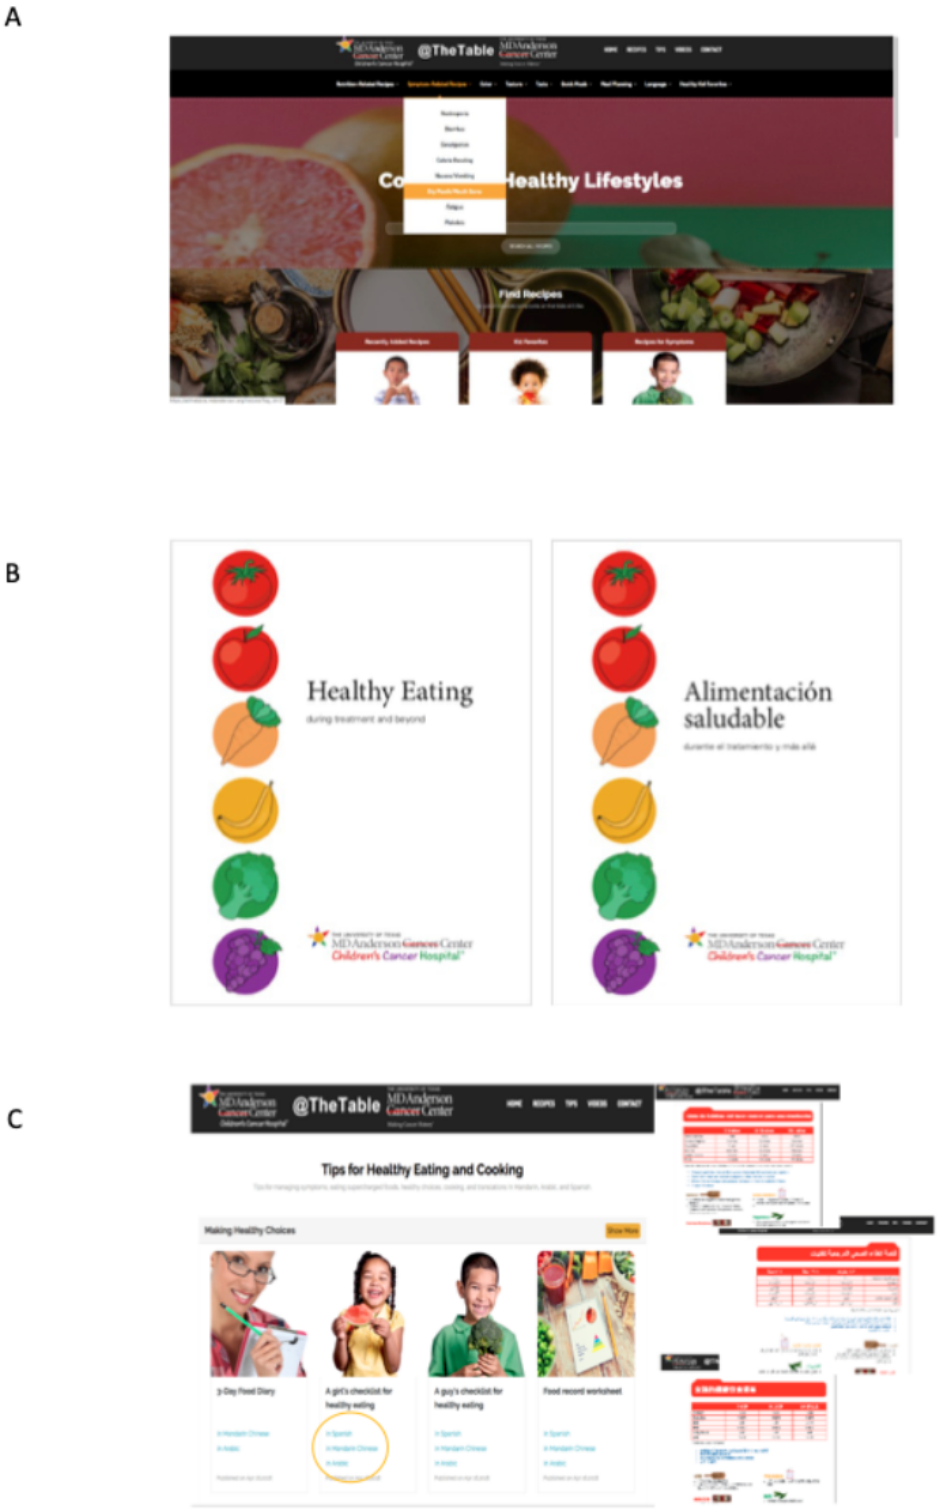

Figure 2. Schematic of additional @TheTable features highlighting its specialty focus and nutritional education, culinary, and multilingual content.

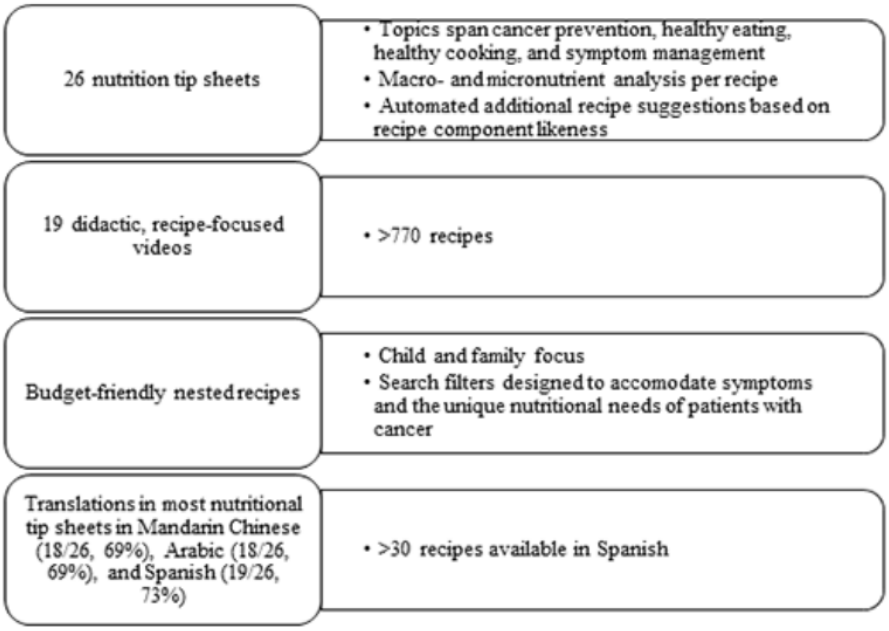

Table 2. Breakdown of nutrition education tip sheets available on @TheTable by broad topic.

Health topic	Example(s) of content	Tip sheet quantity	Available translations		
			Spanish	Mandarin Chinese	Arabic
Cancer prevention	• Add color to your diet! • Fallin' for pumpkin	4	3	3	3
Healthy eating	• Healthy eating during treatment and beyond booklet • What do I eat? • A girl's checklist for healthy eating	10	5	5	5
Healthy cooking	• Meal ideas • Prepping vegetables • Stock your spice cabinet	10	9	8	8
Symptom management	• Fiber and constipation	2	2	2	2

Healthy Recipes Resource

The Healthy Recipes site segments its content into the following two portals that branch off into more focused evidence-based guidelines: cancer prevention and cancer survival. Its recipe search tool is limited to ingredients or meal types; in this way, it does not explicitly focus on the cancer experience. Unlike @TheTable, this web-based resource does not have a child or family focus. Its nutrition-related content is centered around the New American Plate, a broadly used dietary model formulated under the guidance of the American Institute for Cancer Research's *Third Expert Report*, which translates cancer-specific, evidence-based nutrition recommendations into practical visual aids for the patient or consumer.

CHEF Recipe for Life Resource

All content on CHEF Recipe for Life is available in either English or Spanish. Recipes can be searched by difficulty level (ie, beginner, intermediate, advanced), meal type, and special diets (eg, dairy-free, low-fat, nut-free). Moreover, its didactic videos offer either recipe instructions or culinary skill tutorials. Users can sign up for newsletters, submit a form to ask a dietitian a specific question that is subsequently addressed in a site blog, or access a provider referral form to enroll in onsite evidence-based classes in the San Antonio area. However, the site focuses on management and prevention of chronic diseases, including type II diabetes and obesity. Its content is thus not cancer-specific, though this site had the strongest community focus of the included sites.

Cook for Your Life Resource

The web-based resource Cook for Your Life has a substantial recipe collection (>500 recipes) that can be searched by meal type, food preferences, or health considerations. Further, a "menus and collections" feature clusters recipes around commonalities such as "Vegan Kitchen Basics" and "Eat What You Can to Feel Better." This website stands out for its substantial video collection, which includes skill-building,

culinary technique, and recipe demonstrations. Its blog component delivers educational content related to specific food items or ingredients (eg, farro, avocado, curry powder) as well as nutrition guidelines (eg, adequate hydration, survivorship).

Comparison of Included Sources

All of the discussed web-based resources encourage plant-forward eating. Only @TheTable and Cook for Your Life include the option to filter recipes according to treatment-related symptoms. Like CHEF Recipe for Life, Cook for Your Life has all its content in either English or Spanish, whereas @TheTable has only selected content in other languages. Cook for Your Life and @TheTable both focus on cancer, though Cook for Your Life content is not based on the family or pediatric patient. CHEF Recipe for Life and @TheTable stand out among the included web-based resources for their focus on the family and pediatric patient. Notably, family-centered approaches to prevent obesity have proven to be most effective in pediatric nutritional interventions [28,29]. While @TheTable has cancer-specific content, CHEF Recipe for Life centers on chronic disease prevention and management. Further, the Healthy Kid Favorites search filter found in @TheTable, for instance, allows the user to search for recipes commonly enjoyed by children (eg, macaroni and cheese, pizza, nachos), which are altered to some extent to augment the nutritional profile. For example, the "Chicken Rainbow Nachos" recipe has fiber-packed vegetables with protein-rich chicken and black beans as nutritionally dense additions to the traditional ingredients. Moreover, the recipe is designed as part of a set of "nested recipes," which begin with a foundational "parent" recipe (eg, Tomato Poached Chicken Filling) that is used to create "child" recipes (eg, Chicken Rainbow Nachos). This approach stems from a community-based intervention with low-income Hispanic families. It allows for economizing and adds variety in home-prepared meals, though it may increase time spent in the kitchen. In addition, @TheTable has over 30 of approximately 770 recipes (~3.8% of the recipe collection) in Spanish, which allows broader user reach.

An additional aspect unique to @TheTable is the ability to search for recipes according to a color associated with a corresponding phytonutrient. This feature can be used independently, though it is meant to complement a physical trifold brochure given to patients and families at MDACC nutrition-focused events such as the onsite weekly cooking classes held in the inpatient unit at the Ronald McDonald House Kitchen. Users can search for orange or red foods, for example, which they learn are rich in carotenoids by reading the brochure. This offers the dual benefit of considering child food preferences as children may be particular about the color of a food or dish. Recipes from this e-cookbook are routinely used in MDACC onsite cooking classes delivered to patients with childhood cancer and CCS as well as their families [30,31].

Discussion

This paper describes the unique features of the redesigned @TheTable e-cookbook. We compared it to three analogous websites and found that it is unique in its focus on cancer in the pediatric context, as well as search functionality and recipe collection. Further, we found that Cook for Your Life and CHEF Recipe for Life are most similar to @TheTable with respect to cancer and family focus, respectively. Healthy Recipes is the least user-friendly because it has fewer search options than the other websites and no didactic videos.

Web-based resources with a nutrition focus are particularly relevant to pediatric oncology because of the poor diet quality commonly observed in both patients [32-36] and survivors [8,37]. Specialized nutrition resources addressing common treatment-related problems and late effects may help promote healthy eating patterns and improve patient and survivor outcomes [8,15,35,37-39]. While @TheTable and other web-based resources may play an important role in augmenting nutrition literacy and nutrition education in patients with cancer and survivors and their families, these do not supplant dietitian-led nutrition care. These resources are mainly descriptive, which limits conclusions regarding how these resources may be most effectively integrated into patient care.

Web-based resources, such as @TheTable, have the potential for broad utilization in both digital and in-person interventions. For example, @TheTable has been used across diverse settings such as in-person cooking classes at summer camps for CCS, the pediatric inpatient unit, childhood cancer awareness events, and several cooking- and nutrition-focused studies [22,30,31,40]. However, patients and families could face barriers to participating in in-person interventions. Beaulieu-Gagnon et al [41] identified common barriers faced by patients with childhood cancer in attending face-to-face nutrition classes. Notably, low attendance (17 participants over 1 year) resulted in the cancelation of 71% of their healthy cooking courses. Similarly, low attendance is a problem at the in-person weekly cooking classes in the pediatric inpatient unit at MDACC; plans to attend are disrupted for even the most engaged and interested dyads because of unforeseen medical appointments or because the child feels unwell.

A disproportionately higher incidence of treatment-related problems is seen in CCS with low-income or multiracial background [42]. Unfortunately, the need for culturally adapted nutrition- and diet-focused content remains largely unaddressed. Although it is merely a start, @TheTable has most of its educational nutrition content translated into three languages (ie, Spanish, Mandarin Chinese, Arabic), which helps broaden access to this information. Cultural adaptation is imperative for meeting the unique needs of culturally diverse demographic groups. Some innovative digital resources tackle the widespread issue of limited patient access to registered dietitian services [43]. Ina, developed by Savor Health, is a virtual dietitian directed by user input and artificial intelligence. This chat bot provides expert on-demand dietary counseling and recipes via SMS text messaging after patient data is provided. The tools described above highlight ways in which digital applications can potentially enhance patient and survivor care and in turn improve outcomes. Further research is needed to understand the impact of these novel technologies and digital resources.

Acknowledgments

Abstract

Early decisions relating to the implementation of virtual care relied on necessity and clinical judgement, but there is a growing need for the generation of evidence to inform policy and practice designs. The need for stronger partnerships between researchers and decision-makers is well recognized, but how these partnerships can be structured and how research can be embedded alongside existing virtual care initiatives remain unclear. We present a series of case studies that illustrate how embedded research can inform policy decisions related to the implementation of virtual care, where decisions are either to (1) discontinue (red light), (2) redesign (yellow light), or (3) scale up existing initiatives (green light). Data were collected through document review and informal interviews with key study personnel. Case 1 involved an evaluation of a mobile diabetes platform that demonstrated a mismatch between the setting and the technology (decision outcome: discontinue). Case 2 involved an evaluation of a mental health support platform that suggested evidence-based modifications to the delivery model (decision outcome: redesign). Case 3 involved an evaluation of video visits that generated evidence to inform the ideal model of implementation at scale (decision outcome: scale up). In this paper, we highlight the characteristics of the partnership and the process that enabled success and use the cases to illustrate how these characteristics were operationalized. Structured communication included monthly check-ins and iterative report development. We also outline key characteristics of the partnership (ie, trust and shared purpose) and the process (ie, timeliness, tailored reporting, and adaptability) that drove the uptake of evidence in decision-making. Across each case, the evaluation was designed to address policy questions articulated by our partners. Furthermore, structured communication provided opportunities for knowledge mobilization. Structured communication was operationalized through monthly meetings as well as the delivery of interim and final reports. These case studies demonstrate the importance of partnering with health system decision-makers to generate and mobilize scientific evidence. Embedded research partnerships founded on a shared purpose of system service provided an effective strategy to bridge the oft-cited gap between science and policy. Structured communication provided a mechanism for collaborative problem-solving and real-time feedback, and it helped contextualize emerging insights.

Background

Technologies that enable virtual care are a central focus of health care transformation efforts worldwide [1-4], yet their uptake in practice fell considerably short of their potential prior to the COVID-19 pandemic [5-8]. The necessary reorganization of care in response to the pandemic has introduced a plethora of large-scale virtual initiatives [9,10], overcoming many of the oft-cited policy barriers to introduction [11,12]. Nevertheless, the production of scientific knowledge lags behind the proliferation of virtual solutions and focuses largely on efficacy [13-15] and experience [16-18]. Such evidence is critical but does not provide actionable insight into how to best operationalize virtual care, including patients and situations for which it is most appropriate. As a result, system administrators and policy makers are left to make decisions based on incomplete evidence and anecdotal experience.

The COVID-19 pandemic has highlighted the challenges of making decisions in the absence of evidence [19], driven largely by the speed and severity of its spread [20]. Although early decisions during the pandemic relied on necessity and clinical judgement, there is a growing recognition of the need to apply scientific principles with greater vigilance and flexibility than we have traditionally applied [20]. Simply put, we need to generate contextually relevant scientific research informed by policy needs and timelines to support decision-making. There is an increasing understanding of the underlying social and relational processes that drive the use of evidence [21], underscoring the need to evolve beyond the traditional model of *knowledge translation* to focus on *knowledge mobilization*. In this sense, knowledge mobilization refers to the "the reciprocal and complementary flow and uptake of research between researchers, knowledge brokers and knowledge users" [22]. The key distinction is that the presence or production of knowledge alone is insufficient to drive change. Instead, personal contact and interaction between knowledge producers (ie, researchers) and knowledge users (ie, decision-makers) are required to ensure evidence-based transformation [23].

The need for stronger partnerships between researchers and decision-makers is well recognized [24]; however, we were unable to find examples of successful partnerships relating to virtual care in the literature. This paper outlines three novel case examples from an embedded research partnership that adopted the model of *engaged scholarship*—a demand-driven approach that seeks partnership with health system decision-makers by focusing specifically on their needs and the context for decision-making [25]. In a demand-driven approach, key political actors ask for evidence to be made available and are, in turn, receptive to the findings [26]. We present these three cases to illustrate how the core components of such engaged scholarship (ie, prioritizing the needs of decision-makers and responsiveness to decision-maker context) were operationalized in order to embed evaluation alongside system initiatives in order to understand whether or not their aims are being achieved. We describe several underlying characteristics that enabled success to support the tactical realization of engaged scholarship and its replication; we also identify directions to build on these characteristics in the future. Although understanding how and why policy decisions are made is beyond the scope of this paper, we highlight how and why the evaluations were constructed in a way to support this decision-making process.

Operationalizing a Model of Engaged Scholarship in Virtual Care

Barrett et al [27] suggest that acquiring relevant knowledge and skills to produce effective research for decision-making involves researchers spending time in a decision-making environment. Our model of partnership approximates this and builds on recommended knowledge mobilization principles of cross-sector and interagency learning [21] by creating an organizational partnership founded on a mutual interest of driving digital transformation within the health system. It represents a "collaborative form of inquiry in which academics and [clinicians] leverage their different perspectives and competencies to coproduce knowledge about a complex problem" [28].

In 2016, the Women's College Hospital Institute for Health System Solutions and Virtual Care (WIHV) partnered with the Ontario Telemedicine Network (OTN)—a nonprofit, government-funded organization and the largest provider of publicly funded telemedicine services in the province of Ontario, Canada. This partnership was initially founded as a product of funding stipulations set by Canada Health Infoway (CHI) that required an independent evaluation alongside a series of virtual care initiatives implemented by the OTN and funded by the CHI. Although the CHI had a direct relationship with the OTN, they were not involved in, nor did they influence the evaluation. These initial evaluations (including cases 1 and 2 described below) created a platform to invest the necessary time, effort, and resources in developing the partnership and establishing a proof of concept that would serve as a foundation for subsequent evaluations (eg, case 3, among others).

The series of case studies described below represent various system-level initiatives independently led by the OTN, who was responsible for selecting and implementing virtual care technologies through the funding received from the CHI. As policy decisions often relate to the question of whether the system should (1) discontinue (red light), (2) redesign (yellow light), or (3) scale up (green light) a given program, we have selected case studies that are illustrative of how evaluation can support each of these situations. Each case involves the evaluation of a patient-facing technology aiming to enable some aspect of health care delivery (eg, interactions with health care providers, remote monitoring, and self-management).

The OTN's overarching interest in each evaluation was to understand the impact of the technology in question. With this in mind, a team of individuals from each organization engaged in early discussions to clarify specific research questions, methods, and the conditions required for successful execution of the project (eg, access to third-party data from a project partner). The WIHV then prepared evaluation proposals for review and approval by the OTN and identified the interdisciplinary expertise required to execute the evaluation (ie, researchers with expertise in quasi-experimental methods;

researchers with expertise in applied qualitative methods; clinician scientists with relevant content expertise; and advisors with expertise in health system governance, regulation, and policy). Following approval from the OTN, the evaluations were conducted independently by the WIHV according to timelines set by the OTN. For each project, interim and final reports were provided to partners to inform decision-making (see Table 1 for project timelines). Initial versions of the reports were submitted to partners for their comments and consideration. The report was then sent back to our team for revisions, including addressing outstanding questions (where possible within the limits of the data), and to provide clarifications where the report was unclear, or the tacit knowledge of the research team was not made explicit. Since this process could continue ad infinitum, the partnership included an agreed upon limit of two rounds of revisions for all project reports. Monthly check-ins also provided an opportunity for emerging findings to inform ongoing planning and decision-making frequently, and in real time.

Table 1. Project timelines.

	Project launch	Interim report	Final report	Total duration
Case 1	July 2016	August 2017	January 2018	18 months
Case 2	July 2016	August 2017	January 2018	18 months
Case 3	September 2017	April 2018	April 2019	19 months

Case 1: A Mobile Self-management Platform for Type 2 Diabetes (Red Light)

The OTN piloted WellDoc BlueStar as an adjunct to the standard diabetes self-management education provided through provincial diabetes education centers [29,30]. BlueStar provides a web-based mobile coaching app for patients with type 2 diabetes mellitus, with tailored messaging based on user-inputted clinical data and the option to share data with patients' health care providers (eg, physicians, nurses).

The WIHV independently conducted a multicenter, pragmatic, randomized, wait-list controlled trial with blinded outcome assessment, inclusive of a qualitative realist evaluation [29]. This study design was selected to ensure we could answer the OTN's key question, "What is the impact of this technology?" while also accounting for the evaluation team's question of *whether* the technology had an impact compared to usual care and, if so, *who* it appeared to have an impact for. Results showed no difference in blood glucose levels, self-care behaviors, general health status, and self-reported health care utilization between the control and intervention groups [31]. Usage of the mobile app varied considerably by site, suggesting that contextual factors play a central role in achieving impact [31]. A secondary analysis of trial data revealed a potential dose-response relationship. The embedded realist evaluation indicated that patient characteristics were associated with positive outcomes, suggesting that individuals with moderate self-efficacy, no competing priorities, evidence of previous behavior change, and beliefs about the value of technology to support health may be more likely to engage and realize benefits [32].

Findings from this evaluation underscored the importance of implementing the technology for the right patients in the right settings. These insights were first brought to the attention of the OTN in a preliminary report, whereby timely delivery of trusted information enabled internal conversations about future directions. The OTN decided to revisit the clinical model for supporting type 2 diabetes mellitus and, therefore, did not proceed with procurement. Success in this partnership was realized by the informed decision to avoid a significant investment, thereby conserving financial resources for investment in areas with the promise of higher return.

Case 2: A Web-Based Self-management Platform for Mental Health (Yellow Light)

To enhance mental health capacity in Ontario, the OTN piloted the Big White Wall (BWW, now known TogetherAll [33]) as a virtual strategy to support the self-management of mental health for individuals requiring specialized mental health care [34,35]. At the time of the study, the BWW was a subscription-based web intervention that offered users anonymous access to peer support and self-directed learning courses [36,37].

The WIHV independently conducted a multicenter, parallel-arm, pragmatic randomized controlled trial evaluating the effectiveness of the BWW pilot implementation within the Ontario context [34,35,38]. This study design was selected to ensure we could answer the OTN's key question "What is the impact of this technology?" while also accounting for the evaluation team's question of *whether* the technology had an impact compared to usual care and *how much* engagement was required to achieve impact. Participants were recruited from outpatient mental health and addictions programs at three hospital sites in Ontario, and they were randomized to receive immediate or delayed access to BWW for a 3-month period (ie, the primary trial) [34,35]. Those who received immediate access and expressed a desire to continue use were randomized to an additional 3-month extension of use of the BWW, for a total use of 6 months, reflecting the default licensing model offered by the company or a control group comprising those who discontinued use during the extension trial [38].

Small but statistically significant benefits in mental health recovery, anxiety, and depression symptoms were observed among participants who received immediate access [34]. Engagement was variable, with approximately 80% of total logins being accounted for by 20% of all participants. A secondary analysis suggested a dose-response relationship; however, most participants did not engage in the platform in an

ongoing way [34]. This suggested differences in how this intervention might be utilized by participants outside of the trial, and how such use might eventually benefit them. This trend was further evaluated through the extension trial, with 51% (119/233) of the participants from the primary trial indicating an interest in extending their access to the BWW [38]. These participants had significantly higher anxiety levels at baseline, providing evidence of the clinical characteristics of patients who are more likely to derive benefit. Of those who received extended access, only 38% (21/55) engaged during the 3-month extension period, with no significant changes observed [38]. Findings from this study directly informed procurement conversations and policy decisions. Despite the company's default subscription model of 6 months, evaluation findings suggested that patient benefit plateaued at 3 months. Furthermore, most participants who were given access logged on only once or not at all, suggesting that a shared risk model whereby payment is triggered after a second login would be more cost-effective. This credible evidence provided decision-makers with the insights and confidence needed to modify their procurement approach, under the conditions outlined above. The nature of the partnership ensured that findings were delivered in a timely manner, with preliminary findings presented at monthly meetings as they emerged, and a final report delivered as the pilot wrapped up. These characteristics of the partnership allowed the OTN to consider emerging evidence as part of their strategic planning, leading to a province-wide roll-out of the BWW in October 2018 [39].

Case 3: A Platform to Support Video Visits and Asynchronous Messaging in Primary Care (Green Light)

The Enhanced Access to Primary Care (EAPC) proof-of-concept pilot was conducted by the OTN across five primary care sites in the province of Ontario as a model to improve primary care access. It introduced two technology platforms through which virtual visits could be delivered, and a renumeration structure through which primary care providers could be reimbursed.

An embedded cohort study using a mixed methods approach was utilized, including patient and provider interviews, patient and provider surveys, as well as data on technology use from the vendor. This study design was selected to ensure we could support the OTN in understanding "How do we scale this model," while also accounting for the evaluation team's question of *which* components of the model should be scaled (and which should not) and *why*. Findings indicated interest from patients [40,41] and providers [42] in conducting primary care visits through virtual modalities, with secure messaging being utilized for 94% of visits [41]. Providers were generally satisfied with the renumeration structure, although it was unclear whether they knew that it was slightly less than the remuneration offered for in-person visits. Lastly, about 81% of all virtual visits were delivered asynchronously, and they did not require additional follow-ups, suggesting that virtual visits could substitute for in-person primary care visits [41] and that they did not seem to create additional work.

Findings from this evaluation demonstrated the value of virtual care, and secure messaging in particular, in improving access to primary care and the patient experience. Of particular interest to our policy partners was the tailored messaging that helped answer the questions "Does this create additional work?" and "What is the appropriate compensate model?" Our findings highlighted the level of acceptance among providers relating to both the workload and pilot renumeration structure. Based on these findings, a province-wide expansion of EAPC is underway [43], and the Ontario Ministry of Health and Long-Term Care has committed CA $3 million (US $ 2.4 million) in new funding to compensate physicians for these visits [44].

Discussion

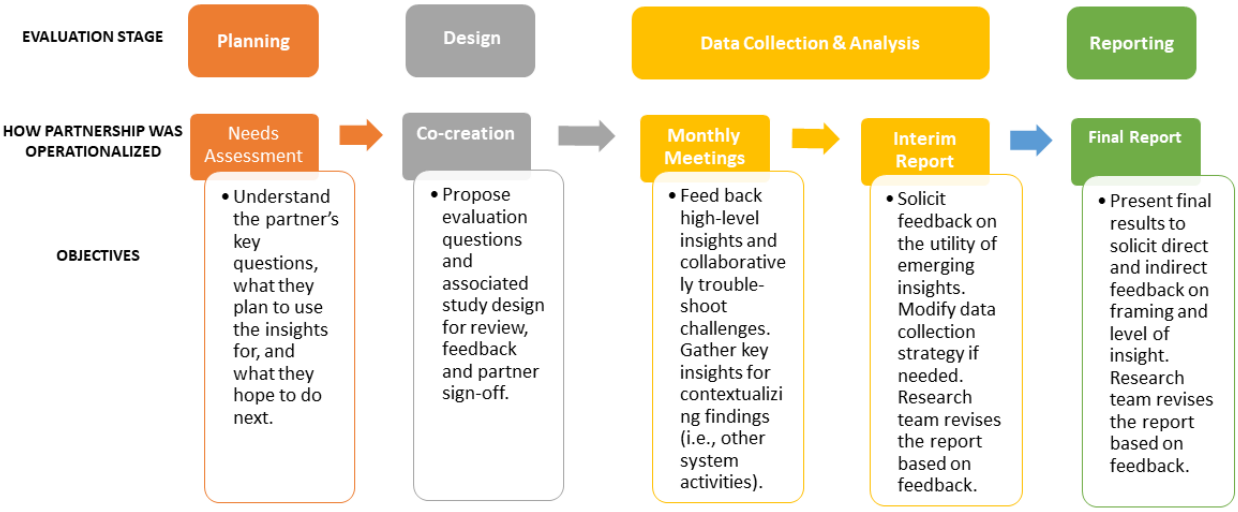
Prior work has characterized the involvement of decision-makers according to different stages of the research process [45], but explicit identification of the relationship-based and practical factors that underpin successful partnerships [46] and how they are realized is poorly described. Furthermore, researchers often cite challenges understanding project context, whereas stakeholders are concerned that results will be delivered well after the agreed deadline [46]. We build upon previous work by identifying the explicit mechanisms through which this partnership avoided the common pitfalls whereby stakeholders do not receive the information or evidence they require [46]. Recognizing that ongoing engagement is key [46], we have explicitly outlined the characteristics of the partnership (Figure 1) and how and why these characteristics were operationalized. This embedded research partnership provides a model to appropriately scale up virtual care initiatives [7] by establishing effective partnerships between policy makers and researchers and enhancing the accessibility of evidence.

Figure 1. Characteristics of embedded scholarship.

The success of this partnership was driven by its underlying characteristics (*the why*) as well as the characteristics of the process (*the how*; see Figure 1). This partnership is founded on a *shared purpose*, which in this instance meant the partnership existed to advance the interests of the health care system and the public it serves. This shared purpose was a function of the OTN's accountabilities to both the funder and the system and the research team's interest in using their expertise for applied impact. Stemming from this, scientific activities were therefore undertaken with the primary goal of providing applied, objective evidence for the health system decision-maker. Although scientific rigor is central to the core values [47], short timelines, limited funding, and the need for local relevance may trump methodological concerns. In this way, this partnership model builds on the existing knowledge base by blending aspects of integrated knowledge translation (ie, an explicit focus on increasing knowledge use and impact) [48] with engaged scholarship (ie, the research process gathers the perspectives of key stakeholders) [25]. Further, this work explicitly describes the tactical elements of the partnership that enabled the core components of engaged scholarship. Built on a fundamentally interdisciplinary approach [47], health system partners are systematically engaged in the discovery, development, and mobilization of scientific knowledge generated through this model [49,50]. In this regard, the process is adaptable but generally aligned with the knowledge-to-action process [51], whereby the tactical elements (ie, regular check-ins with partners) provide an opportunity to solicit feedback with regard to the knowledge inquiry, synthesis, and eventual products, providing a mechanism to inform adaptations to the evaluation to ensure it meets the policy needs. It is important to note that adaptations are made in a way that does not threaten scientific integrity. For example, in case 1, the initial focus of the evaluation was to understand the impact of the technology. While discussing preliminary results, it became clear that the current clinical model was suboptimal, and the evaluation needed to shift to identify the circumstances under which the technology might work and for which types of patients.

Our experience highlights that it is not just the above fundamental characteristics that will ensure success, but how these characteristics were operationalized that will support replication and scale of this model (Figure 2). First, the partnership is driven by *trust* and a *shared purpose*. Trust is established on the strength of the scientific methods, the credibility of the team, and the commitment to delivering insights that meet the needs of decision-makers, and over time, the degree to which the partnership produces such insights. The partnership terms required that evaluation activities be independently conducted to maintain integrity, credibility, and objectivity. This builds trust by ensuring that the resulting evidence is unbiased, rigorous, and respectful of patient, provider, and policy perspectives. Establishing shared purpose requires effective communication and a commitment on behalf of the researchers to describe findings in the context of immediate key challenges faced by system partners [27]. These characteristics inform the processes underlying the partnership, including *timeliness*, *tailored reporting*, and *adaptability*. Across our cases, these characteristics were embodied through an iterative knowledge mobilization strategy. Structured communication activities operationalized timeliness and adaptability in a deliberate attempt to avoid the production of findings that are not available when decisions need to be made or are not aligned to the practical requirements of policy [52,53]. Similarly, providing these empirical insights to decision-makers allowed them to reflect on their assumptions (ie, there is a fit between the problem and the technology) and pivot their questions accordingly to fill gaps in their understanding. Operationalizing the characteristics of trust, shared purpose, timeliness, tailored reporting, and adaptability were central in demonstrating value, maintaining relevance, and achieving mutual benefit [47].

Figure 2. How and why characteristics of the partnership were operationalized.



Embedded research provides the opportunity for the observation and identification of the processes playing a role in the adoption of technology and/or the (in)ability to achieve successful implementation. For example, the findings from the EAPC study [41] not only informed policy but also provided key insights relevant to the provincial response to the COVID-19 pandemic and facilitated the ability to recommend billing for virtual care quickly and confidently, given the evidence on file. Thus, the embedded partnership provides a mechanism to facilitate evidence translation [54] that occurs at the intersection of the knowledge-to-action process (or the transition from the inner to the outer circle) through the production of evidence that is immediately relevant to health system operations. In parallel, the partnership helps stakeholders build credibility and profile through their contribution to evidence generation and operational proof-of-concept [55].

Although this paper demonstrates the value of embedded research alongside policy initiatives and how it can be structured to address policy questions, it was beyond the scope of this work to evaluate the process through which the resulting evidence informed decision-making. Insights into this process would support the design of policy-oriented research as well as provide illustrative examples to decision-makers on how to embed evidence into decision-making. In addition, although these evaluations supported the uptake of evidence-based solutions at scale, no further evaluations were conducted. A longitudinal evaluation of the trajectory of implementation and impact would provide useful insight into the long-term value of this model and the sustainability of its impact.

Conclusions

Involving decision-makers in the formulation of proposals [56] and engaging them throughout the conduct of research [57] increases the likelihood that the resulting evidence will be used. Engaging them throughout the research process also increases the likelihood that resulting evidence is implemented in a sustainable way that can be valuable to policy. Embedded research partnerships founded on a shared purpose of system service provided an effective strategy to bridge the oft-cited gap between science and policy [58-60]. Trust, timeliness, tailored reporting, and adaptability were found to be key characteristics contributing to success that can be operationalized through co-creating evaluation questions, monthly check-ins, and iterative report development when scaling this model to new environments.

Acknowledgments

We would like to thank the Ontario Telemedicine Network for their commitment to embedded evaluation and their investment in a productive partnership. The case studies referred to in this manuscript were funded by Canada Health Infoway through investment projects with the Ontario Telemedicine Network. The publication costs for this article have been covered by Canada Health Infoway Inc., a non-profit corporation funded by the Government of Canada. The funders had no role in study design, data collection, and analysis, or decision to publish the manuscript.

Authors' Contributions

LD, VS, OB, JS, and RSB participated in the original studies. LD, OB, and RSB conceived the current manuscript. SB summarized the case studies. All authors helped interpret the data. LD drafted the manuscript, and all authors critically reviewed it. All authors read and approved the final manuscript

Conflicts of Interest

None declared.

Abstract

Background: Despite the fact that the adoption rate of electronic health records has increased dramatically among high-income nations, it is still difficult to properly disseminate personal health records. Token economy, through blockchain smart contracts, can better distribute personal health records by providing incentives to patients. However, there have been very few studies regarding the particular factors that should be considered when designing incentive mechanisms in blockchain.

Objective: The aim of this paper is to provide 2 new mathematical models of token economy in real-world scenarios on health care blockchain platforms.

Methods: First, roles were set for the health care blockchain platform and its token flow. Second, 2 scenarios were introduced: collecting life-log data for an incentive program at a life insurance company to motivate customers to exercise more and recruiting participants for clinical trials of anticancer drugs. In our 2 scenarios, we assumed that there were 3 stakeholders: participants, data recipients (companies), and data providers (health care organizations). We also assumed that the incentives are initially paid out to participants by data recipients, who are focused on minimizing economic and time costs by adapting mechanism design. This concept can be seen as a part of game theory, since the willingness-to-pay of data recipients is important in maintaining the blockchain token economy. In both scenarios, the recruiting company can change the expected recruitment time and number of participants. Suppose a company considers the recruitment time to be more important than the number of participants and rewards. In that case, the company can increase the time weight and adjust cost. When the reward parameter is fixed, the corresponding expected recruitment time can be obtained. Among the reward and time pairs, the pair that minimizes the company's cost was chosen. Finally, the optimized results were compared with the simulations and analyzed accordingly.

Results: To minimize the company's costs, reward–time pairs were first collected. It was observed that the expected recruitment time decreased as rewards grew, while the rewards decreased as time cost grew. Therefore, the cost was represented by a convex curve, which made it possible to obtain a minimum—an optimal point—for both scenarios. Through sensitivity analysis, we observed that, as the time weight increased, the optimized reward increased, while the optimized time decreased. Moreover, as the number of participants increased, the optimization reward and time also increased.

Conclusions: In this study, we were able to model the incentive mechanism of blockchain based on a mechanism design that recruits participants through a health care blockchain platform. This study presents a basic approach to incentive modeling in personal health records, demonstrating how health care organizations and funding companies can motivate one another to join the platform.

Introduction

Precision medicine aims to define diseases at a higher resolution using genomic data, electronic health records, and life-log data by providing new therapies to each targeted subgroup [1,2]. Electronic health records and life-log data from personal health records are crucial to capture phenotypic information in hospitals and in everyday life in order to deliver precision medicine to health care consumers. This is one of the major reasons why even high-income nations have been struggling over the past couple decades to properly disseminate electronic health records. For instance, the United States implemented the Health Information Technology for Economic and Clinical Health Act in 2009 to provide electronic health records throughout the country [3]. By 2017, 96% of general medical and surgical hospitals, 87% of children's hospitals, and 59% of acute long-term care hospitals in the United States had adopted certified electronic health records [4,5]. South Korea has also tried to disseminate electronic health records since early 2000. The Health Insurance Review and Assessment Service announced that 93.6% of hospitals and 91.6% of private clinics in South Korea utilized electronic health records as of 2017 [6]. Even though the adoption rate of electronic health records has increased dramatically throughout many countries, they are still struggling to find solutions to properly disseminating personal health records. Compared to the implementation and use of electronic health records in health care organizations, the implementation of personal health records, for the collection of life-log data through patient participation, still lags due to challenges related to security, privacy, interoperability, and data quality [7-9]. The implementation of personal health records faces other issues as well, including a lack of auditability, legal risk, health care policies, and data accuracy.

As such, health care blockchain has been implemented to solve these various problems. Blockchain is known as a distributed ledger technology—it records given information into small chunks of data sets called *blocks*, and if recorded data are valid, the blocks are, in turn, chained with a consensus protocol. The data are stored in a peer-to-peer system-based distributed storage environment, which does not permit anyone to arbitrarily modify it, because anyone can determine when a data change occurs [10]. Therefore, applying blockchain technology to personal health records strengthens the integrity and security of the clinical data stored within [11]. In addition, it is expected that automation features, such as smart contracts, will reduce both cost and time in managing patient participation through the dynamic consensus system [12,13]. Such an appropriately designed blockchain token economy can help in devising strategies to find the benefits of participating in clinical data sharing and to ensure their fair distribution among multiple stakeholders [14]. Furthermore, blockchain can improve the auditability of transferred health care records with secure privacy, help authenticate participants in health information exchange networks with distributed identification, and boost patient participation in the platform by providing incentives according to active participation and adherence to the system [15].

For the 2 main advantages of blockchain—namely auditability and identification—many proof-of-concept studies have been conducted [11,16-18], yet few studies have explored the incentive mechanism of blockchain with respect to real-world cases, in which incentives are crucial for recruitment and attention [19].

To examine the effectiveness of incentivization, one study [20] designed a token economy to encourage adherence to activities of daily living—bathing, physical activity, and oral hygiene—to reduce the risk of bloodstream infections, oral complications, and deconditioning in hematopoietic stem cell transplant for pediatric patients. Activities of daily living adherence rate increased from 0.51 to 2.5 after implementing the token economy [20]. In other studies [21-23], the preferred incentive methods were free parking, modest financial compensation, food coupons, guitar lessons, transportation, and donations to charity. Though £100 (approximately US $137.51) as an incentive was effective when recruiting older adult patients in a clinical trial [24], an amount of US $2.00 as an incentive was not effective [25]. This indicates that the amount of monetary compensation is important. Incentivizing also proved to be effective for patient adherence to smoking cessation, diet, and digital therapeutic programs [26-29]. Some questions have arisen—How about giving incentives multiple times? How much should we compensate for participants' effort? How long can we collect patients' information on the blockchain platform? Is it possible that the shorter the collecting time, the bigger the incentives become? In digital therapeutics, one main strategy in behavior modification is to make a contingency plan to address poor adherence, and monetary reward seems to be the most effective way for active engagement [30].

Mathematical studies have been performed to model incentivization for blockchain. For decentralization, designing protocols that make it difficult to tamper with transactions is essential, and a mathematical approach to designing blockchain protocol that achieves secure information exchange has been examined [31,32]. In addition, the analysis of players' mining strategies was conducted on blockchain using game theory [32,33]. Classical mechanism design theories have been examined on some apps, such as Auction [34]. However, there has been no research linking apps in the blockchain system to mechanism design, which is considered to be representative token design theory for blockchain [35-38].

Why is a new theoretical foundation needed for health care blockchain cryptoeconomics? The purpose of cryptoeconomics is to create internet services, but why do we need new theories and methodologies? In short, it is because the design of decentralized networks is completely different from that of traditional business/service planning. Existing business planning is given certain rules (market conditions) and aims to ensure

that companies make the best choices to maximize profits; however, the design of a decentralized network aims for the opposite. Assuming that each entity acts strategically and selfishly, the design of a decentralized network makes rules to achieve desired results.

Despite the pressing need for further research on the cryptoeconomics of health care blockchain, there has been a lack of research on token economy design to induce patient engagement using health care blockchain automated incentive programs. Thus, we aimed to explore parameters to consider when designing incentive programs that can be embedded in the smart contract of blockchain by using experiments based on 2 representative virtual scenarios with mechanism design.

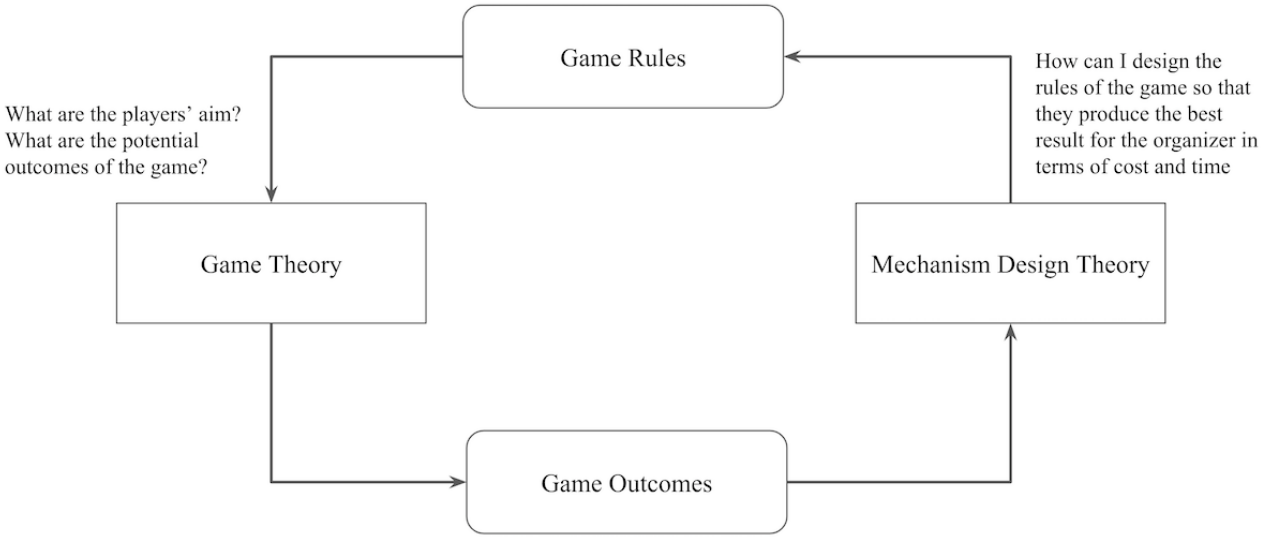
Methods

Methodological Background

Blockchain-based networks have no central principal. Therefore, we need a system that uses tokens (as the medium) and market principles to help individuals grow the network even if they act in pursuit of their own interests. This is called the *Token Model*, which serves as the invisible hand in decentralized networks [39].

To design the token economy, we considered 2 well-known economic theories: game theory and mechanism design. In game theory, existing business planning is given rules (market conditions) and aims to ensure that companies make the best choices to maximize their profits. The theory examines the best strategy in a given game. It explains how to draw conclusions in situations in which several rational decision-makers compete to win over one another. It is called a *game* because it is reminiscent of an actual game with competitors using strategies to win [40]. The relationship between game theory and mechanism design is as described in Figure 1. The organizer of recruitment is able to set the game rules in order to achieve intended goals in terms of cost and time in our scenarios (Figure 1 [41]).

Figure 1. Relationship between game theory and mechanism design theory.



However, the design of a decentralized network is the reverse. Mechanism design uses an engineering approach in which designers act rationally toward desired goals in a strategic environment by applying economic mechanisms and incentives to design strategies. It is also called *reverse game theory* because it starts at the end of the game and moves backward [34].

With the principle of mechanism design, we can reduce cost caused by trial and error and provide a platform for solving real-life problems as a theoretical model. Combined with blockchain, mechanism design has been adopted in various types of research. The auction is a representative example of mechanism design in a blockchain environment with randomness and information disclosure [36]. Based on this possibility, a previous study [35] provided the framework that analyzes the blockchain protocol using mechanism design and game theory. These studies [35,36] suggested that mechanism design can be applied to the blockchain system, especially to the health care blockchain economy, thereby resulting in the development of a basic token economy. We wanted to make ground truth models for the token economy of patient participation and data provision in personal health records. First, we assumed a basic scenario with essential variables—recruiting healthy participants for a vitality program that aims to reduce weight. The vitality program is a technology-based wellness program that is included with most life insurance policies, to support and reward healthy habits [42,43]. Second, we validated model robustness with another hypothetical scenario for validation—recruiting participants for clinical trials of anticancer drugs.

Assumption of Roles on a Blockchain Platform

When recruiting participants to a vitality program in the real world, a life insurance company provides incentives to those involved in the program. This mechanism is easily applied to the blockchain using smart contracts. In addition, the blockchain protects personal health information and is able to conduct universal recruitment through the app; therefore, efficient and safe recruitment of participants can be carried out through health care blockchain.

Meanwhile, the compensation that companies provide to participants on the blockchain is cryptocurrency. Therefore, it is essential to discuss how to calculate the value of this cryptocurrency, which can be performed in many ways. The value of bitcoin is determined by the free market. Suppose a vitality program participant is recruited on a blockchain; the life insurance company must have a certain amount of cryptocurrency. A participant who received the cryptocurrency must be able to exchange it for their benefit. In a conventional blockchain, operators obtain cryptocurrency in exchange for maintaining a blockchain system. However, unless the life insurance company participates in the blockchain operation, it must purchase the cryptocurrency from another party to secure a certain amount of it. In addition, assuming that the value of this cryptocurrency changes, there could be some concern that the total amount of money in the blockchain system would become negative. To solve these problems, we define a concept called *a currency exchange*, which assumes that a certain amount of cryptocurrency can be purchased or exchanged in a certain amount of fiat currency. The advantage of this method is that the total amount of cryptocurrency in the entire blockchain system, and the fiat value of cryptocurrency does not fall below zero, which helps the health care blockchain operate in a stable manner.

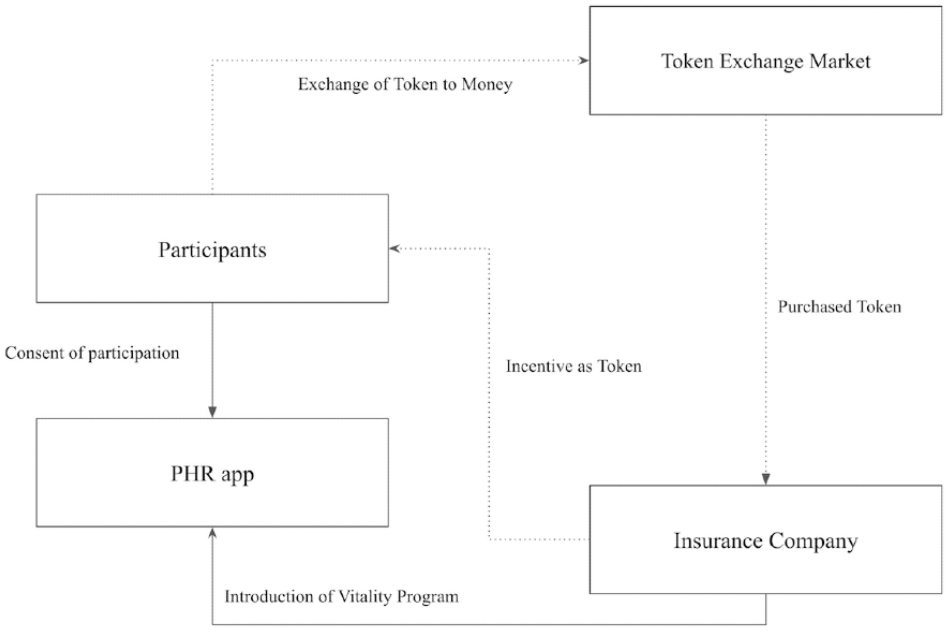
Several members exist in a blockchain system with a currency exchange. First, there is a blockchain operation party that operates the blockchain and acts as a currency exchange. In this study, it is assumed that the blockchain operating party does not affect the token economy because the party only generates cryptocurrency, and the value of cryptocurrency is fixed via the exchange. Second, there is a data provider that has patients' health information. Members who store personal health information include entities such as hospitals or genetic companies. They receive cryptocurrency from members who request information when there is a transaction of the information they store. The reason for receiving the cryptocurrency is the cost of storing the information. The third party is a user on the medical information platform. Users can be patients requesting their genomic information, healthy people uploading their life-log data, or life insurance companies wanting to recruit participants. In this study, we assume a life insurance company prepares a vitality program from the perspective of mechanism design by recruiting participants and finding out how long the recruitment period will be, depending on the amount of the incentive.

Scenarios

Scenario for the Development of the Model

Figure 2 shows a brief process of the basic scenario. The insurance company uploads the following program information through mobile phone apps regarding the collection of life-log data: (1) the institutions that conducts a vitality program; (2) duration of program operation; and (3) token rewards for participating in the program. Based on this information, participants will decide whether to take part in the program. If they decide to participate, they send requests through the app. The vitality program organizer will track participation status until a certain number of participants are obtained. The number of participants obtained here is different from the number of *N* desired by the organizer because the organizer needs to select participants based on their demographic information so that the sample is as unbiased as possible. If participants with certain socioeconomic statuses are enrolled more, the result of the intervention and analysis on effects of the program can be biased. The number *N* is set to greater than the necessary number of participants for the program because some enrollees could be dropped after adjustment for socioeconomic status. The vitality program organizer will pay participants who agree after screening tokens through the app.

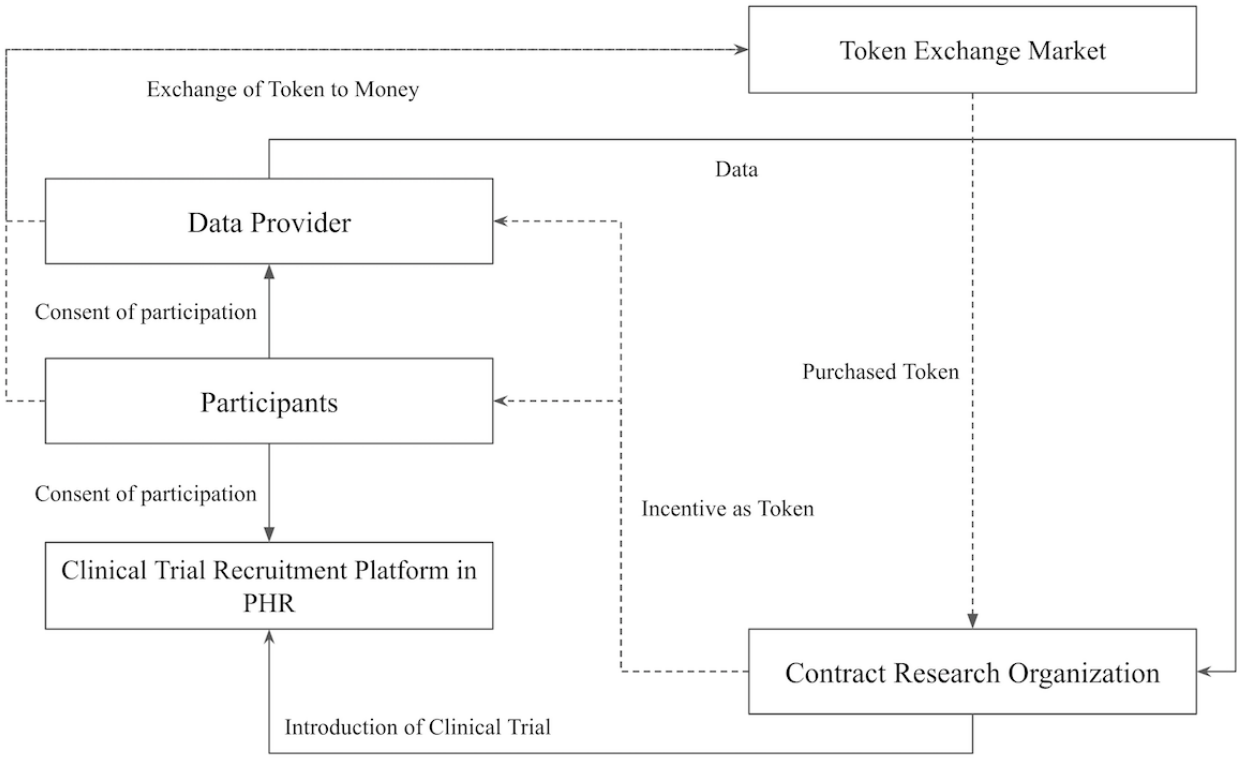
Figure 2. Basic scenario. PHR: personal health record.



Scenario for the Validation of the Model

We established the validation scenario by modifying the basic scenario (Figure 3). In the validation scenario, the research organization searches for participants who have specific gene mutations on the blockchain network for clinical trials of anticancer drugs. For convenience, participants who satisfy all the information required by the researcher are described as group A. Potential participants who do not have necessary clinical information are described as group B. The researcher sends a request for consent to both group A and group B.

Figure 3. Validation scenario. PHR: personal health record.



The participants will decide to participate in the research based on the opinion of doctors who are treating their cancer. In our study, we assumed that the smaller the amount of clinical information that participants are required to send, the higher the probability of consent. This is based on the general assumption that the more information participants have to provide, the more careful they are because normally people care about privacy and security.

For example, if participant X in group A agrees to consent, the institution storing the data of participant X shares the data with the research company and the institution obtains cryptocurrency compensation. In the validation scenario, the companies transfer tokens to data providers that have clinical information for candidate patients in exchange for compensation for storing the data, which is different from the basic scenario in that data providers are added in the token flow

Mathematical Modeling of the Scenario

Mathematical models for both scenarios were constructed; a methodology that minimizes the cost of the organizers was modeled. The essential members were participants and organizers. In both scenarios, the reward was the main parameter that affects participation—we assumed that the higher the reward, the greater the probability of consent. In the case of an organizer, an assumption is needed about which information can be obtained from the participants and the organizers' cost policies. The cost was divided into 2 categories: reward-related parameters and time cost–related parameters.

Cost Function of a Life Insurance Company

We assume that the organizer's cost function is divided into 2 parts—reward and cost. Rewards are provided to participants; therefore, the reward portion is multiplied by the total number of participants. The time is also included in the time cost, and because the rewards and time are different in units, it is necessary to balance both parts by giving one part a weight. In our model, we give a weight to the time cost part (the time weight). The time weight may vary in different recruitment programs. A higher time weight means that an organizer values recruitment time more and wants to recruit participants quickly. We express the cost function as $cost = reward \times N + t \times \alpha$.

When minimizing the cost, if the time weight α is small, cost will be largely dependent on the reward. The unit of time t, where t is a natural number, is assumed to be day for convenience.

In addition, the recruiting time calculation method should be defined. The organizer sends consent requests to those who meet the requirements, and it is assumed that each participant has a probability of consent. Under the assumption, the time taken for recruitment is calculated as follows. On day 1, the organizer sends consent requests to the people in the participant

pool. Some participants agree based on their probability, and others disagree. If the number of people who agree does not satisfy the required number of recruits, on day 2, the organizer will send the consent request again to those who did not agree. This process is repeated to calculate the recruiting time. Recall that the probability of consent to participate in research is dependent upon the reward, and the higher the reward, the greater the probability of consent. Increasing the probability of consent means it will be easier to recruit participants, and the time *t* for recruitment completion will be reduced.

Modeling the Basic Scenario

We assumed that participants can access information about how long the program lasts and the reliability of the insurance company. They also consider inconvenience that may be caused by joining the program.

The welfare of a participant is separated into 2 parts: (1) monetary value and (2) labor. In order to have unbiased results, the socioeconomic status of participants should be considered. The lower the status, the more significant impact on the monetary part, which results in biased recruitment; therefore, we introduced a concave function to represent monetary welfare. Participants have information about their socioeconomic positions, the degree of annoyance for recording tasks, and the reliability of life insurance companies, which are not disclosed to the research companies. Let the socioeconomic status of the *i*th participant be SP_i, let the degree of annoyance be b_i, and let the reliability of the company be R_i. Life insurance companies can set the program period *T* and compensation rewards for the programs, which are communicated to participants through apps.

The participant's welfare is defined using the square root (which is a concave function), which means the higher SP_i, the lower the incremental increase in total welfare of participants. The welfare function of the *i*th participant is

The former term is the weight given to the welfare according to the socioeconomic status, and the latter term is the fatigue of continuously uploading the log by multiplying the basic quadratic function for *T* by weight. Therefore, for participants, a sufficient condition for participation is that the welfare function is positive.

Socioeconomic status is likely to be biased because it provides compensation for participation. Therefore, at initial recruitment, a certain number of the desired population is selected to ensure that socioeconomic status is as evenly matched as possible. In labor-related welfare, fatigue builds up faster over time, and each person's degree of annoyance is different. Hence, the labor-related cost is proportional to the degree of annoyance and the square of the duration.

In addition to consideration of financial benefits, the probability of participating in the program was introduced (to consider the psychology of real-world participants). The probability will be large when the reward is large, the reliability of the organizer is high, and the socioeconomic status is low.

Assuming that the welfare function of the *i*th participant is positive, the probability that the *i*th participant will consent is calculated based on the following assumptions: (1) the higher the rewards, the higher the confidence in the research company; and (2) the lower the socioeconomic level of the participant, the higher the probability of participation. Thus, the probability is calculated as

The normalizer is a buffer weight to allow the rewards to grow. If the right term of equation 2 is greater than 1 for most of *i*, the simulation becomes meaningless; thus, the right term is changed to a slightly more meaningful simulation by multiplying the normalizer by less than 1. In the basic scenario, SP_i=5-10, b_i=0.05-0.1, R_i=0.5-0.7, and *normalizer*=200.

Modeling the Validation Scenario

We modified the previous assumptions and added an intermediate data provider in the validation scenario to ensure that the model is robust after we change variables.

For data providers, assumptions are not necessary because there is no separate strategy available; however, there is a higher chance of making a profit in proportion to the amount of information held by the data providers. A research company can define its cost function, which sets the compensation and time weight per participant. Participants must decide whether to agree or not for the consent request they received. Theoretically, participants decide to agree when their economic gains are greater than 0. In real life, however, other factors play a role in determining whether a patient will be able to participate in clinical trials. Thus, we assume that the agreement probability is based on the expert advice which is provided through the blockchain platform. Normally, patients get expert opinions from their oncologists. If *k* is the number or range of treatment options available, the smaller the *k*, the higher the probability of consent. Utilizing a sigmoid function, the probability of consent has a value between 0 and 1.

Participants in research must disclose whether their genes have been tested, genotype (if they have been tested), and which data provider is storing their data. Moreover, some information on the medical blockchain is open to companies: (1) whether one's genes have been tested and (2) genotype. A few properties are needed to describe this. First, DP_i is defined to determine whether the genetic data of the *i*th participant are stored by the data provider. A DP_i of 0 indicates that there are no genomic data, and a value greater than *n* means that information is stored by the *n*th data provider. The participant's genotype is defined as $Type_i$. If $Type_i$ is 0, it means that the genotype is not known because it has not examined, and DP_i has a value of 0. If $Type_i$ is *n* with a value greater than 0, the dielectric means it is *n*th type.

In the basic scenario, the probability of consent of participants is the expert advice. The greater the rewards, the smaller the number of protocols available to participants and the greater the expert advice. The probability can be defined as a simple

product in the basic scenario, but in the validation scenarios, the sigmoid function is used,

The sigmoid function converts a real value to a value between 0 and 1. Therefore, this value has the advantage of being used directly as a probability. When x is 0, the probability should be close to 0. To shift the sigmoid function to the right, *middle* should be introduced. In the validation scenario, SP_i=0-3, k=1-5, DP_i=1-2, and *middle*=150.

Optimization Formulation

We chose the convex optimization model. For each scenario, we suppose that the expected recruitment time can be found when the clinical trial is given a reward. For each reward and time of completion of the recruitment pair, we obtain the cost of applying the pair. The reward and time t at the lowest cost point will be the optimization values.

To find the expected recruitment time for a given reward amount, the probability of each participant agreeing to participate in the clinical trial is determined. Then using Bernoulli implementation, we obtain the expected number of participants that agreed until N days. Suppose that the probability that the ith participant agrees is q_i. In that case, whether one will eventually agree by the maximum N days is the same as the Bernoulli implementation. The probability of agreeing on the first day is q_i, the probability of agreeing on the first day and agreeing on the second day is $(1 - q_i)q_i$, and the probability of agreeing on the third day is $(1 - q_i)^2q_i$. When this is implemented by the jth day, the expected number of participants that agreed until j days can be obtained as

Therefore, if these expectations are added for all i, the expected number of participants until n days is obtained. When rewards and n are given, the expected number of participants can be obtained, and if n is obtained, this value n is the expected completion of the recruitment.

Aggregating the expected values, we determine the expected number of participants upon N days. When we find the minimal N that the expected number of participants exceeds the company targeted number of participants, then we obtain the reward and the minimal N pair. We put the pairs into the cost function, and find (reward, N, cost) pair that the cost is minimal.

Results

Optimization

The reward affects the probability of consent of each participant, and this probability of consent affects the expected recruitment period t. Note that the expected recruitment period is a function of the reward. Therefore, rewards and expected recruitment period pairs can be obtained. We can make a tuple by considering the cost value of these pairs applied to the cost function. Thus, the relationship of t with the reward and the cost relationship with the reward can be obtained. Figure 4 shows the relationship when the company's time weight is 1500 in the basic scenario, and Figure 5 shows the relationship in the validation scenario in which the company's time weight is 100. Because the basic scenario assumes a company cannot access some of the participant's information, we should use expected values of distributions when we calculate the expected recruitment time. Therefore, even if participants' information is changed through initialization, the graphs are unified into one. On the other hand, the validation scenario allows the company to access all of the participant's information, which means that we should consider each participant’s information when we calculate the expected recruitment time. Therefore, as the participant's information changes, the graph changes accordingly. Figure 5C and Figure 5D show 10 initializations.

In Figures 4 and 5, the graphs on the left are the relationships between rewards and expected recruitment periods, and the graphs on the right are the relationship between rewards and costs. The smaller the rewards, the larger the expected recruitment period, and vice versa. The right graph that puts the rewards and expected recruitment period in the cost function forms a convex curve. The left side of the shape is high because the time cost has grown, and the right side is large because the reward cost affects the entire cost. Therefore, the left part shows a similar appearance as the time decreases dramatically. The right side becomes a linear graph for the reward because the time cost becomes very small. The middle part of the trade-off between these 2 will be the point where the cost is minimized, and the reward value and the expected recruitment period will be *reward** and *t**.

Figure 4. (A) Time–reward and (B) cost–reward trade-offs in the basic scenario when the time weight is equal to 1500.

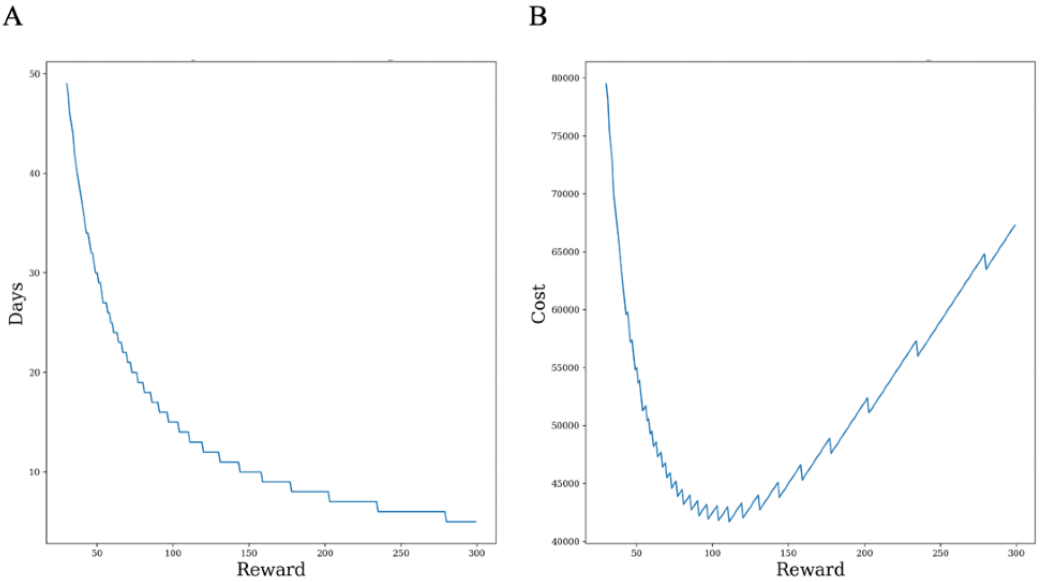


Figure 5. Single-case (A) time–reward and (B) cost–reward and multiple-case (C) time–reward and (D) cost–reward trade-offs in the validation scenario when the time weight is equal to 100.

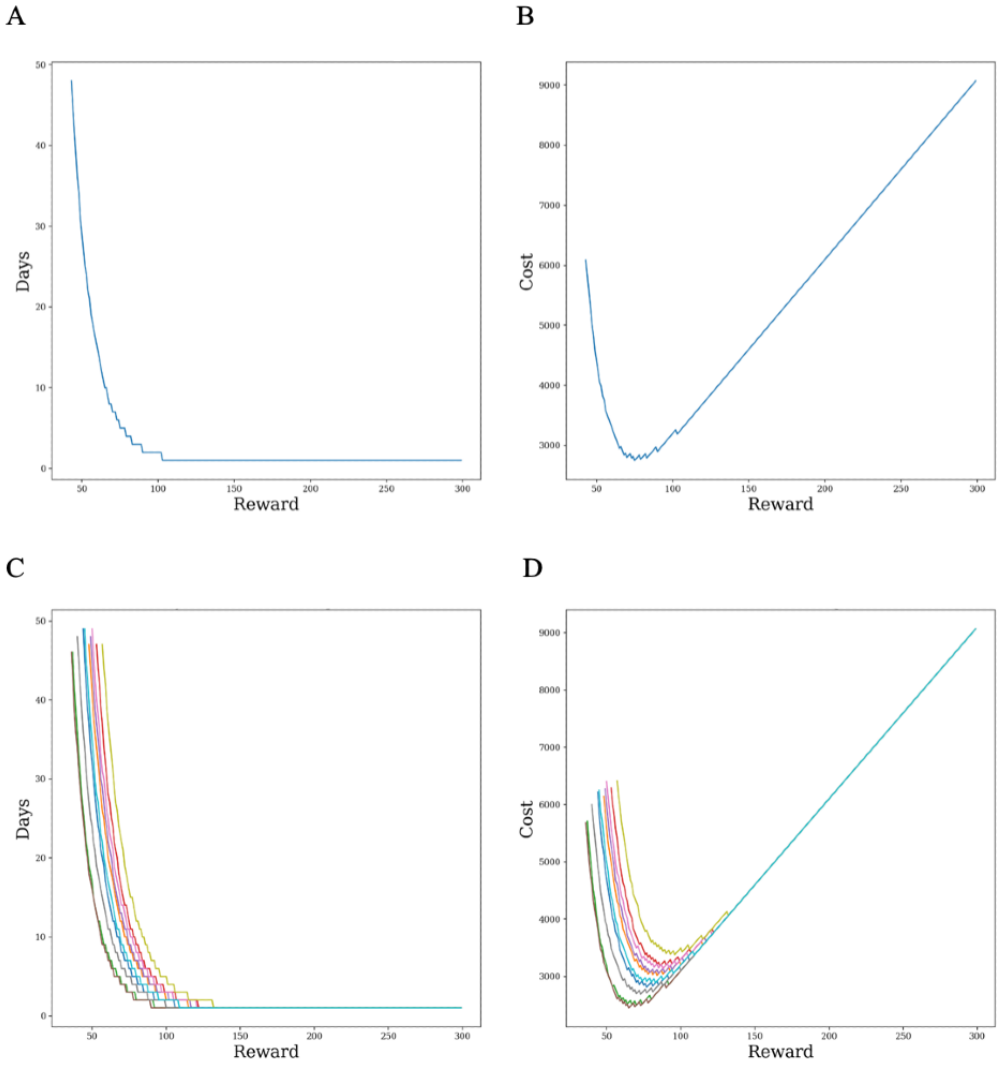

Comparison With Simulation

We compared the simulation results with optimization results. Since *reward** is an independent variable, it is appropriate to compare dependent variable *t**. In order to obtain robust results, we conducted repetitive experiments by changing the variables of participants randomly. For each initialization, we simulated 100 times to get the experimental results. Then, we calculate the error between 100 experimental results and recruitment time, *t**. Finally, we obtained the mean and standard deviation of those values. In the basic scenario, the simulation values are concentrated at the optimized values (Figure 6, Table 1).

Figure 7 and Table 2 show differences between optimized results up to a maximum of 2 days for the validation scenario.

Figure 6. Basic scenario mean values and standard deviation of errors (expected days=13).

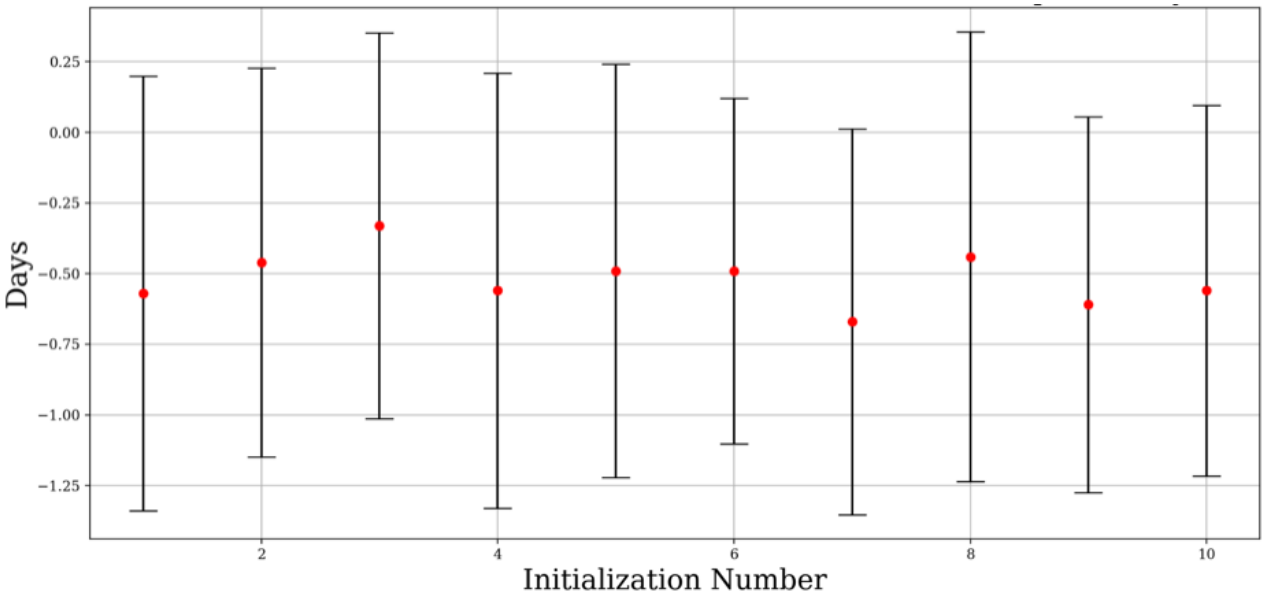

Table 1. Basic scenario.

Experiment	Error, mean (SD)
1	–0.57 (0.77)
2	–0.46 (0.69)
3	–0.33 (0.68)
4	–0.56 (0.77)
5	–0.49 (0.73)
6	–0.49 (0.61)
7	–0.67 (0.68)
8	–0.44 (0.80)
9	–0.61 (0.67)
10	–0.56 (0.66)

Figure 7. Validation scenario mean values and standard deviation of errors.

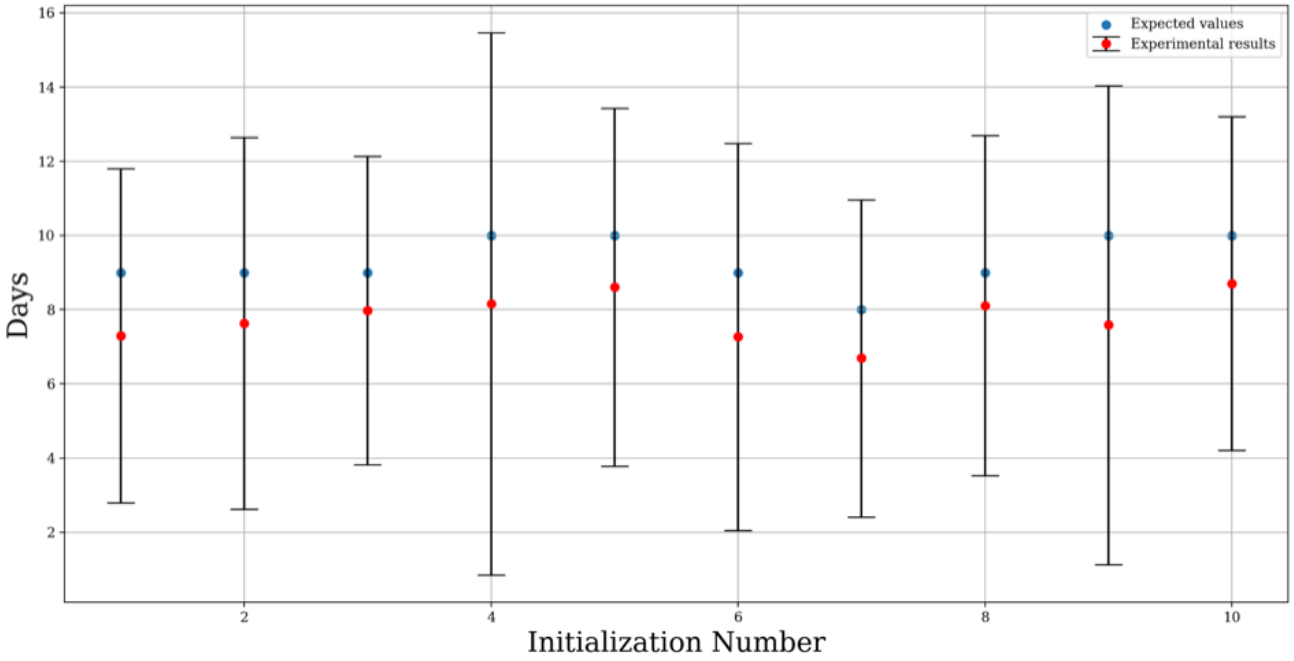

Table 2. Validation scenario.

Experiment	Expected days, n	Error, mean (SD)
1	9	–1.70 (4.51)
2	9	–1.37 (5.01)
3	9	–1.02 (4.16)
4	10	–1.84 (7.31)
5	10	–1.39 (4.82)
6	9	–1.73 (5.22)
7	8	–1.31 (4.28)
8	9	–0.89 (4.59)
9	10	–2.41 (6.45)
10	10	–1.30 (4.50)

Sensitivity Analysis

The company can adjust the number of participants N and time weight α; therefore, we analyzed the sensitivity of t^* as N and α change. For 1% increments of N, recruitment time increases 1.54% and 2.22% in the basic and validation scenarios, respectively. If the time weight is increased by 1%, the recruitment time is decreased by 1.54% and 1.67% in the basic and validation scenarios, respectively, which means this model is in line with our general knowledge and provides a guideline for designing recruitment of participants.

Discussion

Principal Findings

In this paper, we propose 2 token economy scenarios of health care blockchain with mechanism design. We set basic components in each scenario, which were the number of participants and recruitment time, constructed mathematical models to explain the 2 scenarios, and simulated changes in recruitment time and the number of expected participants. Through mechanism design, we demonstrated that the recruiter is able to set a desired and expected number of participants and recruitment time by adjusting the amount of incentive. This study is the first, to the best of our knowledge, to apply mechanism design to health care blockchain for real-world problems.

In classic game theory, designers of the game are not able to determine expected results of games quantitatively. They can expect rational participants to compete with each other for the best results by assuming that participants are reasonable, therefore, act to maximize their profits; however, it is not realistic to apply this assumption directly in the health care blockchain with token economy because it is crucial for a funder of health care blockchain to know expected time, cost, and the number of recruited participants.

In our models that employ mechanism design, the recruiter can set a quantitative outcome of programs by adjusting the relationship of number of participants, recruitment time, and rewards. In addition to the predictability of outcomes, the blockchain system can provide participants more secure environments with immutability of the system, although the system is more open to the public compared to conventional ways of recruiting participants.

Traditionally, the issue of whether direct incentives for health care participants are acceptable has been debated because direct incentives can bias medical research and treatment outcomes [44]. From a medical standpoint, there is less of an ethical problem with direct incentives for healthy people [45], such as those modeled in the basic scenario. In the validation scenario, there may be a concern with direct incentives to participants within the blockchain. However, we assumed a circumstance that allows direct incentives for the participation of clinical trials in the future because patients are selected randomly as participants on a blockchain system, and we assumed that direct incentives can be allowed to increase recruitment and attention rates in clinical trials.

From a mathematical perspective, information about each participant is different depending on whether recruiting companies have access to it or not. While recruiting healthy individuals, we assumed that information about each participant is unobtainable by the company because they usually do not need strict inclusion criteria, which means that they can exclude some of applicants after closing the recruitment. When collecting life-log data, the degree of annoyance for each participant over a long period is unobtainable and we can only see the distribution for the degree of annoyance. In this study, this distribution is assumed to be a uniform distribution. In this case, a clinical trial company uses the expected value of the distribution (ie, the uniform distribution's average value). Meanwhile, in the validation scenario, each participant should provide gene data to the research company. From the gene data, the company can infer the probability of agreement of each participants and can adjust model to fit real-world data.

Recruiting participants is one of the most difficult parts of conducting a clinical research or trial. However, the token economy, through mathematical modeling and simulation techniques proposed in this study, will enable companies to obtain important insight into whether they can recruit participants within the desired period by setting appropriate rewards for recruiting participants. Moreover, due to difficulties in recruiting participants suitable for clinical trials, companies may make a request to hospitals for patients information. However, hospitals do not feel the need and reason to provide data they hold, or even if hospitals are willing to provide data, the consent process for the use of patient data is complicated, and many patients are concerned about privacy and security [46]. Therefore, blockchain token economy can be applied to appropriately compensate entities participating in the blockchain data sharing platform, thereby reducing gaps between the needs of companies, hospitals, and participants (patients) with respect to data utilization, with high security and privacy, enabling efficient recruitment of participants through user-centered participation. This study is meaningful because we were able to make rational models that can be used as a starting point for designing health care blockchain for patient recruitment.

Limitations and Future Research

Our assumptions did not reflect complex circumstances for recruiting participants in the real world. Thus, if the results of our models are different from the expectations of recruiting company, recruitment would not be successful. Models with basic mandatory requirements such as recruitment time, amount of incentives, and number of participants, and without complicated assumptions, can be useful for other researchers as a starting point of their own modeling—they can use our framework as a basic scenario to design their own sophisticated token design in health care blockchain. Another limitation is that comparison and analysis with actual data could not be carried out to provide a more robust framework.

Conclusion

There have been few business models adopting blockchain technology in health care. Token economy of blockchain can be a powerful driver by incentivizing health care consumers with an immutably trackable token transaction system. This research is a starting point of designing the token economy in real-world health care settings; we modeled 2 possible scenarios, optimized the cost of the company, and compared the results with simulation data. This study can be used as a basis for designing an incentive system for companies recruiting clinical trial participants or health care program participants within a set period of time with a blockchain-based patient recruitment platform.

Abstract

Background: Evaluating outcomes of the clinical and translational research (CTR) training of a Clinical and Translational Science Award (CTSA) hub (eg, the KL2 program) requires the selection of reliable, accessible, and standardized measures. As measures of scholarly success usually focus on publication output and extramural funding, CTSA hubs have started to use bibliometrics to evaluate the impact of their supported scholarly activities. However, the evaluation of KL2 programs across CTSAs is limited, and the use of bibliometrics and follow-on funding is minimal.

Objective: This study seeks to evaluate scholarly productivity, impact, and collaboration using bibliometrics and federal follow-on funding of KL2 scholars from 3 CTSA hubs and to define and assess CTR training success indicators.

Methods: The sample included KL2 scholars from 3 CTSA institutions (A-C). Bibliometric data for each scholar in the sample were collected from both SciVal and iCite, including scholarly productivity, citation impact, and research collaboration. Three federal follow-on funding measures (at the 5-year, 8-year, and overall time points) were collected internally and confirmed by examining a federal funding database. Both descriptive and inferential statistical analyses were computed using SPSS to assess the bibliometric and federal follow-on funding results.

Results: A total of 143 KL2 scholars were included in the sample with relatively equal groups across the 3 CTSA institutions. The included KL2 scholars produced more publications and citation counts per year on average at the 8-year time point (3.75 publications and 26.44 citation counts) than the 5-year time point (3.4 publications vs 26.16 citation counts). Overall, the KL2 publications from all 3 institutions were cited twice as much as others in their fields based on the relative citation ratio. KL2 scholars published work with researchers from other US institutions over 2 times (5-year time point) or 3.5 times (8-year time point) more than others in their research fields. Within 5 years and 8 years postmatriculation, 44.1% (63/143) and 51.7% (74/143) of KL2 scholars achieved federal funding, respectively. The KL2-scholars of Institution C had a significantly higher citation rate per publication than the other institutions (P<.001). Institution A had a significantly lower rate of nationally field-weighted collaboration than did the other institutions (P<.001). Institution B scholars were more likely to have received federal funding than scholars at Institution A or C (P<.001).

Conclusions: Multi-institutional data showed a high level of scholarly productivity, impact, collaboration, and federal follow-on funding achieved by KL2 scholars. This study provides insights on the use of bibliometric and federal follow-on funding data to evaluate CTR training success across institutions. CTSA KL2 programs and other CTR career training programs can benefit from these findings in terms of understanding metrics of career success and using that knowledge to develop highly targeted strategies to support early-stage career development of CTR investigators.

KEYWORDS

bibliometrics; Clinical and Translational Science Award; KL2; translational research; career development

Introduction

Evaluating outcomes of a Clinical and Translational Science Award (CTSA) hub's clinical and translational research (CTR) training, such as the KL2 program, requires the selection of reliable, accessible, and standardized measures. The KL2 program is a multiyear mentored training award focusing on early-stage career development of investigators in CTR. The National Center for Advancing Translational Science (NCATS) at the National Institutes of Health (NIH) funds over 60 KL2 programs across CTSA hubs. All CTSA hubs offer a KL2 program, which is a formal, mentored training experience for scholars with doctoral degrees. Each CTSA hub selects KL2 candidates from a variety of fields (eg, medicine, nursing, and biostatistics) to participate in translational research training in a multidisciplinary setting with up to 5 years of career development support.

One of the strategic goals of NCATS for the CTSA program is to "develop and foster innovative translational training and a highly skilled, creative, and diverse translational science workforce" [1]. The KL2 program is one mechanism that offers such training. Each CTSA hub is responsible for evaluating its KL2 program, typically using methods such as surveys, focus groups, exit interviews, and alumni follow-up. Measures of scholarly success are predominantly scholarship products—publication output and extramural funding, such as an R01-equivalent award. The NCATS Common Metrics Initiative also created measures for all KL2 programs to report on the number and percentage of total graduates: women, underrepresented minorities, and KL2 scholars who sustain their translational research engagement [2].

All NCATS-funded KL2 programs follow a set of established requirements. For example, 75% of the time of enrolled KL2 scholars is funded by the program, with the exception of 50% for surgeons [3]. All KL2 programs must provide training in rigorous research methodologies aligned with CTR competencies. KL2 programs must provide opportunities that allow scholars to effectively communicate and collaborate across multidisciplinary teams [3,4]. Beyond these requirements, CTSA hubs are encouraged to innovate and tailor their KL2 programs to their specific needs, leading to some variability in KL2 programs. For example, although programs provide 2 years of KL2 funding, some programs provide funding for 3 or more years [5]. Such differences in hub-level KL2 program characteristics present challenges for defining indicators of success and standardizing the evaluation of KL2 program outcomes across CTSA hubs.

CTSA hubs sometimes use bibliometric analysis to evaluate their impact on moving translational research forward. Bibliometrics refers to the use of quantitative and statistical methods to analyze a chosen group of publications [6,7]. Bibliometrics complement other evaluation methods, such as surveys and interviews, by allowing programs to measure tangible and intangible outcomes such as publications and scholarly impact, which otherwise cannot be objectively measured via self-report methods such as surveys or interviews. One study [8] used bibliometrics to analyze publications citing all CTSA hub grants from 2006 to 2016. This study highlighted bibliometric values to assess the impact of research across all CTSAs as measured by interdisciplinary collaboration, influence on other publications, and breadth of scientific fields. Another study [9] used bibliometrics to compare publications citing one of 6 CTSA hubs with measures from three sources: NIH iCite (publicly available), Thomson Reuters (now Clarivate Analytics), and Elsevier. This study identified relevant data sources and standardized analyses for cross-CTSA comparisons. A more recent CTSA hub-specific study [10] implemented advanced bibliometric measures to assess scholarly productivity, citation impact, the scope of research collaboration, and clusters of research topics of publications supported by their CTSA. Furthermore, some CTSA hubs have evaluated the feasibility of different bibliometric approaches to assessing KL2 scholarly productivity and influence compared with other NIH-funded K-awardees [11,12]. These studies illustrated the importance of standardizing the (1) collection of publication data, (2) definition of success and measures for KL2 training outcomes, and (3) use of bibliometric methods to evaluate the scholarly productivity and impact of KL2 scholars across the CTSA consortium.

To our knowledge, the evaluation of KL2 programs across CTSAs is limited, and the use of bibliometrics and follow-on funding is minimal. This study evaluates scholarly productivity using bibliometrics and federal follow-on funding of KL2 scholars across 3 different CTSA hubs to define and assess CTR training success indicators. Such indicators, coupled with evidence of the feasibility of their collection and use, would allow CTR training programs to demonstrate effectiveness on a wide variety of outcomes.

Methods

Participants

Our sample included KL2 scholars from 3 CTSA institutions, described as institutions A-C throughout the paper. A description of program-level characteristics is provided in the Multimedia

Appendix 1. The 3 institutions were selected as convenience samples based on previous collaborations between the CTSAs. We only included scholars in our analysis if they had at least 5 years of bibliometric data, starting at matriculation (ie, year of entry into the KL2 program). We chose the date range of 2005-2013 to ensure that all scholars met the minimum 5-year data requirement. In other words, scholars beginning their KL2 program in 2013 have 5 years of bibliometric data as of December 2018.

Measures

Overview

We selected bibliometrics and federal follow-on funding because they are objective measures with evidence of reliability and validity and are verifiable. In the following sections we describe various bibliometrics along a continuum of objectivity. Although some metrics, such as number of publications, are objective, other metrics, such as citation impact and collaboration, are quantified representations of construct and are open to interpretation of scale, scope, and reliability.

Bibliometrics

When we selected bibliometric measures and sources for this study, we considered the (1) validity, relevancy, and feasibility of measures, especially the metrics and sources that have been verified and adopted in previous CTSA evaluation studies; (2) coverage of publications of our KL2 scholars in three CTSAs; and (3) availability of bibliometric data sources such as institutional subscriptions and free accessibility. Accordingly, we chose Elsevier SciVal and NIH iCite for the bibliometric measurements. SciVal is a research analytics tool for various bibliometrics gathered from the Elsevier Scopus citation database. Scopus has much broader coverage in biomedical and life sciences than Web of Science [13,14] and has been adopted in multiple bibliometric studies concerning CTSA evaluations [9,10,15]. The 3 CTSA institutions in this study have subscriptions to Scopus or SciVal and have experience in using Elsevier metrics to assist research performance evaluation. In addition, we added the relative citation ratio (RCR) generated by NIH iCite as an additional citation measure. Being freely accessible and increasingly used by CTSA evaluators, RCR is a field-independent metric, measuring the citation impact of an article relative to other NIH-supported research papers produced in the same field during the same timeframe. However, iCite is limited to analyzing only articles indexed in PubMed, whereas SciVal can provide aggregated data from the more comprehensive Scopus database. Extracting data from both sources can help reduce potential bias and provide a more reliable estimate of the quantity and impact of scholarly work. Therefore, we exported bibliometric data for each of the included scholars from both SciVal and iCite to provide evidence of validity and reliability within this sample [16,17].

Data exported from SciVal provide evidence for three metrics of research performance: productivity, impact, and collaboration. Productivity metrics provide an overview of total scholarly output, that is, the number of publications a scholar produces within a specified period. Impact metrics focus on citation counts through raw and calculated variables, accounting for scientific field-weighted or ratio values. We excluded self-citations from the analysis. Collaboration metrics consider all authors in a publication with attention to the affiliated institutions of coauthors. We used iCite data to understand the impact of the publications compared with the average of NIH-funded publications published in the same year and field [18]. Table 1 shows a detailed list of metrics used per domain.

Table 1. Summary of bibliometrics used.

Source, domain, and metric	Definition
SciVal	
Productivity	
Scholarly output	Number of publications indexed in Scopus
Impact	
Citations per publication	Average number of citations received per publication
PPTPJ[a]	Number of publications in the world's top journals
FWCI[b]	Ratio of citations received relative to the expected average for the field, type, and year
Collaboration	
NFWC[c]	Collaboration ratio is computed based on the expected collaboration for that document type, publication year grouping, and subject area assignment
iCite	
Impact	
Average RCR[d]	Cites per year of each paper, normalized to the citations per year received by NIH[e]-funded papers in the same field and year
Average citations per year	Citations per year received since publication; this is the numerator for the RCR.
Average field citation rate	Intrinsic citation rate of this paper's field is estimated using its co-citation network.
Average NIH percentile	Percentile rank of this paper's RCR compared with all NIH publications.

[a]PPTPJ: percentage of publications in the top 10th percentile of journals.

[b]FWCI: field-weighted citation impact.

[c]NFWC: National Field-weighted Collaboration.

[d]RCR: relative citation ratio.

[e]NIH: National Institutes of Health.

Federal Follow-on Funding

Three federal follow-on grant funding measures were also collected: NIH funding at the 5-year, 8-year, and overall time points. These follow-on funding measures include only NIH federal funding received by a scholar as the principal investigator, coprincipal investigator, or coinvestigator. This information can be independently confirmed for all 3 institutions by examining NIH RePORTER (Research Portfolio Online Reporting Tools Expenditures and Results) for NIH funding records [19].

Procedures

This study received institutional review board exemption from 2 institutions, with a third institution determining that this was not human subjects research. Each participating institution developed a list of KL2-scholars awarded since 2005, including gender, race, ethnicity, and highest degree earned for each scholar. We dichotomized race due to sample skewness; however, dichotomization still resulted in unequal group sizes. We excluded ethnicity analysis because of the homogeneity of the sample. We collapsed the categories of degrees to MD and non-MD terminal degrees. Clinical training was the distinction between MD and non-MD degrees. Scholars with both MD and PhD were considered MDs.

Cohorts of scholars were created in SciVal using the year the scholar began their KL2-grant (ie, all 2005 KL2's were in one cohort) according to the SciVal cohort-instructions. To obtain iCite data, a list of publications associated with each KL2 scholar was retrieved from PubMed and then manually verified. The PubMed identification numbers (PMIDs) of the verified publications were filtered to the 2005-2013 date ranges for this analysis. Next, the validated PMIDs were imported into iCite to download the data for each scholar. All metrics from SciVal and iCite were extracted and entered into an SPSS (IBM; version 25) file within 6 months. Grant data were collected using internal records of federal funding and confirmed through NIH RePORTER [19].

Data Analysis

All statistical analyses were computed using SPSS [20]. Nonparametric tests for independent samples (Kruskal-Wallis and Mann-Whitney U) were used when data were not normally distributed. We conducted descriptive and inferential statistical analyses according to demographic subgroups and institutions to assess the bibliometric results of KL2 scholars. Federal funding data were analyzed using logistic regression to evaluate the relationship between categorical variables (eg, gender, race, degree, and institution) and a series of dichotomized variables representing the presence or absence of federal funding at three time points, as described below.

Data were time-bound to include the year the scholar started their K-award (ie, matriculation) through the completion of 2018. Three time points determined analysis: 5 years and 8

years after matriculation and overall (from the start year of the KL2-award through the end of 2018). These time points are based on established precedents from K08 or K23 evaluations and K to R-award funding trajectories, which peak at 8 years [21,22]. iCite data were not included for the 5-and 8-year time points because, at the time of analysis, no time point–specific data could be produced by iCite and only the overall citation metrics were available.

Results

Sample Characteristics

The total sample consisted of 143 KL2 scholars with relatively equal groups across institutions (Table 2). The overall sample at each institution had a slightly greater number of male scholars. The majority of KL2 scholars in this sample were non-Hispanic White people. Most scholars held terminal MD degrees, with PhDs being the second most common degree.

Table 2. Summary of scholar demographics[a].

Demographics	Sample value (N=143)	Institution A value (n=50)	Institution B value (n=48)	Institution C value (n=45)
Gender, n (%)				
Male	*77 (54)*[b]	*27 (54)*	*25 (52)*	*25 (55)*
Female	66 (46)	23 (46)	23 (48)	20 (44)
Ethnicity, n (%)				
Hispanic or Latino	6 (4)	4 (8)	1 (2)	1 (2)
Not Hispanic or Latino	*136 (95)*	*45 (90)*	*47 (98)*	*44 (98)*
Not reported	1 (1)	1 (2)	0 (0)	0 (0)
Race, n (%)

Bibliometrics

SciVal

Data from SciVal for all 143 scholars revealed a median of 17 publications or 3.4 publications per year on average at the 5-year time point. Impact metrics showed a midpoint of 26.16 citations per year or an average of 130.8 citations over 5 years. KL2 scholars were cited approximately 7 times more than other researchers in their field. In addition, 44.01% (1558/3540) of the publications were in the top 10th percentile of the journals. In terms of collaboration, KL2 scholars published work with researchers from other US institutions over 2 times more than others in their research fields. Contrary to the overall trends, investigating scholars at the institution level presented some differences (Table 3). The KL2 scholars of Institution C had a significantly higher citation rate per publication than the other institutions (H_2=12.35; P=.002). Institution A had a significantly lower rate of nationally field-weighted collaboration than did the other institutions (H_2=70.49; P<.001). No other 5-year significant differences were reported.

Data from SciVal for 112 scholars showed an increase in publication rate at the 8-year time point, with scholars from all institutions publishing an average of 3.75 publications per year, up from 3.4 at the 5-year time point. The mean citation rate also slightly increased from 26.16 at the 5-year time point to 26.44 at the 8--year time point. The percentage of publications in the top 10th percentile of journals decreased by less than 1% to 43.34% (2658/6132). Rates of collaboration increased, with KL2 scholars at 8 years publishing with researchers across the nation 3.5 times more than other researchers in their field. Results at the institutional level for the 8-year time point were similar to those at the 5-year time point (Table 3). Institution C scholars had a significantly higher rate of citations per publication (H_2=10.12; P=.006), and scholars of Institution A had a significantly lower rate of field-weighted national

collaboration (H_2=65.08; *P*<.001; n=112; Institution A: n=37; Institution B: n=37; and Institution C: n=38).

Regarding demographics, outcomes from SciVal metrics reported that male scholars published significantly more work at the 5-year time point than female scholars (U=1114.50; *P*=.008; Table 4). There were no differences between the scholar race and any reported bibliometric outcomes. Scholars with an MD degree had significantly higher field-weighted citation indices than scholars without an MD degree (U=1202.50; *P*=.04).

Table 3. Postmatriculation SciVal bibliometric summary (medians reported).

iCite

Data from iCite only provided a comprehensive report from all the years included in this study, as illustrated in Table 5. KL2 publications from all institutions were cited twice as much as other researchers in their fields, earning an average of 4.5 citations per year. The average NIH percentile was 53%, indicating that KL2 publications had an RCR higher than 53% of all NIH-funded publications [17]. At the institutional level, Institution A reported significantly lower results for the average field-weighted citation rate (H_2=8.96; *P*=.01). No other significant results were reported.

Table 5. iCite bibliometric outcomes by institution (medians reported).

Bibliometric	Value, median			
	All institutions	Institution A	Institution B	Institution C
Average RCR[a]	1.67	1.51	1.72	*1.78*[b]
Average citations per year	3.47	2.76	*3.84*	3.82
Average field citation rate	4.05	3.79	*4.27*	4.09
Average NIH[c] percentile	52.91	51.86	*54.17*	52.69

[a]RCR: relative citation ratio.

[b]Italicized values indicate the largest value.

[c]NIH: National Institutes of Health.

Federal Follow-on Funding

Grant analysis of KL2 scholars at all 3 institutions indicated that 44.1% (63/143) of KL2 scholars received federal funding within 5 years postmatriculation. At the 8-year time point, 51.7% (74/143) of scholars had achieved federal funding as a principal investigator, coprincipal investigator, or coinvestigator. Significant differences between institutions were found at the 5-year, 8-year, and overall funding rates using the chi-square test (Table 6). Scholars from Institution B were more likely to have received federal funding than scholars at Institution A or C at the 5-year (χ^2_2=15.28; P<.001) and 8-year (χ^2_2=7.07; P=.03) time points. Investigating federal grant funding by scholar characteristics showed no significant differences between gender, race, or degree at the 5-year or 8-year time points. Male scholars in our sample appeared to receive federal funding at higher rates than females, but this did not reach significance (χ^2_2=3.56; P=.06).

Table 6. Scholars with extramural federal funding by institution.

Time point	All institutions (N=143), n (%)	Institution A (n=50), n (%)	Institution B (n=48), n (%)	Institution C (n=45), n (%)
5-year	63 (44.1)	16 (32)	*31 (64.5[a])*	13 (28.9)
8-year	74 (51.7)	24 (48)	*32 (66.7)*	18 (40)
Overall	74 (51.7)	24 (48)	*32 (66.7)*	19 (42.2)

[a]Italicized values indicate the largest value.

Discussion

Principal Findings

Overall, this study emphasizes the high level of scholarly productivity, impact, collaboration, and funding achieved by KL2 scholars. This study also provides insights into the utility of both bibliometric and federal follow-on funding to evaluate CTR training success, especially for measuring the scholarly work of training participants. Bibliometric data provide a better understanding of the impact of research publications produced by KL2 scholars. Federal funding data demonstrate the extent to which KL2 scholars are receiving subsequent federal funding and therefore successfully sustaining their research.

Bibliometrics

On the basis of previous experience of applying bibliometrics to CTSA performance assessment [8-12], this study adopted a proprietary research analytics tool, SciVal, and a publicly available federal government–developed bibliometric tool, iCite, to investigate the productivity and citation impact of KL2 scholars across 3 institutions. Both SciVal and iCite metrics showed that the examined research publications of KL2 scholars had a more significant citation influence than those published simultaneously by other researchers in the same fields. For instance, SciVal metrics (eg, field-weighted citation impact [FWCI] and percentage of publications in the top 10th percentile of journals) showed that, on average, at 5 years, KL2 scholars were cited almost 7 times more than other researchers in their field. Approximately half of their articles were published in the top 10th percentile of the world's journals, which indicates the distinguishing influence of CTSA-supported KL2 scholars. Similarly, the RCRs generated by iCite disclosed that the KL2 scholars at 3 institutions received almost twice as many citations per year as other researchers in their fields, which is consistent with results reported in a previous study [12]. The difference of citation impact results produced by SciVal (FWCI) versus iCite (RCR) is associated with varied time ranges and citation tracking scopes that these two tools examined. In this study, FWCI results were generated at the 5- and 8-year time point, whereas the RCR of an institution was the average of all included publications from 2005 to 2019. In addition, the Scopus database, from which SciVal data are derived, is one of the largest citation databases in the world and covers the MEDLINE database, which is the primary component of PubMed in addition to thousands of international publishers. Consequently, the citation counts and FWCIs provided by SciVal or Scopus are often higher than those generated by iCite, which only tracks citation counts within the NIH Open Citation Collection, including MEDLINE, PubMed Central, and CrossRef [23].

Furthermore, KL2-scholars demonstrated significant collaborations with researchers across the United States, with coauthorship occurring 2 times more than others in their research

fields at the 5-year time point and 3.6 times more at the 8-year time point, as measured by the National Field-Weighted Collaboration score generated by SciVal. Therefore, our results confirm the feasibility of applying bibliometrics to assess scholarly work supported by CTSA programs and corroborate the effectiveness of three CTSA programs in supporting KL2 scholars for translational research [8,9].

Nevertheless, a subanalysis highlighted a few critical demographic differences between scholars across institutions. Male scholars published significantly more than female scholars did at 5 years postmatriculation; however, this difference was not observed at the 8-year time point. Previous research confirms the difference in publications by males, but limited research has investigated any long-term differences [24]. Our results suggest that differences over time may be a critical point where female scholars reduce this gap, which may arise from a variety of personal commitments that impact the pace of the career of a female scientist. At 8 years postmatriculation, scholars with an MD degree had a significantly higher FWCI than those without an MD degree. These demographic differences should be further studied to better understand the role the scientific field plays in supporting scholarly work across different scientific areas.

Similarly, bibliometrics brought institutional differences to our attention (Multimedia Appendix 1). We found that KL2 scholars at Institution C had a significantly higher rate of citations per publication. In comparison, Institution A had a significantly lower rate of National Field-Weighted Collaboration than the other 2 institutions. These cross-institutional differences emphasize the need to invest in the standardization of measures (eg, bibliometrics), improving the ability to evaluate scholarly success across the nation. In previous research, CTSA hubs reported various techniques for reporting and tracking publications [8,9,25]. In addition, differences in publication characteristics have been shown to impact bibliometric outcomes (eg, reviews are usually cited more than original articles; open-accessible articles are cited more than nonopen accessible ones), such as in journal coverage of bibliographic databases, and the size and establishing time of CTSA programs [9,10,25]. Therefore, although it is feasible to use bibliometrics to analyze the scholarly output and influence of multiple CTSA programs, there are complications in applying citation metrics, interpreting results, and benchmarking the performance of multi-institutional programs. Future research should consider the role of the program-level characteristics outlined in the Multimedia Appendix 1.

Federal Follow-on Funding

Our analysis reveals that federal funding award rates for KL2 scholars are higher than the national average of 20.2% [26]. Previous research reported a 34% R01 funding rate for KL2 scholars 6 years postmatriculation [27]. Our study included R01 equivalent awards, but nonetheless suggests that the federal funding rate for KL2 scholars in this sample (63/143, 44.1% at 5 years) may be slightly higher than other institutions. The data also show that male KL2 scholars are more likely to receive federal funding than their female counterparts; however, this was not statistically significant. Previous studies examining gender differences in obtaining grant funding have been mixed. There were mitigating effects by both the type of training and the length of time following training [21,22,28]. In our analysis, we investigated the attainment of any NIH funding, and thus, we might have picked up additional funding mechanisms not examined in previous research. To our knowledge, none of the studies, including ours, has examined funding from foundations or other sources. This exclusion is a limitation and potential area of further research, especially to better understand the underlying factors associated with male KL2 scholars having a higher likelihood of receiving follow-on funding.

Limitations

The limitations of this study include programmatic differences between the 3 institutions, differences in scholarly scientific fields, and grant data. We intended to investigate the scholarly success of a multi-institutional sample of KL2 scholars and to identify appropriate and feasible methods that could be used across institutions. However, the analysis of these measures revealed that performance on certain metrics could be linked to institutional characteristics. Perhaps the most considerable difference between these three KL2 programs is the length of KL2 funded training time. Each institution had a different length of funding, ranging from 2 to 4 years, provided to scholars. Other programmatic distinctions, such as variations in grant writing support, also exist. Future research should identify which program characteristics are related to the outcomes studied here. Other possible analyses include investigating the impact of scholarly field and degree on outcomes given the differences between MDs and PhDs that we highlighted in our analyses.

Conclusions

This study emphasized the use of bibliometrics and federal follow-on funding as necessary evaluation measures for assessing scholarly productivity, impact, collaboration, and funding achieved by KL2 scholars. We have shown that evaluators can use these metrics to evaluate CTR training programs that focus on scholarly productivity as a critical outcome. These methods can be used to complement existing evaluation strategies to demonstrate program performance. The findings of this study highlight the need to better understand barriers and facilitators of scholarly productivity. Institutions should consider similar subanalyses within their evaluations to explore equity within their programs. In addition, there is a need to investigate the impact of programmatic components and best practices that yield high follow-on funding rates. Program-level goals within and among institutions influence funding outcomes, scholarly productivity, and collaboration. Identifying these differences will enhance the specificity of KL2 program evaluations. CTR training programs, such as CTSA KL2 programs, can benefit from the findings of this and future analysis as they continuously adapt their program strategy to support the early-stage career development of CTR investigators.

Abstract

Background: School food outlets represent a key setting for public health nutrition intervention. The recent proliferation of web-based food ordering systems provides a unique opportunity to support healthy purchasing from schools. Embedding evidence-based choice architecture strategies within these routinely used systems provides the opportunity to impact the purchasing decisions of many users simultaneously and warrants investigation.

Objective: This study aims to assess the effectiveness of a multistrategy behavioral intervention implemented via a web-based school canteen lunch ordering system in reducing the energy, saturated fat, sugar, and sodium content of primary students' web-based lunch orders.

Methods: The study used a parallel-group, cohort, cluster randomized controlled trial design with 2207 students from 17 Australian primary schools. Schools with a web-based canteen lunch ordering system were randomly assigned to receive either a multistrategy behavioral intervention that included choice architecture strategies embedded in the web-based system (n=9 schools) or the standard web-based ordering system only (n=8 control schools). Automatically collected student purchasing data at baseline (term 2, 2018) and 12 months later (term 2, 2019) were used to assess trial outcomes. Primary trial outcomes included the mean energy (kJ), saturated fat (g), sugar (g), and sodium (mg) content of student lunch orders. Secondary outcomes included the proportion of all web-based lunch order items classified as *everyday*, *occasional*, and *caution* (based on the New South Wales Healthy School Canteen Strategy) and canteen revenue.

Results: From baseline to follow-up, the intervention lunch orders had significantly lower energy content (−69.4 kJ, 95% CI −119.6 to −19.1; *P*=.01) and saturated fat content (−0.6 g, 95% CI −0.9 to −0.4; *P*<.001) than the control lunch orders, but they did not have significantly lower sugar or sodium content. There was also a small significant between-group difference in the percentage of energy from saturated fat (−0.9%, 95% CI −1.4% to −0.5%; *P*<.001) but not in the percentage of energy from sugar (+1.1%, 95% CI 0.2% to 1.9%; *P*=.02). Relative to control schools, intervention schools had significantly greater odds of having *everyday* items purchased (odds ratio [OR] 1.7, 95% CI 1.5-2.0; *P*<.001), corresponding to a 9.8% increase in *everyday* items, and lower odds of having *occasional* items purchased (OR 0.7, 95% CI 0.6-0.8; *P*<.001), corresponding to a 7.7% decrease in

occasional items); however, there was no change in the odds of having *caution* (least healthy) items purchased (OR 0.8, 95% CI 0.7-1.0; *P*=.05). Furthermore, there was no change in schools' revenue between groups.

Conclusions: Given the evidence of small statistically significant improvements in the energy and saturated fat content, acceptability, and wide reach, this intervention has the potential to influence dietary choices at a population level, and further research is warranted to determine its impact when implemented at scale.

nudge; choice architecture; intervention; online canteen; online ordering systems; digital interventions; school children; school food service; canteens; menu labeling

Introduction

Background

Dietary risk factors are a leading cause of disease [1]. Schools are a key setting for public health nutrition [2], and school food outlets can play an important role in children's nutrition. Studies of Australian school canteens show energy-dense, nutrient-poor foods are the most commonly purchased items [3,4], despite the existence of interventions to encourage healthier choices [5-7]. Such interventions typically include supply-based approaches that target the relative availability of healthier foods. For example, the New South Wales (NSW) Healthy School Canteen Strategy (the NSW Strategy) requires that canteen menus have at least 75% *everyday* items (healthy foods consistent with the Australian Dietary Guidelines) and no *should not be sold* items (unhealthy items high in saturated fat, sugars, or salt) [8]. The NSW Strategy is mandatory in government schools and is strongly encouraged in nongovernment schools [8]. However, the impact of such supply-based interventions is highly variable due to less than optimal implementation [5-7,9,10].

The rise of web-based technology represents a unique opportunity to provide broader support to consumers to encourage healthy canteen purchases in schools using demand-based or consumer-focused approaches. In particular, choice architecture strategies [11], including menu labeling [12-16], prompts [17-19], and changing the position of food [20], have been shown to influence food choices in schools and other settings. Embedding these strategies within routinely used systems is appealing from a public health perspective as they provide the opportunity to reach many people simultaneously at low cost, require only minimal engagement, and are not reliant on the education or skills of the consumers [11].

We previously evaluated a choice architecture intervention delivered via an existing, routinely used web-based canteen ordering system in Australian schools. The pilot study, conducted in 10 NSW government primary schools, established that choice architecture strategies could be successfully embedded within a web-based canteen ordering system [21]. Web-based ordering allows parents and carers (hereafter *parents*) and students to view the school canteen menu and prepurchase items on the web. This cluster randomized controlled pilot trial found that a 2-month intervention, which incorporated menu labeling, positioning, prompting, and availability strategies, significantly increased healthy food purchases [21]. At follow-up, the lunch orders from the intervention schools contained less energy, saturated fat, and sodium than lunch orders from control schools (*P*<.001) [21]. However, the pilot study tested only a limited range of strategies within a small number of government schools for a short period. Furthermore, since the pilot, the NSW canteen guidelines have changed [22]. In 2017, the Fresh Tastes at School Strategy [22], which adopted a traffic light system to classify foods as *green*, *amber*, or *red* from most to least healthy, was replaced by the current NSW Healthy School Canteen Strategy [8], which was revised to align with the Australian Dietary Guidelines. The current NSW Strategy uses the national Health Star Rating front-of-pack labeling system and specific portion limits to classify foods as *everyday*, *occasional*, or *should not be sold* (*caution*). Schools were provided with support to help implement the guidelines, with the goal of complete implementation in NSW schools by 2019.

Objectives

This study seeks to extend the impact of the pilot by testing additional strategies in a changed policy context with schools from additional sectors (ie, Catholic and independent schools) for a longer period (approximately 12 months) to determine the broader utility of this novel approach in improving public health nutrition. This trial aims to assess the effectiveness of a multistrategy behavioral intervention embedded within an existing web-based canteen ordering system in reducing the energy, saturated fat, sugar, and sodium content of primary school students' web-based lunch orders.

Methods

Study Design

This study used a parallel-group, cohort, cluster randomized controlled trial (RCT) design and is reported according to the CONSORT (Consolidated Standards of Reporting Trials) extension for clustered RCTs. This trial was prospectively registered (ACTRN12618000855224) and approved by the University of Newcastle Human Research Ethics Committee (H-2017-0402) and the Catholic Education Office Dioceses of

Sydney, Parramatta, Lismore, Maitland-Newcastle, Bathurst, Canberra-Goulburn, Wagga Wagga, Wollongong, and Wilcannia-Forbes. Schools (clusters) with a web-based canteen ordering system were randomly assigned to either an intervention group (receiving choice architecture strategies embedded in the web-based systems, plus audit and feedback) or a control group (receiving the standard web-based canteen only), as it was not possible to randomize individuals. A detailed protocol has been published [23], which is summarized below.

Participant Recruitment

Participating Schools

Nongovernment (Catholic and independent) primary schools within NSW, Australia, were approached to participate by mail and telephone. Although it was originally intended that government schools would be included, extensive delays in obtaining ethical approval meant that these schools were excluded, as the timeframe of intervention exposure would have been too short to warrant inclusion. Although the NSW Healthy School Canteen Strategy is mandatory in government schools, all schools are strongly encouraged to adopt this strategy [8].

Recruitment took place from May to September 2018 (17 weeks).

Inclusion and Exclusion Criteria

Textbox 1 describes the inclusion and exclusion criteria.

Textbox 1. School, user, and order inclusion and exclusion criteria.

Inclusion Criteria

- Schools: schools were eligible if they used the Flexischools web-based canteen service and had done so for at least a month before recruitment. Flexischools is the largest provider of web-based canteen services in Australia, servicing more than 1200 schools and processing more than 13 million lunch orders per year [21].
- Users: students from kindergarten to grade 5 who placed a web-based lunch order in the baseline data collection period were included in the study.
- Orders: all new orders placed on a mobile device were included (typically representing approximately 70% of all orders). Orders placed on a desktop or where order modality could not be determined were excluded as users would not have been exposed to any of the intervention strategies.

Exclusion Criteria

- Schools
  - Externally licensed school canteens were excluded as these private operators often service multiple schools, increasing the risk of intervention contamination. However, two recruited canteens that were not initially identified as being externally licensed were retained, as they did not service any other school within the sample.
  - Combined primary and secondary schools were ineligible unless they had separate menus for primary and secondary students, as the New South Wales Strategy is applied differently across these age groups.
- Users: grade 6 and grade 5 and 6 composite students were excluded from the baseline as they would have moved on to secondary school during the follow-up period. School staff members were excluded.
- Orders: the baseline and follow-up periods were intended to run for the 10-week school term. However, orders from 2 weeks of the baseline term were excluded as the order mode (mobile vs desktop) could not be determined because of a software update. The follow-up data collection period was subsequently reduced to 8 weeks to match the baseline. Recurring orders placed before the intervention period and orders from special food days were excluded, as users would not have been exposed to the intervention strategies. Lunch orders with an implausible number of items (ie, 15 or more) were excluded based on consensus from research dietitians with extensive canteen experience.

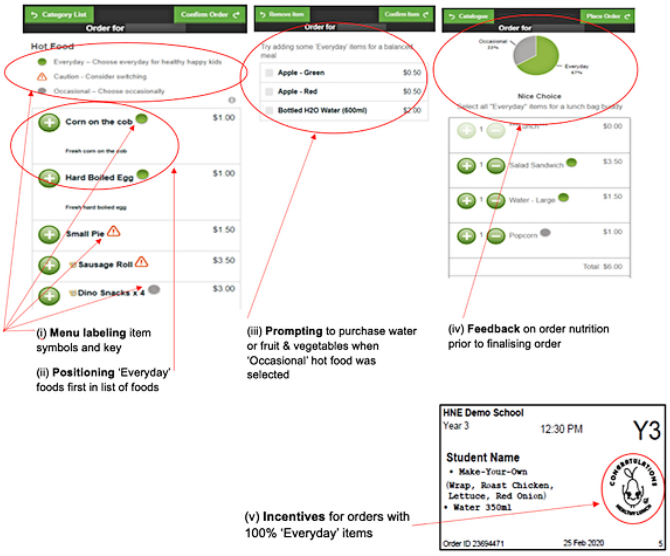
Intervention

Overview

A multistrategy behavioral intervention targeting users of the web-based system was implemented by modifying the interface of the Flexischools web-based ordering system. The intervention (Figure 1) is fully described in the published protocol [23] and incorporated choice architecture strategies [11], including the following:

- Menu labeling: a colored symbol denoting *everyday*, *occasional*, or *caution* (also referred to as *should not be sold*) items based on the NSW Healthy Canteen Strategy was added next to each menu item along with a key explaining each of the symbols.
- Positioning: menu items and categories were arranged to make healthier *everyday* options more prominent (ie, positioned first within the list of menu items), and where there were multiple flavors of an *occasional* or *caution* item, users were required to *click* on the category before the full list of flavors was displayed in a separate pop-up box.
- Prompting: an appealing image and brief text prompt were placed next to all healthy categories. When users selected an *occasional* or *caution* hot food item, they received a prompt to purchase water and a piece of fruit or vegetable (*healthy add-ons*).
- Feedback: before finalizing and paying for their lunch order, the user was shown a pie graph with tailored feedback based on the proportion of *everyday* items in the order.
- Incentives: orders that contained 100% *everyday* items had a cartoon character and congratulatory text printed on the lunch label, which was printed out and stuck on the paper bag in which the lunch order was delivered to students.

Figure 1. Screenshot of the Click & Crunch intervention.



Canteen Supportive Strategies

An audit and feedback report were emailed to canteen managers and principals, classifying each menu item as per the NSW Strategy (ie, *everyday* or *occasional*) and providing general information about pricing items to encourage healthy purchases [6].

Control

Control schools received no change to their web-based canteen menu and no audit or feedback reports. However, NSW Local Health Districts support all schools to use the Menu Check Service—a free service that reviews canteen menus against the NSW Strategy and provides feedback to schools.

Outcomes and Measures

Overview

Student purchasing data automatically collected by the Flexischools system was used as the basis for evaluation. Data were collected simultaneously for all schools, for two 8-week periods, 12 months apart (term 2, 2018, and term 2, 2019). Baseline data were retrospectively collected.

Primary Outcomes

The primary outcomes were the mean lunch order content of energy (kg), saturated fat (g), sugar (g), and sodium (mg). For prepackaged foods, this was based on a blinded dietitian's assessment using a series of sources in the following order: (1) a database containing more than 2000 commonly stocked canteen products developed by canteen researchers for the past 5 years, (2) the *Healthy Food Finder* database (NSW Government) [24], (3) the *FoodSwitch* website (The George Institute for Global Health) [25], and (4) a web search for the nutrient information panel. For canteen-prepared food, the recipe was obtained from the canteen manager and analyzed using *FoodWorks 9 Professional* nutrition analysis software (Xyris Software) [26].

Secondary Outcomes

Healthier Purchasing

The proportion of all web-based lunch order items that were *everyday*, *occasional*, and *caution* was calculated by a dietitian using the criteria underpinning the NSW Strategy; the mean proportion of energy within lunch orders that was derived from saturated fat and sugar was also calculated based on 37 kJ/g of fat and 17 kJ/g of sugar [27].

Canteen Revenue (Adverse Outcome)

Purchasing data that were automatically collected by the web-based system were used to calculate mean weekly canteen revenue.

Canteen Characteristics

At the end of the follow-up period, a telephone interview with canteen managers was conducted to collect information regarding canteen operations (eg, principal operated; parent and citizen operated; or externally licensed—privately operated), type of manager (eg, paid or volunteer manager), the days of operation, and the usual number of web-based orders per week.

Process Measures

Change in Availability

The proportion of schools with canteen menus meeting the NSW Strategy was calculated at baseline and follow-up based on dietitian menu assessment.

Change in Pricing

The average price of *everyday*, *occasional*, and *caution* items was calculated at baseline and follow-up based on each school's web-based menu.

Intervention Acceptability

During the telephone interview, canteen managers were asked to rate the acceptability of the intervention (eg, individual strategies and the intervention overall) using a Likert scale (Multimedia Appendix 1).

Additional Support Received

To determine the potential impact of canteen managers making changes to their menu, they were also asked about any additional support they had received during the 12-month intervention period.

School Characteristics

School characteristics were obtained from a national website [28]. The following information was extracted: the number of student enrolments, the proportion of Aboriginal and Torres Strait Islander enrolment, and the school postcode.

User Characteristics

User characteristics were derived from automatically collected data within the Flexischools system. *Student class* (eg, 3F) contains student grade (eg, Grade 3) and is a required field entered by the parents at system registration, and the frequency of use was based on a count of all orders placed by a student within the baseline data collection period and an average per week was calculated.

Randomization and Blinding

Following the provision of principal (cluster) consent, and after the completion of the baseline menu assessment, an independent statistician used Microsoft Excel to randomize schools to an intervention or control group in a 1:1 ratio, using block randomization with block size between 2 and 4. Randomization was stratified by school sector (ie, independent schools and Catholic schools) and socioeconomic status based on school postcode using Socioeconomic Indexes for Areas (SEIFA) [29]. Due to the difficulty in blinding participants, this was run as an open trial.

Fidelity and Data Quality

During each school term for the duration of the intervention, a research assistant checked the web-based menus to ensure that the menu labels were correctly applied and recorded whether other intervention strategies were present or absent. An exception was the incentive strategy, which, being printed on lunch labels, was not verifiable by checking the web-based menu. Canteen visits were conducted in 6 schools (including 3 intervention schools) to verify the automatically collected purchasing data against the orders received and distributed by the canteens.

Sample Size

Recruitment of 26 schools and 194 students per school (allowing for 86% follow-up and 70% of orders placed using a mobile device) would allow detection of a between-group difference of 195 kJ per average lunch order, assuming an intraclass correlation coefficient of 0.05, with 80% power, and a significance level of $P<.0125$ (Holm-Bonferroni adjusted for the four primary outcomes).

Analysis

An intention-to-treat approach was adopted, whereby all student orders and schools were analyzed based on the groups to which they were originally allocated and included data from all students who had baseline purchasing data. To adjust for multiple outcomes, $P<.0125$ was adopted as the prespecified level of significance.

Primary Outcomes

Each primary trial outcome was assessed using a separate linear mixed model. The nutritional content (ie, energy, saturated fat, sugar, and sodium) of all web-based lunch orders placed by students was compared between the intervention and control groups throughout time by including a group-by-time interaction fixed effect. All models included a random intercept for school (to account for potential school-level clustering), a nested random intercept and random time effect for students (to account for repeated measurements between and within baseline and follow-up), and fixed effects for the school sector and SEIFA.

Secondary Outcomes

Healthier purchasing outcomes (ie, *everyday*, *occasional*, and *caution*) were assessed using separate logistic mixed models. To assess whether there was a significant change in the purchase of *everyday*, *occasional*, and *caution* items between groups, three separate logistic regressions were used (ie, items that are *everyday* vs items that are not *everyday*), including a group-by-time interaction fixed effect. As with the primary outcomes, all models included a random intercept for school (to account for potential school-level clustering), a nested random intercept and random time effect for students (to account for repeated measurements between and within time points), and fixed effects for the school sector and SEIFA. Differences in the proportion of energy derived from saturated fat and sugar within each order and differences in average weekly revenue were assessed according to the primary outcomes.

Per-Protocol Analysis

A per-protocol analysis was conducted to determine the effect on energy content (kJ) and proportion of *everyday* foods when the intervention was applied in full. Schools were included if they had >80% of verifiable strategies correctly applied at follow-up and if the incentive strategy was reported as present in the canteen manager survey. Prespecified subgroup analyses were conducted based on energy content (kJ), student grade (kindergarten-grade 2 vs grade 3-5), school sector (Catholic vs independent), and order frequency (*low* <1 order/week on average vs *high* ≥1 order/week on average) by adding a three-way interaction fixed effect (group-by-time-by-subgroup). The following assumptions underpin the prespecified subgroup analyses: (1) parents may have more control over the lunch orders of younger students and may be more influenced by the intervention, leading to healthier purchasing for younger students. (2) There may be differences in the implementation of the NSW Healthy Schools Canteen Strategy between the school sectors (Catholic vs independent), which may have influenced the menu composition, and therefore the ability of the intervention to have an effect. (3) Users who ordered less frequently may consider canteen lunch orders to be more of a *treat* purchase rather than part of their usual diet and therefore be less influenced by the intervention strategies.

Statistical analyses were performed using the SAS version 9.3 (SAS Institute).

Results

Overview

The CONSORT diagram (Figure 2) shows the number of schools and students participating in the trial. After 17 weeks of recruitment, 40% (17/43) of eligible schools had consented, 33% (14/43) had refused, and 28% (12/43) were undecided. In total, 9 schools were randomized to the intervention group, and 8 schools were randomized to the control group. None of the schools dropped out of the study. Four *combined* schools that enrolled kindergarten to grade 12 students were included in the sample (3 intervention schools and 1 control school).

Only four orders, representing <0.01% of all orders, were excluded because they were implausibly large. The characteristics of participating schools and students are described in Tables 1 and 2. Intervention schools had approximately 30% higher student enrolments than control schools (no significance testing) [30], and as such, the average number of web-based lunch orders per week was higher in intervention schools.

[a]Frequency of use based on baseline purchasing characteristics.

[b]Orders ≥8 during the 8-week baseline data collection period.

Primary Outcomes

Overview

The linear mixed model analysis indicated that the between-group differences throughout time for the intervention group were as follows: −69.4 kJ energy (95% CI −119.6 to −19.1; *P*=.01), −0.6 g saturated fat (95% CI −0.9 to −0.4; *P*<.001), −32.1 mg sodium (95% CI −56.3 to −7.9; *P*=.013), and +0.4 g sugar (95% CI −0.7 to 1.5; *P*=.47). The differences in energy and saturated fat were statistically significant at the prespecified level of *P*<.0125, and sodium was borderline (Table 3).

Table 3. Primary and secondary outcomes in intervention and control groups from baseline to follow-up for 2207 student participants (linear mixed model analysis).

Variable	Baseline, mean (SD)		Follow-up, mean (SD)		Intervention versus control[a]			
	Intervention (N=1359 children; N=9726 orders; N=23,526 items)	Control (N=848 children; N=6279 orders; N=14,124 items)	Intervention (N=1108 children; N=9434 orders; N=22,061 items)	Control (N=691 children; N=6334 orders; N=14,087 items)	Main analysis		Per-protocol analysis

[a]Data were analyzed using separate linear mixed models adjusted for Socioeconomic Indexes for Areas, the school sector, and clustering at the school and student levels.

[b]Baseline intraclass correlation coefficient values: energy 0.100; saturated fat 0.130; sugar 0.131; sodium 0.111.

[c]Italics indicate statistical significance *P*<.0125.

[d]Baseline intraclass correlation coefficient values: percentage energy from sugar 0.104; percentage of energy from saturated fat 0.117.

Per-Protocol Analysis

In total, 4 schools partially implemented the intervention, with 3 schools not implementing the healthy add-ons strategy (see the section *Fidelity Checks*), and 4 schools where it could not be confirmed that the incentive strategy was delivered. The per-protocol analysis of the 5 intervention schools that implemented the intervention in full, relative to control schools, showed larger significant effects for three of the four primary outcomes (−89.4 kJ energy, *P*=.007; −0.7 g of saturated fat, *P*<.001; Table 3).

Secondary Outcomes

Healthier Purchasing

From baseline to follow-up, relative to control schools, intervention schools had greater odds of having *everyday* items purchased (odds ratio [OR] 1.69, 95% CI 1.46-1.96; *P*<.001) corresponding to a 9.77% increase in *everyday* items, and lower odds of having *occasional* items purchased (OR 0.67, 95% CI 0.57-0.78; *P*<.001) corresponding to a 7.69% decrease in *occasional* items (Table 4). The decrease in *caution* items was not significant at the prespecified significance level (OR 0.82,

95% CI 0.68-1.00; *P*=.05). The per-protocol analysis revealed that the intervention effect and significance remained similar for both *everyday* (OR 1.50, 95% CI 1.27-1.78; *P*<.001) and *occasional* (OR 0.70, 95% CI 0.59-0.84; *P*=.001) items. There were very small between-group differences in the percentage of energy from saturated fat (−0.9%, 95% CI −1.4% to −0.5%; *P*<.001) and percentage of energy from sugar (+1.1%, 95% CI 0.2%-1.9%; *P*=.02) with the result for energy significant in the main analysis, and both energy and sugar significant in the per-protocol analysis (Table 3).

Table 4. Secondary outcomes in intervention and control groups from baseline to follow-up (logistic mixed model analysis; analysis of 73,798 items purchased)[a].

Classification[b]	Baseline, n (%)		Follow-up, n (%)		Main analysis		Per-protocol analysis	
	Intervention (n=23,526)	Control (n=14,124)	Intervention (n=22,061)	Control (n=14,087)	Relative odds ratio (95% CI)	*P* value	Relative odds ratio (95% CI)	*P* value
Everyday[c]	7423 (31.55)	5711 (40.43)	8518 (38.61)	5276 (37.45)	1.69 (1.46-1.96)	*<.001*[d]	1.50 (1.27-1.78)	*<.001*
Occasional[c]	11,261 (47.87)	6185 (43.79)	9943 (45.07)	6821 (48.42)	0.67 (0.57-0.78)	*<.001*	0.70 (0.59-0.84)	*.001*
Caution[c]	4842 (20.58)	2228 (15.77)	3600 (16.32)	1990 (14.13)	0.82 (0.68-1.00)	.05	0.92 (0.74-1.14)	.39

[a]Separate logistic mixed models were used, which included a random intercept for school (to account for potential school-level clustering), a nested random intercept and random time effect for students (to account for repeated measurements between and within time points), and fixed effects for sector and Socioeconomic Indexes for Areas. Variables were dichotomized (eg, *everyday* vs other items).

[b]Baseline intraclass correlation coefficient values: percentage of *everyday* foods 0.07; percentage of *occasional* foods 0.135; percentage of *caution* foods 0.231.

[c]Chicken nuggets are commonly sold in multiple units. Some schools prepackage them (ie, 1 serve=6 nuggets), whereas other schools allow any quantity to be purchased. To account for this difference, this analysis counted the number of nuggets purchased by a single child at 1 purchasing occasion as a single item.

[d]Italics indicate statistical significance *P*<.0125.

Revenue

There was no between-group difference in the average weekly revenue from web-based canteen purchases over time (*P*=.36; Table 3).

Subgroup Analysis

There were no differences in intervention effectiveness with respect to energy content across student grade, school sector, or frequency of order (Table 5).

Table 5. Intervention impact on mean energy content (kJ) of lunch orders from baseline to follow-up: subgroup analysis for 2207 student participants.

Variable	Baseline, mean (SD)		Follow-up, mean (SD)		Intervention versus control[a]			
	Intervention (n=9726 orders)	Control (n=6279 orders)	Intervention (n=9434 orders)	Control (n=6334 orders)	Group-by-time differential effect (95% CI)	*P* value	Group-by-time-by-subgroup differential effect (95% CI)	*P* value
Student grade

Process Measures

Change in Availability

At baseline, no intervention schools and 1 control school had menus consistent with the NSW Strategy, and at follow-up, this had changed to 1 intervention school and zero control schools. The proportion of *everyday*, *occasional*, and *caution* menu items was similar between intervention and control menus at both baseline (489/858, 56.9% and 406/694, 58.5% *everyday* items; 138/858, 16.1% and 107/694, 15.4% *occasional* items; 231/858, 26.9% and 181/694, 26.1% *caution* items, respectively) and follow-up (554/876, 63.2% and 424/703, 60.3% *everyday* items; 150/876, 17.1% and 121/703, 17.2% *occasional* items; 172/876, 19.6% and 158/703, 22.5% *caution* items, respectively).

Change in Pricing

There was no between-group difference throughout time in the average price of *everyday* (*P*=.54), *occasional* (*P*=.92), or *caution* (*P*=.66) items.

Intervention Acceptability

All intervention canteen managers who completed the interview (7/9, 78%) were satisfied and would recommend the intervention to other canteen managers. Almost all agreed that the intervention strategies were acceptable (6/7, 86%; range 6/7, 86% to 7/7, 100%; Multimedia Appendix 1).

Additional Support Received

Of the 15 schools (7 intervention and 8 control schools) that completed the interview, 71% (5/7) of intervention schools and 38% (3/8) of control schools reported using the Menu Check Service during the 12-month intervention period. All intervention schools (7/7, 100%) and 75% (6/8) of the control schools reported receiving other menu support.

Fidelity Checks

Menu labeling was the basis for all automated strategies (ie, positioning, provision of tailored feedback, and incentives). As such, verifying that the labels were correctly applied indicated that these other strategies were implemented as intended. The proportions of correct labels across all 9 intervention schools were 93.6% (673/719), 94.3% (666/706), 93.4% (657/703), and 95.3% (696/730) for each of the 4 fidelity checks. There were initial issues with applying the *healthy add-ons* strategy, whereby users were overcharged for add-ons when the chosen menu item was ordered in multiples. This strategy was removed from all intervention menus for items commonly ordered in multiples (ie, chicken nuggets). In addition, this strategy caused changes to the usual layout of the production lists that could be used by managers to make up the orders. As a result, 3 intervention schools requested that the *healthy add-ons* strategy be turned off, and 5 of 9 intervention canteen managers verified that incentives were printed on lunch labels of orders with all *everyday* items.

Data Quality

In 6 schools, the purchasing data from the provider (Flexischools) was validated against observed data collected from within the school canteen during school visits. There was a 95.8% (767/800) agreement between the data sources.

Discussion

Principal Findings

This trial investigated the effect of *Click & Crunch* on the nutritional quality of students' web-based lunch orders. Intervention orders had significantly lower energy and saturated fat content relative to controls, but there was no significant difference in sugar or sodium content. Encouragingly, there was no impact on canteen revenue, suggesting no adverse intervention effect in this regard. Intervention schools had significantly greater odds of having *everyday* items purchased and lower odds of having *occasional* items purchased, corresponding to a 9.8% increase in *everyday* items and a 7.7% decrease in *occasional* items, respectively.

There was no significant difference in the odds of having *caution* items purchased between groups throughout time. The fact that all foods are classified into one of three categories means that the significant increase in *everyday* foods must happen at the cost of a decrease in other foods. In this case, the decrease is split into a reduction in the other two categories. The point estimates reflect this decrease, but only the reduction in *occasional* foods was significant, given it is the more common option, whereas the reduction in *caution* foods was not significant, given that it is the rarer option and hence there is less power to detect this effect.

Very few studies have tested the effect of delivering nudge strategies via web-based food ordering systems. In a cluster RCT conducted with 4th-7th grade students from a US school, nudge strategies delivered via a web-based ordering system led to a higher selection of fruit, vegetables, or low-fat milk in lunch orders compared with controls receiving no nudge [31]. However, the study was conducted in a single school with only a 2-week follow-up period. A nonrandomized trial of traffic light nutrition labels applied to 53 products across five food categories within a web-based supermarket found no difference in sales in a 10-week period relative to the comparison store [32]. However, a trial of web-based nudging by providing default orders resulted in a higher purchase of whole grains, fruits, and vegetables among 50 participants from New York food pantries, relative to those receiving brief nutrition education before ordering [33].

The patterns of results for this trial are similar to those of the pilot trial, which found significant reductions in the average energy, saturated fat, and sodium content of intervention lunch orders, and an increase in the proportion of healthy items ordered in the 2-month period immediately after the intervention strategies were switched on [21]. However, the effect sizes in the pilot (ie, −572 kJ between-group difference; 22% increase in *healthy* purchases) were larger than in this trial. Methodological differences between the pilot and this trial may account for the apparent differences in effect sizes. Specifically, the pilot trial was conducted for a much shorter period (2-month vs 12-month follow-up) within government schools, using different classifications (*Fresh Tastes @ School*) [22] and a different labeling system (traffic light symbols). Nonetheless, although modest, the effect on the primary outcomes may be meaningful at the population level and should be considered in light of the potential intervention reach. In NSW, 95% of primary schoolchildren access a canteen, with 55% ordering at least weekly and 4% ordering 3 to 5 times a week [34]. As such, many students could potentially benefit from intervention if disseminated broadly through the school system.

This study planned to include 26 schools. Although ethical approval was eventually obtained for government school participation, the differences in the time of exposure to the intervention between the government and nongovernment schools would have been too great to include in this 12-month trial. As such, the final sample included only 17 schools, reducing the precision of the detected effect estimates. Nonetheless, the trial was still able to detect small differences in primary trial outcomes as significant. In total, 14 schools did not consent to participate and 12 were undecided. As the principal was required to provide consent for this canteen-based intervention, it is recommended that future studies evaluate intervention acceptability with a range of stakeholders, including school principals.

Limitations

Although the intervention and control schools were broadly similar (no significance testing was conducted) [30], intervention schools had higher enrolments and more lunch orders at baseline. However, factors that are more closely related to the healthiness of student orders (eg, proportion and price of healthy foods available) were similar between groups. The research team did not have any access to individual demographic characteristics beyond student grade, and future research should seek to collect more information regarding user sociodemographic characteristics to allow an analysis of whether the intervention was more effective in certain subgroups. No data were collected from intervention end users regarding intervention acceptability, and findings regarding canteen manager acceptability were based on only 7 participants. The delay in ethics approval meant that the intervention duration varied from 8 to 10.5 months and that government schools were excluded. Previous research demonstrated no differences between government and nongovernment schools in terms of awareness of or current use of web-based canteens [35]. However, there may be differences among school sectors in terms of compliance with the NSW Strategy, which may affect the relative healthiness of canteen menus (ie, the proportion of *caution* foods vs *everyday* foods). Compliance with the strategy may influence the ability of the intervention to have an effect, in that a school compliant with the guidelines at baseline will have less room to show an improvement (ie, a *ceiling effect*). As such, future research with a larger sample of schools should investigate whether there are differences in intervention effectiveness among school sectors and investigate the relationship with strategy compliance. Finally, our analysis is based on purchasing data and not consumption data. However, objectively recorded purchasing data can provide a reasonably accurate estimate of diet quality [36,37].

The strengths of this trial include a rigorous clustered randomized controlled design. The evaluation of the intervention was based on purchasing data automatically collected by the web-based system for more than 2200 students and verified

through in-school observations. The nutritional information extracted from the purchasing data was based on rigorous menu assessment, independently verified by 2 dietitians, and based on established nutrition databases. The 12-month follow-up is also a study strength and addresses the limitations of previous trials involving web-based school lunch ordering systems [21,31,38].

Conclusions

The *Click & Crunch* intervention evaluated in this cluster RCT used existing web-based canteen ordering systems to implement choice architecture strategies to encourage healthier lunch orders for primary school students. Given the evidence of its effectiveness in decreasing the energy content of student lunch orders and increasing the purchase of *everyday* foods, its acceptability among canteen managers, and its wide reach, this intervention has the potential to influence dietary choices at a population level. The intervention may be a useful addition to the suite of strategies available to policymakers to improve child diet, including supply-side interventions encouraging the increased availability of healthier food options and interventions in nonschool settings, including after-school activities, sporting clubs, and the home. Additional research is required to determine if the results are consistent across all school sectors and sustained for a longer period and to determine intervention cost-effectiveness before investigating intervention impact in primary schools when implemented at scale.

Acknowledgments

The authors would like to thank Flexischools, the Research Advisory Group, and the participating schools, canteen managers, and canteen users. The food composition data available on the Healthy Food Finder were provided by SP Health Co Pty Ltd, trading as *Digital Wellness* (Australian Business Number 73 123 248 046) in collaboration with the NSW Ministry of Health. The data sets generated and analyzed during this study are available from the corresponding author on reasonable request and pending ethics approval. This work was supported by the National Health and Medical Research Council (NHMRC; grant number APP1120233). In-kind support was provided by the Hunter New England Population Health and the Hunter Medical Research Institute. RW is supported by a Heart Foundation Postdoctoral fellowship (ID: 102156). LW receives salary support from an NHMRC Career Development fellowship (ID: APP1128348) and Heart Foundation Future Leader fellowship (ID: 101175). Neither the NHMRC nor the Heart Foundation had any role in the design of the study, data collection, analysis or interpretation, or dissemination of findings. The provider (Flexischools) was selected through a competitive tender process. Flexischools is a commercial organization that provided the web-based canteen ordering infrastructure to schools included in the study. Flexischools had no role in the study design, data analysis, data interpretation, or manuscript writing.

Authors' Contributions

RW conceived the study; RW, LW, KC, KB, JW, CR, and TD developed the overall research plan; RW, LW, SY, NN, RS, and KR provided study oversight; RW, TD, RZ, HL, LW, and FS conducted the research; CL, FGS, and TD analyzed data; JA, CO, and CL provided statistical advice; RW led the writing of the paper with all authors contributing to paper revisions. RW has primary responsibility for the final content.

Abstract

Background: The COVID-19 outbreak has spurred increasing anti-Asian racism and xenophobia in the United States, which might be detrimental to the psychological well-being of Asian people living in the United States.

Objective: We studied three discrimination-related variables, including (1) experience of discrimination, (2) worry about discrimination, and (3) racism-related social media use during the COVID-19 pandemic among Asians in the United States. We examined how these three variables were related to depression, and how the association between racism-related social media use and depression was moderated by personal experience of and worry about racial discrimination.

Methods: A web-based, cross-sectional survey was conducted. A total of 209 people (mean age 33.69, SD 11.31 years; 96/209, 45.93% female) who identified themselves as Asian and resided in the United States were included in the study.

Results: Experience of discrimination (β=.33, *P*=.001) and racism-related social media use (β=.14, *P*=.045) were positively associated with depressive symptoms. Worry about discrimination (β=.13, *P*=.14) was not associated with depression. Worry about discrimination moderated the relationship between racism-related social media use and depression (β=–.25, *P*=.003) such that a positive relationship was observed among those who had low and medium levels of worry.

Conclusions: The present study provided preliminary evidence that experience of discrimination during the COVID-19 pandemic was a risk factor of depressive symptoms among Asian people in the United States. Meanwhile, racism-related social media use was found to be negatively associated with the well-being of US Asians, and the relationship between social media use and depression was significantly moderated by worry about discrimination. It is critical to develop accessible programs to help US Asians cope with racial discrimination both in real lives and on social media during this unprecedented health crisis, especially among those who have not been mentally prepared for such challenges.

KEYWORDS

racial discrimination; experience of discrimination; worry about discrimination; depression; social media use; COVID-19

Introduction

Since the COVID-19 outbreak, anti-Asian racism and xenophobia has been spurred in the United States, and violent attacks against people who appear to be Asian have been documented [1,2]. The growing discrimination against the Asian community, combined with multifaceted pressures from the COVID-19 crisis, can make Asian people more vulnerable to

mental health problems. Recent work has provided insights into the deteriorating impact of COVID-fueled discrimination on Asians' mental health conditions [3,4], but it leaves two important gaps. First, Asians were more likely to use social media for COVID-19–related information than other media sources, thereby amplifying the possibility to encounter discrimination-related news reports or personal narratives [5,6]. However, there has not been sufficient attention toward how using social media to read, post, and talk about discrimination and racism associated with COVID-19 would relate to Asians' well-being. Second, worry emerges as a common emotional response among these individuals after having directly experienced discrimination and/or reading about personal stories shared on social platforms. Worry could negatively influence one's mental health, depending on the levels of exposure to racial discrimination. More empirical research is needed to fully explore these contributing factors to mental health outcomes, as Asian ethnic groups face lingering metal health consequences from the COVID-19 pandemic.

In an attempt to empirically examine the psychological consequences of racial discrimination associated with the COVID-19 outbreak among Asian people in the United States, we looked into three factors related to discrimination during this period and examined their associations with depressive symptoms among US Asians. These factors included: (1) experience of discrimination, (2) worry about discrimination, and (3) racism-related social media use during the COVID-19 outbreak. We also investigated whether the relationship between social media use and depression was contingent upon one's experience of and worry about discrimination.

Racial discrimination is defined as a phenomenon wherein people are unfairly treated or disadvantaged because of their race or phenotypic difference [7]. This could occur in interpersonal interactions, at the workplace, in education settings, or in receiving services and justice [8]. In some worse cases, racial discrimination could take forms of hate crimes or physical attacks [9]. It is not a new phenomenon that the outbreak of an infectious disease could trigger discrimination against racial and ethnic minorities [10]. Several recent studies have documented the salient evidence that Asians in the United States have encountered increasing levels of racial discrimination since the COVID-19 outbreak [11,12].

A huge amount of research has provided empirical evidence that racial discrimination can have negative impacts on the well-being of the stigmatized [13-15]. Racial discrimination can likely damage well-being through the process where one feels being rejected or excluded by the society and thus finds it harder to take control of their lives [16]. The above-described findings were also applicable to the Asian population in the United States. [17-19]. Recent studies have found that racial discrimination against Asian people is negatively associated with psychological well-being among this group during the COVID-19 outbreak [20,21]. One study found that direct experiences of racial discrimination during this period were associated with higher levels of anxiety and depressive symptoms among Chinese American parents and youth [20]. Another study found that vicarious racism, defined as indirect experiences of discrimination experienced by hearing about or seeing racist acts against other members of one's racial group, was also associated with higher levels of depression and anxiety among Asian Americans [21].

Current conceptualizations of racial discrimination vary across literatures, but almost all attempt to measure it in a subjective way, asking about the perception of racial discrimination in cognitive, affective, and behavioral domains [22]. Some scholars explain that it is because most incidents of discrimination are subtle and hard to document [23]. Importantly, scholars have pointed out the necessity to differentiate two related but distinct constructs of perceived racial discrimination: one is the perception of discrimination actually encountered by oneself and the other is the general worry about the fact that oneself could be a potential target of racial discrimination in the future [24]. It is worthwhile to examine the two constructs' unique relationship with depression, as previous literature suggested that the two might have different psychological implications. Although experienced discrimination was consistently associated with poor well-being [20,21], the role of worry seemed less conclusive. Worry is a normal mental reaction to impending events in our lives, and it only poses a threat when it becomes persistent and less controllable [25,26]. Under some situations, it can be instrumental by motivating people to cope, to conduct more analytical thinking, and to take more goal-oriented actions [27,28]. In the current study, we included both direct experience of discrimination during the COVID-19 outbreak among our study participants, as well as their worry about being discriminated. Together, we proposed the following hypothesis and research questions:

- Hypothesis 1 (H1): Experience of discrimination would be positively associated with depression among US Asians during the COVID-19 outbreak.
- Research question (RQ) 1: How would worry about discrimination be associated with depression among US Asians during the COVID-19 outbreak?

In addition to the experience of and worry about discrimination, social media also plays a role in US Asians' psychological well-being during the COVID-19 pandemic [19]. During the pandemic, racism-related content has become more visible on social media. A study found a nearly 10-fold increase of tweets containing "Chinese virus" or "China virus" in the week after former US President Trump mentioned this term on March 16, 2020, compared to the tweets in the week prior [29]. The sentiment analysis of these tweets suggested that the majority contained negative emotions, such as fear, sadness, anger, and disgust [29]. Another study also analyzed the sentiment of race-related tweets before and following the emergence of COVID-19 and found that the proportion of negative tweets referencing Asians increased by 68.4% from November 2019 to March 2020 [30].

Social media use during this period can thus expose Asian users to greater risk for mental health concerns. Incidental and frequent encounter with racist posts on social media might make racism-related information in memory particularly accessible, leading to a perceived social reality where being Asian is unsafe and devalued [31]. A study showed that social media exposure to COVID-related information was associated with higher odds

of anxiety and depression among the public in China during the COVID-19 outbreak, after controlling for various demographic factors [32]. The authors attributed the findings to misinformation on social media and users' risk perception of contracting COVID-19. Although the interpretation is reasonable, for US Asians, engagement with COVID-19–related information on social media, which commonly included anti-Asian sentiments [29,30], may trigger another layer of fear—fear for becoming the target of discrimination or victimization [33]. Nevertheless, to our knowledge, no research has been conducted on how reading, posting, and talking about COVID-19–related racism on social media would relate to US Asians' mental health. To bridge the gap, we proposed the following hypothesis:

- Hypothesis 2 (H2): Racism-related social media use would be positively related to depression among US Asians during the COVID-19 outbreak.

Finally, this study attempted to examine how the association between racism-related social media use and depression would be moderated by personal experience of and worry about discrimination. As posited in cultivation theory [34,35], the effect of media exposure on personal opinions and feelings would be moderated by personal experiences. They further proposed that the moderation effect could go in two different directions, which were defined as the mainstream effect (ie, people would be more influenced if they have limited experiences of the media content) and the resonance effect (ie, people would be more influenced if they have more experiences of the media content).

The vulnerability-stress model also argues that the extent to which a stressful event could trigger a mental disorder would depend on an individual's vulnerability, which could be psychological, biological, or situational factors [36]. We considered depression as the result of the interaction between worry about discrimination and racism-related social media use. As mentioned above, worry is an emotional reaction to future uncertainties, which could play a positive role in problem-solving in some situations [27,28]. In our case, worry might buffer the influence of racism-related social media use on depression by motivating people to solve the problem. Meanwhile, it is also possible for worry to play a negative role in such relationships if it does not direct people to take positive actions. As the moderating roles of discrimination-related experience and worry remained unclear, we proposed the following two additional research questions:

- RQ2: How would the experience of discrimination moderate the relationship between social media use and depression among US Asians during the COVID-19 outbreak?
- RQ3: How would worry about discrimination moderate the relationship between social media use and depression among US Asians during the COVID-19 outbreak?

Methods

Procedures

A web-based, cross-sectional survey approved by the institutional review board was first created on Qualtrics and then distributed to qualified participants via Amazon Mechanical Turk (MTurk) in mid-May 2020. Eligible participants included those belonging to Asian ethnic groups and residing in the United States. The first page of the questionnaire was a consent form providing the participants with brief background on the study and information about anonymity, confidentiality, and compensation. The rest of the pages asked questions about demographic information, media usage, discrimination-related experiences and perceptions during the COVID-19 outbreak, and some psychological measurements. Attention checkers were included to ensure data quality. The survey took an average of 15 minutes to complete.

Participants

We recruited 242 eligible participants who were Asians residing in the United States, and a total of 209 participants were included in this study after using a listwise deletion approach (ie, those who answered "not sure" or "prefer not to answer" in any questions were coded as having a missing value and were excluded from the analyses). To determine if we achieved the needed sample size for our regression analyses, an a priori sample size calculator for multiple regressions was used. The result showed that, with the anticipated medium effect size set at 0.15, the statistical power level set at 0.80, and the significance level set at P=.05, the minimum sample size required for the current study was 131. Thus, we had reached the sample size requirement in this study.

The participants were between the ages of 18 and 73 years (mean 33.69, SD 11.31 years). Among them, 96 (45.93%) were female and 113 (54.07%) were male participants. Most participants were either single (n=105, 50.24%) or married (n=97, 46.41%). The majority of the participants had a bachelor's degree (n=106, 50.72%), with the remaining holding a degree below (n=50, 23.92%) or above the bachelor's level (n=53, 25.36%). About half of the participants (n=97, 46.41%) has a full-time employment. The income levels were relatively evenly distributed among participants, but more than half of the participants (n=115, 55.02%) reported that their income had somehow been affected by the COVID-19 pandemic. Meanwhile, most participants did not identify themselves as Chinese (n=135, 64.59%). Table 1 presents demographic information of the sample.

Table 1. Descriptive analysis of the sample (N=209).

Variables	Respondents, n (%)
Age in years (range: 18-73 years)

Variables	Respondents, n (%)
Yes	74 (35.41)
No	135 (64.59)

Measurements

Experience of Discrimination

The 5-item Everyday Discrimination Scale [37] was adapted to measure how often the respondents had experienced discrimination since the COVID-19 outbreak. The scale ranged from 1 ("never") to 5 ("a lot"). The five items were as follows: (1) "You are treated with less courtesy or respect than other people"; (2) "You receive poorer service than other people"; (3) "People will act as if they think you are dangerous"; (4) "People act as if they are afraid of you"; (5) "You are threatened or harassed." The item "People act as if they think you are not smart" from the original scale was changed as "People act as if you are dangerous" to better indicate the common bias against Asians during the COVID-19 pandemic. Cronbach α for this scale was .94 (mean score 9.60, SD 4.78).

Worry About Discrimination

Participants were also asked to rate the extent to which they worry about the listed things in Everyday Discrimination Scale [37]. The items were changed to future tense since worry tends to be an emotion related to things that may happen in the future. Cronbach α for this scale was .96 (mean score 12.96, SD 5.91).

Racism-Related Social Media Use

We created a 4-item scale to measure the extent to which the participants used social media to read, post, and talk about racism-related information associated with COVID-19 since the outbreak of the pandemic. The 4 items on this scale were as follows: (1) "On social media, how much do you pay attention to and read about racism related to COVID-19?" (2) "On social media, how much do you post or repost information and news about racism related to COVID-19?" (3) "On social media, how much do you discuss racism related to COVID-19 with others through commenting?" and (4) "On social media, how much do you discuss racism related to COVID-19 with others through private messaging?" A 7-point Likert scale, ranging from 1 ("not at all") to 7 ("very much"), was used. Cronbach α for this scale was .85 (mean score 12.76, SD 6.40).

Depression

A 10-item depression scale [38] was adopted to measure the level of depression among US Asians. Respondents were asked to rate how often they felt they "[C]ouldn't shake off the blues even with help from your family and your friends," for example. The scale ranged from 1 ("rarely or none of the time") to 4 ("most or all of the time"). After performing confirmative factor analysis, three reverse-coded items were removed (see details below). Cronbach α for this 7-item scale was .88 (mean score 21.51, SD 5.97).

Control Variables

Respondents reported basic demographic information, including age, gender, marital status, education level, employment status, and income. In addition, self-identification as Chinese was also considered as a control factor because of the close connection between the COVID-19 outbreak and China. We also asked respondents whether their family incomes had been affected since the COVID-19 outbreak, as it has been documented as a key stressor during the pandemic [39].

Data Analysis

To address the issues of measurement errors, we performed confirmatory factor analysis in Mplus (version 7; Muthén & Muthén) by considering experience of discrimination, worry about discrimination, social media use, and depression as *latent variables*. The initial model fit was mediocre, and 3 reverse-coded items of the depression scale had low loadings (<0.40). After removing these 3 items, the measurement model fit was acceptable (comparative fit index=0.92, Tucker–Lewis index=0.91, root mean square error of approximation= 0.08).

We then used SPSS software (version 26.0; IBM Corp) to perform a 3-step hierarchical regression analysis. The first model included *control variables*. We dichotomized gender, marital status, employment status, and self-identification as Chinese, with those who were male, married, employed full-time, and self-identified as Chinese being coded as "1," and the other categories coded as "0." In the second model, the following 3 key independent variables were added: (1) experience of discrimination, (2) worry about discrimination, and (3) racism-related social media use. These variables were mean-centered. In the third model, the two interaction terms examining the moderating roles of experience of discrimination and worry about discrimination were added. No collinearity problems were identified after the mean-centering approach. The significance level was set at $P<.05$.

Results

As shown in Table 2, all three regression models were significant: model 1 ($R^2=0.11$, $F_{8,200}= 3.07$; $P=.003$), model 2 ($R^2=0.35$, $F_{11,197}= 9.71$; $P<.001$), and model 3 ($R^2=0.38$, $F_{13,195}= 9.21$; $P<.001$). Model 2 with three discrimination-related variables significantly increased the explaining power for depression (R^2 change=0.24; F change=24.51; $P<.001$).

Experience of discrimination was positively associated with depressive symptoms (β=.33, $P=.001$), supporting hypothesis 1. Racism-related social media use (β=.14, $P=.045$) was also positively related to depression, supporting hypothesis 2. Worry about discrimination (β=.13, $P=.14$) was not associated with depression (RQ1).

To answer RQ2 and RQ3, we found the significant interactive effect of social media use and worry about discrimination on depression (β=–.25, $P=.003$). To visualize the moderation effect, we used Process version 3.5 to conduct simple slope analysis and produce the figure of the interaction. As depicted in Figure

1, among participants with low (1 SD below the mean) and medium levels of worry, social media use was positively and significantly related to depression (simple effect coefficient=0.29 for low worry, 95% CI 0.15-0.44; simple slope coefficient=0.11 for medium worry, 95% CI 0.0023-0.21). No significant relationship between social media use and depression was found at a high level of worry.

In addition, female Asians were found to be more depressed than male Asians (β=–.14, *P*=.02), and Chinese Asians were less depressed than those Asians who were not Chinese (β=–.12, *P*=.045).

Table 2. Ordinary least squares multiple regression analysis of depression scores as a function of discrimination-related variables and control variables (N=209).

Variables	Model 1		Model 2		Model 3	
	β	*P* value	β	*P* value	β	*P* value

Discussion

Principal Findings

The present study provides preliminary evidence that experience of discrimination during the COVID-19 pandemic is a risk factor for depressive symptoms among Asians in the United States. Meanwhile, racism-related social media use was also found to be negatively related to the well-being of US Asians, and the relationship between social media use and depression was moderated by worry about discrimination, such that social media use was associated with greater depression among those who were less worried about discrimination.

Drawing on survey data from 209 Asians residing in the United States, the study presents the findings consistent with earlier research [20,21] showing that experience of racial discrimination induced by the COVID-19 pandemic was negatively related to the well-being among Asian people. Effective interventions should be designed to provide timely assistance to Asians who have experienced discrimination during the pandemic to prevent them from developing further depressive symptoms. One limitation of the current study is the use of an existing measurement of experienced racial discrimination, which may fail to capture the specific experiences of racial discrimination associated with the COVID-19 pandemic. Further research could focus on understanding the unique elements of racial discrimination in the COVID-19 context so that more accurate conclusions could be made.

Using social media to read, post, and talk about racism was also found to be associated with higher depression. It is noteworthy that the relationship was significant when controlling for direct experience of discrimination (albeit with a smaller effect size than direct experience). Given how fast-growing and visible anti-Asian sentiments have been on social media during the pandemic [29,30], and that Asians were more likely to use social media than other media sources to obtain COVID-19–related information [5,6], our finding deserves serious attention. It is also worth mentioning that our social media use scale includes a variety of social media activities (eg, reading, posting, commenting, private messaging) through which individuals may be exposed to and engage with racism-related information. Relative to single-item questions asking about participants' social media use in one particular way, such as exposure to or consumption of a certain type of information [32,40], our scale has the strength of more comprehensively capturing multiple ways of social media use during the pandemic.

Worry about discrimination was not directly associated with depression in the present study. When worry about discrimination was considered alongside the actual experience of discrimination, it was the actual experience that was detrimental. As shown in previous literature, the benefits and detriments of worry may have cancelled out each other, leading to a nonsignificant direct association [25-28]. It may be worthwhile for future research to explore possible moderators of this relationship, such as coping styles and social support-seeking behaviors, to better understand the implications of this type of worry for mental health.

Although worry was not a significant independent variable, it was a significant moderator for the relationship between social media use and depression. Specifically, among Asians with low and medium levels of worry about discrimination, social media use was related to higher levels of depression. A possible explanation for our finding might be that Asians with low to medium worry were less prepared for anti-Asian discrimination. Thus, they felt more overwhelmed and depressed when exposed to greater amount of racism-related information on social media. Future research should explore in detail how US Asians with low and high worry cope with racial discrimination in different ways that may buffer or exacerbate the influence of social media use on depression. Meanwhile, it is also worthwhile to explore more factors that might moderate the relationship between social media use and depression, such as coping strategies, perceived social support, and so forth.

In terms of demographic factors considered in our regression model, we found that female Asians were more depressed than male Asians, which is consistent with findings of previous studies [41,42]. Surprisingly, Chinese Asians were found to be less depressed than Asians who were not Chinese. Although Asians are normally being treated as one single ethnic group in the United States, research does indicate that there might be differences in the mental health mechanisms among various Asian ethnicities. For example, it was indicated that Chinese Americans had lower prevalence of depression than Korean and Vietnamese Americans [43]. Further study is needed to identify how the mental health conditions of different Asian groups have been impacted by the COVID-19 pandemic.

Limitations and Conclusions

The study has some limitations. The first is that the research model was not evaluated with a random sample. Therefore, readers are advised to take caution when generalizing the results to the overall Asian population in the United States or Asian groups in another country. Another limitation is that the cross-sectional study does not allow for drawing causal conclusions, and thus the findings should be interpreted as correlations rather than as having a cause-and-effect relationship.

Despite all these limitations, the present study extends the current literature on rising anti-Asian discrimination and associated mental health outcomes in several ways. First, we differentiated the actual experience of discrimination and worry about discrimination and revealed their unique relationship with depression among US Asians in the context of the COVID-19 pandemic. Another theoretical contribution is providing important insights into the specific role of racism-related social media use in mental health among a minority group. Importantly, the results suggest that US Asians with higher versus lower levels of worry face different degrees of susceptibility to the negative influences of racism-related social media use on mental health.

From a practical perspective, immediate and effective interventions should be implemented to decrease racist and discriminatory behaviors against US Asians, as direct experience of discrimination was found to be a robust risk factor for depression among this group, after controlling for various demographic variables. It is also critical to develop accessible

programs to help US Asians cope with racial discrimination both in real lives and on social media during this unprecedented health crisis, especially among those who have not been mentally prepared for such challenges.

Abstract

Background: In general, early intervention in disease based on early diagnosis is considered to be very important for improving health outcomes. However, there is still insufficient evidence regarding how medical care that is based on the early diagnosis of confirmed cases can affect the outcome of COVID-19 treatment.

Objective: We aimed to investigate the effect of the duration from the onset of clinical symptoms to confirmation of COVID-19 on the duration from the onset of symptoms to the resolution of COVID-19 (release from quarantine).

Methods: For preliminary data collection, we performed data crawling to extract data from social networks, blogs, and official websites operated by local governments. We collected data from the 4002 confirmed cases in 33 cities reported up to May 31, 2020, for whom sex and age information could be verified. Subsequently, 2494 patients with unclear symptom onset dates and 1349 patients who had not been released or had no data about their release dates were excluded. Thus, 159 patients were finally included in this study. To investigate whether rapid confirmation reduces the prevalence period, we divided the duration from symptom onset to confirmation into quartiles of ≤1, ≤3, ≤6, and ≥7 days, respectively. We investigated the duration from symptom onset to release and that from confirmation to release according to these quartiles. Furthermore, we performed multiple regression analysis to investigate the effects of rapid confirmation after symptom onset on the treatment period, duration of prevalence, and duration until release from isolation.

Results: We performed multiple regression analysis to investigate the association between rapid confirmation after symptom onset and the total prevalence period (faster release from isolation). The time from symptom onset to confirmation showed a negative association with the time from confirmation to release (t_1=−3.58; P<.001) and a positive association with the time from symptom onset to release (t_1=5.86; P<.001); these associations were statistically significant.

Conclusions: The duration from COVID-19 symptom onset to confirmation date is an important variable for predicting disease prevalence, and these results support the hypothesis that a short duration of symptom onset to confirmation can reduce the time from symptom onset to release.

Introduction

The COVID-19 Outbreak

COVID-19 was first reported on December 31, 2019, in cases of pneumonia with an unknown etiology in Wuhan, China [1]; the disease subsequently spread to neighboring countries, including South Korea and Japan [2]. On March 11, 2020, the World Health Organization (WHO) reported a total of 118,000 confirmed cases and approximately 4000 deaths due to COVID-19 in 114 countries. On the afternoon of the same day, the WHO formally declared COVID-19 to be a global pandemic [3]. The first confirmed case in South Korea, a Chinese woman in her 30s, was reported on January 20, 2020, followed by another confirmed case, a 55-year-old man who had visited Wuhan, China. Subsequently, COVID-19 appeared to be stably controlled for almost a month; however, the number of cases increased explosively after February 20, whereby South Korea became the second country after China to experience the beginning of an epidemic. Subsequently, on February 29, the daily incidence of confirmed cases peaked at 900 and has since been following a downward trend. As of November 30, 2020, a total of 64 million cumulative confirmed cases of COVID-19 had been reported worldwide [4].

Treatment and Management of Confirmed COVID-19 Cases in South Korea

The WHO defines a confirmed case of COVID-19 as a person with a laboratory-confirmed COVID-19 infection, regardless of clinical signs and symptoms [5]. The symptoms mainly include fever, cough, shortness of breath, and breathing difficulties [6], although more than 15% of cases are asymptomatic [7]. In South Korea, individuals who have entered the country or have been in close contact with a confirmed COVID-19 case must undergo a test for COVID-19. The rapid antigen test is an efficient tool for rapid confirmation of SARS-CoV-2 infection, although it is not used as an official tool for confirmatory diagnosis in view of the capacity of laboratories to conduct the requisite number of tests and considering the number of confirmed and suspected cases. In the early stages of the COVID-19 epidemic, confirmatory testing involved two stages: pan-coronavirus and base sequencing analysis. However, the real-time polymerase chain reaction (RT-PCR) has subsequently been used for basic confirmation [8]. Individuals who are suspected of having COVID-19 based on the clinical presentation of symptoms or close contact with a confirmed patient with COVID-19 are diagnosed based on test results from two clinical samples, one each from the upper and lower respiratory tract [8,9]. RT-PCR requires at least 24 hours for the results to become available, and everyone who is tested is quarantined until the final diagnosis is determined.

The treatment strategies for COVID-19 can generally be divided into supportive care, respiratory support, symptomatic treatment, nutritional support, and psychological intervention [10]. Moreover, antibiotics can be administered to prevent secondary infections [11]. Furthermore, remdesivir is prescribed as an antiviral treatment for SARS-CoV-2, although its effectiveness is debated [12,13]. In South Korea, patients are classified according to disease severity, and patients with high severity are treated in hospitals dedicated to infectious diseases and at national inpatient treatment centers. Patients who are classified as having mild symptoms or those who do not require inpatient treatment due to improvement in clinical symptoms may be admitted to residential treatment centers. In these facilities, the medical staff monitors patients at least twice per day.

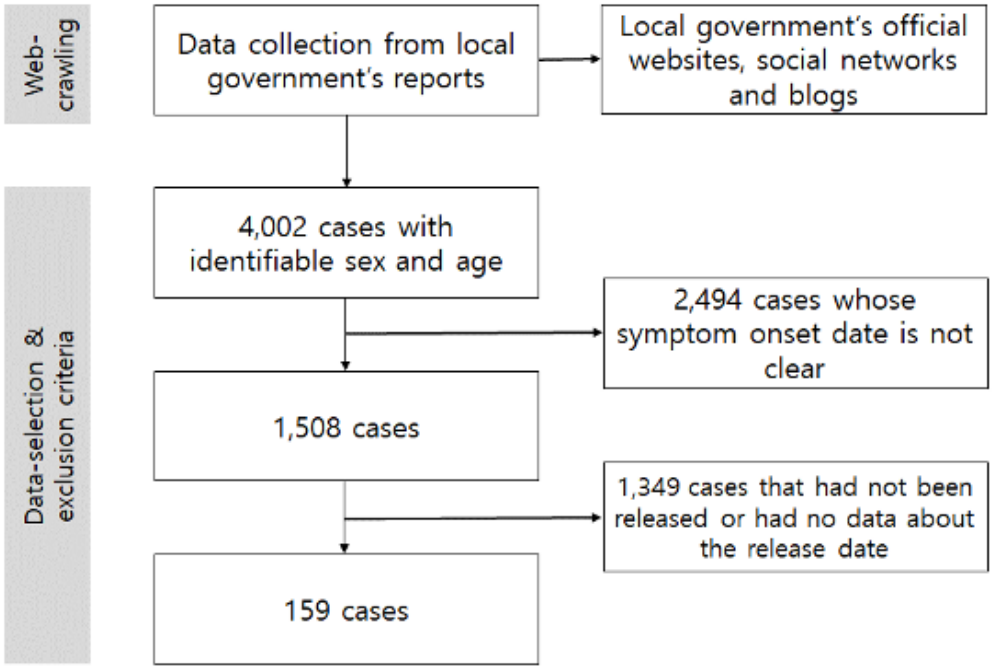
COVID-19 is highly contagious, therefore, confirmed patients must avoid contact with other people and should immediately be placed in quarantine [14-16]. In general, early intervention based on early diagnosis of the disease is considered to be very important for improving health outcomes [17-19]. However, most of the studies on COVID-19 conducted to date have focused on preventing the spread of the disease by quickly identifying confirmed patients and minimizing their contact with other people [15,20]. In contrast, there is very little evidence of how medical care that is based on the early diagnosis of confirmed cases of COVID-19 can affect the treatment outcomes. Accordingly, we aimed to investigate the effects of the duration from the onset of clinical symptoms to confirmation on the duration from the onset of clinical symptoms to the resolution of COVID-19 (release from quarantine).

Methods

Data Collection

South Korea comprises 228 si (cities), gun (counties), and gu (districts), with 17 metropolitan city and province levels, including Seoul, its capital. All local governments disclose basic information on official websites about confirmed cases. Almost all Korean local governments have provided anonymized public information regarding confirmed COVID-19 cases, such as symptom date, release date, and age, up to the first half of 2020. We performed web crawling using Python's Selenium module and additionally used the Beautiful Soup and Pandas libraries to collect data. In the early stage of the pandemic, the local government deidentified the information of the confirmed persons with COVID-19 and disclosed their movements, region, and age. At this time, many people connected to the local government homepages to check these data, and the server was overloaded. Accordingly, many local governments provided information to their official social networks and blogs to distribute data traffic and improve access to information. Therefore, we only collected information on local government official websites, social networks, and blogs, and we did not use information from other sites that are not guaranteed to be reliable. For preliminary data collection, we performed data crawling to extract data from social networks, blogs, and official websites operated by local governments. Second, the data were manually reviewed and revised. Data obtained in this manner underwent a final review and revision process that included the use of various check codes to complete the final data set. Data were extracted and reviewed from June 1-7, 2020 (Figure 1).

Figure 1. Flowchart of the data extraction process.



Study Design and Participants

We collected data from the 4002 confirmed cases from 33 cities reported up to May 31, 2020, for whom sex and age information could be verified. Subsequently, 2494 patients with an unclear symptom onset date and 1349 patients who had not been released or had no data about their release date were excluded. Thus, 159 patients were finally included in this study.

A confirmed case of COVID-19 was defined based on a confirmed diagnosis from positive RT-PCR results on 2 or more clinical specimens, regardless of clinical signs and symptoms [21]. For a patient to be released from isolation, at least 7 days must pass from the day of confirmation; the patient must be afebrile without the administration of any antipyretic agents; and the clinical symptoms must show an improving trend. In addition, the patient must test negative on 2 consecutive PCR tests, each conducted at least 24 hours apart [22].

Statistical Analysis

We performed descriptive analysis of the mean, minimum, and maximum values for the durations from symptom onset to release, symptom onset to confirmation, and confirmation to release according to the sex and age of the patients. To investigate whether rapid confirmation reduces the prevalence period, we divided the period from symptom onset to confirmation into quartiles, 1Q, 2Q, 3Q, and 4Q, of ≤1, ≤3, ≤6, and ≥7 days, respectively. We investigated the durations from symptom onset to release and confirmation to release according to these quartiles. Furthermore, we performed multiple regression analysis to investigate the effects of rapid confirmation after symptom onset on the treatment period, duration of prevalence, and duration until release from isolation.

To measure the predictive power of duration from symptom onset to release, we used logistic regression (LR) after setting the duration from symptom onset to release and other variables (age, sex, and symptom onset to confirmation) as the dependent and independent variables, respectively. We transformed the number of days from symptoms to release into tertiles (T1, T2, and T3). Two scenarios were evaluated: (1) the classification of early symptom onset to release after setting T1 and T2-T3 as 1 and 0 coding, respectively, and (2) the classification of late symptom onset to release after setting T3 and T1-T2 as 1 and 0 coding, respectively. We randomly divided the data into training and test sets by ratios of 70% and 30%, respectively. We determined two lists of variables with the following combinations: (1) age + sex and (2) age + sex + duration from symptom onset to confirmation. We constructed an LR model using a training set to predict early or late symptom onset to release. Thereafter, we measured the predictive performance of early or late symptom onset to release in the test sets. With 100 iterations of the random division of training and test sets, we measured the average performance of the classification for early or late symptom onset to release. For the 2-tailed *t* tests, we considered a *P* value <.05 to be statistically significant.

Results

The study population (N=159) included 67 men (42.1%) and 92 women (57.9%), whereas the age groups appeared in the following order: 40-59 years (n=71, 44.7%), 20-39 years (n=59, 37.1%), ≥60 years (n=21, 13.2%), and 0-19 years (n=8, 5.0%). The mean duration from symptom onset to confirmation was 6.1 days, and the mean duration from confirmation to release was 25.3 days. The mean duration from symptom onset to confirmation was shorter among females (5.6 days) than among males (6.7 days), whereas the mean duration from confirmation to release was similar for males (25.4 days) and females (25.2

days). The mean duration from symptom onset to release was 32.1 and 30.8 days among male and female patients, respectively. With regard to age, the mean duration from symptom onset to confirmation was longest in the 0-19 years group (7.9 days), followed by the 40-59 years (7.3 days), 20-39 years (5.0 days), and ≥60 years (4.3 days) groups. The mean duration from confirmation to release was longest in the ≥60 years group (27.8 days), whereas the mean duration from symptom onset to release was longest in the 40-59 years group (33 days; Table 1).

Both the duration from confirmation to release and the duration from symptom onset to release were investigated by quartiles of duration from symptom onset to confirmation, and 4Q, 3Q, 2Q, and 1Q were ≥7 days, 4-6 days, 2-3 days, and 1 day, respectively. The duration of symptom onset to release was shortest, at 28.5 days, when the duration of symptom onset to confirmation was 1Q (≤1 day); this was followed sequentially by 2Q, 3Q, and 4Q, with 28.9, 31.6, and 36.5 days, respectively. The results indicated that the prevalence increased with increasing duration of symptom onset to confirmation (Figure 2).

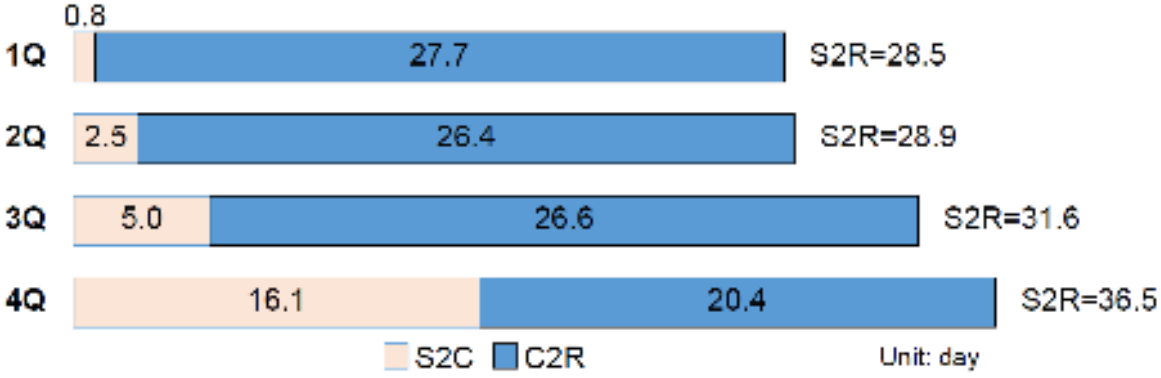
Table 1. Characteristics of confirmed COVID-19 cases (N=159) and their durations from symptom onset to confirmation, confirmation to release, and symptom onset to release.

Characteristic	Value, n (%)	Dependent variable		Independent variables			
		Duration of symptom onset to confirmation		Duration of confirmation to release		Duration of symptom onset to release	
		Mean (SD)	Range	Mean (SD)	Range	Mean (SD)	Range
Total sample	N/A[a]	6.1 (8.9)	−1 to 48	25.3 (12.0)	4 to 72	31.4 (12.8)	7 to 73
Sex							
Male	67 (42.1)	6.7 (10.4)	−1 to 48	25.4 (12.7)	7 to 72	32.1 (13.4)	11 to 73
Female	92 (57.9)	5.6 (7.6)	0 to 47	25.2 (11.6)	4 to 69	30.8 (12.4)	7 to 70
Age (years)[b]							
0-19	8 (5.0)	7.9 (11.0)	−1 to 33	22.3 (12.9)	12 to 44	30.1 (15.7)	14 to 54
20-39	59 (37.1)	5.0 (6.6)	0 to 48	24.4 (12.1)	4 to 69	29.4 (13.3)	7 to 70
40-59	71 (44.7)	7.3 (11.0)	0 to 47	25.7 (11.7)	7 to 72	33 (11.9)	14 to 73
≥60	21 (13.2)	4.3 (3.6)	0 to 12	27.8 (12.9)	6 to 54	32.1 (13.6)	9 to 60

[a]N/A: not applicable.

[b]Mean 42 years (SD 14.7), range 1 to 81.

Figure 2. The duration from the confirmation date to release (C2R) and from the symptom onset to release (S2R) according to the quartile of the duration from symptom onset to confirmation (S2C) quartile. 1Q: ~1 day (mean age: 42.5 years), 2Q: 2–3 days (mean age: 43.8 years), 3Q: 4-6 days (mean age: 39.5 years), and 4Q: ≥7 days (mean age: 42.6 years). 1Q: first quartile; 2Q: second quartile; 3Q: third quartile; 4Q; fourth quartile; C2R: duration from confirmation date to release; S2C: duration from symptom onset to confirmation; S2R: duration from symptom onset to release.



We performed multiple regression analysis to investigate the association between rapid confirmation after symptom onset and the total prevalence period (faster release from isolation). Sex and age did not show a significant association with the duration from confirmation to release or the duration from symptom onset to release. However, the duration from symptom onset to confirmation showed a negative association with the duration from confirmation to release (t_1=−3.58; P<.001) and a positive association with the duration from symptom onset to release (t_1=5.86; P<.001); these associations were statistically significant (Table 2).

We measured the informative power of the duration from symptom onset to confirmation to predict early or late symptom onset to release. We found that the duration from symptom onset to confirmation resulted in improved performance for both models (P<.001 for both the early and late symptom onset

to release models) compared to the model that used age and sex as input features (Figure 3).

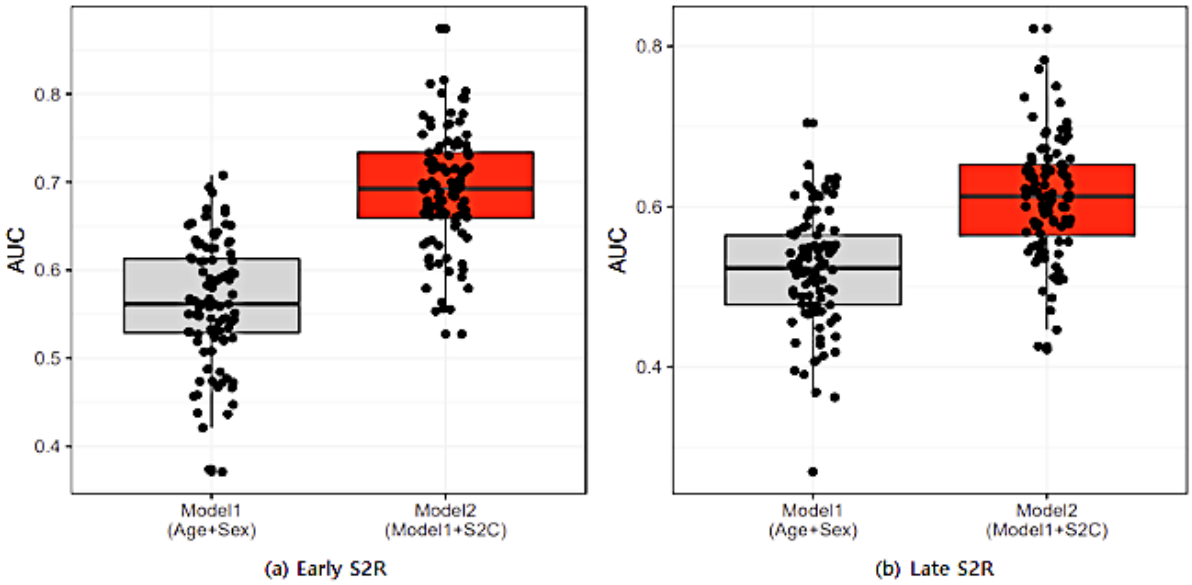
Table 2. Association between the durations from symptom onset to confirmation, confirmation to release, and symptom onset to release based on the results of multiple regression analysis.

Characteristics and categories	Duration from confirmation to release[a]		Duration from symptom onset to release[b]	
	T *(df)*	*P* value	T *(df)*	*P* value
Sex				
Male (reference) versus female	−0.55 (1)	.58	−0.55 (1)	.58
Age (years)				
≥60 (reference) versus 40-59	0.30 (1)	.76	0.30 (1)	.76
≥60 versus 20-39	0.83 (1)	.41	0.83 (1)	.41
≥60 versus 0-19	0.94 (1)	.34	0.94 (1)	.34
Duration of symptom onset to confirmation (days)	−3.58 (1)	<.001	5.86 (1)	<.001
F	2.99	.01	7.66	<.001

[a]R^2=0.089; adjusted R^2=0.059.

[b]R^2=0.200; adjusted R^2=0.174.

Figure 3. Predictive power determined through logistic regression after setting S2C and other variables (age, sex, and S2C). The analysis comprises 100 iterations by the random division of training and test data sets. AUC: area under the curve; S2C; duration from symptom onset to confirmation; S2R: duration from symptom onset to release.



Discussion

Principal Findings

Rapid diagnosis of confirmed cases enables prompt infection control and environmental decontamination of patients with suspected infection and places, such as environmental decontamination of related places and the management of close contacts [9]. Most of the studies published to date have tended to approach the early detection of COVID-19 from the perspective of prevention of the infection and spread of the disease [23]. Reducing the time to isolation through rapid diagnosis has been proven to help prevent the spread of SARS-CoV-2 infection [15,21,23]. In this context, studies published to date have claimed that early detection of COVID-19 is important because it can lower the mortality rate [24,25]. However, this claim is an inference based on general medical knowledge about pneumonia and complications and is not rooted in actual COVID-19 data.

Through linear regression analysis, we verified that the duration from symptom onset to confirmation is a factor that influences the duration from symptom onset to release. In addition, we used LR to test the predictors of duration from symptom onset to release, and we found that the inclusion of the duration from symptom onset to confirmation as a variable in the model significantly increased the predictive power. Therefore, the duration from symptom onset to confirmation is an important variable for predicting prevalence, and these results support the hypothesis that a short duration from symptom onset to confirmation can reduce the duration from symptom onset to release. Consequently, this study demonstrated that rapid diagnosis leads to faster release from isolation. If COVID-19 could be diagnosed early, the symptoms and progression of the

disease could be controlled with only simple treatment, and the reduced number of patients with severe disease could result in stable availability of hospital beds [20]. In the current COVID-19 pandemic, confirmed COVID-19 patients in many countries are not receiving proper treatment because of a shortage of medical resources; thus, efficient use of limited medical resources is extremely important. Under such circumstances, treating patients and releasing them from isolation as quickly as possible is one of the most important strategies for infectious disease control. Clinically, shortening the treatment period could be one of the best methods to improve the personal safety and quality of life of patients as well as the safety of medical staff and to reduce the workload of medical staff.

Any person with symptoms or suspicion of SARS-CoV-2 infection should be tested immediately, and intervention must take place as soon as possible upon confirmation. Delays in the confirmation of COVID-19 increase the social burden of the spread of this infectious disease but also contribute to the clinical burden of an increase in the prevalence period. The results of the regression analysis in this study showed that sex and age were unassociated with the prevalence and isolation periods of patients with COVID-19. These findings are not consistent with a previous study which reported that the prognosis of COVID-19 is influenced by age [10]. An earlier study focused on the qualitative aspect of patients' health or medical condition after treatment or release from isolation [10], whereas this study investigated the prevalence period. Therefore, a direct comparison is difficult because of the differences in the level of variables. The COVID-19-related mortality rate is higher among the older population [5,26]; therefore, rapid diagnosis is important for older persons. The older population has a high likelihood of having underlying diseases and onset of complications, whereas the risk of disease progression to severe conditions is also higher. Thus, higher mortality is to be expected and, therefore, early intervention through rapid confirmation is expected to reduce the mortality rate [27]. Consequently, considering the results of this and previous studies, rapid confirmation could shorten the prevalence period, lead to better prognosis, and reduce the mortality rate. Along with the advancement in the diagnosis of COVID-19, such as nucleic acid tests, among which the PCR method is considered as the "gold standard" for detection of the virus, rapid confirmation is very important to not only prevent the spread of disease but also enable better patient care.

This study has some limitations. First, we could not distinguish between severely and mildly ill patients, and it is possible that the prevalence period may differ between these two groups. Second, the study only considered a quantitative variable of duration of symptom onset to release, instead of clinical outcomes such as complications and posttreatment prognosis. Third, a sufficiently large sample size could not be obtained. Fourth, because we only used crawled data available on the web, other factors besides the duration from symptom onset to confirmation that could affect the duration from symptom onset to release could have resulted in uncorrected bias in the results of the study. Nonetheless, in this study, we obtained information on the confirmed diagnosis date for every patient, although many cases did not have a symptom onset date. This was due to the fact that many patients could not accurately remember their symptom onset date. To overcome these challenges, efforts to secure a record on the date of symptom onset in the clinical field are necessary, and additional studies should be conducted that consider disease severity and treatment.

Conclusion

The duration from symptom onset to the date of confirmation of a disease is an important variable for predicting prevalence, and our results support the hypothesis that a short duration from symptom onset to confirmation of COVID-19 can reduce the duration from symptom onset to release. Consequently, this study demonstrated that rapid diagnosis leads to faster release from isolation.

Abstract

Background: The control of vaccine hesitancy and the promotion of vaccination are key protective measures against COVID-19.

Objective: This study assesses the prevalence of vaccine hesitancy and the vaccination rate and examines the association between factors of the health belief model (HBM) and vaccination.

Methods: A convenience sample of 2531 valid participants from 31 provinces and autonomous regions of mainland China were enrolled in this online survey study from January 1 to 24, 2021. Multivariable logistic regression was used to identify the associations of the vaccination rate and HBM factors with the prevalence of vaccine hesitancy after other covariates were controlled.

Results: The prevalence of vaccine hesitancy was 44.3% (95% CI 42.3%-46.2%), and the vaccination rate was 10.4% (9.2%-11.6%). The factors that directly promoted vaccination behavior were a lack of vaccine hesitancy (odds ratio [OR] 7.75, 95% CI 5.03-11.93), agreement with recommendations from friends or family for vaccination (OR 3.11, 95% CI 1.75-5.52), and absence of perceived barriers to COVID-19 vaccination (OR 0.51, 95% CI 0.35-0.75). The factors that were directly associated with a higher vaccine hesitancy rate were a high level of perceived barriers (OR 1.63, 95% CI 1.36-1.95) and perceived benefits (OR 0.51, 95% CI 0.32-0.79). A mediating effect of self-efficacy, influenced by perceived barriers (standardized structure coefficient [SSC]=−0.71, P<.001), perceived benefits (SSC=0.58, P<.001), agreement with recommendations from authorities (SSC=0.27, P<.001), and agreement with recommendations from friends or family (SSC=0.31, P<.001), was negatively associated with vaccination (SSC=−0.45, P<.001) via vaccine hesitancy (SSC=−0.32, P<.001).

Conclusions: It may be possible to increase the vaccination rate by reducing vaccine hesitancy and perceived barriers to vaccination and by encouraging volunteers to advocate for vaccination to their friends and family members. It is also important to reduce vaccine hesitancy by enhancing self-efficacy for vaccination, due to its crucial mediating function.

COVID-19 pandemic; vaccination behavior; vaccine hesitancy; health belief model

Introduction

COVID-19 has spread worldwide, causing more than 88 million infections and more than 1.9 million deaths as of January 2021 [1]. Due to the lack of effective treatments, the development and use of a new COVID-19 vaccine has become an important strategy to control the epidemic. Since COVID-19 broke out, according to the World Health Organization (WHO), 60 new coronavirus-inactivated vaccines and more than 10 nucleic acid vaccines, vector vaccines, and protein subunit vaccines have been developed [2]. Vaccination is recognized as the most successful and cost-effective public health intervention in the world today, and it has made a very large contribution to improving global health by reducing the incidence and deaths of many infectious diseases [3,4]. China and the whole world are experiencing the third wave of epidemics, so it is especially important to establish herd immunity by vaccinating against COVID-19 [5].

On December 30, 2020, the first homegrown COVID-19 vaccine in China was approved for marketing by the China National Medical Products Administration, and open volunteer vaccination to the public was announced through official media. On January 9, 2021, the National Health Commission promised free vaccinations for the Chinese population [6]. As of February 2021, the COVID-19 vaccine in China is suitable for people aged 18 to 59 years; the COVID-19 vaccine is not suitable for pregnant women, lactating women, and people with the following conditions: acute stages of fever, infections and other diseases, immune deficiency or immune disorders, serious liver and kidney diseases, hypertension, diabetic complications, and malignant tumors with uncontrolled drugs [7]. As of February 2021, common adverse reactions to vaccines in China mainly include headache, fever, local redness or lumps at the inoculation site, and cough, as well as loss of appetite, vomiting, and diarrhea in some people [8]. In first month of COVID-19 vaccinations, up to January 26, 2021, 22.8 million doses of the COVID-19 vaccine were administered in China, and less than 5% of the vaccine-eligible population among them, the main group, was at high risk of infection in all regions [9]. Considering the occupational exposure risk of COVID-19 infection, some populations with priority for vaccination were those with occupations at border ports, in key places such as international and domestic transportation, and in key industries such as medical and health care as well as basic social operation services. These populations are mass vaccinated on the basis of individual willingness [6]. According to the director of the National Health Commission, National Bureau of Disease Control and Prevention, all residents could be vaccinated in an orderly manner where there is an ample supply of vaccine and where vaccination units are health service centers, township health centers, or general hospitals located in their respective jurisdictions. Local governments have been required to make public in a timely manner the vaccination sites and units that can administer vaccines in their respective jurisdictions, including their locations and service hours [8]. From the beginning of 2020 to February 2021, the State Council Information Office has held regular press conferences to invite experts from relevant departments to brief the population on the joint prevention and control of COVID-19 [10]. Not only have the daily numbers of new cases, close contacts, patients who recovered, and patients who died been announced, but the latest number of vaccinated people as well as side effects and psychological changes following vaccination have also been announced. In addition to communications at the national level, provinces, municipalities, and autonomous regions released the latest information about the epidemic through various channels, such as press conferences or short videos, specific to their own situations, to ensure mastery and understanding of information regarding the epidemic and vaccines [11,12]. As of May 2021, 6 months after countries had begun carrying out vaccinations, the global number of COVID-19 vaccinations has exceeded 1.5 billion doses. Among them, nearly 60% are concentrated in China (420 million doses), the United States (270 million doses), and India (180 million doses). Except for a few countries with a vaccination rate exceeding 50% (eg, Israel), most countries in the world have a vaccination rate below 20% [13]. According to a recent study, predicted vaccine coverage of 55% to 82% of the population is needed to achieve COVID-19 herd immunity [5]. In addition to the supply of vaccines, individuals' psychological mechanisms of vaccine behavior are particularly critical to vaccination [14]. Therefore, it is of great significance to explore the possible influencing factors of individuals' vaccination willingness when vaccination rates are low in order to improve COVID-19 vaccination willingness and coverage in China and other parts of the world.

Although vaccines are currently an effective means of improving global health, in many parts of the world there are still quite a few people who question the necessity of vaccination, postpone vaccination, or even refuse vaccination; this is especially true when vaccines first came to market and were met with considerable hesitation and even outright opposition [15]. In 2012, the WHO established the Strategic Advisory Group of Experts (SAGE) working group to address and define vaccine hesitancy and its scope [16]. Vaccination hesitancy was defined as the refusal or delay of vaccination when vaccination services were available [17], and vaccination hesitancy was listed among the 10 threats to global health in 2019 [18]. Vaccine hesitancy is reflected in many factors, including confidence in the efficacy and safety of the vaccine and in the health service system providing the vaccine, such as the reliability and competence of the health service system and the professionals involved in the vaccination service [19]. In the first month after vaccines became available to all vaccine-eligible members of the Chinese population, a nationwide cross-sectional study reported the prevalence of COVID-19 vaccination hesitancy to be 35.5%. After an instance of illegal marketing of vaccines, 32.4% of parents became hesitant of vaccines [20]; rapid sociocultural changes have also contributed to vaccine hesitancy [21,22]. A study on COVID-19 vaccine hesitancy of Italian college students showed that among the 735 students who answered questions about their vaccination intentions, more than 1 in 10 students showed hesitancy [23]. An investigation during Israel's mandatory quarantine revealed that nurses and medical workers showed high levels of vaccine hesitancy [24]. According to a literature review, 68.4% of the global population is willing to receive the vaccination [25].

Recent studies of factors associated with COVID-19 vaccination have identified a number of demographic, cognitive, and psychosocial factors, including age, gender, educational level, insurance status, attitudes toward the vaccine, confidence in government information, perceived susceptibility to COVID-19, and perceived benefits and side effects of the vaccine [26,27]. In the current age of Web 2.0, the spread of false news about vaccine safety and validity on social media, such as that COVID-19 vaccination can affect individuals' reproductive function, influence vaccination willingness and confidence [28]. Several typical behavioral theories, such as the health belief model (HBM), the theory of planned behavior (TPB) [29], and the diffusion of innovation theory (DIT) [14], have been used to explain COVID-19 vaccination intent combined with demographic, cognitive, and psychosocial factors. The HBM is a widely used theory that proposes a variety of psychological factors that affect people's health protective behaviors, such as attitudes, beliefs, and intentions [30-32]. The HBM assumes that health-related actions depend on the simultaneous occurrence of three factors [33]: (1) the presence of sufficient motivation (or health concern) to make the health problem salient or relevant, (2) the belief that a person is vulnerable to serious health problems or the sequelae of that illness or condition is often referred to as a perceived threat, and (3) believing that following a specific health recommendation will help reduce the perceived threat at a subjectively acceptable cost. The TPB assumes that an individual's behavioral posture, activity attraction, and behavioral control jointly affect and direct the individual's behavior [34]. The DIT aims to disseminate innovation awareness, technology, or innovative ideas related to the masses, so that patients can develop innovative thinking or health awareness. In recent years, the DIT has been gradually introduced into medical and health industries, mainly for the guidance of health education strategies [14]. The HBM has been one of the most widely used theories in understanding health and illness behaviors, and due to its design, it has been previously used in vaccination studies to identify behavior relationships [35,36]. When compared with other models that explain behavior and resulting actions, the HBM was specifically developed to focus on preventative health research [35-38], which has been modified since its early use in the 1950s to be more inclusive and encourage interventions that improve health behaviors [39]. Thus, the HBM was chosen as the preferred model to investigate intention and behavior regarding COVID-19 vaccination. There are six main components of the HBM: perceived susceptibility, perceived severity, perceived benefits, perceived barriers, self-efficacy for health protective behaviors, and cues to action [40]. Previous studies, including those on H1N1 [41], hepatitis [42], human papillomavirus (HPV) [43], and measles [44], have identified HBM factors as important predictors of vaccination intentions. Therefore, it is necessary to explore the possible influence of these factors on people's willingness to vaccinate against COVID-19 in order to improve individual immunity and slow the epidemic. Although the aforementioned studies suggested that there were associations between HBM constructs and vaccine acceptance or hesitancy, relatively few studies have focused on COVID-19 vaccination behavior, especially in China and other countries where vaccinations are available to the domestic population [45].

In summary, we explored whether HBM constructs were associated with vaccine hesitancy and vaccination at the time when COVID-19 vaccination became available to the public in mainland China. A previous study identified that vaccine intention and willingness were important predictors of vaccination behavior, with more than 50% of the explained variance in influenza [46] and HPV [34] vaccinations. However, a gap seems to exist between intention and vaccination behavior [47], such as the willingness of students to receive the HPV vaccine predicting less than 10% of actual vaccinations [34]. Our first hypothesis (Hypothesis 1) was that vaccine hesitancy was negatively associated with COVID-19 vaccination behavior. In particular, we examined our major hypothesis (Hypothesis 2), which was that the HBM constructs of perceived barriers, self-efficacy, and cues to action would predict vaccine hesitancy and vaccination behavior. As in a previous study, self-efficacy is defined as the confidence in one's ability to facilitate decisions to carry out a health behavior such as vaccination, which is useful only to the extent that one feels one can adequately implement the steps needed to perform the behavior [48]. Evidence based on the HBM poses several mechanisms regarding how self-efficacy is associated with vaccine intention and behaviors. Self-efficacy was able to mediate the relationship between perceived barriers to HPV vaccination and HPV vaccine intentions among young women [49]. A similar mediation effect was found in the association between perceived severity and susceptibility and the intent to receive the Zika vaccine [50]. It was also suggested that self-efficacy could influence the path from cues to action (eg, physician recommendation, family members recommendation, media coverage, and public health communication) to HPV vaccine uptake [51] and acceptance of the H1N1 vaccine [52]. The aforementioned studies suggested our third major hypothesis (Hypothesis 3), which was that self-efficacy of the COVID-19 vaccine would mediate the influence of other HBM constructs on vaccine hesitancy and vaccination.

Methods

Study Design and Participants

From January 1 to 24, 2021, we used convenience and snowball sampling to recruit a sample of 2580 participants from 31 out of a total of 34 provinces and autonomous regions in China, with each area consisting of at least 30 participants; we then conducted a web-based cross-sectional study. A digital questionnaire link was sent to a WeChat "Friends circle," a function that can be used to share personal photos or public website links in one's "Moments" to make them visible to friends on platforms such as Twitter and Facebook. This questionnaire link, on the Wenjuanxing platform, could then be forwarded or shared by participants with friends in their WeChat contact list whom they considered appropriate for this survey; their friends were also encouraged to send the link to their friend networks. The snowball sampling process continued until a sufficient sample size was reached. The first page of the questionnaire contained an electronic consent form. Each

respondent received a small monetary reward of ¥5 (a currency exchange rate of ¥1=US $0.15 is applicable) after authentically completing the questionnaire, which took approximately 5 to 10 minutes. To prevent repeated entries from the same individual, who may attempt multiple entries for the enrollment reward, additional measures were adopted: (1) the same IP address was only allowed to be used once to fill in the questionnaire, which was a built-in function of the Wenjuanxing platform, and (2) participants were only allowed to fill in questionnaires after logging in to their WeChat accounts—they needed to register with this platform with a personal identity card—and each WeChat account could only be used once to fill in the questionnaire. The minimum sample size was calculated to be 1100 by using the following formula:

where the latest reported prevalence of COVID-19 vaccination hesitancy (p) was 35.5%, based on research that was conducted in China, nationwide, from January 10 to January 22, 2021 [53]. The type I error () was .05; thus, $z_{1-/2}$=1.96, the precision (d) was 0.04, and the design effect (deff) was 2 [54]. The inclusion criteria for participants' enrollment were as follows: (1) aged 18 to 59 years, (2) able to understand the questionnaire by themselves, and (3) could use online services, such as mobile phones, computers, and tablet computers. The questionnaires of participants who met the following exclusion criteria were discarded: (1) aged less than 18 years (n=16) or more than 59 years (n=32) and not eligible for vaccination until April 2021 in China and (2) returned invalid questionnaires (n=32). Questionnaires were deemed invalid if the following occurred: (1) participant gave one or two wrong answers to two quality control questions, including "Where is capital of China?" and "What's three plus five?"; (2) occurrence of a logic check result error, which occurred when the participant selected both "no disease" and "any type of disease" in response to the question "Do you have any type of the following diseases or diagnosed medical histories"; and (3) participant took less than the minimum time of 3 minutes to complete the questionnaire. Cognitive interviewing with 5 subjects was done to refine the questionnaires through the web-based platform WeChat. Participants were required to respond to each item by answering three questions: (1) "What does '……' mean to you?", (2) "Can you repeat this question in your own words?", and (3) "When you think about '……' what comes to your mind?" We also asked participants to answer three questions for the overall survey, including the following: (1) "Are there additional questions you believe should be asked?", (2) "Are there questions you believe should be deleted?", and (3) "Are there questions you believe should be modified?" The entire questionnaire was tested and modified to appropriately conduct the survey. Finally, 2531 participants were included in this study. All participants consented to written ethics approval before the survey was conducted. This study was approved by the Institutional Review Board of Fudan University, School of Public Health (IRB00002408&FWA00002399), and approval expired on March 3, 2021.

Measurements

Vaccine Hesitancy and Vaccination

Vaccine hesitancy was assessed with a one-item self-report measure that quantified the demand for, and acceptance of, vaccination: "How willing would you be to get the COVID-19 vaccine?" The respondents were asked to answer the question using the following 7-point scale recommended by the SAGE working group on vaccine hesitancy: "accept all [vaccines]," "accept but unsure," "accept some," "delay," "refuse some," "refuse but unsure," and "refuse all" [17]. Vaccine hesitancy was defined as any response on the scale except for "accept all" or "accept but unsure." Vaccination was assessed by asking the participants to answer "yes" or "no" to a single question: "Have you gotten the COVID-19 vaccine?"

Health Belief Model

Items derived from the HBM were adopted from a previous study or modified to measure the participants' beliefs about COVID-19 vaccination. Five essential dimensions of health beliefs were measured as follows: (1) perceived susceptibility to COVID-19 in the future (three items; eg, "I was vulnerable to infection with SARS-CoV-2"), (2) perceived severity of COVID-19 infection (four items; eg, "It would be very harmful for me if I got COVID-19"), (3) perceived benefits of COVID-19 vaccination (three items; eg, "COVID-19 vaccination can protect me from infection with SARS-CoV-2"), (4) perceived barriers to COVID-19 vaccination (six items; eg, "The COVID-19 vaccine might have side effects, such as fever or soreness in the arm"), and (5) self-efficacy for COVID-19 vaccination (five items; eg, "I believe I can deal with side effects of the COVID-19 vaccine with doctors' help"). Cues to action refer to external recommendations that might affect individuals' health-related behaviors. In this study, the Cronbach α coefficients indicating internal consistency (ie, reliability) were .78 for the total HBM factors, .84 for perceived susceptibility to COVID-19, .80 for perceived severity of COVID-19 infection, .83 for perceived benefits of COVID-19 vaccination, .80 for perceived barriers to COVID-19 vaccination, and .82 for self-efficacy for COVID-19 vaccination. The sampling adequacy for the HBM factor scale was excellent (Kaiser-Meyer-Olkin=0.82). Inter-item correlations were sufficiently large for principal component analysis (PCA) (Bartlett test of sphericity: $^{2}_{210}$=23,122.6, P<.001). The PCA revealed five factors, which in combination explained 68.58% of the variance, and each factor accounted for 24.23%, 20.55%, 10.32%, 8.16%, and 5.32% of the explained variance, respectively. An examination of the factor loadings after rotation suggested, as expected, that factor 1 (perceived barriers to COVID-19 vaccination) had six items with loading factors between 0.74 and 0.79, factor 2 (self-efficacy for COVID-19 vaccination) included five items with loading factors between 0.71 and 0.80, factor 3 (perceived severity of COVID-19 infection) included four items with loading factors between 0.67 and 0.85, factor 4 (perceived benefits of COVID-19 vaccination) included three items with loading factors between 0.68 and 0.85, and factor 5 (perceived susceptibility to COVID-19) included three items with loading factors between 0.78 and 0.89.

External Cues to Action

External cues to action were assessed based on four cues used in previous surveys [36,55]: recommendations from authorities, recommendations from friends or family, vaccination of authorities, and vaccination of friends or family. Participants were asked to state their level of agreement with each of the statements, with a score of 1 for positive responses (strongly agree or agree) and a score of 0 for neutral or negative responses (neither agree nor disagree, disagree, or strongly disagree). The Cronbach α coefficient for cues to action was .82. The sampling adequacy for the cues to action scale was excellent (Kaiser-Meyer-Olkin=0.75). Inter-item correlations were sufficiently large for PCA (Bartlett test of sphericity: $^{2}_{6}$=2829.1, *P*<.001). The PCA revealed a single factor, which in combination explained 59.72% of the variance, and an examination of the factor loadings after rotation suggested, as expected, that the single factor included four items whose loading factors were between 0.65 and 0.84.

Demographic and Health-Related Characteristics

Demographic characteristics in this study included gender, age, educational level (high school degree and below, bachelor's degree, or master's degree and above), marital status (married or not married [including unmarried, divorced, and widowed]), occupation (medical worker or nonmedical worker), region (urban or rural), monthly salary (<¥6000, ¥6000-¥10,000, or >¥10,000), and family members with backgrounds in medical work or with medical education (yes or no). Health-related characteristics included self-rated health and self-reported chronic diseases having been diagnosed by doctors. Self-rated health was evaluated by a single question: "How is your perceived health in general?"; responses included "excellent," "very good," "good," "general," or "poor" [56]. We listed 16 common chronic diseases, such as hypertension and diabetes, and categorized the number of reported chronic diseases into 0, 1 or 2, and 3 or over.

Statistical Analysis

Frequencies were first calculated for all variables, and the prevalence and 95% CIs of vaccine hesitancy and vaccination were determined according to the participants' demographics, health-related characteristics, and HBM factors. Multivariable logistic regression analyses were used to explore the demographic and health-related characteristics (Table 1) as well as the HBM factors (Table 2) associated with vaccine hesitancy and vaccination. We then ran the multivariable logistic regression again to determine the HBM factors associated with vaccine hesitancy and vaccination after controlling for covariates (ie, demographic and health-related characteristics), with a significance level of *P*<.05. Odds ratios (ORs) with 95% CIs were calculated for each independent variable and were visualized in forest plots (Figures 1 and 2). All of the analyses were performed using SAS software, version 9.4 (SAS Institute Inc), and all tests were two-tailed with a significance level of *P*<.05. We used the forest plot package in R software, version 3.5.3 (The R Foundation), to generate the forest plots. We used Mplus, version 8.4 (Muthén & Muthén), to establish structural equation modeling (SEM) and to assess the standardized structure coefficients (SSCs) among the HBM factors of vaccine hesitancy and vaccination. The mean- and variance-adjusted weighted least squares method was employed as the method of estimation because the analyses included categorical endogenous variables (ie, vaccine hesitancy and vaccination), and the link was the probability unit in the current model [57]. We freed covariances between error terms based on their modification indices during the estimation process to improve model fit. The most common indices and acceptable reference values included the magnitude of χ^2 divided by its degrees of freedom (χ^2/df <5), the comparative fit index (CFI >0.90), the Tucker-Lewis index (TLI >0.90), and the root mean square error of approximation (RMSEA <0.08), which were used to determine whether the data fit the model [58].

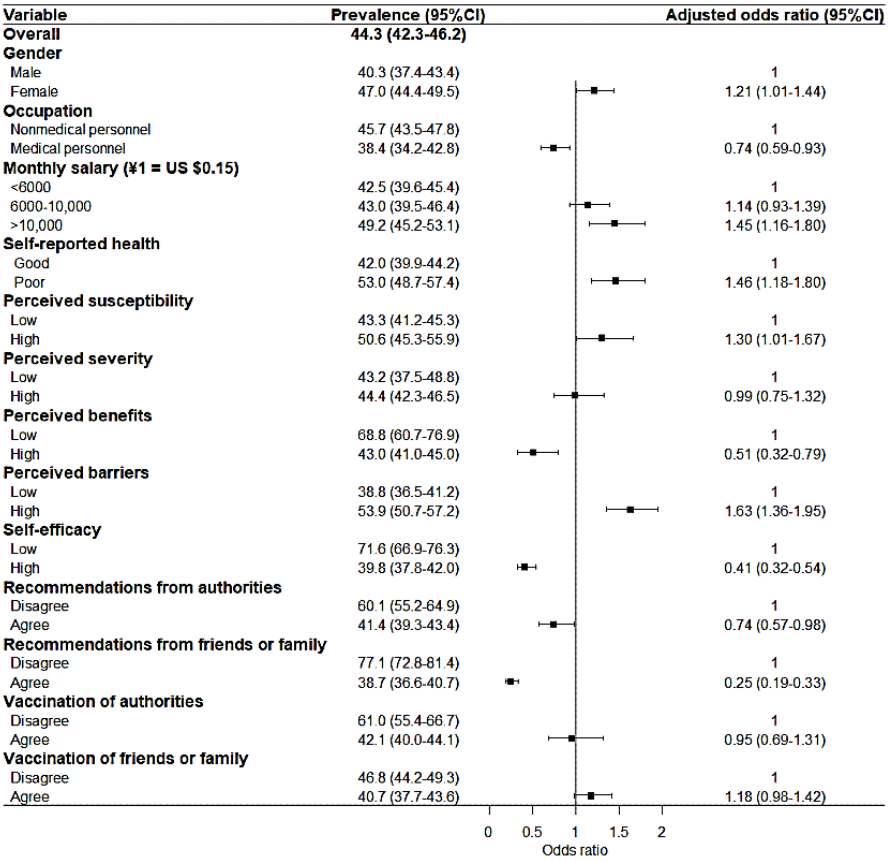

Figure 2. Associations between the health belief model and vaccination rate.

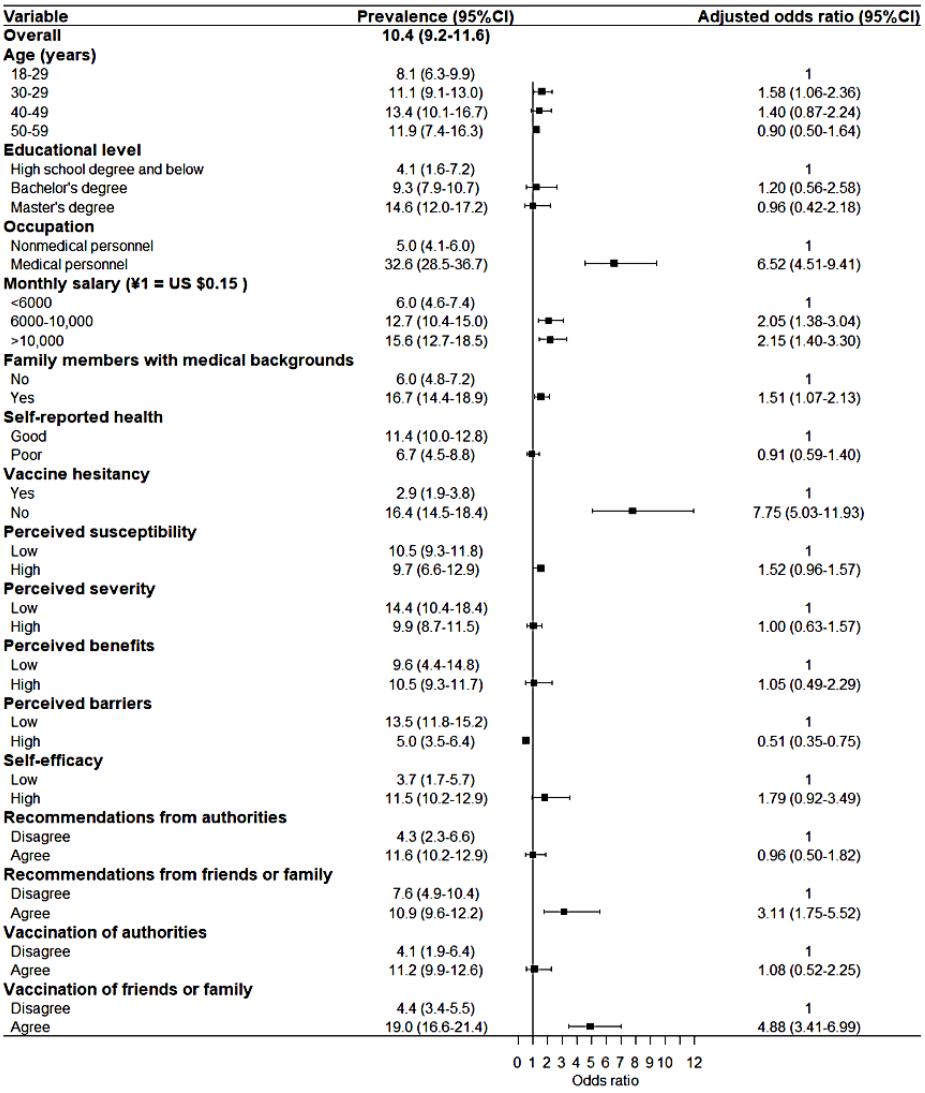

Results

Participant Characteristics

Our analysis included 2531 participants aged between 18 and 59 years (mean 33.92 years, SD 8.94); 58.7% (1486/2531) of the participants were female. Most of the participants were married (1660/2531, 65.6%), had a bachelor's degree (1609/2531, 63.6%), were nonmedical personnel (2034/2531, 80.4%), lived in urban areas (2262/2531, 89.4%), reported good health (2020/2531, 79.8%), and did not have chronic diseases (1617/2531, 63.9%). Slightly less than half of the participants reported monthly salaries lower than ¥6000 (1128/2531, 44.6%) and had family members with medical personnel backgrounds (1056/2531, 41.7%) (Table 1).

Distribution of Vaccine Hesitancy and Vaccination by Participant Characteristics and Health Belief Model Factors

Overall, 44.3% (1120/2531; 95% CI 42.3%-46.2%) of the participants were classified as vaccine hesitant: 1.4% responded "refuse all," 5.3% responded "refuse but unsure," 3.7% responded "refuse some," 18.8% responded "delay," and 15.1% responded "accept some." Overall, 55.7% (1411/2531) of the participants were classified as vaccine accepting: 25.1% responded "accept but unsure" and 30.6% responded "accept all." Only 10.4% (264/2531; 95% CI 9.2%-11.6%) of the participants had been vaccinated for COVID-19, while the majority (2267/2531, 89.6%) had not been.

According to the multivariable logistic regression analyses including participant characteristics (Table 1), the participants were more likely to be vaccine hesitant if they were female (OR 1.31, 95% CI 1.11-1.53), were nonmedical personnel (OR 1.35, 95% CI 1.10-1.64), had poor self-rated health (OR 1.56, 95% CI 1.28-1.89), or had a monthly salary over ¥10,000 (OR 1.31, 95% CI 1.08-1.60). The participants were more likely to have been vaccinated if they were 30 to 39 years old (OR 1.41, 95% CI 1.04-1.92), had a bachelor's degree (OR 2.23, 95% CI 1.12-4.43), had a master's degree and above (OR 3.71, 95% CI 1.12-4.43), were medical personnel (OR 3.71, 95% CI 1.12-4.43), had good self-rated health (OR 1.82, 95% CI 1.23-2.63), were not vaccine hesitant (OR 6.69, 95% CI 4.58-9.77), had a monthly salary between ¥6000 and ¥10,000 (OR 2.27, 95% CI 1.64-3.13), had a monthly salary over ¥10,000 (OR 2.88, 95% CI 2.07-4.17), or had family members with medical personnel backgrounds (OR 3.13, 95% CI 2.28-4.17).

According to the multivariable regression analyses including the HBM factors (Table 2), the participants were more likely to be vaccine hesitant if they had high perceived susceptibility to COVID-19 (OR 1.34, 95% CI 1.07-1.69) or had high perceived barriers to vaccination (OR 1.84, 95% CI 1.56-2.17). The participants were less likely to be vaccine hesitant if they had high perceived benefits of vaccination (OR 0.34, 95% CI 0.23-0.50), had high self-efficacy for vaccination (OR 0.26, 95% CI 0.20-0.34), agreed with recommendations from authorities (OR 0.47, 95% CI 0.38-0.58), agreed with recommendations from friends or family (OR 0.19, 95% CI 0.14-0.24), agreed with the vaccination of authorities (OR 0.46, 95% CI 0.36-0.60), or agreed with the vaccination of friends or family (OR 0.77, 95% CI 0.66-0.91). The participants were more likely to have been vaccinated if they had high self-efficacy for vaccination (OR 3.39, 95% CI 1.92-6.00), agreed with recommendations from authorities (OR 2.89, 95% CI 1.75-4.78), agreed with the vaccination of authorities (OR 2.94, 95% CI 1.62-5.31), or agreed with the vaccination of friends or family (OR 5.05, 95% CI 3.77-6.76).

Table 2. Distribution of vaccine hesitancy and vaccination by health belief model (HBM) factors and cues to action.

HBM factors and cues to action	Participants (N=2531), n (%)	Vaccine hesitancy			Vaccination		
		Vaccine hesitancy, n (%)	OR[a] (95% CI)	*P* value	Vaccination, n (%)	OR (95% CI)	*P* value
Perceived susceptibility							
Low	2191 (86.6)	948 (43.3)	1		231 (10.4)	1	
High	340 (13.4)	172 (50.6)	1.34 (1.07-1.69)	.01	33 (9.7)	0.91 (0.62-1.34)	.64
Perceived severity							
Low	292 (11.5)	126 (43.2)	1		42 (14.4)	1	
High	2239 (88.5)	994 (44.4)	1.05 (0.82-1.36)	.69	222 (9.9)	0.66 (0.46-0.93)	.02
Perceived benefits							
Low	125 (4.9)	86 (68.8)	1		12 (9.6)	1	
High	2406 (95.1)	1034 (43.0)	0.34 (0.23-0.50)	<.001	252 (10.5)	1.01 (0.95-1.07)	.76

[a]OR: odds ratio.

Influencing Factors of Vaccine Hesitancy and Vaccination

We included the participant characteristics and HBM factors in the vaccine hesitancy logistic regression, and the influencing factors are shown in Figure 1. The risk factors for vaccine hesitancy were female gender (*P*=47.0%, 95% CI 44.4%-49.5%; OR 1.12, 95% CI 1.01-1.44), monthly salary over ¥10,000 (*P*=49.2%, 95% CI 45.2%-53.1%; OR 1.45, 95% CI 1.16-1.80), poor self-rated health (*P*=53.0%, 95% CI 48.7%-57.4%; OR 1.46, 95% CI 1.18-1.80), high perceived susceptibility to COVID-19 (*P*=50.6%, 95% CI 45.3%-55.9%; OR 1.30, 95% CI 1.01-1.67), and high perceived barriers to vaccination (*P*=53.9%, 95% CI 50.7%-57.2%; OR 1.63, 95% CI 1.36-1.95). Additionally, the protective factors against vaccine hesitancy were occupation as medical personnel (*P*=38.4%, 95% CI 34.2%-42.7%; OR 0.74, 95% CI 0.59-0.93), high perceived benefits of vaccination (*P*=43.0%, 95% CI 41.0%-45.0%; OR 0.51, 95% CI 0.32-0.79), high self-efficacy for vaccination (*P*=38.4%, 95% CI 48.7%-57.4%; OR 1.46, 95% CI 1.18-1.80), agreement with recommendations from authorities (*P*=41.4%, 95% CI 39.3%-43.4%; OR 0.74, 95% CI 0.57-0.98), and agreement with recommendations from friends or family (*P*=41.4%, 95% CI 39.3%-43.4%; OR 0.74, 95% CI 0.57-0.98).

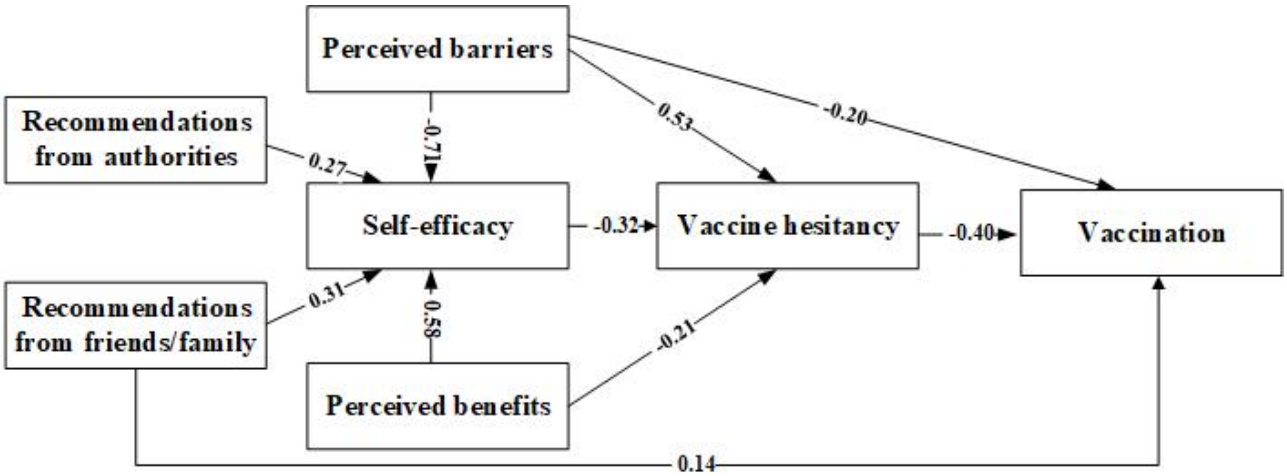
We included the participant characteristics, the HBM factors, and vaccine hesitancy in the vaccination logistic regression, and the influencing factors are shown in Figure 2. The promoting factors for vaccination were occupation as medical personnel (*P*=32.6%, 95% CI 28.5%-36.7%; OR 6.52, 95% CI 4.51-9.41),

monthly salary between ¥6000 and ¥10,000 (*P*=12.7%, 95% CI 10.4%-15.0%; OR 2.05, 95% CI 1.38-3.04), monthly salary over ¥10,000 (*P*=15.6%, 95% CI 12.7%-18.5%; OR 2.15, 95% CI 1.40-3.30), family members with medical personnel backgrounds (*P*=16.7%, 95% CI 14.4%-18.9%; OR 1.51, 95% CI 1.07-2.13), a lack of vaccine hesitancy (*P*=16.4%, 95% CI 14.5%-18.4%; OR 7.75, 95% CI 1.01-1.67), agreement with recommendations from friends or family (*P*=10.9%, 95% CI 9.6%-12.2%; OR 3.11, 95% CI 1.75-5.52), and agreement with the vaccination of friends or family (*P*=19.0%, 95% CI 19.6%-21.4%; OR 4.88, 95% CI 3.41-6.99). Additionally, a lower vaccination rate was associated with higher perceived barriers to COVID-19 vaccination (p=5.0%, 95% CI 3.5%-6.4%; OR 0.51, 95% CI 0.35-0.75).

Structural Equation Modeling of Vaccination

We used SEM to examine the underlying psychological mechanism of vaccination behavior (Figure 3). Based on the goodness-of-fit statistics, SEM showed a better fit to the data than the regression models (χ^2/df=4.62; RMSEA=0.05; CFI = 0.95; TLI = 0.91), and all of the paths were statistically significant (*P*<.05). The findings suggested that a mediating effect of self-efficacy, influenced by perceived barriers (SSC=−0.71, *P*<.001), perceived benefits (SSC=0.58, *P*<.001), agreement with recommendations from authorities (SSC=0.27, *P*<.001), and agreement with recommendations from friends or family (SSC=0.31, *P*<.001), was negatively associated with vaccination (SSC=−0.45, *P*<.001) via vaccine hesitancy (SSC=−0.32, *P*<.001). Additionally, perceived barriers (SSC=0.53, *P*<.001) and perceived benefits (SSC=−0.21, *P*<.001) were directly associated with vaccine hesitancy. Perceived barriers (SSC=−0.20, *P*<.001) and recommendations from friends or family (SSC=0.14, *P*<.001) were directly correlated with vaccination behavior.

Figure 3. The paths among vaccine hesitancy, vaccination, and health belief model factors. The numbers on the lines are the standardized structure coefficients.



Availability of Data and Materials

The data that support the findings of this study are available from the School of Public Health, Fudan University. The data were used under license for this study and are not publicly available. The data are, however, available from the authors upon reasonable request and with permission from the School of Public Health, Fudan University.

Discussion

Principal Findings

The findings of our study suggest that five HBM constructs—in the absence of perceived barriers, a high level of perceived benefits, and self-efficacy—as well as individuals' agreement with recommendations from authorities and friends or family were negatively associated with COVID-19 vaccine hesitancy and positively associated with vaccination behavior. Furthermore, psychological mechanisms were found to mediate the relationship between perceived barriers, perceived benefits, recommendations from authorities and friends or family, and vaccination uptake behavior via vaccine hesitancy. Self-efficacy, perceived barriers, and perceived benefits were correlated with vaccine hesitancy, while perceived barriers and recommendations from friends or family were directly correlated with vaccination.

In this study based in China, the prevalence of vaccine hesitancy was 44.3% (95% CI 42.3%-46.2%), and the vaccination rate was 10.4% (95% CI 9.2%-11.6%), representing high vaccine hesitancy and low vaccination behaviors. Vaccine hesitancy has been universally reported in recent research, with over half of participants (53%) across 19 countries showing vaccine hesitancy, which is similar to our results [59] and in accordance with the decline in vaccine acceptance (from >70% in March 2020 to <50% in October 2020) reported by a recent review [60]. Undoubtedly, eliminating vaccine hesitancy would be beneficial to voluntary vaccination behaviors, as seen in this study, which showed that the vaccination rate was nearly 8 times higher among the participants who were accepting of vaccines compared to those who were vaccine hesitant. In the SEM results, vaccine hesitancy was also strongly negatively associated with vaccination behaviors (Hypothesis 1 confirmed). Therefore, the control of vaccine hesitancy and the promotion of voluntary vaccination still seem to be challenges in the context of the COVID-19 pandemic.

In this study, female participants showed more COVID-19 vaccine hesitancy, which is consistent with previous findings in the literature [61,62]; a possible reason for this finding is that women are more likely to be concerned about side effects [63] and take nonpharmaceutical protective measures (eg, masking and maintaining social distance) [64], while men are more inclined to adopt medical intervention [65]. Medical personnel showed less vaccine hesitancy and a much higher vaccination rate in this study, which may be inconsistent with the general argument that health workers have strong negative attitudes toward vaccines, with strong skepticism about their safety and effectiveness, especially regarding the influenza vaccine [66,67]. Another finding seems unexpected; that is, that the participants with higher monthly salaries were associated with both vaccine hesitancy and a higher vaccination rate; in other words, even though these individuals were vaccine hesitant, they were still vaccinated. Vaccine hesitancy was not only a direct determinant of vaccination but also a perceived barrier. Participants with higher salaries were more likely to have higher socioeconomic status [68], so they could more easily access social resources; that is, they had lower barriers to obtaining vaccines, which could then increase the vaccination rate among this group.

Although some of the HBM factors were not directly associated with the vaccination rate, perceived benefits of vaccination, perceived barriers to vaccination, self-efficacy for vaccination, and recommendations from authorities were correlated with vaccine hesitancy (Hypothesis 2 partially confirmed), which was consistent with previous research among the Malaysian public [36] and the Chinese general population [69]. In all HBM constructs associated with vaccine hesitancy and vaccination, self-efficacy for COVID-19 vaccination was an important predictor of vaccination behaviors, via vaccine hesitancy. This result is similar to the findings of previous studies on influenza vaccination, according to which self-efficacy is a key factor of willingness, which in turn predicts behavior [46,70]. Self-efficacy also plays a mediating role between vaccine hesitancy and other HBM components, including perceived barriers, perceived benefits, and recommendations from authorities and friends or family, and it indirectly influences vaccination uptake. This finding was supported by the HBM hypothesis (Hypothesis 3 partially confirmed) that HBM constructs and cues to action may not share a juxtaposition or parallel relationship, but self-efficacy functioned as a serial mediator [71]. Hilyard et al noted that public self-efficacy for COVID-19 vaccination could be promoted by enhancing the perceived benefits of vaccination, confidence in overcoming possible side effects (ie, perceived barriers), and recommendations from authorities, such as the Obamas' modeling of H1N1 vaccine acceptance for their daughters [52]. In this study, self-efficacy was measured as a specific domain with confidence in the safety of the COVID-19 vaccine, a low prevalence of side effects of the COVID-19 vaccine, and success in dealing with side effects. Vaccine safety or side effects, which are regarded as contributing to the development of disease, are of paramount importance to individual efficacy when deciding whether to vaccinate [72,73] and are even relevant aspects that help explain the antivaccine movement in Europe [74]. A study argues that a perceived risk-benefit balance may influence confidence in vaccine uptake; in other words, a combined decision-making process relies on a trade-off between benefits and risks [66]. In addition to cues to action, this result was consistent with a previous study showing that compliance with recommendations from health workers may also be correlated with confidence in vaccine efficacy [73], because they can share personal knowledge about being immunized and motivate vaccine uptake efficacy [75].

In addition to the direct and mediating effect of self-efficacy, some HBM constructs were directly associated with vaccine hesitancy and vaccination behavior. Perceived barriers were both positively correlated with vaccine hesitancy and detrimental to vaccination, as measured by the safety, side effects, and inaccessibility of the COVID-19 vaccine, in which safety may influence self-efficacy as aforementioned, while inaccessibility would hinder the perceived convenience of COVID-19 vaccination behavior directly. With a more specific formulation, a controlled before-and-after trial study showed that arranging time and transportation were key predictors of both intention and behavior regarding influenza vaccination [76]. A previous survey also found that the side effects and safety of influenza vaccination were the most common reasons for vaccine hesitancy [77]. Perceived benefits were associated with vaccine hesitancy, which was measured by preventing the self and one's family from being infected after COVID-19 vaccination. From an altruistic motivation perspective, people could be vaccinated to protect not only themselves but also their loved ones; in other words, there could be more willingness to receive the vaccine if individuals believe that it helps reduce the transmission of COVID-19 [78]. Recommendations from family were found to be directly associated with vaccination behavior in this study. An online survey in Canada showed that respondents reported that encouragement from both colleagues and employers was beneficial to their vaccination decision-making process [55]. Another finding implied that a recommendation from a spouse or a friend is an important cue to action in determining willingness to accept the Zika virus vaccine [79]. However, perceived susceptibility and severity were not enough to reduce vaccine hesitancy and promote vaccination behavior. A review indicated that perceived barriers were the most powerful single predictor of preventive health behavior across all studies and behaviors, and perceived severity was the least powerful predictor [71].

From the perspective of the HBM on understanding vaccination behavior, it is valuable that self-efficacy is an important and direct predictor of COVID-19 vaccine hesitancy because it can also mediate the influences from cues to action, perceived barriers, and perceived benefits. Furthermore, vaccine hesitancy was strongly correlated with vaccination behavior but was not the only determinant, since perceived barriers and recommendations from friends or family were also associated with vaccination behavior directly and in combination.

In practice, it is valuable for other nations to know what the Chinese vaccine hesitancy and vaccination statuses were at the beginning of the critical period when COVID-19 vaccination became available to the public, free of charge. This finding indicates that health authorities or doctors may be less effective in motivating people to action, while it may be useful to advocate for more volunteers to engage in motivating their

friends or family members. Although the antivaccine movement that occurred in other nations was not popular in mainland China, vaccine hesitancy and refusal were not rare occurrences without mandatory vaccination in this study. Moreover, it is essential to reinforce the publishing of information regarding the safety and validity of COVID-19 vaccines and incentives of vaccination completion, which could then promote public confidence in overcoming vaccination barriers and in achieving benefits after vaccination.

In summary, there was a high prevalence of vaccine hesitancy and low vaccination behavior in China during the first month (January 2021) when vaccinations became available to the vaccine-eligible population. The HBM framework is a useful framework to guide the development of future campaigns to reduce vaccine hesitancy and promote COVID-19 vaccination.

Limitations

There are some potential limitations to this study. First, due to the convenience sampling and snowball recruitment methods that were part of the online survey process, selection bias, such as the participation of fewer respondents with low education attainment and fewer older adults (aged over 50 years), may have affected the generalizability of the results. Second, vaccine hesitancy was measured by a single item derived from a definition from the SAGE working group, which may promote more accurate measurement tools in future research. Furthermore, the vaccination rate in this study may not reflect future trends because only some participants had received the vaccine in a timely manner, vaccinations were available to the public for only 1 month, and there were no incentives except to receive a free vaccination before participating in the study.

Acknowledgments

This work was supported by the National Key R&D Program of China (grants 2018YFC2002000 and 2018YFC2002001) and the National Natural Science Foundation of China (grant 71573048).

Authors' Contributions

JD, JG, HF, PZ, and YJ designed the study and obtained the data. HC and X Li undertook the analysis, supervised by JD, JG, and HF, and wrote the manuscript. X Liu translated the questionnaire. HC, X Li, X Liu, YM, and RW performed the survey. All authors read the final manuscript and agreed with the content.

Abstract

Background: SARS-CoV-2 is one of the most threatening pandemics in human history. As of the date of this analysis, it had claimed about 2 million lives worldwide, and the number is rising sharply. Governments, societies, and scientists are equally challenged under this burden.

Objective: This study aimed to map global coronavirus research in 2020 according to various influencing factors to highlight incentives or necessities for further research.

Methods: The application of established and advanced bibliometric methods combined with the visualization technique of density-equalizing mapping provided a global picture of incentives and efforts on coronavirus research in 2020. Countries' funding patterns and their epidemiological and socioeconomic characteristics as well as their publication performance data were included.

Results: Research output exploded in 2020 with momentum, including citation and networking parameters. China and the United States were the countries with the highest publication performance. Globally, however, publication output correlated significantly with COVID-19 cases. Research funding has also increased immensely.

Conclusions: Nonetheless, the abrupt decline in publication efforts following previous coronavirus epidemics should demonstrate to global researchers that they should not lose interest even after containment, as the next epidemiological challenge is certain to come. Validated reporting worldwide and the inclusion of low-income countries are additionally important for a successful future research strategy.

KEYWORDS

COVID-19; SARS-CoV-2; incidence, research funding; socioeconomic factors; bibliometrics; bibliometric analysis; global health; public health; health database; online research; research database

Introduction

In December 2019, a new coronavirus (CoV) variant infected some patients in China. It was transmitted at a seafood and wet animal wholesale market in Wuhan city, Hubei Province. This novel zoonotic coronavirus was named SARS-CoV-2 because it also causes severe acute respiratory syndrome (SARS) [1]. Previously detected coronaviruses such as SARS-CoV and Middle East Respiratory Syndrome (MERS)-CoV led to temporary pandemics and consequently to serious public health challenges, which, however, came to an end with the containment of the diseases and their spread. The first cases of the infectious disease caused by SARS-CoV-2, designated COVID-19, indicated the beginning of an outbreak that would become a still ongoing global pandemic on a scale not seen since the Spanish flu in 1918, which killed up to 50 million people [2].

As of this analysis (January 12, 2021), more than 93 million COVID-19 cases have been confirmed, with the number continuing to rise rapidly. Over 2 million people have died in association with SARS-CoV-2 infection as of that date [3]. The enormous impact is catastrophic and affects all areas of public, political, economic, and private life. For sure, it will for a long time. The associated demands and restrictions on citizens and the social systems of all nations are undeniable.

Indeed, it was expected that the number of publications on CoV would increase sharply in 2020, but to what extent and with what participation were not clear [4]. There already have been some studies on the general output of COVID-19–related publications [5-7]. In addition, however, it is necessary to identify and evaluate the general and national research efforts according to additional influences such as epidemiological and funding characteristics to enable successful and determined planning, funding, and implementation of science-based research in the future that reaches all necessary areas through balanced multidisciplinary research.

To achieve this objective, this study mapped the world according to various influencing factors, leading to an advanced and meaningful assessment of the research of the first COVID-19 pandemic year 2020, which will certainly not be the last.

Methods

Methodological Platform and Data Source

This study followed the methodological approach of the bibliometric platform New Quality and Quantity in Science (NewQIS) [8]. For the first time, NewQIS combined bibliometric analyses with density-equalizing mapping (DEMPs) [9] to depict the global publication landscape on scientific topics. DEMPs enable the rapid acquisition of large-scale data. In this process, countries are distorted according to the density-equalizing principle applied by an algorithm developed by Gastner and Newman [9]. The result is a distorted world map according to the respective evaluation parameter, with countries with high values enlarged and countries with low values reduced.

The aim was to provide solid information on research patterns in terms of trends, incentives, challenges, obstacles, and necessities for all parties involved. Socioeconomic parameters and research-specific conditions at the country level were included in the analyses to assess regional performance according to the need for valuable and balanced research that is accessible and appropriate for all parts of the world.

Search Strategy

To capture all CoV-related articles published in 2020, the following elaborated search term was applied in the Web of Science Core Collection (WoS) search field: Title: “corona virus*” OR “coronavirus*” OR “SARS” OR “MERS” OR “covid-19” OR “severe acute respiratory syndrome” OR “middle east respiratory syndrome” AND Topic: virus* OR epidem* OR CoV OR Co-V OR patient* OR outbreak* OR “corona virus” OR “coronavirus” OR “covid-19” OR “severe acute respiratory syndrome” OR “middle east respiratory syndrome”. This string ensured the representativeness of the database generated. Then, the entries were filtered by original articles to base the evaluation on actual research on coronavirus. No language filter was applied. The year 2020 was chosen as the time frame. The date of data collection was January 12, 2021.

The metadata of the datasets collected in this way were stored and sorted according to the individual evaluation parameters and linked by assigning identification numbers to each entry. Some parameters had to be additionally corrected manually, such as matching institution names and funding sources.

Utilized Parameters and Analyses

In addition to established bibliometric parameters such as publication performance, citation parameters, and networking, CoV-specific parameters were also analyzed in this study. These relate to epidemiological characteristics (numbers of cases associated with COVID-19 [3]), socioeconomic characteristics (gross domestic product [GDP], population size), and funding characteristics of the publishing countries. The socioeconomic and epidemiological parameters were used as absolute numbers to allow comparison with absolute publication numbers. The use of per capita values would also require the use of publication figures per capita, which would be redundant when calculating the ratio. International collaborations were defined by the participation of at least two countries of origin, as indicated in the author's affiliations. China and Taiwan were analyzed separately.

In addition, an analysis of the development of publication and citation numbers in 10 time intervals, into which the year 2020 was divided, was carried out. Furthermore, an analysis of research areas was performed employing clustering with the application VOSviewer developed by van Eck and Waltman [10]. Author keywords were clustered and displayed by nodes and connecting lines that represent the different research areas.

Methodological Limitations

Although the methodology used provides a valid source of data, some limitations must be considered when evaluating the results. First, all analyses can only be as good as the database used. For all NewQIS studies, WoS serves as the standard data source. Despite the often-documented English bias and the limitation of a somewhat restricted dataset, according to the high indexing requirements [11], the database provides representative and qualitative results for the further analyses of this study [12]. Some entries had to be manually unified, such as funding sources, which is a nonrepeatable, standardized procedure. In addition, citation-based analyses are prone to error and cannot be considered a proxy for research quality. Nevertheless, the combination of applied ones provides a deep insight into publication performance.

Results

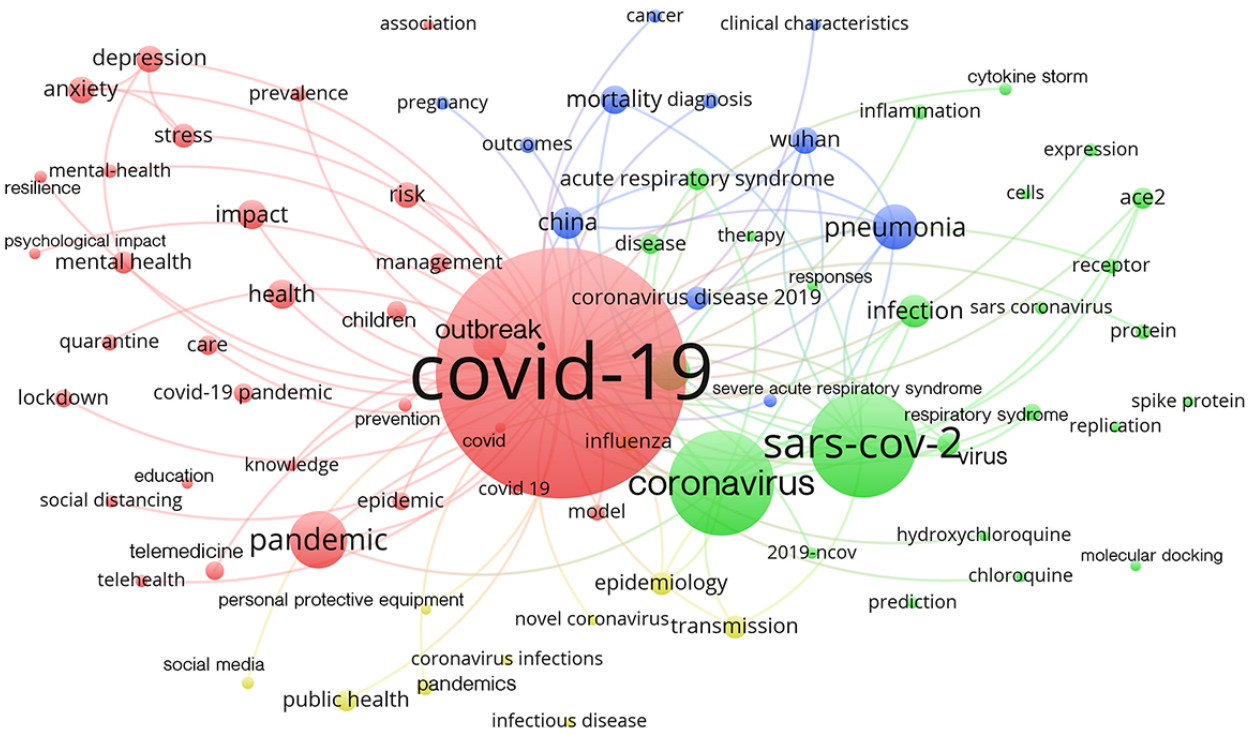
Main Research Foci of CoV Research in 2020

COVID-19 as the most frequently occurring keyword indicates that almost all coronavirus research in 2020 related to SARS-CoV-2 infection, as confirmed by a manually performed review of the articles included in the database.

In addition, analysis of the most frequently used keywords (threshold: 200 occurrences) revealed 4 thematic clusters dealing with the psychological and physical impacts of COVID-19, immunological and biochemical issues, and epidemiological and public health issues (Figure 1). The articles could mainly be assigned to the WoS categories “General and Internal Medicine” (n=8488), “Public, Environmental & Occupational Medicine” (n=2845), “Infectious Diseases” (n=1830), “Science

& Technology – Other Topics" (n=1671), "Environmental Science & Ecology" (n=1397), and "Psychiatry" (n=1116).

Figure 1. Clusters of keywords (threshold: 200 occurrences). Red: psychological health effects; blue: physical health effects and mortality; green: biochemistry and cell biology; yellow: epidemiology and public health.



Evolution of CoV Research in 2020

Applying search terms yielded 67,437 publications on CoV in 2020, of which just under half were original articles (n=32,402) that comprised the analysis database. Of the other document types, 12,435 were letters, 12,245 were editorial material, 6956 were classified as early access, and 6556 were reviews, to name the most common publication types. Looking at the overall evolution of CoV research, the year 2020 was exorbitantly outstanding (Figure 2). The epidemics of SARS in 2003 and MERS in 2012 caused the number of articles to increase to 679 in 2004 and to 340 in 2016, which decreased as soon as the epidemics were contained [4]. These figures show that the number of articles on CoV in 2020 was almost 50 times higher than in the previous peak year of 2004.

Although the 2020 articles are still very young to generate a significant number of citations and thus recognition in the scientific community, which underlies a citation half-life of 7-8 years for biomedical articles, some articles already received an exceptionally high number of citations. The 10 most frequently cited articles are summarized in Table 1. They were published in high-impact journals and are predominantly from China, where SARS-CoV-2 first appeared. Two international collaborations are also represented in the ranking: 1 is an international collaboration of German, Austrian, and Russian scientists, and the other is a Chinese-Australian partnership. All received financial support through government programs from China or Germany.

Figure 2. Development of the numbers of articles about coronavirus research. The comparative figures from 1970-2019 are taken from a previous study by Klingelhöfer et al [4] to show the immense increase in publication numbers in 2020. MERS: Middle East Respiratory Syndrome; SARS: Severe Acute Respiratory Syndrome.

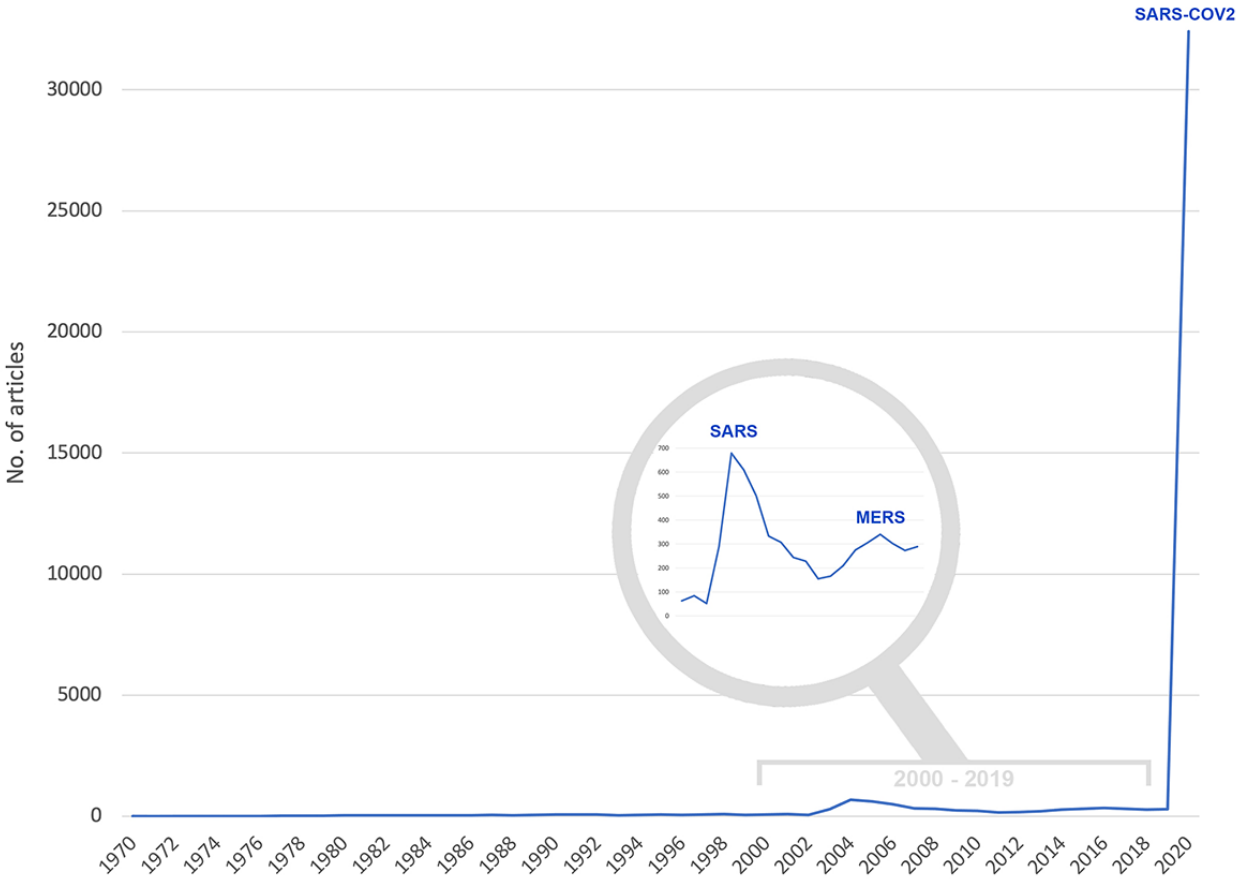


Table 1. Most frequently cited articles on coronavirus (CoV) in 2020 (as of January 12, 2021).

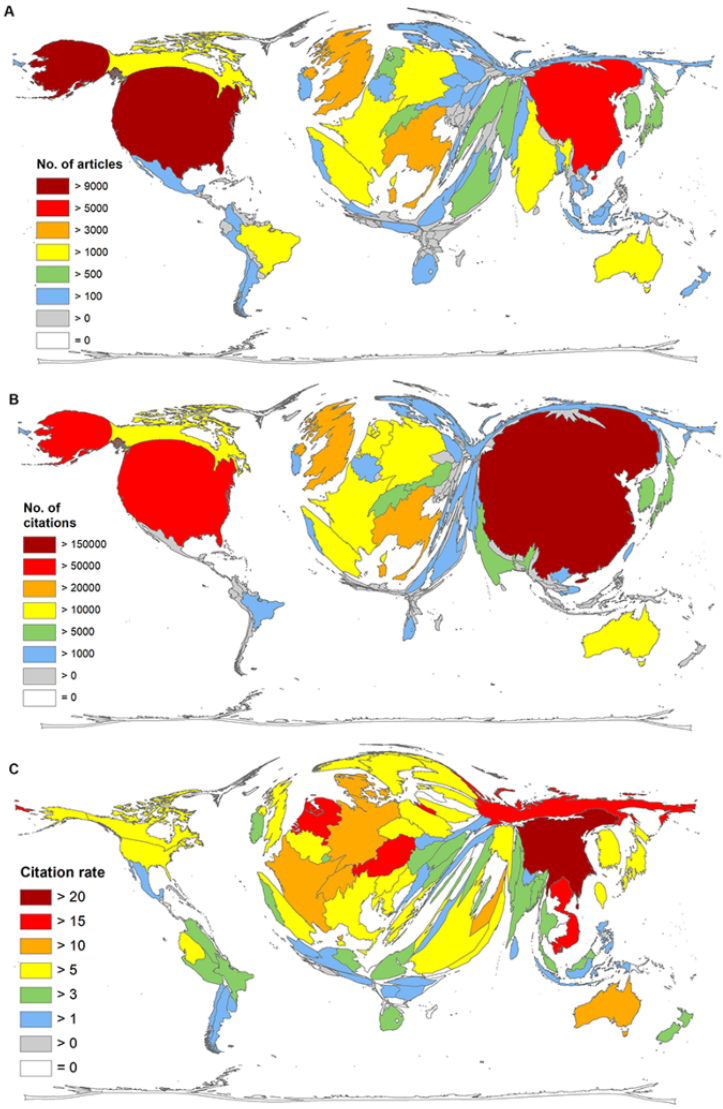
Highest Publishing Countries on CoV in 2020

In total, 170 countries or autonomous regions participated in research on CoV in 2020 that was indexed in WoS. By far, the United States had the most publications (n=9018), followed by China (n=5053), Italy (n=3195), the United Kingdom (n=3135), and India (n=1847; Figure 3A).

Figure 3. Density-equalizing maps showing the (A) number of articles, (B) number of citations, and (C) citation rate (citations per article), threshold >30 articles.

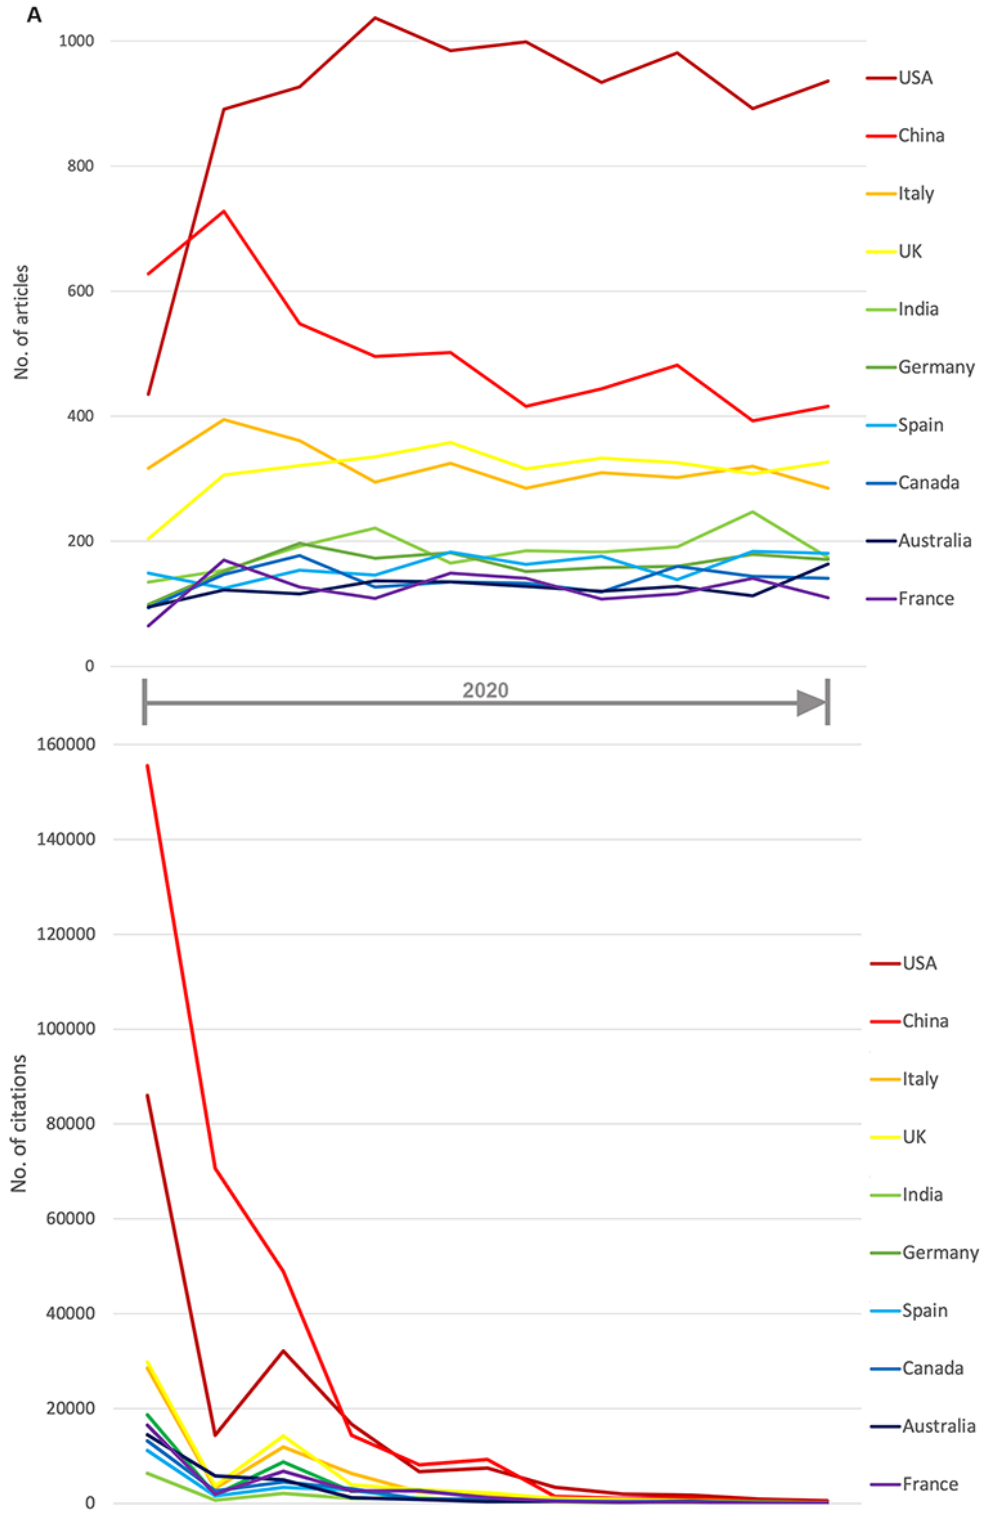


In contrast, China received the most citations (n=155,522). The United States got considerably fewer citations on their CoV-related articles (n=86,003). It is followed by the United Kingdom (n=29,840), Italy (n=28,530), and Germany (n=18,695). India ranked only 12th with 6351 citations (Figure 3B).

Resulting from these numbers, China also led the ranking when looking at the citation rates of countries with at least 30 articles on CoV in 2020 (threshold) with a citation rate of 30.78. It was followed by the Netherlands (citation rate=19.56), Russia (citation rate=17.04), Austria (citation rate=16.18), and Vietnam (citation rate=16.07). In this term, the United States and the United Kingdom ranked nearly similarly, at only 22nd (citation rate=9.54) and 23rd (citation rate=9.52), and India was even only ranked at 79th (citation rate=3.44; Figure 3C).

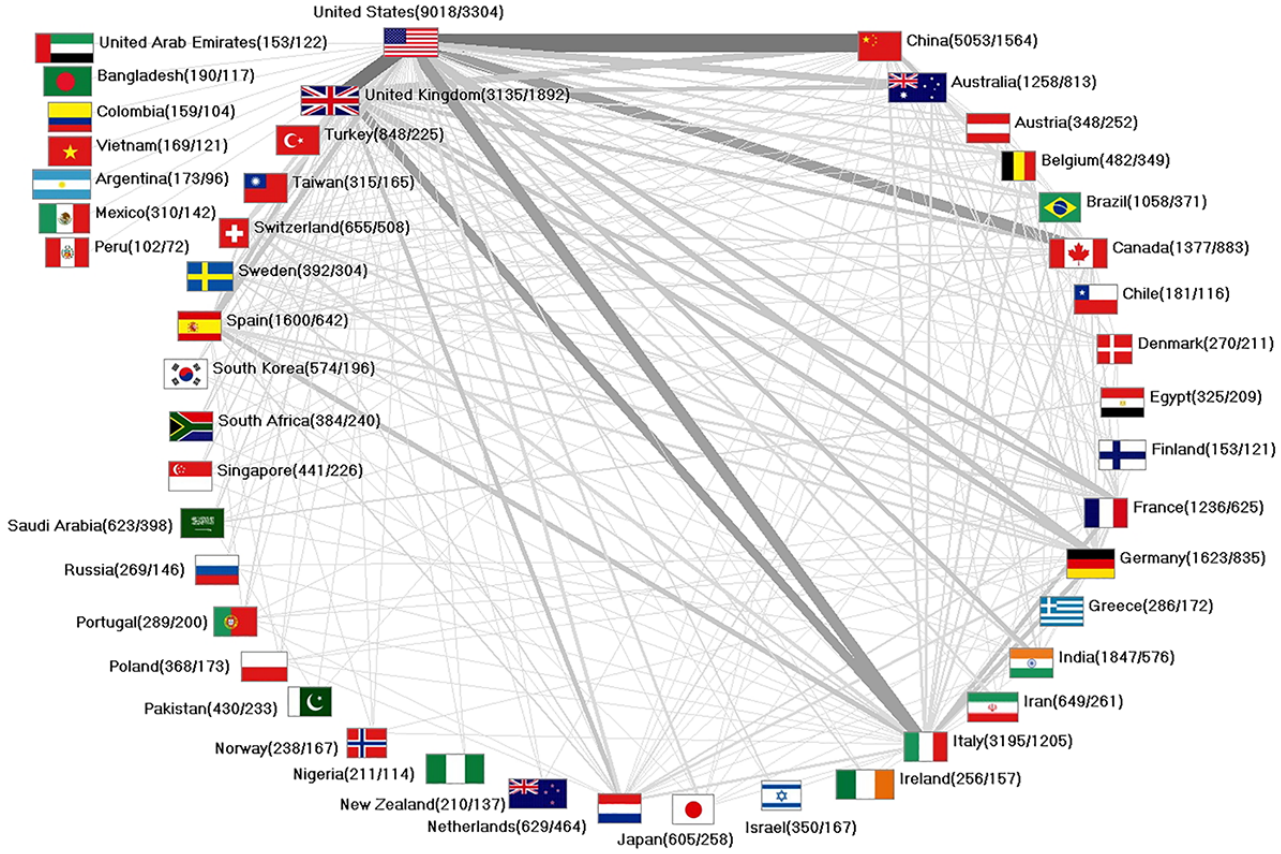
The dominance of US-American and Chinese researchers in terms of CoV research over the entire year 2020 could be shown by the numbers of articles and citations. Nevertheless, their share varied over the year. While Chinese articles dominated in the early phase, US-American articles gained momentum as the year progressed. The United Kingdom's share also increased during the year, eventually overtaking the share of Italy (Figure 4A). The same holds true for the trend in the number of citations, although this depends on the minimum time the articles had to generate citations by other publications (Figure 4B).

Figure 4. Development in 2020 of the 10 countries with the highest number of articles, including the (A) number of articles on the topic of coronavirus and (B) number of citations of the articles on the topic of coronavirus.



A broad international network on CoV research has developed, with the United States and China being the main cooperation countries with 800 collaborations (Figure 5). In general, the United States acts as the main core country when considering international partnerships. In addition to the Chinese collaborations, there were 640 collaborations with the United Kingdom, 496 collaborations with Italy, and 496 collaborations with Canada, to name the most collaborating nations. There were 412 collaborations between the United Kingdom and Italy and 279 collaborations between Italy and Spain.

Figure 5. International network on coronavirus (threshold 35 collaborations).



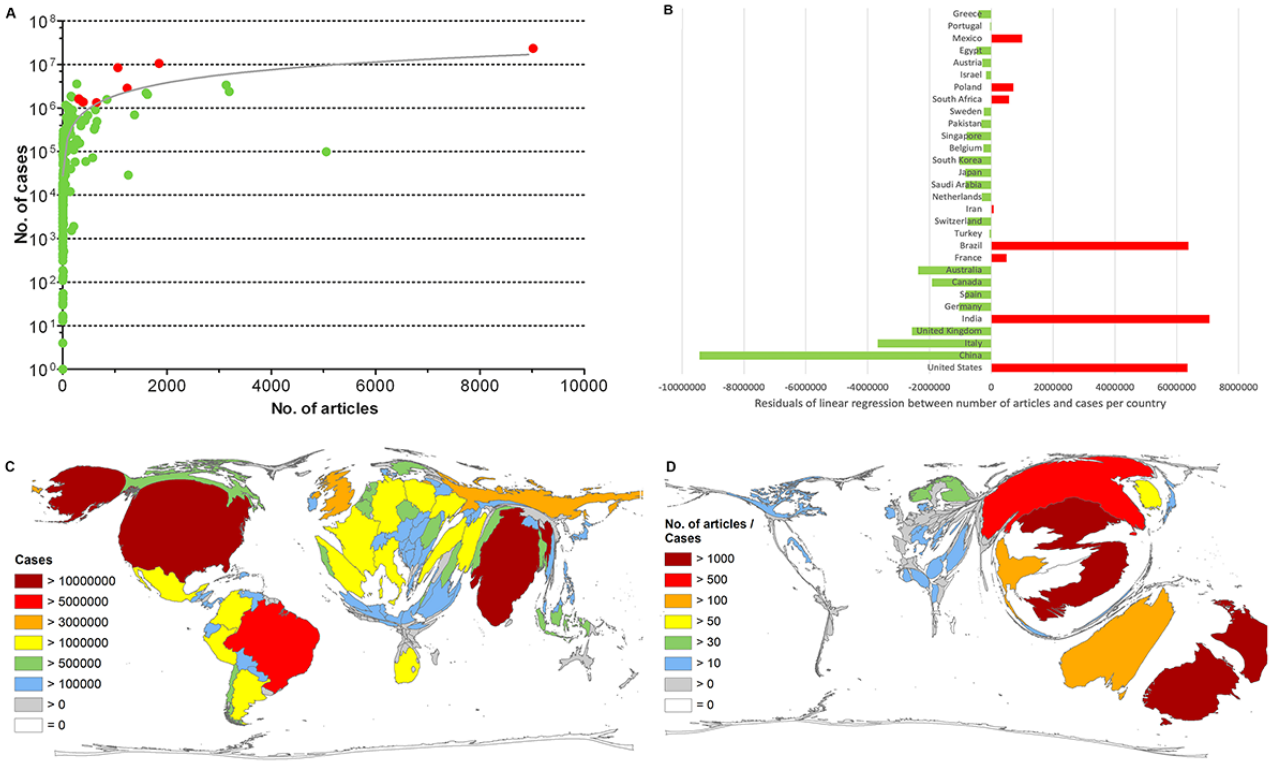
Factors Influencing CoV Research in 2020

Epidemiological Factors

To consider the need for research on CoV according to the national burden of disease, the relationship of the number of articles on CoV to nationally registered cases of COVID-19 (as of January 18, 2021) was analyzed. The coefficient of determination was r^2=0.64 (Figure 6A) showing a significant correlation (Spearman; *P*<.001). China showed the highest distance from the regression line (residual) toward a favorable publication performance (negative values), while India, the United States, and Brazil showed the highest deviations toward a more negative relationship (positive values). The most publishing European countries were also in the positive range of deviation from the regression line but on a lower level than China (Figure 6B).

To provide a picture of the occurrence of COVID-19 cases, a DEMP was generated showing the corresponding distortions on the world map (Figure 6C), with the highest numbers occurring in the United States, India, Brazil, Russia, the United Kingdom, France, Italy, Spain, and Germany, to indicate the countries with more than 2 million cases by January 18, 2021 (date of data collection) [3]. Relating these numbers to COVID-19 cases by calculating the ratio of countries (R_{CASES}) with at least 30 articles on CoV (threshold), southeastern countries were ahead. New Zealand, with only 1900 registered cases, could be ranked first (R_{CASES}=1105.26), followed by Vietnam (R_{CASES}=1099.54), China (R_{CASES}=512.34), Australia (R_{CASES}=438.50), and Thailand (R_{CASES}=119.46). On the other hand, among the most publishing countries besides China, Italy ranked next at 21st, followed by the United Kingdom (26th), Germany (30th), the United States (51st), and India (69th) due to their enormous incidence rates (Figure 6D).

Figure 6. Relationship between the number of articles and COVID-19 cases per country, based on (A) linear regression (logarithmic display of y-axis), with red indicating the countries with an unfavorable ratio in terms of the number of articles among the top 30 countries; (B) residuals of the linear regression of the 30 most publishing countries, with red indicating the countries with an unfavorable ratio in terms of the number of articles; (C) density-equalizing map projection of the number of COVID-19 cases as of January 18, 2021; (D) density-equalizing map projection of the ratio between the number of articles and the number of COVID-19 cases (threshold >30 articles).



Socioeconomic Factors

The inclusion of socioeconomic features of the publishing countries revealed a different ranking. The first ratio related the publication output per country with its economic power (ranked GDP [R_{GDP}]). When looking at the countries with more than 100 articles on CoV in 2020, Jordan, as an upper-middle-income economy, led the ranking (R_{GDP}=1543.10). It was followed only by high-income economies until position 21 (upper-middle-income economy=South Africa). Rank 2 could be attributed to Italy (R_{GDP}=1438.54), followed by Switzerland (R_{GDP}=1325.11), New Zealand (R_{GDP}=1201.37), and Israel (R_{GDP}=1178.45). In addition, the number of articles was significantly correlated with gross expenditures on research and development in purchasing power parity in international $ (ppp$; Spearman, P<.001).

In terms of the population size (R_{POP}) of the same countries, only high-income countries were leading. Switzerland ranked first (R_{POP}=80.08), followed by Norway (R_{POP}=45.20), Israel (R_{POP}=42.82), Belgium (R_{POP}=42.25), and Austria (R_{POP}=39.95; Table 2).

[a]GDP: gross domestic product.

[b]R_{GDP}: ratio of number of articles and GDP in US $1000 billion.

[c]R_{POP}: ratio of number of articles and population in millions.

[d]UMI: upper-middle-income [23].

[e]HI: high income [23].

[f]LMI: lower-middle-income [23].

Funding Factors

In total, 17,590 articles received 27,150 grants from many governments and other funding agencies, including universities, hospitals, research institutions, nonprofit organizations, and private companies, among others (Table 3).

Table 3. Coronavirus research funding in 2020.

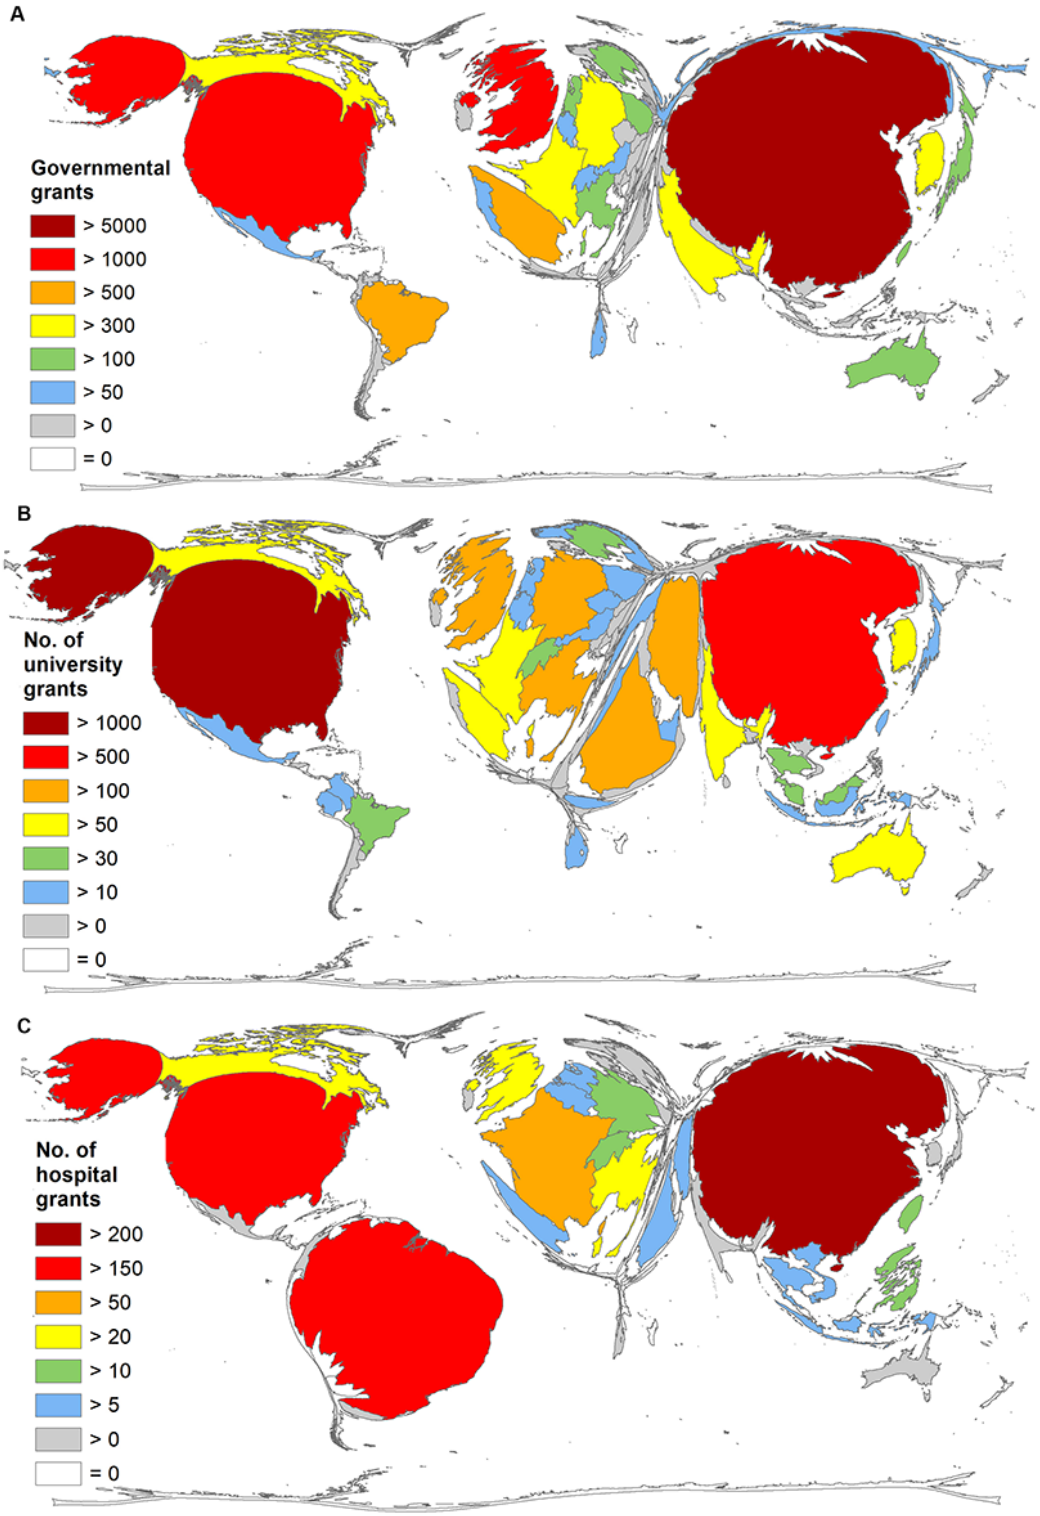
Funder	Number of grants
Governments	17,334
Universities/collages	4264
Trust/foundations	2004
International	967
Companies	947
Hospitals/health care	833
Societies/associations	379
Research institutes	186
Nonprofit organizations	95
Charities	52
Banks (private, nonprivate)	42
Networks/platforms	36
Parishes/churches	6
Publishers/journals	3
Unions	2

The government that funded the most CoV research was that of China (number of grants=6342), followed by the United States (number of grants=3983), the United Kingdom (number of grants=1179), Spain (number of grants=589), and Brazil (number of grants=504; Figure 7A). Thus, China — as the only country — had awarded more grants than published articles,

resulting in a rate of 1.26 grants per article. Applying the methodological 30-article threshold, the next highest rate was achieved by South Korea (0.58 grants per article), followed by Brazil (0.48 grants per article), the United States (0.44 grants per article), and the Czech Republic (0.44 grants per article).

Looking at university funding, the United States supported the most CoV research (number of grants=1023; Figure 7B), followed by China (number of grants=899), the United Kingdom (number of grants=215), Saudi Arabia (number of grants=173), and Italy (number of grants=164). Analysis of hospital grants showed China at the top (number of grants=222; Figure 7C), followed by Brazil (number of grants=161), the United States (number of grants=160), France (number of grants=53), and Italy (number of grants=27).

Figure 7. Density-equalizing maps of funding for coronavirus-related research, including (A) governmental funds, (B) university funds, and (C) hospital funds.



In the analysis of individual funders, the US National Institutes of Health led the way, followed by the Chinese National Natural Science Foundation, the European Union, the British National Institutes for Health Research, and the Wellcome Trust based in London, United Kingdom. The top 10 funding organizations are listed in Table 4.

Table 4. Top 10 funders supporting coronavirus research.

Funder	Number of grants
US National Institutes of Health (NIH)	2505
National Natural Science Foundation of China (NSFC)	1467
European Union (EU)	861
UK National Institute for Health Research (NIHR)	390
French National Research Agency (ANR)	343
Wellcome Trust United Kingdom	192
Brazilian National Council for Scientific and Technological Development (CNPq)	169
Chinese Academy of Sciences (CAS)	132
Bill & Melinda Gates Foundation	120
Chinese Academy of Medical Science (CAMS)	110

Discussion

Principal Findings

Undoubtedly, it is not surprising that the year 2020 was marked by an immense increase in the number of publications on CoV that addressed SARS-CoV-2 infections. Nevertheless, the scale of increase is surprising: from 289 articles in 2019 to 32,402 articles in 2020 — more than a 100-fold growth.

The global COVID-19 pandemic threatens all countries' societies with high incidence and mortality rates, so the scientific community vehemently sought solutions to contain this viral infection and the resulting symptoms through various approaches. These followed the interests of the national governments, which funded scientific endeavors just as highly.

Nevertheless, the proportion of original articles was relatively low compared to publications on other biomedical topics that are currently the talk of the town, such as climate change, where the share of articles is almost 70%, while the proportion of original research documented in CoV publications is less than 50% with a large proportion of letters and editorial material. A comparison between US-American and Chinese publications showed that the United States followed this result with nearly 70% of the article share, while Chinese articles accounted for over 90% [24]. Under the conditions of the present study, this pattern seems to be overridden in favor of shorter document types — also in the sense of rapid publication.

A closer look at the published document types also revealed that 15 papers had to be retracted although they had not even been published for a year. This demonstrates the immediacy with which results had to be published and the susceptibility to error that this occasionally entails. The pressure to be the first to publish on a new approach and deliver new results, and not be overtaken by colleagues working on the same topic, became very exigent in research on CoV in the 2020s.

The citation speed is similarly rapid. Three high-impact articles with more than 5000 citations were published in 2020 — remarkable because these papers have not yet had a year to be read or cited. The Chinese author groups reported clinical features of COVID-19 patients hospitalized in Wuhan [13-15]. Certainly, these findings have been taken up as background information for many subsequent articles.

Nevertheless, this extremely rapid publication activity, albeit at a much lower level, could also be demonstrated for the SARS and MERS epidemics, with a notable loss of research effort once the threat had subsided [4]. Had this not occurred, the state of knowledge at the onset of the SARS-CoV-2 outbreak would certainly have been sounder and the resulting measures better scientifically validated. These patterns should therefore be considered when the current pandemic has hopefully soon subsided.

It is also not surprising that in early 2020, most articles were submitted by Chinese authors reporting clinical manifestations that occurred during the outbreak in Wuhan, which was also noted in a study using the COVID-19 Open Research Dataset [25]. Subsequently, US-American researchers overtook the Chinese in terms of volume and citations received. Nevertheless, China has received the most citations so far, which is because of early publication. Articles published later have not had the time to receive so many citations. How these numbers will continue to evolve is for later studies to show. It is also not surprising that the share of Italian articles decreased slightly, considering the extreme incidence rates in Italy at the beginning of 2020. As the numbers of COVID-19 cases and mortality rates dropped, so did study numbers in Italy. As a result, Italy's share was overtaken by the British, which is not surprising due to the usually high share of British articles corresponding to the highly developed scientific infrastructure. However, the evaluation of the relationship between research performance and the number of cases showed that Italy was still in second place in the ranking of our study. Here, China was able to present itself best. The United States, which ranks first in absolute numbers in our analysis, together with India and Brazil showed a rather negative deviation due to by far the highest number of cases.

In this context, the success of the Chinese COVID-19 control must be pointed out. Certainly, the centralized epidemic response system functioning and radical surveillance had played its part. In addition, the SARS epidemic, which was accompanied by a huge mortality rate in China in 2013, was not long ago, so the awareness and compliance of the Chinese population were still very high. Both lead to an extremely fast and strict response [26,27]. In particular, in contrast to the policy response of the government of the United States, which was sparse and delayed under the regime of former President Trump, who even refused to wear a mask for a long time, China had a very quick response and was stringent with its containment measures.

Nevertheless, the US research output passed China's during 2020. It is partly assumed that the key position of US-American science will soon be overtaken by Chinese research. However, the scientific infrastructure of the United States is profound and well prepared for rapid adaptation and ramp-up. Currently, both countries are certainly competing for the top spot in global research performance.

The dynamic nature of global CoV publication output led to the similarly dynamic development of its perception in the scientific community, resulting in enormous citation numbers already in the first year. The outbreak location in China and the reporting of hospitalized patients there with the first COVID-19 symptoms explain the high citation rate of Chinese articles, which was not presentable for other research topics.

The recognition that the virus forms a sister clade to SARS-CoV led to the taxonomy of SARS-CoV-2 by the Coronaviridae Study Group (CSG) of the International Committee on Taxonomy of Viruses. The involvement of the Netherlands in the CSG contributes to its high citation rate (rank 2 behind China) because the term is internationally accepted, and subsequent publications naturally are in unison on the designation of SARS-CoV-2 [28]. In addition to the Netherlands, Russia, among others, was also involved in this taxonomy procedure, ranking therewith third in national citation rates. Moreover, Russia, together with Germany (rank 16) and Austria (rank 4), was also involved in the highly cited cell biology study by Hoffman et al [21]. This study identifies angiotensin-converting enzyme 2 as the entry receptor and a cellular serine protease as priming the spike protein with the possibility of its blocking by proven inhibitors. Since the research field "biology and biochemistry" was identified as one of the 4 focus clusters, the importance and the level of its perception are explainable. The other key clusters addressing mental and physical health impairments as well as public health and epidemiology issues are related to the other high-impact studies identified.

When the publication numbers are related to the number of COVID-19 cases, other countries showed up in leading positions. With New Zealand, Vietnam, China, Australia, and Thailand at the top, parts of the eastern and southeastern world showed leading performances due to their very low case numbers in combination with relatively high publication numbers. Countries' awareness of the problem influences not only the containment of the pandemic but also their research efforts and the amount of government spending on research and development. The success of achieving low case numbers was explained by the rapid implementation of nonpharmaceutical measures, determined responses, rigor and brevity of containment measures, and testing strategies by public health authorities [29,30]. Vietnam's effective response is also explained by its early preparation and strict control measures such as contact tracing, isolation, and mass testing combined with border closures. The same is true for other countries that have been successful in reducing the COVID-19 spread [31]. The success of Thailand was furthermore explained by hospitalizing any person with SARS-CoV-2 infection even without symptoms and also by demographic and environmental reasons, such as the high proportion of people living in rural areas and spending much time outdoors [32].

Africa has the lowest confirmed case rate of any continent. Only South Africa reported numbers among the 20 most-affected countries. [3] This is also reflected in the corresponding publication performance and also the related distorted maps. Beneficial demographic and geographic factors have been shown to have a significant negative correlation with the number of COVID-19 cases (eg, population density, temperature) [33].

Nevertheless, the low incidence rates in countries with poor health care systems and the associated low quality of the tests are often questioned. High risk is associated with misdeclaration or misreporting of the COVID-19 development. Therefore, globally transparent and traceable reporting is of immense importance, and the development in these regions must be closely monitored in the future [34].

On the other hand, regions with extremely high case numbers, such as the United States, India, Brazil, and some European countries, were proportionally more involved in CoV research. That is also shown by the correlation between COVID-19 cases and article numbers, which is highly significant. Only Russia, with the fourth highest case numbers, fell slightly behind but still shows an enhanced contribution rate to CoV research compared to other scientific topics.

This is also made possible by the intensive funding of the governments of the severely affected countries. In line with these figures, the high Italian case numbers prompted unusually high levels of cooperation with the United States, the United Kingdom, and Spain.

Saudi Arabia, which ranks in the middle of COVID-19 case numbers, was funded primarily through its universities, resulting in a relatively high ranking in publication numbers. This is likely due to the experience gained during the MERS epidemic, which mainly affected Saudi Arabia, accounting for 77% of cases globally. The results of an earlier analysis looking at CoV research up to the COVID-19 outbreak showed that Saudi Arabia even ranked 11th in overall publication performance [4]. Jordan, where MERS cases are also occurring, also had a prominent position in this analysis when socioeconomic characteristics were included. Other countries still affected by MERS, such as Egypt and Iran [35], are also in the field of CoV research in 2020 and are in the top 30.

Conclusions

The awareness and preparedness of countries affected by previous CoV epidemics also led to high interest in CoV research during the 2020 COVID-19 crisis. Although disease containment may have led to a rapid decline in publication numbers, this experience appears to have been so fresh that the propensity for ad hoc research was high. On the other hand, maintaining a reasonable level of interest would have resulted in a better scientific baseline for all containment efforts at the onset of COVID-19 worldwide. This lesson learned should be kept in mind for all future research planning.

The results of this study demonstrate the extraordinary momentum of CoV research in 2020 due to the ongoing global spread of COVID-19. They also reveal the need for continued interest and dedication by scientists even after pandemics are contained. It is to expect that the next pandemic will come and also become a threat anywhere in the world. Well-prepared and sound scientific support enables decisive measures. The experience of highly developed scientific nations must be linked with that of less developed research structures to be of global benefit.

Authors' Contributions

DK and DAG conceptualized the study and the methodology. DK, MB, and DB performed the investigation. DK created the visualizations of the results. The original manuscript draft was written by DK and MB, and final review and editing were performed by DK, MB, DB, and DAG.

Abstract

Background: The COVID-19 outbreak required prompt action by health authorities around the world in response to a novel threat. With enormous amounts of information originating in sources with uncertain degree of validation and accuracy, it is essential to provide executive-level decision-makers with the most actionable, pertinent, and updated data analysis to enable them to adapt their strategy swiftly and competently.

Objective: We report here the origination of a COVID-19 dedicated response in the Israel Defense Forces with the assembly of an operational Data Center for the Campaign against Coronavirus.

Methods: Spearheaded by directors with clinical, operational, and data analytics orientation, a multidisciplinary team utilized existing and newly developed platforms to collect and analyze large amounts of information on an individual level in the context of SARS-CoV-2 contraction and infection.

Results: Nearly 300,000 responses to daily questionnaires were recorded and were merged with other data sets to form a unified data lake. By using basic as well as advanced analytic tools ranging from simple aggregation and display of trends to data science application, we provided commanders and clinicians with access to trusted, accurate, and personalized information and tools that were designed to foster operational changes and mitigate the propagation of the pandemic. The developed tools aided in the in the identification of high-risk individuals for severe disease and resulted in a 30% decline in their attendance to their units. Moreover, the queue for laboratory examination for COVID-19 was optimized using a predictive model and resulted in a high true-positive rate of 20%, which is more than twice as high as the baseline rate (2.28%, 95% CI 1.63%-3.19%).

Conclusions: In times of ambiguity and uncertainty, along with an unprecedented flux of information, health organizations may find multidisciplinary teams working to provide intelligence from diverse and rich data a key factor in providing executives relevant and actionable support for decision-making.

Introduction

SARS-CoV-2 was first reported in Wuhan, China, by early December 2019 [1,2] and by March 11, 2020, COVID-19 was declared a pandemic by the World Health Organization [3]. To date, the global reported death toll of the disease exceeds 1.5 million individuals, while many countries continue to struggle with the pandemic and show an ascending number of cases and mortality rate [4].

Under immense uncertainty, and based on ominous models describing disease exponential expansion [5,6], Israel, like the many other countries, began preparing for the potential threat of the pandemic [7]. The Israel Defense Forces (IDF), one of the largest organizations in the country, was responsible for all health care–related aspects of its own personnel and also took action on the national front and maintained full preparedness for any of its assignments and duties—military and civilian.

One of the key understandings early during response-planning was the paramount importance of reliable data as a substrate for policy changes and decision-making [8,9]. With this mindset, the IDF surgeon general commissioned the establishment of an operational IDF Data Center for the Campaign against Coronavirus (ID3C) in March 2020. The ID3C was ordered to collect and analyze data from all venues and produce concise, data-driven, up-to-date, and relevant recommendations to guide both medical and commanding echelon policy makers.

This paper describes the assembly of the ID3C, the architecture of data utilization, and few samples of the deliverables for which the center was responsible. With much more to learn about the COVID-19 response, worldwide authorities and medical communities strive for quality data as the base for their decision- and policy-making [8-10]. We believe that sharing the lessons from our experience of creating a data center amid a raging pandemic can help other organizations to respond currently an in future to this global event and to other incidents where prompt effective action needs to be based on robust data.

Methods

Methods Overview

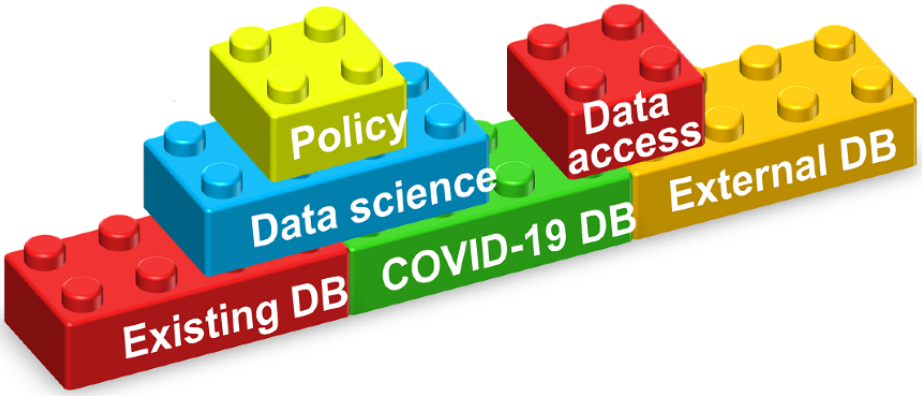
The first step of designing the ID3C was rooted in several key assumptions. We assumed that the disease will have distinct characteristics within our organization compared with the general population, mostly owing to the age of the young population and a relatively low rate of individuals with known risk factors for severe disease [11,12]. Notably, we considered this a dynamic process, as the definition of risk factors kept changing with more evidence accumulating globally at a very high pace [13]. In addition, based on reports suggesting a relatively high rate of asymptomatic individuals among young adults [14,15], we created a digital pathway to shorten the time from patient diagnosis to the completion of contact-tracing. Throughout the process, we weighted the impact of disease spread and policy modifications against the need for preparedness, and assessed the cost-effectiveness of the measures taken by using accurate data.

Modus Operandi

First, we launched an extensive mapping of data sources and assessed the quality of data required to plan a unified data lake diverse enough to establish prediction models to act on. Next, we prioritized mirroring of trends and basic insights from aggregated data to serve as actionable information for executives. The design of a digital platform that will allow them to easily access it followed with the main vectors of action (Figure 1):

1. Harnessing existing IDF data sets: the IDF has a comprehensive digital data set of all service persons derived from decades-long data collection as part of the recruitment process of draftees, as well as electronic medical records of all military personnel. These data were merged with other "nonmedical" parameters on an individual and unit level to deepen the understanding of factors related to the risk of infection and deterioration to severe disease.
2. Construction of new COVID-19–specific information platforms and sensors.
3. Importing and merging of relevant external data provided by the Ministry of Health.
4. Unification of all data sets to 1 "data lake" and extraction of actionable knowledge followed by the use of data science tools to provide a means for pandemic management. The main attempt was to identify trends and patterns to direct the efforts to negate morbidity, especially among units critical to the competence of the organization.
5. Provision of direct data accessibility to executives: a central study objective was to improve executive-level involvement by promotion of data-driven decision-making.

Figure 1. Schematic overview of the rationale for the Israel Defense Forces' Data Center for the Campaign against Coronavirus. The operation was based on the ability to bring together large databases into 1 central COVID-19 data lake. Consequently, 2 parallel efforts were conducted: the first enabled executives and commanders in the organization to gain direct access to actionable data and insights, and the second used advanced analytics to provide additional level of understanding, including using data science–based model to influence policy changes. DB: database.



Team Assembly

The ID3C was led by 3 executives from complementary disciplines: a senior physician commanding officer, a senior intelligence officer, and a senior information technology and data officer. The ID3C comprised 5 small, specified task forces, each consisting of medical personnel, a data specialist, and a project manager. This was a first-of-its-kind military joint venture organization synergizing Medical Corps with the Computer and IT Directorate and intelligence officers. Lean task forces were responsible for gathering relevant published and collected data, providing clear insights and analyzing merged data sets, while other teams oversaw the design of "executive-friendly" dashboards.

Data Collection

To obtain relevant insights, the IDF COVIDataLake (CDL) was created. The CDL is a fusion of existing data sets, existing COVID-19–oriented data sets, and new data sets designed by the ID3C. Existing data sets included medical records, sociodemographic data obtained from a mandatory prerecruitment survey, transportation usage, occupational characteristics, unit characteristics (ie, unit under quarantine conditions and age distribution), service characteristics (ie, daily attendance, close encounter with civilians, etc). These data helped estimate interactions among particular individuals once a suspicion of infection arose. Newly formed COVID-19–oriented data sets included the following: laboratory-based COVID-19 reverse transcription polymerase chain reaction (RT–PCR) test results of the IDF; central command and control platform, which documented all suspected, quarantined, and confirmed cases, as well as all registration of all calls to the call center with structured fields to report on symptoms and exposure to confirmed patients with COVID-19; and special data annotations to highlight quarantined and hospitalized personnel.

Based on the concept of the triple T ("trace, test, treat") [16,17], throughout the ID3C workflow, a system of surveys was developed to collect data deemed essential for early identification of suspected individuals; these included a habits and baseline risk factors survey and a daily survey with a single "yes/no" question regarding exposure and symptoms. For those who had an indication of exposure or symptoms, a more detailed survey was prompted automatically.

To improve the accuracy and efficiency of epidemiological investigations, a designated web-based platform designed by public health officers was introduced where all data from conducted epidemiological investigations were maintained in a structured database.

Lastly, as national-level data collection improved drastically, several sources of data were found to be relevant for the IDF, including daily reports of "hot zones"; a national patients registry elaborating on symptom distribution and disease severity by age; public symptoms surveys conducted through open-source apps, health maintenance organizations, and the Ministry of Health [18]; and risk models for progression to severe disease developed by the "Clalit health services" [19].

Data Security and Ethics

The CDL was treated as a medical database in accordance with national regulations. Data collection and analysis were approved by institutional review board of the IDF Medical Corps (submission 2082-2020).

Data Analysis and Predictive Data Science

The proportions of soldiers treated with respiratory symptoms but without a COVID-19 diagnosis were compared between units. The annotation of theses visits was available using natural language processing techniques to search through medical records and seek signs and symptoms related to COVID-19 (eg, shortness of breath, fever, cough, anosmia, and ageusia). Units were updated once an alarming increase in such visits was evident as an early sign for a possible concealed cluster of COVID-19 cases. Additionally, rates of individuals at risk for severe disease were calculated on the basis of computerized exploration of the medical records for a list for pre-existing medical conditions and treatments, in accordance with updated literature concerning risk factors for severe COVID-19. Shortlists of all at-risk individuals at the unit level were provided to the commanding level daily to reconsider the importance of the individual in terms of the unit's preparedness and functionality.

Machine learning models were used to optimize the IDF's queue for RT–PCR examination for COVID-19. The data points were split into three sets: training, testing, and validation. The validation set comprised 15% of the most recent data points. This set was used to estimate the generalization error of the model. A chronological partition was chosen so as not to underestimate the generalization error: the data were observably chronologically irregular, stemming from the rapid change in the policies, guidelines, and spread of the disease. To deal with these trends, 2 additional sources were incorporated into the data set. First, cities and towns with high contagion counts were recorded daily from public data provided by the Ministry of Health. This allowed us to approximate the suspects' risk of exposure stemming from their city of residence. Second, the number of quarantined personnel in the individual's unit was calculated from the IDF's daily attendance record. This allowed us to account for the current extent of quarantine and policies mandated in the individual's close work environment. Including these 2 variables in the data set led to an observable improvement in the models' performance. The testing set was used by the models' internal optimization procedure to evaluate intermediate trained models and to tune the models' parameters. The training set was used to train the intermediate models. Models were evaluated in accordance with the intended use case: prioritizing the RT–PCR testing queue, with the goal of increasing the proportion of positive cases among those tested. Given the typical daily laboratory capacity and queue length, the score used to evaluate the models was the proportion of true-positive cases among 10% of cases with the highest predicted risk score. This is essentially the pretest probability of the model, with a dynamic threshold (ie, the first predicted high-risk decile of the test queue, in contrast with a constant risk score threshold). Data handling and utilization were conducted using database SQL (Toad for Oracle, version 18c; Quest Software Inc) and SAS (version 9.4, the SAS Institute). Python (version 3.6, Python Software Foundation) was used throughout the study. Preprocessing and exploratory data analysis were conducted with Pandas and Seaborn Python packages. The Scikit-learn Python package was used for training and evaluation of models.

Results

Nearly 300,000 responses for daily questionnaires were recorded by the end of July 2020 with compliance variance from 50% of all personnel in some periods to less than 10% in most units routinely.

Data Sharing Platforms for Executives

One centralized digital platform was designed to provide every unit and senior commanders the following daily updated information about their unit (Figure 2):

1. Identifying individuals living in "hot zones": indeed, analysis conducted using military epidemiological data revealed that 56% of disease contraction was outside of the military base or activity.
2. Identifying individuals attending the unit, who are at risk for severe disease: a decline of ~30% was observed in the attendance of such individuals after the implementation of this tool (Figure 3).
3. Notification on units with alarming clusters of respiratory complaints.

Figure 2. ID3C 360° individual data components. The unique datasets collected during the operation of the ID3C included three layers of data in particular: data set available routinely in the IDF, including medical records, a human-resources data set with demographic and occupational characteristics, and daily attendance and logistic data including transportation usage; a new data set designated to collect COVID-19–related data such as laboratory findings, epidemiological investigations' outputs, designated surveys, and confirmed cases' medical records; and external data sets from government agencies, other health organizations, and open-source publications on broad population surveys. ID3C: Israel Defense Forces' Data Center for the Campaign against Coronavirus; IDF: Israel Defense Forces; HMO: health maintenance organization; MOH: Ministry of Health.

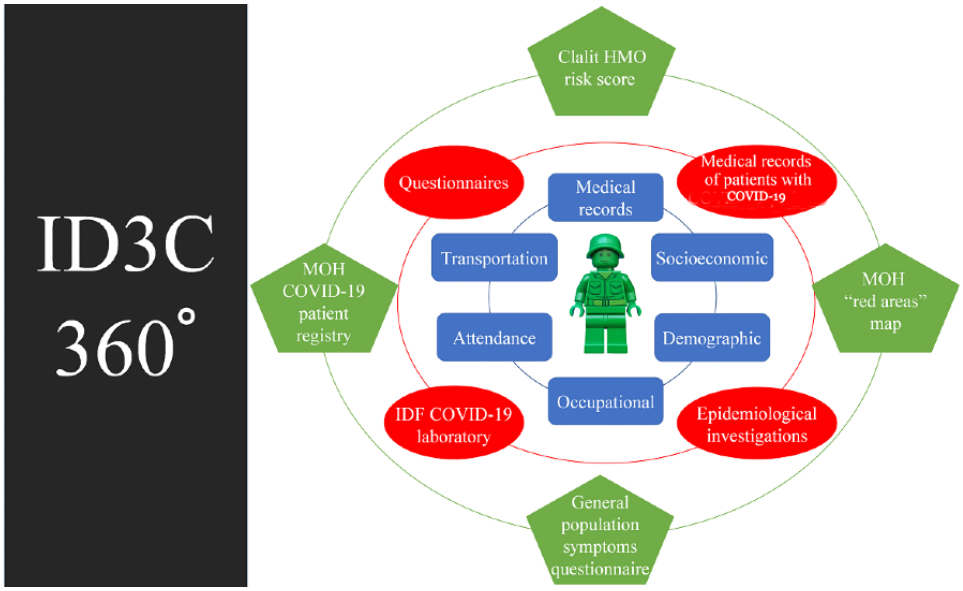


Figure 3. Daily updated main display of the Israel Defense Forces' Data Center for the Campaign against Coronavirus digital platform designed for commanders' use. This includes the daily survey completion rate, which is the proportion of the unit's potential (purple, top panel); red zones, which refers to active soldiers living in an area with a high rate of infection (blue, second panel from the top); risk for severe illness, which refers to soldiers with risk factors for severe disease if infected with SARS-CoV-2, who attend the unit (red, third panel from the top); and suggestive symptoms, which is the proportion of on-duty soldiers presenting to unit's clinic for symptoms related to COVID-19 (increase rate refers to the increase in visits compared to the past week; percentage of active potential refers to soldiers complaining of symptoms as a percentage from the weekly total unit's attendance; brown, bottom panel).

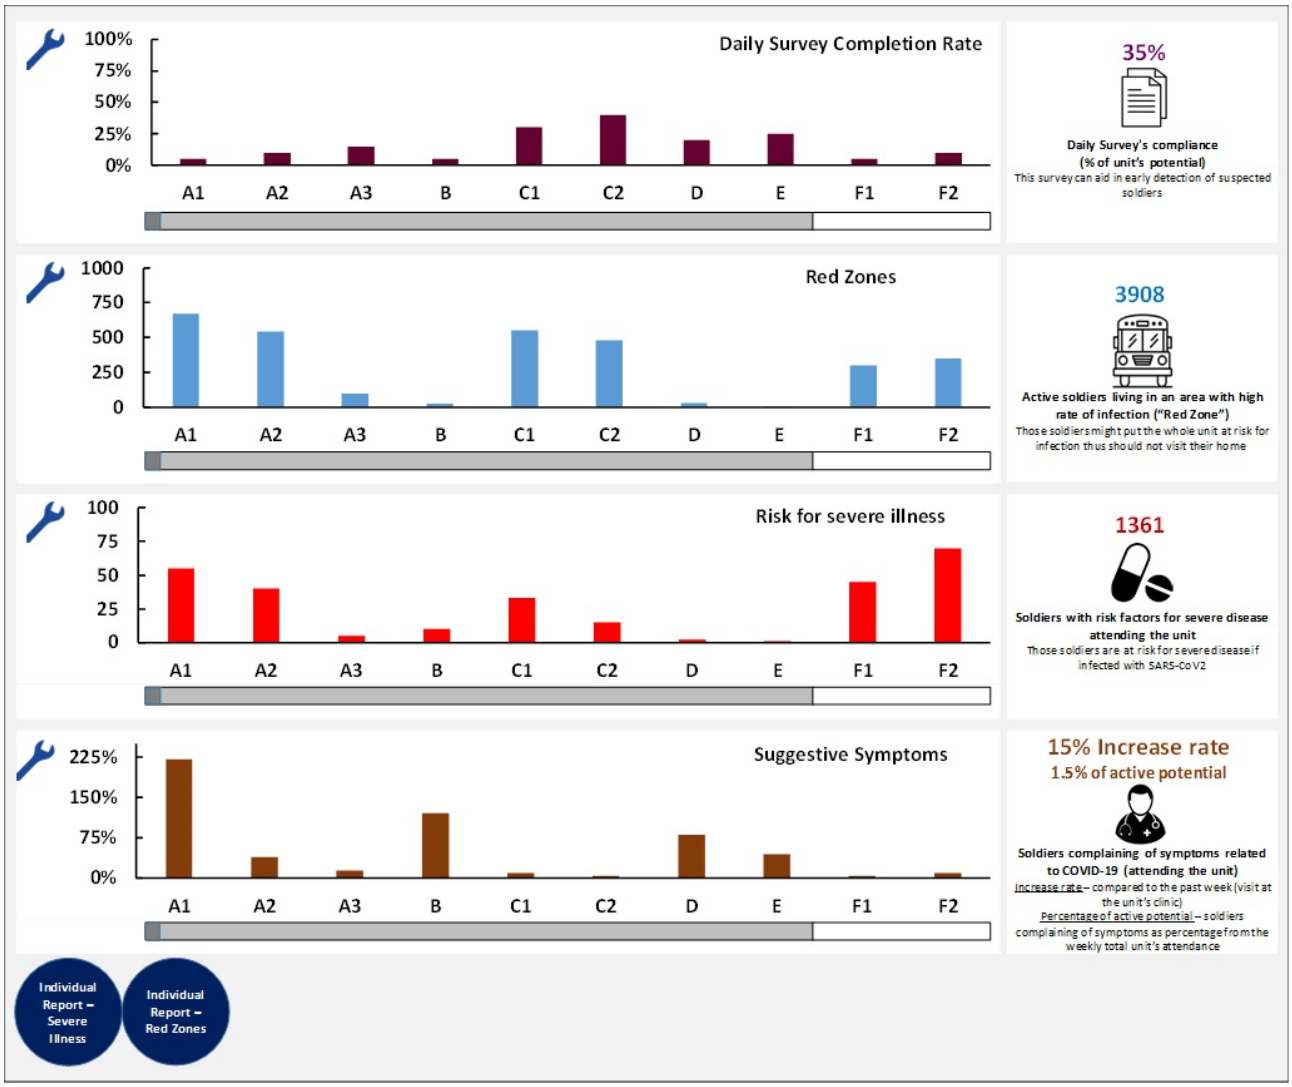


Data Sharing Platforms for Medical Personnel

Unit medical staff had access to a daily updated dashboard, which contained the following information:

1. Notification of individuals at high risk for severe disease: direct communication between the ID3C and units' primary physicians was facilitated with respect to extremely-high-risk individuals by using the Clalit algorithm.
2. Alert on individual cases that form a part of clusters presenting with respiratory symptoms, allowing physicians to revisit cases if an alarming number of patients with suspicious symptoms presented at a specific clinic.
3. Medical indicators from surveys promoted proactive summoning of individuals reporting suspicious symptoms and exposures before they approached the clinic, and those found to be at substantial risk were directed to undergo a nasopharyngeal swab test.

Optimization of the Queue for Laboratory-Based COVID-19 Testing

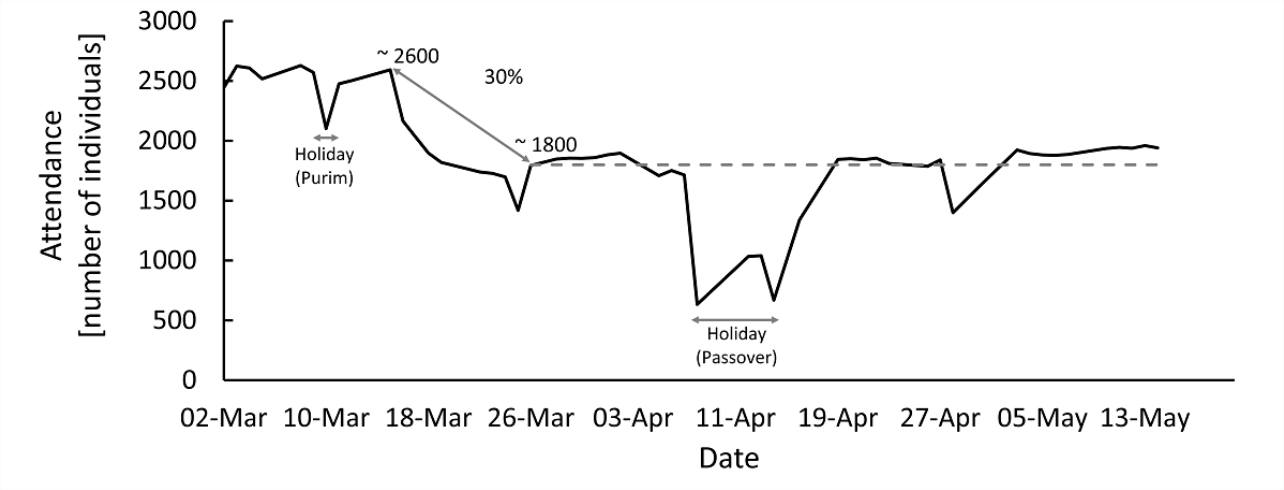
For each individual in the examination queue, which included thousands of individuals at peak periods, the model produced a risk score, which was used to prioritize the predicted high-risk suspect. Based on CDL, a prediction model was trained and tested on 10,428 examinations and validated on additional 1698 examinations. The model indicated daily the potential top 10% high-risk suspects with a very high pretest probability and prioritized the processing of their nasopharyngeal swabs. This optimization process resulted in a high true-positive rate of 20% from among the total examination results processed, which was more than twice as high (2.28%, 95% CI 1.63%-3.19%) as the baseline true-positive rate (8.8%) without using the model recommendation for the same period.

Discussion

Principal Findings

We report here the origination of a COVID-19 dedicated response by the IDF with the assembly of the ID3C. The multidisciplinary team utilized existing and newly developed platforms to collect and analyze large amounts of information for each individual in the context of SARS-CoV-2 contraction and infection. With nearly 300,000 responses for daily questionnaires merged into 1 data lake, we could identify high-risk individuals, and we observed a 30% decline in their attendance to their units (Figure 4). Moreover, we introduced an optimization model for the queue for laboratory-based COVID-19 testing and obtained a high true-positive rate, which was twice as high as the baseline rate (20% vs 8.8%, respectively).

Figure 4. The attendance of individuals deemed at high risk for severe disease in the Israel Defense Forces' units, between March 2 and May 13, 2020. The graph shows a sharp decline in attendance with the implementation of the designated unit-specific tool, allowing to monitor the individuals at risk for severe disease.



Both health care providers and leaders are in the midst of a global crisis, which is characterized by extreme uncertainty and unprecedented flux of information. In this “infodemic” and pandemic, policy makers pursue trustworthy measures to help them make strategic decisions in response to the threat [20,21].

A call for innovative, modern methods of rapidly collecting and processing data has been made by countries and organizations around the world from the beginning of the pandemic. Taiwan—a neighboring country to China, which was one of the first countries to be affected by the pandemic—took rapid action by merging the borders and customs databases with their national medical database to link clinical symptoms with flight and travel history.

As early as January 2020, Sun et al [22] and Qin et al [23] used social media searches to track the trends and spread of COVID-19 through China. Indeed, web-based discussions on social media platforms prompted an international group of rheumatologists to create the COVID-19 Global Rheumatology Alliance [24]. This alliance created a web-based registry in which clinicians and researchers around the world could share their knowledge and findings. The American Academy of Dermatology, American College of Surgeons, American Academy of Orthopedic Surgeons, Spanish Neurological Society, and others have also created specialized registries to track and analyze relevant data in their fields [25,26].

Many other methods have been implemented, such as web-based surveys to detect the spread of the disease in the population [27,28], and the use of machine learning techniques to quickly and reliably test for COVID-19 by private firms such as *Infervision*, *Diagnostic Robotics*, and others [29].

This atmosphere of uncertainty has many similarities to other emergency situations, especially those concerning security, where leaders depend on intelligence officers to provide them with data and estimations. We describe here the prompt establishment of a unique organizational structure set to provide live intelligence, using a synergism of “conventional” military intelligence methods, medical knowledge, and research, as well as data-driven artificial intelligence platforms. The center was based on multidisciplinary teaming, utilization of data, and leaning on digital platforms for providing accurate, relevant, and comprehensive information to executives. The novelty in this process covers multiple aspects and was catalyzed by the intensity of the challenge, and in fact fulfilled many of the perspectives that health care professionals had envisioned in the last decade with respect to the era of information, personalized medicine, and digital health [30-32].

Identifying the engagement of medium-tier commanders as the key to maximize the chance to make an impact dictated our pivotal effort to design tools that would not merely end up with data analysis but would be delivered almost immediately as actionable data, to affect their daily routine. Similar to the approach adopted by others, we found the delivery of accurate and timely knowledge translation an inevitable effort in light of the surging pandemic [33].

The tools used in the ID3C were designed to promote the prevention of contagion, earlier detection of disease clusters, and better control of at-risk individuals. Other data-driven tools were actually developed in response to an emerging challenge with an extreme shortage of RT–PCR testing and provided optimization to make better use of existing testing methods [34],

using computer-aided prioritization of examinations, thus increasing the proportion of positive test results and decreasing the mean diagnosis time of positive cases.

Notwithstanding, the experience of collecting large amounts of data provided valuable insights into the importance of careful planning of the delicate architecture and the quality assurance measures that are a "must-have" in this type of endeavor. Data science and machine learning are very common "buzzwords" in the discussion about the health care revolution [35-37], but one should be very cautious to not overload expectations from these set of tools, especially when the data are gathered at different paces and through different channels. Moreover, this emphasizes the need for local and global medical data sharing among organizations and countries, which would be key for enabling the utilization of emerging computational proficiencies and potentially shed light on clinical interpretation of events, thereby accelerating the discovery and validation of promising interventions [8,38-40].

A centralized medical intelligence arm, where public health officers, physicians, and data experts work together to construct the process of data collection, analysis, and reflection, was found to be very efficient and had a true synergistic value in our experience. The ability to combine the technological arm that designs and broadcasts the different applications for data collection had an additional value and enabled swift changes guided by real-time field feedback. This is further outlined when compared with conventional public health methods primarily based on manually collected data and the tendency to work in isolated professional silos, limiting prompt data analysis and action required to effectively respond to the current COVID-19–imposed challenges [41]. The agility in producing the right set of tools for constantly changing circumstances is crucial for successful efforts in the long term, as the pandemic changes and evolves.

A vital consideration we felt obligated to maintain was the high standard of medical confidentiality, highly ethical standards of data science research, and privacy of data. Despite the urgency and the need to deliver data, we insisted on and maintained 2 separate routes of data flow: one for medical personnel and the other for nonmedical executives. This allowed us to provide meaningful alerts and information at the executive level while keeping the medical staff at the center of the decision-making process, being able to consult judiciously with a very broad clinical overview, and simultaneously not breaching any medical privacy standard.

Limitations

We experienced several difficulties that are worth mentioning in this context. First, we saw very modest compliance rates to the extensive survey effort that we initiated, especially as the timing of broadcasting of the full-scale survey coincided with a sharp decline in cases and an increase in survey compliance with the substantial surge in cases. As with other noncompliance issues in medicine, it is our belief that for the time being, a cultural change is the key to deliver a discernible change. Given its potential effectiveness in the early identification of suspicious domains, a survey should be considered a routine procedure throughout the pandemic. Second, the current pandemic is very dynamic, and the nature of disease spread was different between the 2 main pandemic periods we observed. The knowledge base to understand this specific new infection is lacking and evolves constantly, and this might have a substantial effect on any mathematical model, thus necessitating cautious evaluation of models based on concurrent data. To ensure our tools are valid, we continuously evaluated the yield and accuracy of our models and modified the included parameters to adapt to the changing circumstances. Lastly, despite our extensive effort in building data-driven tools, it is of paramount importance to recall their role as advisory tools and highlight the central role of human judgment in integrating professional, medical, and organizational considerations at all times.

Conclusions

In conclusion, we described the assembly of a specialized multidisciplinary team weighing on diverse, rich data and advanced analytics to assist decision-makers with formulating policies in the context of the unexpected and unfamiliar chain of events throughout the COVID-19 pandemic. With anticipated disease spread, we believe that additional collaborative initiatives are in place to largely utilize accumulating local and global data in an attempt to develop impactful interventions.

Acknowledgments

We acknowledge the contribution of Mrs Dorit Tzur, Mrs Victoria Yoffe, Mrs Maya Simchoni, Mr Itay Klopshtock, Mr Dan Vershov, Mr Doron Stupp, Dr Daniel Gabai, Mr Moti Atkind, Dr Eva Abramovitch, Dr Inbal Galor, and Prof Gilad Twig to this study.

Authors' Contributions

GAG and IK carried out the investigation, curated the data, and drafted the manuscript. MN curated the data, conducted the formal analysis, and drafted the manuscript. S Simon conceptualized the study, was responsible for its administration, interpreted the findings, and reviewed and edited the manuscript. BI conceptualized the study and the methodology, oversaw the data science and the information technology architecture, verified the analytical methods, and reviewed and edited the manuscript. IT developed the software; performed the formal analysis; carried out the investigation; designed the models and the computational framework; handled, processed, and analyzed the data; performed the computations using data science methods; and reviewed and edited the manuscript. MS developed the software, curated the data, analyzed the output and results, and reviewed and edited the manuscript. BV developed the software, handled the data, oversaw the information technology framework design and data architecture, and

reviewed and edited the manuscript. YV developed the software, supervised and verified the information technology design, developed the models and the computational framework, and reviewed and edited the manuscript. DF developed the software; carried out the formal analysis and the investigation; handled, processed, and analyzed the data; performed computations using data science methods, and reviewed and edited the manuscript. RY performed the investigation; handled, processed, and analyzed the data; and performed computations using data science methods. SAS and NH carried out the investigation and data analysis, and reviewed and edited the manuscript. MP designed the methodology, carried out the formal analysis, interpreted the results and output design, and reviewed and edited the manuscript. NF and EG conceptualized the study and oversaw its administration, supervised the study overall, and reviewed and edited the manuscript. AF conceptualized the study and oversaw its administration, analyzed and interpreted the data, and drafted the manuscript and approved its final version for publication.

Abstract

Background: Cognitive behavioral therapy–pain is an evidence-based treatment for chronic pain that can have significant patient burden, including health care cost, travel, multiple sessions, and lack of access in remote areas.

Objective: The study aims to pilot test the efficacy of a single-session videoconference-delivered *empowered relief* (ER) intervention compared to waitlist control (WLC) conditions among individuals with chronic pain. We hypothesized that ER would be superior to WLC in reducing pain catastrophizing, pain intensity, and other pain-related outcomes at 1-3 months posttreatment.

Methods: We conducted a randomized controlled trial involving a web-based sample of adults (N=104) aged 18-80 years with self-reported chronic pain. Participants were randomized (1:1) to 1 of 2 unblinded study groups: ER (50/104, 48.1%) and WLC (54/104, 51.9%). Participants allocated to ER completed a Zoom-delivered class, and all participants completed follow-up surveys at 2 weeks and 1, 2, and 3 months posttreatment. All the study procedures were performed remotely and electronically. The primary outcome was pain catastrophizing 1-month posttreatment, with pain intensity, pain bothersomeness, and sleep disruption as secondary outcomes. We also report a more rigorous test of the durability of treatment effects at 3 months posttreatment. Data were collected from September 2020 to February 2021 and analyzed using intention-to-treat analysis. The analytic data set included participants (18/101, 17.8% clinic patients; 83/101, 82.1% community) who completed at least one study survey: ER (50/101, 49.5%) and WLC (51/104, 49%).

Results: Participants (N=101) were 69.3% (70/101) female, with a mean age of 49.76 years (SD 13.90; range 24-78); 32.7% (33/101) had an undergraduate degree and self-reported chronic pain for 3 months. Participants reported high engagement (47/50, 94%), high satisfaction with ER (mean 8.26, SD 1.57; range 0-10), and high satisfaction with the Zoom platform (46/50, 92%). For the between-groups factor, ER was superior to WLC for all primary and secondary outcomes at 3 months posttreatment (highest $P<.001$), and between-groups Cohen *d* effect sizes ranged from 0.45 to 0.79, indicating that the superiority was of moderate to substantial clinical importance. At 3 months, clinically meaningful pain catastrophizing scale (PCS) reductions were found for ER but not for WLC (ER: PCS −8.72, 42.25% reduction; WLC: PCS −2.25, 11.13% reduction). ER resulted in significant improvements in pain intensity, sleep disturbance, and clinical improvements in pain bothersomeness.

Conclusions: Zoom-delivered ER had high participant satisfaction and very high engagement. Among adults with chronic pain, this single-session, Zoom-delivered, skills-based pain class resulted in clinically significant improvement across a range of pain-related outcomes that was sustained at 3 months. Web-based delivery of ER could allow greater accessibility of home-based pain treatment and could address the inconveniences and barriers faced by patients when attempting to receive in-person care.

Introduction

Background

Chronic pain is a significant public health concern. It is one of the most common reasons for seeking medical care [1], with considerable societal and financial burden [2,3] in addition to human suffering. Chronic pain treatment is challenging due to limitations of existing pharmacological approaches, particularly intolerability of many medicines [4], health risks [5-9], and lack of sustainable availability. In contrast, behavioral medicine approaches are low risk and have been shown to have low-to-moderate efficacy for a range of chronic pain conditions [5,7,10-12], with cognitive behavioral therapy (CBT)–pain as the established evidence-based treatment for chronic pain [8,9]. However, several barriers prevent broad access to CBT-pain, including out-of-pocket costs, burdensome travel, lack of availability in remote or rural areas, and a lack of adequately trained clinicians [6,13]. The length of treatment (ie, eight sessions or more for CBT-pain) is associated with increased dropout [14], which may perpetuate the overuse of medical services and health disparities. The COVID-19 pandemic has further challenged the feasibility of multisession in-person treatment options [15], and this creates the need for accessible solutions that are low-cost, low-burden, and remove the need for face-to-face meetings [16].

Brief web-based and remotely delivered psychological interventions have been demonstrated to accomplish this goal and have been found to be as effective as face-to-face therapy, while decreasing health care use and barriers to treatment [17]. Effective web-based treatments now exist for various psychological disorders, including depression, panic disorder, and social phobia [18]. Web-based CBT has been effective for a number of chronic health conditions, including irritable bowel syndrome, tinnitus, and headache [19,20]. In a systematic review of web-based interventions for chronic back pain, Garg et al [21] reported that web-based interventions, including CBT, effectively reduced pain catastrophizing scale (PCS) scores. Effect sizes for web-based interventions for chronic pain have been estimated to range from small to moderate (Cohen *d* range 0.04-1.23) [18]. In addition to CBT, existing web-based interventions for patients with pain include compassionate mind training [22], social media–based web-based community intervention [23], pain self-management [24], and hypnosis [25]. Despite the promise of web-based interventions for pain, multisession treatments typically range from 20 days to 12 weeks in duration, which can be costly, burdensome, and limit access to adequate care [26].

Single-session interventions (SSIs), which have been defined as the intentional delivery of a specific, structured program involving a single visit with a clinic, provider, or program [27], have the potential to reduce the burden of traditional multisession treatment approaches and expand access to behavioral medicine. SSIs have been found to be effective for a variety of psychological and health conditions, including severe mental illness [28], anxiety and youth conduct disorder [27], acute insomnia [29], heavy alcohol consumption in college students [30], trauma and adversity [31,32], postsurgical pain [33], and chronic pain [11,12,34-36]. SSIs that have been further optimized via web-based delivery have demonstrated feasibility and efficacy similar to face-to-face interventions [11,12,37] and include interventions for multiple sclerosis pain [38], disordered gambling [39], and adolescent mental health [40-42]. In addition to reducing treatment burdens, web-based SSIs have the vital advantage of ease of scalability, as they can be completed by patients in any location [37]. Effective web and digital-based SSIs would eliminate or reduce many of the existing barriers to treatment, such as cost, lack of trained therapists, and insurance limits on the length of treatment. However, despite the promise of SSIs, rigorously designed and randomized controlled studies are needed to establish their efficacy [43].

Objectives

Building on the limited literature on web-based SSIs for chronic pain, we aim to evaluate a Zoom-delivered version of a previously developed and efficacious, skills-based, behavioral medicine SSI *empowered relief* (ER) [11,36]. Previously, our group conducted a three-arm randomized controlled trial conducted in 263 adults with chronic low back pain comparing in-person ER to a health education class or 8-week CBT [12]. However, web-based delivery of ER has not been tested, particularly in mixed-etiology chronic pain, and the COVID-19 context underscores the importance of providing effective home-based chronic pain care. Extending this work to the digital platform, in this study, we conducted a parallel-group, randomized (1:1) comparative efficacy trial to assess the impact of a single-session videoconference-delivered ER group pain relief skills class versus waitlist control (WLC). We hypothesize that at 3 months posttreatment, (1) ER would be superior to WLC for reductions in pain catastrophizing, an index of pain coping; (2) ER would be superior to WLC for reductions in pain intensity, bothersomeness, and sleep disturbance; and (3) ER would be superior to WLC in reducing anxiety, depression, and physical function.

Methods

Overview and Setting

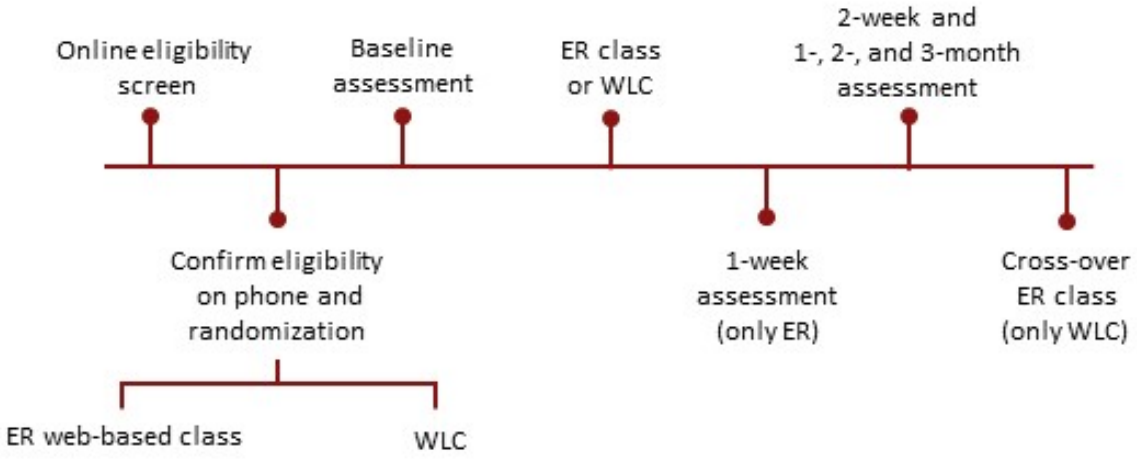
This study was a parallel-group, randomized, clinical trial comparing ER, a 2-hour single-session videoconference-delivered class, to a WLC. Enrolled participants (N=104) aged 18-80 years with mixed chronic pain etiology were randomized (1:1) to one of the two study arms. Participants completed outcome assessments at pretreatment, week 2, and 1, 2, and 3 months posttreatment. The primary outcome was pain catastrophizing levels at the 1-month follow-up [35], with pain intensity, pain, bothersomeness, and sleep disturbance as secondary outcomes. The tertiary outcomes

included PROMIS (Patient-Reported Outcomes Measurement Information System) measures of anxiety, depression, and physical function at the 1-month follow-up time-point. We also report a more rigorous test of the durability of treatment effects at 3 months posttreatment as highlighted in the *Results* section. A crossover intervention class was offered to participants who were initially randomized to the WLC and was conducted in February 2021. Of 48 participants who were offered the treatment, 20 (42%) attended the crossover class at no cost, and no data were collected. This study was conducted between August 2020 and February 2021.

Study Sample, Recruitment, and Participant Compensation

Participants were recruited remotely through targeted emails to lists of patients who agreed to be contacted for research purposes through two databases: (1) the Stanford's Collaborative Health Outcomes Information Registry comprising patients who have received care at the Stanford Pain Management Center (a tertiary referral pain clinic in Redwood City, California) and (2) the Stanford Systems Neuroscience and Pain Lab database of individuals with chronic pain. Interested individuals were directed to a web-based screening form, and those who met the initial eligibility criteria were contacted by research staff by phone to confirm their eligibility. Approximately 18.3% (19/104) of the study sample were clinic patients, and 81.7% (85/104) were from the larger community. Eligible and interested participants were invited to participate in a pain-skills treatment class compared with a WLC and completed an electronic informed consent form (see Multimedia Appendix 1 for the study consent form). After informed consent was obtained, study participants were randomized one-to-one using a REDCap (Research Electronic Data Capture; Vanderbilt University) [44] cloud random number generator and allocated to the study group. All study procedures were completed remotely, and no in-person visits were required. Figure 1 displays the participants' study activities.

Figure 1. Participant activities. ER: empowered relief; WLC: waitlist control.



All the study procedures were performed remotely and electronically. Enrolled participants completed a baseline survey, which was conducted 4 days before the scheduled class, followed by posttreatment surveys at 2 weeks, and 1, 2, and 3 months. The intervention was conducted on Zoom [45], and details of the Zoom session were emailed to participants before the scheduled class time. Overall, in the ER arm, two cohorts were recruited, each consisting of 24-26 participants per class. The class sizes were consistent with studies on web-based interventions [46-51]. Participants received US $10 in the form of an Amazon electronic gift code for each survey they completed and could receive up to US $50 following completion of all study procedures. The research procedures were approved by the Stanford institutional review board.

Inclusion and Exclusion Criteria

All study recruitment efforts directed interested individuals with chronic pain to the web-based screening form to complete an automated eligibility form that screened for initial inclusion and exclusion criteria. Participants who met initial eligibility were then contacted by the research staff to confirm study eligibility according to the inclusion and exclusion criteria provided in Textbox 1. Internet and computer literacy were the implicit de facto eligibility criteria. If interested participants indicated that they had never used the Zoom platform, the research coordinator contacted them by phone to schedule an individual meeting; their skill to participate in the web-based class would increase because they were more familiar with the Zoom platform and navigating the tool in a supervised setting. Of the 9 participants who indicated that they had never used Zoom, none requested to schedule an individual meeting.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Pain >3 months more than half the time
- English fluency
- Ability to attend a one-time web-based class (if assigned) and complete web-based surveys
- Females and males, aged ≥18 years

Exclusion criteria

- Ongoing legal action or disability claim
- Previous participation in the empowered relief class
- Cognitive impairment, non–English-speaking, or psychological factors that would preclude comprehension of material or full participation in the study

Randomization and Blinding

Participants were randomized 1:1 (no blocking applied) and allocated to one of two study arms: (1) ER or (2) WLC. REDCap was used to apply an automatic and blinded randomization program and ensure equal allocation to both groups. Participants were not blinded to the study arm, given the nature of WLC. Statisticians performed blinded analysis of data sets that were randomly labeled as group 1 and group 2, with statistician unblinding occurring only after posttreatment month 3 data were analyzed. The study coordinator (LGC) was unblinded to the individual study arm assignments and was not involved in any data analyses. The study protocol was reviewed and approved [52].

Study Groups

Single-Session Videoconference-Delivered Skills-Based Pain Class (ER)

Overview

ER was developed in 2013, with pilot data [36] showing a reduction in pain catastrophizing 1-month posttreatment, despite comorbid emotional disorders. Notably, a National Institute of Health-funded, three-arm, randomized controlled trial [11,12] conducted in 263 individuals with chronic low back pain demonstrated that 3-month posttreatment, the ER class was equally effective to an 8-week CBT-pain intervention and was superior to a health education control class in reducing pain catastrophizing and pain intensity. ER *compresses* key elements and skills from CBT-pain and mindfulness into a single-session 2-hour class [11,12,34,36]. The class is didactic and delivered with a standardized instructor slide deck and manual. Participants learn self-management skills to decrease physiological hyperarousal, which includes diaphragmatic breathing, cognitive reframing, and self-soothing strategies. During the class, participants self-tailor the skills content by completing a personalized plan for ER. They also received an MP3 audio file with a 20-minute version of the relaxed breathing exercise. The participants can download the audio file from a secure web-based storage platform onto their various devices (mobile or tablet) for convenience. The participants were encouraged to practice the learned skills daily.

Class Platform

The Zoom platform was used to deliver the ER classes, and instructors shared their PowerPoint presentation slides throughout the class. Class participants were encouraged to ask questions at any time through the Zoom chat box and unmute themselves to participate. Zoom is password-protected and hosted within the firewalled Stanford University School of Medicine and Stanford HealthCare systems.

Instructors

The class instructors were doctoral-level clinical psychologists certified by Stanford University [53] to deliver the intervention.

Training and Monitoring of Instructors

The instructors were familiar with the study protocol, were certified in ER delivery, and had extensive experience delivering the class. ER was developed to ensure fidelity (eg, standardized slide deck and instructor manual; instructor certification process), and cohort effects were minimal due to the single session and didactic nature of the intervention, with minimal participant interaction.

Waitlist Control

The study used a WLC group because the ER class web-based delivery is a new approach that has not been previously tested [54,55]. During the screening phone call, participants randomized to the WLC were advised to continue any ongoing clinical care. Although the WLC group did not receive any study intervention, participants were informed that they would be offered the ER treatment class after study completion at 3 months.

Data Collection and Variable Measurement

All surveys were collected through REDCap [44], a web-based electronic data capture platform, which is a secure (password protected), HIPAA (Health Insurance Portability and Accountability Act)–compliant platform, and hosted by the Stanford University School of Medicine.

Data collection consisted of electronically collected participant-reported measures across the four phases of the study: screening, pretreatment, treatment, and posttreatment. For both groups, posttreatment survey collection was conducted at 2 weeks and 1-3 months posttreatment. The ER group

completed an additional brief survey 1-week posttreatment to assess participant satisfaction with the intervention and Zoom platform. Table 1 shows the data collection time-points for both the groups. Baseline surveys included demographic information, pain intensity, pain bothersomeness, pain catastrophizing, and PROMIS measures. Posttreatment surveys included the same measures, excluding the demographics.

[a]Variable assessed.

[b]PCS: pain catastrophizing scale.

[c]PROMIS: Patient-Reported Outcomes Measurement Information System.

Study Variables and Measures

Pain Catastrophizing

The 13-item PCS [56] measures negative thoughts and emotional responses to pain. PCS is a 1D measurement with three subscales: helplessness, magnification, and rumination. It is scored by summing all items and generates a total score, with higher scores indicating greater catastrophizing. The PCS is a reliable, validated, and psychometrically trusted instrument [57].

Pain Bothersomeness

Participants rated their pain bothersomeness during the previous 7 days on a 0-10 numeric rating scale anchored by 0 (not at all bothersome) and 10 (extremely bothersome) that is commonly used in chronic low back pain research [58], “How bothersome has your pain been during the past week?”

National Institutes of Health PROMIS Measures

The National Institutes of Health PROMIS short-form measures have been applied in pain research [59-67], and selected domains were identified by the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials [68,69] as core outcomes. Respondents reference the previous 7 days to rate items for pain intensity (version 3a), sleep disturbance (version 6a), physical function (version 6b), depression (version 6a), anxiety (version 6a), and social isolation (4a). Higher scores on PROMIS measures indicate greater symptom severity, except for physical function, wherein higher scores reflect better function. The web-based PROMIS assessment center [70] software [71] was used to calculate the short-form T scores using Item Response Theory scoring algorithms that apply the Bayesian expected A posteriori method [72]. Depression, anxiety, and physical function are major correlates of chronic pain [73-76], and as such, changes in these variables were examined as a function of treatment. Social isolation was included because of the COVID-19 pandemic. We did not expect it to change, per se, but given the dynamic nature of COVID-19 and lockdowns, we measured this variable throughout the study.

Sample Size and Statistical Analysis

The planned enrollment accounted for 4% attrition in each study arm. The enrolled sample size ensured significant statistical power (80%) to detect medium-to-large treatment effects between the two treatment groups. Of the 104 enrolled participants (ER: 50/104, 48.1%; WLC: 54/104, 51.9%), intent-to-treat analyses were used to analyze the data of 101 (97.1%) participants (ER: 50/101, 49.5%; WLC: 51/101, 50.5%) who met the study criteria and completed at least one survey.

Baseline scores on continuous variables were summarized using mean (SD), and categorical variable scores were summarized by count and proportions. The differences between conditions at baseline for continuous and categorical variables for the treatment groups were assessed using one-way analysis of

variance and Fisher exact test, respectively. For primary analyses, we used a between-within mixed design to assess the effect of treatment, time, and treatment × time, where time represented the within-subjects factor and treatment was specified as a between-subjects factor. Within-subjects' dependency was modeled by specifying participants as a random effect with a heterogeneous compound symmetry covariance structure. Similar analyses were used to examine the treatment effects for all secondary and tertiary outcomes at each posttreatment month. Intention-to-treat analysis was used to investigate the causal effects of the treatment. All statistical significances were applied at a two-sided level of 0.05, with Benjamini-Hochberg adjustment for multiple comparisons. Cohen *d* effect sizes for the between-subjects' factor were calculated from the between-subjects' *F* statistic adjusting for sample size. Responder analyses were conducted by calculating the proportion of participants with 15% (minimal), 30% (moderate), and 50% (substantial) improvement from baseline for pain-related outcomes. All data processing and statistical analyses were performed using the SAS version 9.4 (SAS Institute, Inc).

Results

Study Participants

Figure 2 shows the CONSORT (Consolidated Standards of Reporting Trials) diagram for the study. In total, 196 individuals were assessed for initial eligibility, and 92 were excluded because they did not meet the study criteria. In total, 104 participants were enrolled and randomized, and 101 (97.1%) participants completed the baseline surveys (ER: 50/101, 49.5%; WLC: 51/101, 50.5%). A total of 49 participants received the ER intervention, of whom 2 (4%) were lost to follow-up due to feeling unwell or being too busy to complete follow-up surveys. A final sample of 94 participants provided complete follow-up data. Nearly 94% (47/50) of participants in the ER group and 86% (44/51) of participants in the WLC group completed their 3-month follow-up surveys (end of study).

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) flow diagram. ER: empowered relief; ITT: intention-to-treat; WLC: waitlist control.

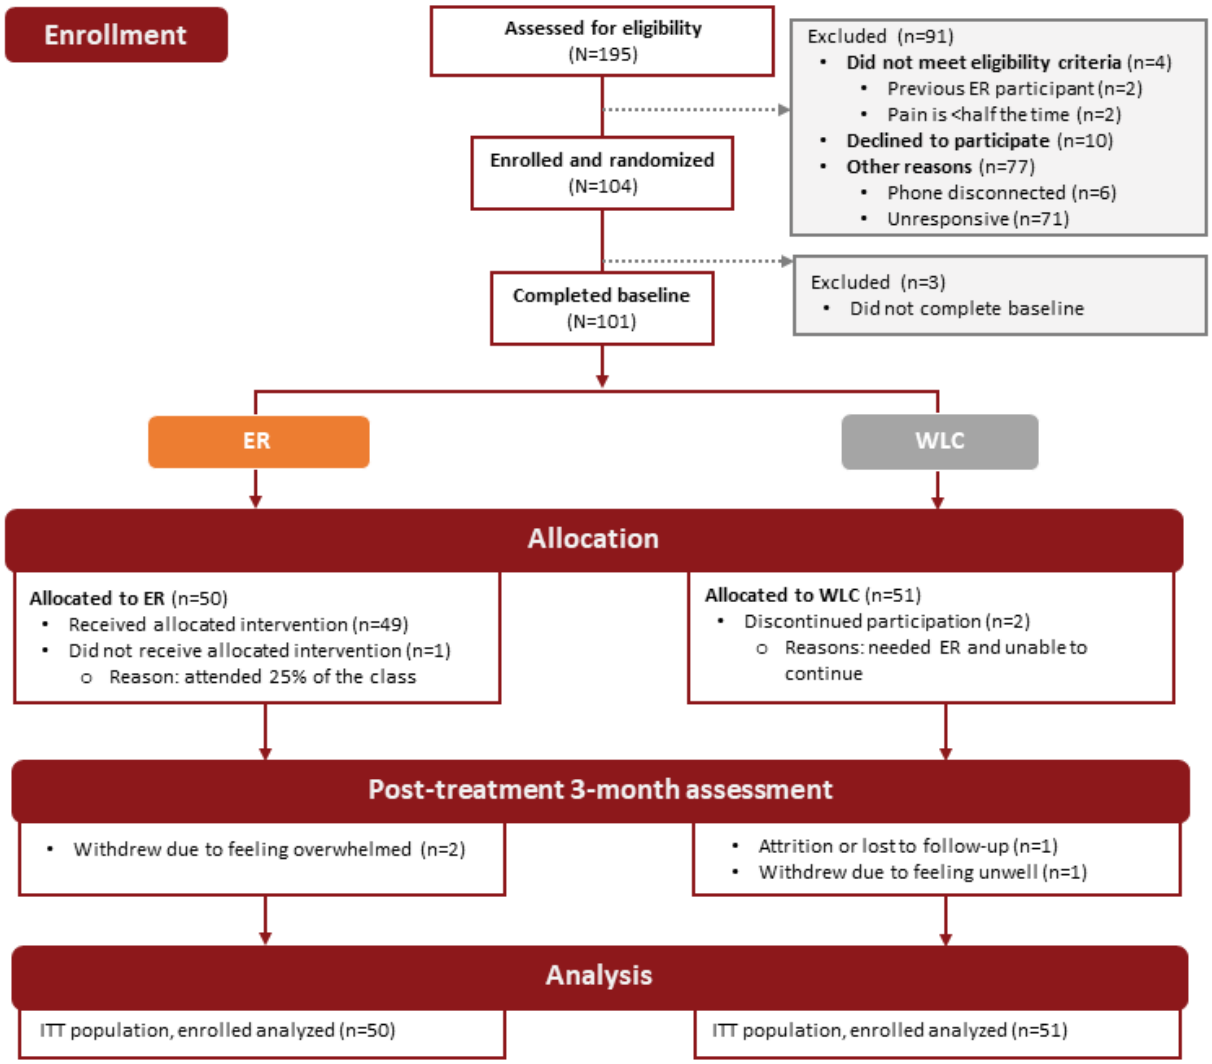

Table 2 shows the baseline demographic characteristics of the study arm. The sample included 101 participants recruited primarily from northern California. The sample was predominantly female (70/101, 69.3%), White (75/101, 74.3%), and with at least some college education (66/101, 65.3%), and a mean age of 49.76 years (SD 13.90; range 24.00-78.00). No significant between-group differences were observed for any demographic variables, demonstrating that randomization was effective.

Table 3 presents the baseline pain and clinical characteristics of the sample by the study arm. The mean pain intensity T score was 62.2 (mean 50, SD 10). No significant differences were observed between the two study groups for any of the variables assessed, except for sleep disturbance (*P*=.04), which was controlled for in the analysis.

Treatment Satisfaction (ER Group Only)

For satisfaction with ER treatment on a scale of 0 (completely dissatisfied) to 10 (completely satisfied), participants (n=47) reported high satisfaction with all items related to overall satisfaction with the class (mean 8.26, SD 1.57), likelihood of recommending the class (mean 8.77, SD 1.43), class relevance (mean 7.94, SD 2.03), the usefulness of the presented

information (mean 8.37, SD 1.79), and likelihood of using the skills and information learned (mean 8.66, SD 1.58).

Primary Outcomes

Table 4 reports the between-group comparisons at 2 weeks and 1-3 months posttreatment for all outcomes. Figures 3-12 compare group effects over time for pain-related outcomes. For all figures, the trend of the pain-related variables is displayed over time for participants in both groups. Values in the x-axis refer to the number of weeks in the study, where 0 represents the baseline (roughly 4 days preintervention) time-point. The color band represents the 95% CI for the mean outcome variable. Overlapping bands indicate nonsignificant treatment group differences (*P* value) of simple main effects within each time-point. The corresponding model effects for each outcome are displayed in Figures 3-12.

We observed a significant treatment effect (*P*=.005) on pain catastrophizing; on average, the ER group had lower PCS scores than the WLC group (Cohen *d*=0.50). Separately, we observed a time effect; the average PCS significantly decreased over time for both study groups (time effect; *P*<.001). Most importantly, the decrease was greater for ER versus WLC (group×time effect; *P*<.001). At 3-month posttreatment, clinically meaningful reductions in PCS were found for ER but not for WLC (ER: PCS −8.72, 42.25% reduction; WLC: PCS −2.25, 11.13% reduction). Figure 3 displays the average PCS at 3 months by study arm, and Table 4 displays the between-group comparisons for PCS at baseline and posttreatment months. ER was superior to WLC (difference −6.05, 95% CI −9.92 to −2.18; *P*=.002 at 3-month posttreatment.

The ER group effect size was 0.89, with combined results showing a large effect size and moderate clinical importance. As much as 62% (31/50) of ER and 24% (12/51) of WLC participants achieved a 30% or more reduction in PCS. For ER, 46% (23/50) achieved ≥50% in PCS reduction, whereas for WLC, 12% (6/51) reached that threshold.

Table 4. Outcome measures from baseline to 3 months by treatment group with between-group comparisons.

Outcome measure time-point	Empowered relief, mean (SE)	WLC,[a] mean (SE)	Between-group differences		Effect size[b] (Cohen *d*)
			Mean difference (SE; 95% CI)	*P* value

Secondary Outcomes

Pain Intensity

Analyzing all data from baseline to 3 months, we observed a significant treatment effect (*P*=.02) on pain intensity; on average, the ER group had lower pain intensity scores than the WLC group (Cohen *d*=0.41). Separately, we observed a time effect; the average PCS significantly decreased over time for both study groups (time effect; *P*<.001). Most importantly, the decrease was greater for ER versus WLC (group×time effect; *P*=.01).

At 3 months, significant reductions in pain intensity were found for ER but not for WLC (ER: pain intensity −4.98, 8% reduction; WLC: pain intensity −1.46, 2.34% reduction). Figure 4 displays the average pain intensity during the 3-month follow-up by the study arm, and Table 4 displays the between-group comparisons for pain intensity at baseline and posttreatment months. At 3 months, ER was superior to WLC (difference −6.05, 95% CI −9.92 to −2.18; *P*<.001). Notably, when applying the 15% threshold for clinical meaningfulness, the reduction in pain intensity was not clinically meaningful for either group.

The ER group effect size was 0.76, with combined results showing a moderate-to-large effect size but no clinical importance. As much as 30% (15/50) of ER and 6% (3/51) of WLC participants achieved a 15% or greater reduction in pain intensity. For ER, 4% (2/50) achieved ≥30% reduction in pain intensity, whereas for WLC, 2% (1/51) reached that threshold.

Pain Bothersomeness

We observed a time effect; average pain bothersomeness significantly decreased over time for both study groups (time effect; *P*<.001); however, during the 1- to 3-month follow-ups, the between-group difference was significant (*P*=.01 to *P*=.02) per Table 4. This significance is largely driven by the initial decline in pain bothersomeness, which was steeper in the ER group and eventually plateaued for both groups (Figure 5). At 3 months, ER was superior to WLC (difference −1.30, 95% CI −2.29 to −0.31; *P*=.01).

At 3 months, clinically meaningful reductions in pain bothersomeness were found for ER but not for WLC (ER: pain bothersomeness −1.16, 20.07% reduction; WLC: pain bothersomeness −0.38, 6.03% reduction). This meets the threshold for moderate clinical meaningfulness. Figure 6 displays the average pain bothersomeness during the 3-month follow-up by the study arm, and Table 4 displays the between-group comparisons for pain intensity at baseline and posttreatment months.

The ER group effect size was 0.61, with combined results showing a moderate effect size and minimal clinical importance. As much as 34% (17/50) of ER and 12% (6/51) of WLC participants achieved ≥30% reduction in pain bothersomeness. For ER, 22% (11/50) achieved ≥50% in pain bothersomeness reduction, whereas for WLC, 3.9% (2/51) reached that threshold.

Sleep Disturbance

At 3 months, significant reductions in sleep disturbance were found for ER but not for WLC (ER: 2.82, 5.01% reduction; WLC: 1.7, 2.86% increase; Table 4). Separately, we did not observe a time effect (*P*=.52), and we observed a significant interaction effect (*P*=.02). Sleep disturbance was lower in the ER group than in the WLC group (*P*=.02). At 3 months, ER was superior to WLC (difference −7.74, 95% CI −11.61 to

−3.87; *P*<.001). The ER group effect size was 0.37, with combined results showing a small-to-moderate effect size and no clinical importance. As much as 12% (6/50) of ER and 8% (4/51) of WLC participants achieved a 15% or more reduction in sleep disturbance.

The Benjamini-Hochberg adjustment for multiple comparisons was applied across primary and secondary variables, and statistical significance was maintained (*P*=.02 to *P*<.001).

Tertiary Outcomes

Anxiety

At 3 months, significant reductions in anxiety were found for ER but not for WLC (ER: −4.71, 7.91% reduction; WLC: −0.42, 0.7% reduction; Table 4). Anxiety decreased over time in both groups, and the decline was significantly steeper in the ER group (*P*=.009). ER was superior to WLC (difference −5.14, 95% CI −8.7 to −1.58; *P*<.001). The ER group effect size was 0.59, with combined results showing a moderate effect size and no clinical importance.

Depression

We did not observe a treatment effect (*P*=.08) on depression. Separately, we observed a time effect; average depression significantly decreased over time for both study groups (time effect; *P*=.002). Most importantly, the decrease was greater for ER versus WLC (group×time effect; *P*=.03). However, between-group differences showed that ER was superior to WLC only during months 1 and 2 (*P*=.04 and *P*=.02, respectively). The overall interaction effect appears primarily driven by these two time-points and maintains the trend and directionality, but not statistically significant, at the 3-month follow-up (*P*=.07).

Physical Function

We did not observe a treatment effect (*P*=.36) or a time effect (*P*=.36) on physical function. We observed a trend for the interaction effect (*P*=.09). Between-subjects analysis revealed no significant differences at any of the follow-up time-points (*P*=.30 to *P*=.43), except at 2-months posttreatment (*P*=.01).

Exploratory Outcomes

For social isolation, we observed a time effect; average social isolation scores significantly decreased over time for both study groups (time effect; *P*=.02). Most importantly, this was qualified by a significant group×time interaction (*P*=.02); there was a decrease in social isolation in the ER group but not in the WLC group. No time or interaction effects were observed for pain interference or anger.

Zoom Platform Satisfaction

Participants in the ER arm provided feedback on their experience using the Zoom platform on a scale from 1 (strongly disagree) to 7 (strongly agree), with higher scores indicating a higher endorsement of each item. Overall, participants reported high satisfaction with the platform, including the ease of operating Zoom (46/50, 92% satisfaction: mean 6.45, SD 1.43), engaging with class material (mean 6.02, SD 1.45), comfort in engaging with Zoom instructor and participants (mean 5.68, SD 1.45), and feeling connected to the instructor (mean 5.43, SD 1.64).

Discussion

Principal Findings

We conducted the first Zoom-delivered randomized controlled trial of the group-based, SSI *ER* in a sample of individuals with mixed-etiology chronic pain. The primary goal of this study was to evaluate the feasibility, acceptability, and engagement of a single-session Zoom-delivered intervention for chronic pain. We also aimed to determine the preliminary efficacy of Zoom-delivered ER for reducing average pain intensity, pain catastrophizing, pain bothersomeness, and sleep disruption at 1-month posttreatment. Secondary and tertiary pain-related outcomes included physical function, anxiety, depression, and physical function. We also report a more rigorous test of the durability of treatment effects at 3-month posttreatment, as well as report the clinical meaningfulness of effects.

ER demonstrated high feasibility as indexed by high enrollment rate and excellent engagement; 94% (47/50) of participants in the ER group attended the class and completed all surveys through the 3-month duration of the study. The enrollment rate was 53.1% (104/196), which is five times higher than that observed in other studies [12,77] and stands as an index of both the inclusivity of the study protocol (few exclusionary criteria; all types of chronic pain) and the convenience of a single-session pain treatment study. Importantly, participants reported high overall satisfaction with the class (mean 8.26-8.77), the usefulness of presented information, and the likelihood of using the skills and information learned. In addition, participants reported high satisfaction with operating the Zoom platform (46/50, 92% satisfaction), in addition to high satisfaction with engaging with class material, other attendees, and the class instructor. Importantly, of the 9 participants who indicated they had never used the Zoom platform during screening, none requested additional or individual training with the platform. These metrics indicate superior feasibility, accessibility, and engagement with the Zoom-delivered ER intervention.

With respect to preliminary efficacy, time effects showed reductions in pain intensity and most pain-related indices, except for sleep disruption. ER demonstrated superior treatment effects on average pain intensity and pain-related catastrophizing, pain bothersomeness, and sleep disruption over the 3 months following treatment. The between-groups Cohen *d* effect sizes at 3-month posttreatment ranged from 0.60 to 0.91 for primary and secondary variables. For ER, pre- or posttreatment Cohen *d* effect sizes ranged from 0.37 to 0.89, demonstrating no clinical importance to moderate clinical importance for reducing pain-related catastrophizing, bothersomeness, and sleep disruption at the end of treatment. The treatment effect sizes across the primary and secondary outcomes suggested that a single-session, digital, skills-based intervention may have clinically meaningful effects on patient-reported outcomes. The durability of the treatment effects was demonstrated at the 3-month follow-up time-point. A greater proportion of participants in the ER group exceeded the thresholds for the clinical importance of effects at 3 months posttreatment.

First, for moderate importance in PCS reduction (≥30% reduction in PCS), 62% (31/50) in ER versus 24% (12/51) in

WLC met this threshold. For substantial clinical importance in PCS reduction (≥50% reduction in pain), 46% (23/50) in ER versus 12% (6/51) in WLC met this threshold. PCS reductions for ER (mean −8.72, SD 1.03) exceeded the clinically meaningful threshold of 6.8 reported in the literature [78] and is notably greater than that reported in other studies examining in-person 8-week CBT [7,10,79]. Our findings on PCS are expected and aligned with the literature suggesting that pain catastrophizing, an index of pain coping, is highly responsive to behavioral treatments [7,10,79], including SSI [11,12]. For context, multidisciplinary pain rehabilitation research has shown that PCS reductions of 38% are clinically important and associated with less disability and work status at one-year follow-up [80].

Second, for minimal clinical importance in pain reduction (≥15% reduction in pain), 30% (15/50) in ER versus 6% (3/51) in WLC met this threshold. The moderate clinical importance of pain reduction was low in both groups. Importantly, this study used a PROMIS pain measure with a stricter range (5-point scale) versus a traditional 11-point Numeric Pain Rating Scale. As such, the lack of variability in this measure may have negatively impacted our ability to detect the effects of pain intensity.

The tertiary outcomes yielded mixed findings. Reductions in anxiety and depression over time were found in both groups, and the decline was significantly greater for ER than WLC. However, these reductions did not reach the threshold for clinical significance. Notably, for depression, we observed regression to the mean at 3 months with the treatment effect lost, thus suggesting that more intensive treatment might be needed for durable reductions in depressive symptoms. This may be contextualized within widespread social isolation due to COVID-19, which has been shown to worsen depression symptoms over time [81,82], or other stressors related to COVID-19 or the seasonal context of this study.

Interestingly, no treatment or time effects were observed for physical function, only a trend toward significance (P=.09), which suggests that the study may be underpowered to detect differences or identify subgroups where effect may exist. In addition, due to a coding error, the short form used in this study did not capture upper extremity function, and scale items focused on lower mobility. As this was a mixed-etiology chronic pain study, comprehensive assessment of physical function is warranted to definitively explore its effects. Exploratory analyses revealed interaction effects for reductions in social isolation, which is a notable and important therapeutic target during the COVID-19 pandemic social restrictions. Although the two groups did not differ at 3 months, the interaction effect revealed a decrease in social isolation in the ER group but not in the WLC group. These findings lend support to ER serving as a buffer against the social threat perpetuated by the pandemic [16,83], which can ameliorate its impact on people's overall health status [65,66].

Although a growing body of research exists on the efficacy of ER for chronic and acute pain management [12,33,36,52], the use of Zoom as a platform to deliver behavioral medicine for chronic pain, particularly single-session treatment, remains novel and understudied. In addition, the extant literature on digital behavioral health research has reported participant treatment engagement rates ranging from 20% to 60% [33,84-86]. Strikingly, the current trial demonstrated a 94% (47/50) engagement rate in the treatment arm. These results also highlight the public interest in the web-based delivery of behavioral medicine interventions as a home-based chronic pain treatment modality. Combined with high participant engagement data and high satisfaction with using the Zoom platform, these data extend prior work [18-25] supporting the utility, user satisfaction, and efficacy of videoconference-delivered interventions for chronic pain.

Strengths and Limitations

Several findings should be considered within a number of limitations. First, given that the participant population was on average of higher socioeconomic status, as evidenced by their average education and income levels, the results may not be generalizable to populations of different demographics. No data were available on medical diagnoses, current prescriptions, over-the-counter medication use, or concurrent treatments for either study group. In addition, all data were self-reported, and we did not control for receipt of medical care. In light of COVID-19 restrictions, participants were likely to receive their care via web-based delivery as well. In addition, the pain intensity measure used was a 5-point Numeric Pain Rating Scale, as opposed to the 11-point Numeric Pain Rating Scale [87] typically used in research, limiting variability and may have obscured treatment effects and clinically meaningful findings. Finally, the participants were unblinded to the study group assignment. However, given that ER is low risk and low burden, placebo effects are less concerning. Replication studies were indicated with participants with more demographic variability over a longer follow-up period. Finally, future studies should characterize pain diagnoses and pain types.

Despite these limitations, this web-based study evidenced strong interest and participant engagement with single-session skills-based pain treatment, thus supporting further research and extension of web-based ER into clinical care. Second, the COVID-19 context and web-based delivery modality support the ecological validity of the study findings. Notably, the study was conducted remotely and did not benefit from any in-person contact that occurred when research was conducted in medical treatment settings (ie, halo effects). Additional aspects of methodological rigor included analyst blinding, intention-to-treat analyses, and randomization. Finally, our sample included minimal exclusions, which rendered it highly generalizable to other *real-world* individuals.

This study examined class cohorts comprising approximately 25 participants, and in-person class sizes ranged between 20 and 85, thus illustrating the promise of scalable pain care. Indeed, ER may help address pain disparities by ensuring rapid and more equitable access to pain treatment. Our findings provide initial evidence that the web-based delivery of ER may efficiently reduce the burden of chronic pain and improve symptom management. Additional research is needed to test the pragmatic comparative effectiveness of web-based ER to other treatments, such as gold-standard 8-week CBT, and to determine the heterogeneity of treatment effects.

Conclusions

In 2019, the US Health and Human Services cited ER as a promising scalable behavioral pain treatment [88]. For the first time, this study determined the preliminary efficacy of the Zoom-delivered class in reducing the burden of chronic pain and improving symptom management. Importantly, the web-based single-session class addresses the rapidly expanding need for alternatives to face-to-face encounters due to the COVID-19 pandemic. Web-based delivery of ER stands to largely improve patient access and engagement because it is adaptable to medical or community settings, is readily extendable to underserved populations (eg, rural locations), and may be offered at a low cost.

Abstract

Background: Although past research has focused on COVID-19–related frames in the news media, such research may not accurately capture and represent the perspectives of people from diverse backgrounds. Additionally, research on the public attention to COVID-19 as reflected through frames on social media is scarce.

Objective: This study identified the frames about the COVID-19 pandemic in the public discourse on Twitter, which voices diverse opinions. This study also investigated the amount of public attention to those frames on Twitter.

Methods: We collected 22 trending hashtags related to COVID-19 in the United States and 694,582 tweets written in English containing these hashtags in March 2020 and analyzed them via thematic analysis. Public attention to these frames was measured by evaluating the amount of public engagement with frames and public adoption of those frames.

Results: We identified 9 frames including “public health guidelines,” “quarantine life,” “solidarity,” “evidence and facts,” “call for action,” “politics,” “post-pandemic life,” “shortage panic,” and “conflict.” Results showed that some frames such as “call for action” are more appealing than others during a global pandemic, receiving greater public adoption and engagement. The “call for action” frame had the highest engagement score, followed by “conflict” and “evidence and facts.” Additionally, “post-pandemic life” had the highest adoption score, followed by “call for action” and “shortage panic.” The findings indicated that the frequency of a frame on social media does not necessarily mean greater public adoption of or engagement with the frame.

Conclusions: This study contributes to framing theory and research by demonstrating how trending hashtags can be used as new user-generated data to identify frames on social media. This study concludes that the identified frames such as “quarantine life” and “conflict” and themes such as “isolation” and “toilet paper panic” represent the consequences of the COVID-19 pandemic. The consequences could be (1) exclusively related to COVID-19, such as hand hygiene or isolation; (2) related to any health crisis such as social support of vulnerable groups; and (3) generic that are irrespective of COVID-19, such as homeschooling or remote working.

KEYWORDS

COVID-19; framing; Twitter; social media; public opinion; engagement; public attention; thematic analysis; public health

Introduction

Public Opinion on Twitter

COVID-19 is a global public health pandemic threatening millions of lives worldwide, leading to approximately 188,655,968 confirmed cases and 4,067,517 deaths across the globe as of July 16, 2021 [1]. Twitter was used as one of the major platforms for disseminating information and knowledge about the COVID-19 pandemic, resulting in massive data generated by the public about various aspects of the virus [2]. Twitter has become the most frequently used communication medium for disseminating health information since the outbreak of H1N1 in 2009 [3] and later during the outbreak of the H7N9 virus, or bird flu, in 2013 [4]. It was also a platform for discussing the Zika virus epidemic in 2015 and 2016 [5].

People use Twitter and other social media platforms to interact with, share their opinion about, and engage with public health messages in real time. Twitter allows public health gatekeepers to interact with the public directly. For instance, the Centers for Disease Control and Prevention, the World Health Organization (WHO), health care officials, and organizations used Twitter regularly to share public health messages about the pandemic and communicate its risks to the public [2].

The data shared on Twitter can be used to analyze and study public opinion. Understanding public opinion could help researchers and authorities identify the public's needs, priorities, preferences, and behavior in real time. In turn, these data could impact public policy by encouraging governments and health care officials to distribute proper resources, take actions, and plan accordingly [6-8]. For instance, Avery [9] reported that monitoring public opinion about the Zika virus crisis on social media helped public information officers have a higher level of preparedness for managing the crisis.

Frame Analysis of Public Opinion

Public opinion refers to people's collective opinion about an issue such as COVID-19. The public consists of all the groups and subgroups in society, such as workers, doctors, officials, politicians, journalists, and students [10]. An effective strategy to understanding public opinion and attention to an issue is analyzing how people perceive and frame the issue [11,12]. Framing refers to selecting some aspects of an issue, promoting them, and making them salient [13]. Journalists and news media often use framing to conceptualize an issue, bring public attention to some aspects of the issue, and minimize attention to other aspects of it [14,15]. People also use framing to make sense of complex information, interpret and organize these ideas into comprehensible concepts, and present them to others [16].

Analyzing public opinion by frame analysis provides insights into the content and sentiment-based aspects of an issue [17]. Frames can serve as a starting point for designing effective messages to address people's needs and concerns during public health crises [18]. Journalists, policymakers, professionals, and scientists use frames to communicate their messages in a more effective way that is easily understandable by the public [19]. Frames can also be used by governments, advocacy groups, and authorities to design public education materials, present more engaging and effective public dialogue, write more relevant stories for the public, and expand their audience, reach, and impact [20]. For instance, framing of messages related to COVID-19 can be used to design and target messages in an effective way to enhance public engagement with public health guidelines [21].

Effect of Frames on Public Attention

An important aspect of framing research is to study the effect of frames on public attention. "Public attention refers to the general acknowledgement of a subject in the public sphere and subsequent civic discourse on the subject" [22]. Different frames about an issue can cause varied effects on public attention. A small change in how a topic is presented can sometimes cause a butterfly effect on public attention [15]. Framing or reframing an issue can shift how people understand the story, consequently changing how people respond to it [16]. Once the public turns its attention towards a series of frames about an issue and adopts those frames, it is likely that they collectively agree on the best decision and course of action [15]. The study by Krishnamurthy et al [23] showed that, when discussing the performance of medical treatments, the messages that are framed positively (ie, the chance of treatment success rather than its failure) had a greater impact on health treatment decisions. Almashat et al [24] indicated that survival frames (ie, the likelihood of surviving a certain procedure) would lead to making more informed medical decisions than mortality frames (ie, the possibility of dying from a certain procedure). Analyzing the effect of COVID-19 frames on public attention can be used to determine which frames are more effective in receiving greater public attention and impacting public opinion.

In summary, Twitter provides valuable user-generated data that can be beneficial for different stakeholders to respond to health crises. Although some studies have analyzed the frames about COVID-19 with a focus on the news media of politicians [18,25-28], there is no systematic study about the frames in public discourse on Twitter for this global pandemic. Therefore, this study aimed to fill this gap with the following research objectives.

Research Objectives

The aim of this research was to (1) identify the frames associated with the COVID-19 pandemic in public discourse on Twitter and (2) analyze which of the COVID-19 frames in public discourse have received greater public attention on Twitter.

Literature Review

Framing of the COVID-19 Pandemic

During public health emergencies, it is critical to communicate public health messages and guidelines to the public effectively. One way to make public health messages more effective is to frame them in a way that helps people understand health crises and positively impact their decision making and behavior. Previous empirical research shows that the news media play an important role in framing public health crises [25]. As evident in Multimedia Appendix 1, Ogbodo et al [26] analyzed the frames in 8 leading global media outlets globally, such as the BBC, News York Times, CNN, and People's Daily. Poirier et

al [27] investigated the frames used on the front pages of 12 well-known Canadian news media sources. Park et al [18] analyzed Korean COVID-19–related tweets to identify medical and nonmedical news frames, and Yu et al [25] studied the frames in the tweets of 2 major newspapers in Spain: El Mundo and El País.

The literature on the framing of COVID-19 shows that most past studies have focused on how COVID-19 has been framed by political figures and the news media [28]. These studies reflect the frames promoted by established gatekeepers, namely the news media, in society who may have some hidden agenda. Unlike previous framing studies, this study attempts to fill this gap by focusing on the frames related to COVID-19 in public discourse on Twitter, which voices the opinions of diverse groups of people.

Hashtags for Framing Messages on Twitter

Framing studies uses the features of communicating text to identify frames. The linguistic features include headlines or subheads of newspapers; photographs and photo captions; paragraphs of articles [29]; social media posts, such as tweets [30]; and other visual images, like icons [31]. For instance, Hellmueller and Zhang [32] used photographs to identify frames regarding the European refugee crisis in CNN International and Der Spiegel online news sites. Benziman [28] used US President and British Prime Minister speeches to identify how they framed issues related to COVID-19.

Hashtags are a linguistic feature that can be used to identify frames on Twitter and other social media platforms. Hashtags serve as catchphrases that can identify frames in tweets [33]. They represent a shared meaning or context [34] that, similar to frames, can highlight the most salient aspects of an issue (see [35]) in such a way as to promote it (see [13]).

In such circumstances as breaking or emerging events, a specific hashtag (eg, #BlackLivesMatter) or a set of hashtags (eg, #StayHome, #WashYourHands) become the main channel to represent an issue in online conversations by social media users. Hashtags that gain community-wide adoption and popularity can be used to identify the ad hoc framing of an event. Widely adopted hashtags show how the public frames a topic and can be used to determine the thematic frames of the issue [17]. Nevertheless, limited studies have acknowledged the possibility of using hashtags to identify frames (eg, [17,33]). Hence, this research explored hashtags in frame analysis as a new approach for framing theory and research.

Trending Hashtags in Frame Analysis

Among the numerous widely adopted hashtags on social media, some may become trendy and viral. Popular hashtags emerge in response to breaking news and other unexpected events, such as when an important, nationwide, or global issue happens [36,37].

Hashtags may go viral on Twitter as more and more people begin to use them [38]. Many users engage with trending topics and hashtags on social media [36]. Trending hashtags or topics often do not last long on Twitter [39]; however, they receive an initial increase of public attention, and then the focus of the public shifts elsewhere [34]. Trending topics and hashtags represent which issues have drawn the most public attention [36]. Trending hashtags also represent a community of online users who attend a unique topic or event for a limited period [34]. The mechanisms by which Twitter identifies the top trending topics and hashtags [36] or what causes some topics to become widely popular are not clear [39]. Nonetheless, such popularity peaks are of great relevance for identifying the issues that are the focal point of the public. As such, trending hashtags are suitable tools to be used in frame analysis of social media posts.

Benefits of Using Hashtags in Frame Analysis

Using hashtags in frame analysis has 2 benefits: It facilitates framing public opinion on social media, and it mitigates the subjectivity issue in frame analysis. Hashtags, similar to photographs [40], make it easy for researchers to understand what the tweet's content is about because they are the commonly accepted public signals for framing and presenting an event or topic among all social media platforms. While framing research on social media has focused mostly on analyzing social media posts, the question of how issues are framed through hashtags has remained relatively underexamined.

Content analysis is a dominant method for analyzing and identifying frames on social media (eg, [41]) and in non-social media contexts (eg, [42]). Matthes and Kohring [43] noted that a major issue with identifying frames through content analysis is that it involves researchers' subjective biases in analyzing and coding the text differently. Researchers' subjective biases question the validity and reliability of content analysis and the results in frame analysis [43]. Subjectivity is nearly impossible to avoid [19]; however, using hashtags to identify frames mitigates the subjective role of the researcher in frame analysis because hashtags have a "classificatory function" of indicating what a social media post is about [44]. Therefore, hashtags enhance the researcher's capability to describe online information [45] and identify "textual aboutness" [46] of social media posts. In some cases, hashtags may not stand alone in understanding textual aboutness because textual aboutness can be sensitive to context. For instance, a hashtag might reflect 2 different meanings simultaneously [44].

The Effect of Frames on Public Attention on Social Media

There is no standard way for measuring public attention on social media [47]. However, some previous studies have used tweet activity, such as the retweet frequency, to measure public attention [47,48]. Ripberger et al [48] studied public attention by assessing the number of tornado-related tweets posted on Twitter. Ripberger et al [48] assumed that the increase in the number of tornado warnings and number of tornado watches (issued by 2 different institutes) led to an increase in the number of tweets (representing public attention). Chew and Eysenbach [3] also indicated a coincidence between major H1N1 news and the frequency of H1N1 tweets in April 2009. The presence of a relationship between tweet activity and public attention has been shown in other studies about swine flu [49] or influenza [50].

None of the framing studies on COVID-19 [18,21,25-28] have identified the effect of frames on public attention. This study investigated the effect of COVID-19 frames in public discourse on Twitter on public attention. This study took a new approach that measures public attention more accurately than the methods used in previous studies because it measured not only tweet activity (ie, number of likes and retweets a frame receives) but also how many unique Twitter users have adopted a frame. In this new approach, public attention was measured by evaluating the score of public engagement with frames and the score of public adoption of frames (see Methods, Measuring Public Attention). Public engagement refers to the number of likes and retweets each frame has received. Public adoption is assessed by the number of unique users in each frame category [51].

Methods

Data Collection

Twitter was the primary source of data collection (ie, hashtags and tweets) in this study. The *get_trend* function from the *rtweet* package in the R software was used to collect trending hashtags related to COVID-19 on Twitter in March 2020. Additionally, the trending feature on the Twitter website was observed at least 3 times a day for the entire month of March 2020 to track and record trending hashtags. The trending hashtags identified by the *get_trend* function were exactly similar to those identified on Twitter. In March 2020, 22 trending hashtags related to COVID-19 were identified on Twitter. Additionally, the trending hashtags from each day were searched in the search box of the Twitter website to find other relevant hashtags and achieve a greater degree of reliability in data collection. For instance, by searching #QuarantineLife, a trending hashtag on March 16, 2020, additional hashtags, including #QuarantineDogs and #QuarantineCats, were identified.

This study then collected the tweets that contained at least one of the trending or associated hashtags. The *search_tweets* function in the *rtweet* package was used to collect tweets by the R software and the streaming application programming interface (API). R, Salesforce Social Studio, and Brandwatch were used to collect 694,582 tweets written in English from March 1, 2020 to March 31, 2020.

This study removed the retweets in the dataset to analyze initial tweets posted by people on Twitter. Additionally, quote tweets (ie, the retweets with comments), representing the original comments posted by Twitter users, were analyzed.

Bot Account Removal

Bots are automated accounts that can manipulate and impact public attention on social media [52]. Ferrara [52] indicated that bots were active during the COVID-19 pandemic and found that hashtags like #bitcoin, #smartnew, and #grreatwakening were mostly posted by bot accounts on Twitter. This study removed 269,854 (269,854/694,582, 38.85%) tweets posted by bot accounts to increase the validity of results, leaving 424,728 (424,728/694,582, 61.15%) tweets in the dataset.

The default model of the *tweetbotornot* package in R software was used to remove bot accounts [53]. The default model is 93.53% accurate in classifying bots and 95.32% accurate in classifying nonbots. It uses user-level features (eg, bio, location, number of followers and friends) and tweet-level features (eg, number of hashtags, mentions, capital letters) of Twitter accounts to identify bot accounts [53]. Accounts that received a score of at least 50% or a probability of 0.5 were considered bots and were removed [54].

Thematic Analysis to Identify Frames

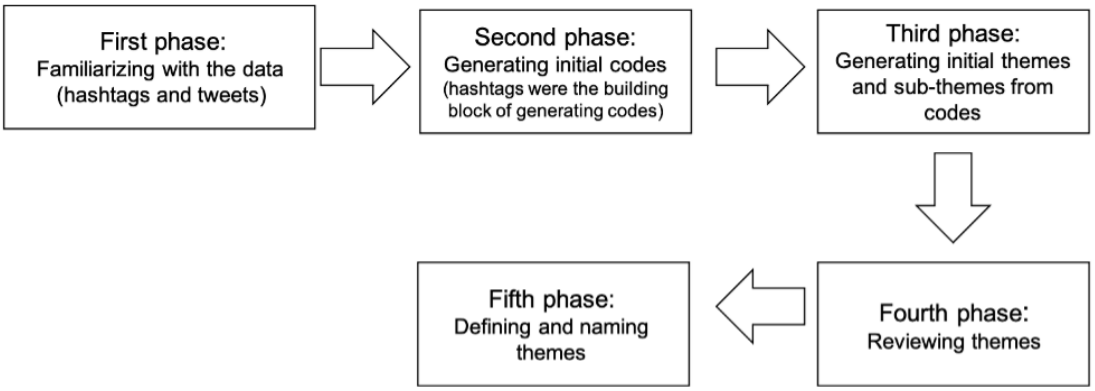
Hashtags were the main unit of analysis in this research and the building blocks of identifying frames. The frames identified in this study are primarily informed by the classification of trending and associated hashtags to different categories. Additionally, to identify the frames about COVID-19 in the public discourse on Twitter, thematic analysis was used. Thematic analysis is a method that provides a detailed description of the textual data [55]. In this research, public opinion includes all Twitter users such as workers, doctors, officials, journalists, politicians, teachers, and any other group on Twitter.

In thematic analysis, the judgment of the researcher or analyst is adequate for identifying themes [55]. The researcher analyzes the text and identifies themes within the “surface meanings of the data” without looking for anything beyond the text [55].

The thematic analysis helped us provide a more detailed and nuanced description of hashtags and find repeated patterns of meaning [55]. The contents of up to 100 randomly selected tweets were checked to ensure alignment between the hashtags and the contents of tweets. For instance, #WashYourHands, #HandWashing, #SafeHand, #SafeHands, and #HandWashChallenge were classified as one category named “hand hygiene.” Using thematic analysis, this study analyzed the content of the tweets associated with these hashtags to ensure they were related to hand hygiene. The thematic analysis also helped provide a more accurate description of this category. In some cases, the thematic analysis helped us redefine the theme assigned with a set of grouped hashtags.

We followed 5 phases to analyze the themes in the tweets. Figure 1 presents the workflow visualization for the 5 phases of the thematic analysis. In the first phase of thematic analysis, researchers familiarized themselves with the data [56] by reading the hashtags and the tweets associated with them several times before coding. It helped researchers obtain some knowledge of the hashtags, related tweets, and the initial list of ideas and themes.

Figure 1. Workflow visualization for the 5 phases of the thematic analysis.



In the second phase, initial codes were generated from trending and associated hashtags [56]. Hashtags were used to describe what a particular tweet was about and to create codes. For instance, #ToiletPaperPanic is a hashtag in the data referring to the public's panic for the possible shortage of toilet paper during the early days of the COVID-19 pandemic. Additionally, #WashYourHands is a hashtag that emphasizes the importance of hand hygiene to prevent contracting the COVID-19 virus.

In the third phase, codes were analyzed and classified into potential themes and subthemes [56]. For instance, the following set of hashtags — #SocialDistancing, #SocialDistancing, #KeepYourDistance, #PhysicalDistancing, #SocialDistance, #SocialDistancingNow, #YouAreTooCloseIf, #Dont BeASpreader, and #StoptheSpread — and the tweets associated with them helped the researchers to identify and propose the "social distancing" theme.

In phase 4, the researchers reviewed the themes and, when necessary, combined, refined, or separated them [56] to generate the final themes. In the fifth phase, the themes were clustered into frames. Concise names were assigned to the themes to help readers comprehend the theme's meaning [56].

Measuring Public Attention

This study used the scores of public engagement with and public adoption of frames to measure public attention to frames on Twitter. Following DeMasi et al [51], this study defined public engagement as the extent to which users engage with a frame. Public engagement was measured by the number of times a given frame had received at least one like or retweet divided by the frequency of that frame in the entire dataset. The lowest public engagement score that each frame could receive was 0, with a maximum of 1.

Public adoption refers to how broadly Twitter users adopt a frame. High adoption indicates a diverse community with many unique users who have posted tweets with hashtags in each frame. Low diversity shows a tight community with only a few users posting tweets with the hashtags in a given frame multiple times [51]. Public adoption was measured by the number of unique Twitter user accounts in a given frame divided by the frequency of the frame [51]. The public adoption score ranges from 0 to 1 as the minimum and maximum scores, respectively.

Results

Framing of COVID-19 on Twitter

We identified 9 categories of frames through thematic analysis (see Multimedia Appendix 2). Each frame is defined by a set of consequences of COVID-19 along with hashtags, characterizing what each frame category describes. The frames are "public health guidelines," "quarantine life," "solidarity," "evidence and facts," "call for action," "politics," "post-pandemic life," "shortage panic," and "conflict."

Public Health Guidelines

Public health guidelines consisted of 5 main themes: isolation, social distancing, hand hygiene, face hygiene, preventive tips, and awareness. Isolation included hashtags that encourage and advise people to isolate themselves to prevent the spread of the virus. Some of the hashtags in this theme, such as #StayHomeStayHealthy or #StayHomeSaveLives, positively motivate people to self-isolate by staying home. This frame also included the recommendations people made to call others' attention to the precautionary measures required to reduce the chance of being infected by the virus, such as practicing social distancing and face and hand hygiene (eg, #SocialDistancing, #WashYourHands, and #WearAMask). Sometimes tweets contained hashtags with a sense of humor and positive sentiments, such as #YouAreTooCloseIf or #How toKeepPeopleHome.

Other hashtags in this frame, such as #CoronaVirusTips, were used to provide guidelines and tips about various aspects of the virus, including how to clean smartphones, wash hands, and do contactless delivery of food. Additionally, this frame included tips for preventing potential exposure to the virus. For instance, #CoronaVirusPrevention was used to show how police departments should prevent potential disclosure and provide coronavirus prevention tips for people with disabilities.

Quarantine Life

This frame contained several themes that focused on people's daily lives during the quarantine. People used various hashtags to share stories, pictures, or videos of their home offices, the homeschooling of kids, and their pets. Pet owners used hashtags such as #QuarantineCats or #QuarantineDogs to share humorous content about their living experiences in isolation. #After3WeeksWithMyFamily and #SideEffectsofQuarantineLife

were used to post amusing messages along with photos or videos, often to make fun of the lived experience and actual difficulties people were dealing with during the pandemic. Quarantine life also focused on the impact of the pandemic on how people worked and learned during the quarantine. People posted videos or pictures of themselves using hashtags such as #RemoteLearning, #DistanceLearning, #RemoteWorking, or #OnlineLearning while working or learning from home.

Solidarity

Solidarity focused on inspiring, encouraging, and giving hope to each other; social support; providing voluntary services to communities; acknowledging health care professionals; and emphasizing unity. People used hashtags such as #StayStrong or #TogetherApart to inspire "staying home together" during the pandemic. The hashtags #CoronaWarriors, #ClapForCarers, #HealthCareHeroes, and #ClapForOurCarers were used to show appreciation to the frontline workers in fighting the pandemic, namely health care professionals.

A major theme in solidarity was social support, which consisted of hashtags used to assist various (vulnerable) populations or services. For instance, #ProtectOurSeniors was used to emphasize the importance of supporting seniors medically, financially, and emotionally. Other hashtags such as #OpenForTakeout, #OpenForDelivery, #SupportSmallBusiness, and #SupportLocal were used to support businesses and acknowledge the stores open for takeout or delivery during the pandemic.

Call for Action

This frame refers to a lack of accountability and responsibility in governments for not taking necessary actions to close public places. This frame also consisted of hashtags that show that the public is also responsible for their lack of compliance with public health guidelines. For instance, #CloseTheBeaches was used in tweets to emphasize that a public space like beaches should be closed as many people went to Florida's beaches during the pandemic.

Evidence and Facts

This category focused on updates, reality, and truths about various aspects of the COVID-19 virus, such as the total number of deaths, new cases, discharged patients, and further evidence about how the virus spreads. For instance, #CoronaVirusUpdates was used on March 29, 2020 to refer to emerging hotspots of coronavirus and emphasized that New York remained the worst-hit US state. Another hashtag in this category was #CoronaVirusTruth, which was used to provide people with the facts and truths about COVID-19, such as the increasing number of deaths across the globe.

Politics

This frame refers to the accountability of politicians for their national policies and actions during the pandemic. Some hashtags were used to hold political officials accountable for their policies, decisions, and actions regarding the COVID-19 pandemic. The tweets in this category often had a negative sentiment. For instance, #TrumpLiedPeopleDied was used to show a lack of transparency and timely action to control the virus, not taking the pandemic seriously, and not following public health guidelines and policies. #ChinaLiedPeopleDied was, on the other hand, used to make China responsible for the transmission of the COVID-19 virus to other countries.

Post-Pandemic Life

This frame focused on the positive sentiment surrounding people's plans, feelings, and life after the pandemic is over. #WhenCoronaVirusIsOver and #WhenILeaveMyHouseAgain are the hashtags in this category that sometimes were posted with tweets with a sense of humor. For example, a tweet stated, "people are going to stay home even when the pandemic is over." People used the hashtags in this category to refer to the food they like to eat; to describe the places or people they enjoy visiting; to recommend things people should avoid, like eating animals; to emphasize that the world would be a cleaner place after the pandemic; and to suggest that people would love and respect nature more than in the past.

Shortage Panic

This frame showed panic about the shortage of products as a top priority of people when the pandemic had just started in March 2020. Shortage panic refers to the public reaction to and anxiety about the shortage of resources, including bottled water, toilet paper, hand sanitizer, and food. Most tweets in this category contained an image showing empty shelves in stores or people lined up in stores trying to purchase products such as toilet paper.

This frame demonstrated uncertainty in the public about how much supplies were needed because the future was unpredictable [57]. The uncertainty about the pandemic led to an "exaggerated sense of urgency and a fear of scarcity," which resulted in actual scarcity [57].

Conflict

Conflicts refers to arguments and disagreements among people. Hashtags such as #FilmYourHospital or #EmptyHospitals were used to imply that COVID-19 was not as severe as stated by the media, governments, or health officials. Some people used these hashtags to frame their disapproval of the lockdown and social distancing or to suggest that COVID-19 is not real by filming empty hospitals. Another hashtag in this category was #FakeNews, which people used to share opposing views about various aspects of COVID-19. It was also used to show disapproval with the information and news spread about the virus, mostly by the news media or politicians from both the Democratic and Republican parties. #FakeNews was sometimes used to argue in favor of issues related to COVID-19, and other times, it was used to argue against those issues (see [19]).

Public Attention to Frames

Public attention to frames was assessed using the 2 measures of "public engagement" and "public adoption." Public engagement shows how engaging a frame has been on Twitter, counted by the number of retweets and likes a frame had received. Public adoption refers to the number of unique Twitter user accounts in a given frame category, divided by the frequency of frames in that frame category [58].

Table 1 shows public engagement with each frame. "Call for action" had the highest engagement (0.68), followed by "conflict" (0.67) and "evidence and facts" (0.59). Table 2 shows the public adoption score for each frame. "Post-pandemic life" (0.99) had the highest adoption score, followed by "call for action" (0.92) and "shortage panic" (0.91).

Table 1. Public engagement with frames.

Frame number	Frame	Frequency of the frame, n	Labeled Yes[a], n	Labeled No[a], n	Public engagement score (Yes/Yes+No)
1	Public health guidelines	171,009	94,545	76,464	0.55
2	Quarantine life	86,983	48,701	38,282	0.56
3	Solidarity	46,164	25,253	20,911	0.54
4	Evidence and facts	31,819	18,874	12,945	0.59
5	Call for action	31,809	21,881	9928	0.68
6	Politics	24,346	11,903	12,443	0.49
7	Post-pandemic life	20,442	11,439	9003	0.56
8	Shortage panic	16,815	9321	7494	0.55
9	Conflict	3550	2384	1166	0.67

[a]Each frame receiving at least a retweet or like was labeled as "Yes"; otherwise, it was labeled as "No."

Table 2. Public adoption of frames.

Frame number	Frame	Frequency of unique users (U), n	Frequency of frame (F), n	Public adoption score (U/F)
1	Public health guidelines	142,105	171,009	0.83
2	Quarantine life	75,439	86,983	0.87
3	Solidarity	37,424	46,164	0.80
4	Call for action	29,134	31,809	0.92
5	Evidence and facts	27,957	31,819	0.88
6	Politics	21,724	24,346	0.89
7	Post-pandemic life	20,149	20,442	0.99
8	Shortage panic	15,255	16,815	0.91
9	Conflict	2095	3550	0.60

The distribution of public engagement and public adoption is illustrated in Figure 2. According to this figure, although conflict had the lowest frequency (n=3550), it received the second-highest engagement score (0.67). Public health guidelines had the highest frequency (n=171,009), followed by quarantine life (n=86,983); however, their public adoption and engagement scores were not high. Pearson correlation did not show any correlation between public adoption and public engagement: r_8=–0.46, P=.18.

Figure 3 presents the distribution of public engagement with and public adoption of frames in terms of frame frequency. No meaningful patterns can be observed in frame engagement and adoption based on frequency. Pearson correlation showed no correlation between engagement and frequency (r_8=–0.26, P=.46) nor between adoption and frequency (r_8=0.13, P=.70). The insignificant results could mean that, if a frame receives high adoption by the people, it does not indicate that the frame would also achieve a high engagement (or vice versa).

Figure 2. Distribution of the frames "public engagement" and "public adoption".

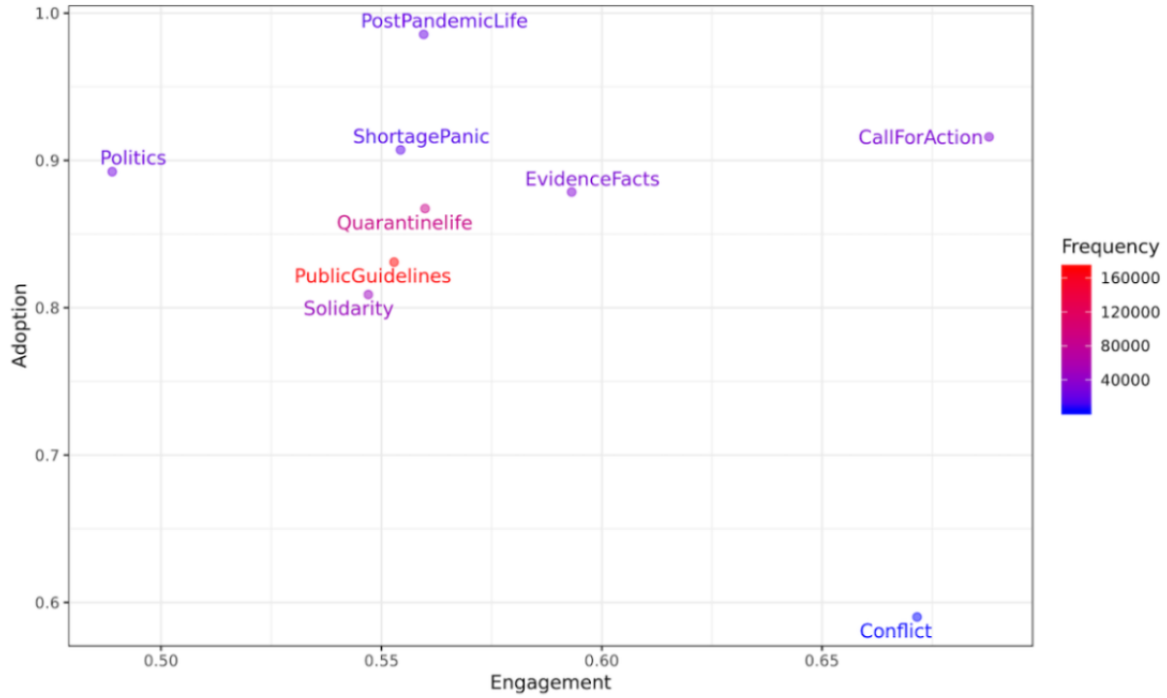


Figure 3. Distribution of the frames "public adoption" and "public engagement" in terms of frequency.

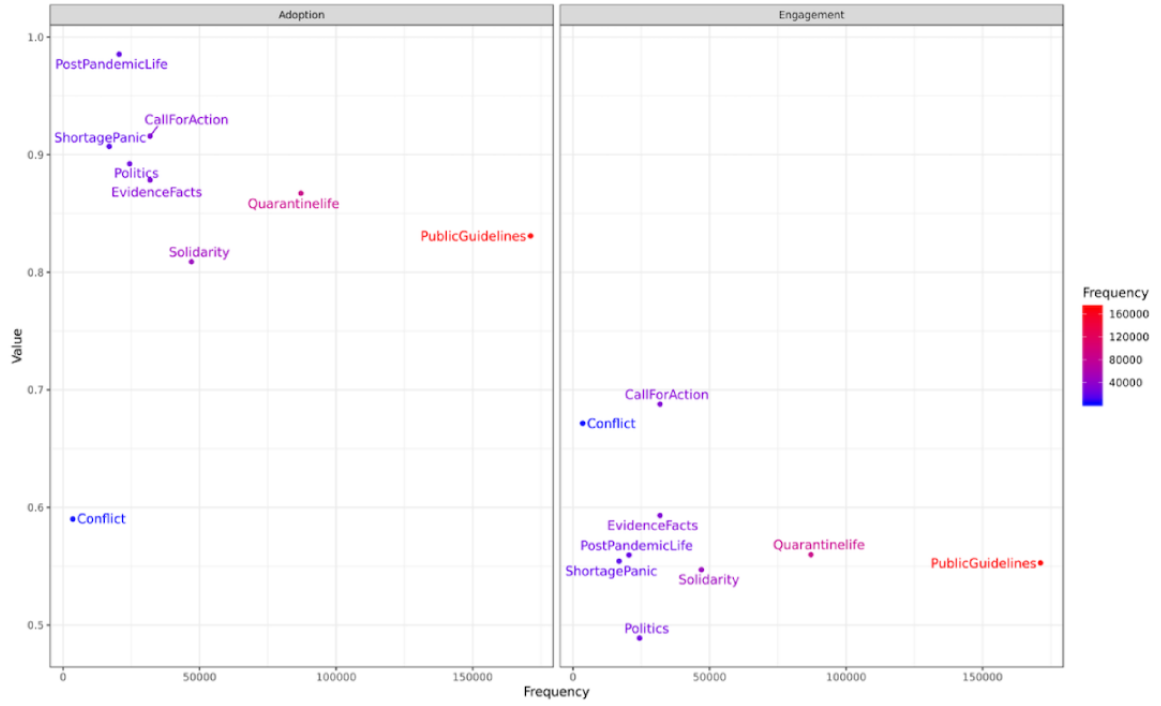

Discussion

Principal Findings

This study analyzed the trending and associated hashtags in March 2020 during the initial phases of the COVID-19 pandemic. We found 9 frames in the public discourse on Twitter: “public health guidelines,” “quarantine life,” “solidarity,” “evidence and facts,” “call for action,” “politics,” “post-pandemic life,” “shortage panic,” and “conflict.” These frames and the hashtags within them such as #SupportSmallBusinesses and #StayPositive can be used to identify the types of information that should be delivered during any public health crisis, specifically the initial phase of the crisis. Furthermore, some of the frames such as solidarity, evidence and facts, call for action, politics, shortage panic, and conflict can be used in any local or global crisis such as social movements, earthquakes, tornadoes, hurricanes, and floods. For instance, the solidarity frame can be used to design messages to encourage people during an earthquake to show solidarity to those impacted by the crisis.

This study also evaluated public attention to the identified frames by assessing the amount of public engagement with and public adoption of frames. Among all frames, "call for action" had the highest engagement score, followed by "conflict" and "evidence and facts." Additionally, "post-pandemic life" had the highest adoption score, followed by "call for action" and "shortage panic."

According to Price and Tewksbury [59], framing is more effective when it is relevant to people, such as when the frames resonate with the audience's beliefs or ideology [20]. The effects of frames on public opinion could be more substantial when the quality or logic of the argument and source credibility are more reliable [60]. The frames with greater public attention could be used strategically to design messages that affect public opinion more efficiently during public health emergencies. Additionally, these frames could be used to increase the performance of social media posts and encourage public compliance with public health messages.

Theoretical Contributions and Implications

This study informs framing theory and research in several ways, mentioned in the following sections.

Frames as the Manifestation of COVID-19 Consequences

This research informs framing theory by indicating that frame analysis of public discourse on social media via hashtags is valuable not only in understanding public opinion about various aspects of the pandemic but also in recognizing the consequences of the pandemic on people's lives, such as panic over the shortage of products.

The findings indicated that frames are the manifestation of COVID-19 consequences. The consequences discussed by people on Twitter about COVID-19 could be classified and analyzed based on whether (1) they were exclusively related to COVID-19, such as hand hygiene or isolation (ie, people are isolated or wash their hands because of COVID-19); (2) consequences could be related to any health crisis such as social support of vulnerable groups (ie, vulnerable groups require social support in any pandemic); and (3) consequences were generic irrespective of COVID-19, such as homeschooling or remote working (ie, some people homeschooled or worked remotely even before the pandemic).

Motivations and Sentiments in Frames

The findings showed that hashtags can promote intrinsic or extrinsic motivations among social media users. Hashtags can also convey a positive or negative sentiment. For instance, #StayHomeStayHealthy promotes an extrinsic motivation in people because this hashtag motivates people to stay home for external factors, such as prevention of contracting or spreading the virus. Another example could be #StayHomeStayHealthy, which has a positive sentiment because it indicates that staying healthy is a positive aspect of staying home.

Frames Promote the Collective Interest

Most hashtags promoted collective interest among people. For instance, #SocialDistancingNow was used by Twitter users to motivate people to prevent the potential transmission of COVID-19 for the public good. Another example could be #WearAMask in public, which promotes a collective interest to prevent the spread of the virus rather than merely preventing oneself from contracting the virus [61].

Conflict and Disagreement With Evidence and Facts

People used the "conflict" frame to discredit the evidence, facts, and updates about the COVID-19 virus, such as its fatality rates. Previous studies indicate that the news media sometimes use the "conflict" frame to report disagreements and arguments among people or groups to capture more audiences [42]. Using the conflict frame in social media posts can "increase the perceived seriousness and news value of an event" [62].

The conflict frame seems to be important in both the news media and public discourse during public health emergencies. Shih et al [14] stated that the conflict frame (defined as the arguments and disagreements among news sources) is the main frame in the media coverage of public health pandemics. Park et al [18] also found that conflict was a main frame in the Korean news media tweets about COVID-19. The popularity of the conflict frame demonstrates that there are always groups of people with disagreements about facts and evidence during public health emergencies.

This frame had the lowest frequency and lowest public adoption score among all frames identified in this study. A few previous studies have also indicated that news with conflict frames has been shared less on social media than news without conflict frames [62]. However, in this study, the conflict frame received the second-highest score for public engagement. This high score could be an indication that hashtags with conflicting information, such as #FilmYourHospital, are highly engaging on social media, despite their low frequency. A low adoption score with a high engagement score could indicate a focused community structure [51].

The "conflict" and "evidence and facts" frames indicate the presence of a chain of reactions, in that in response to the people who post information about facts and updates related to COVID-19 (ie, the evidence and facts frame), another group of people used the conflict frame to challenge those facts and updates (ie, the conflict frame). Some people would then, in turn, react to the conflict frame by sharing evidence and facts about the virus.

Vulnerable Groups

Our results indicated that frame analysis could be used to identify groups of vulnerable populations (eg, seniors, workers, and local and small businesses) and how the people frame their concerns and opinions about the needs of such populations on Twitter. It was found that vulnerable populations have been in need of prompt attention and support during the COVID-19 pandemic. For instance, seniors require social support, workers need safe workplaces, and local and small businesses need financial support. The findings did not show any hashtag referring to race or ethnic minority groups and health disparity populations, such as refugees, immigrants, homeless individuals, countries with fewer resources, or other marginalized communities. Overall, frame analysis through hashtags can be

used to identify the populations that need more attention and support during global crises.

Accountability of Gatekeepers

Frame analysis can also identify who or which groups are responsible for managing a public crisis in the public view. The "call to action" frame indicated that Twitter users held federal and local governments accountable for their lack of actions regarding the closure of public places like beaches or restaurants. The "politics" frame also demonstrated people's reaction to politicians' decisions, policies, and insufficient actions during the pandemic. The politics frame includes hashtags that show those responsible for the situation in the public view. For instance, many hashtags in this category were used to make the US President accountable for the increasing number of COVID-19 cases and deaths. This frame could also show a lack of trust between politicians and the public, which often occurs during the initial phases of a pandemic [63].

The Use of Humor in Public Health Messages

The results in this study inform framing research by showing that people used hashtags such as #QuarantineCat or #HowToKeepPeopleHome to share information with humorous content. These hashtags were not directly related to COVID-19 but were generated and used by Twitter users due to COVID-19. Additionally, people used these hashtags to share their experiences of living in isolation. Some tweets with these hashtags were used to make fun out of the lived experience and actual difficulties people were dealing with during the pandemic. The use of humor in tweets has been previously reported in some past studies [64,65]. For instance, Kopper [65] noted that the use of humor in diplomatic tweets has a conflict-mediating role. In this study, the use of humor in public health tweets had a role in mitigating public anxiety or fear as the consequences of the pandemic. Perhaps people use humor in tweets to convey complex public health messages that are more attractive to audiences.

Although humorous hashtags may simply not seem appropriate for use in public health communication, they can make up part of a broader information-sharing strategy. For example, to communicate safety guidelines, social media posts could be labeled with humorous hashtags that are appealing. The safety-related messages may then be transferred to and adopted by the public through such hashtags. Additionally, practitioners, activists, organizations, and authorities can actively embed relevant and meaningful hashtags into their posts that are framed more generally within appealing concepts.

Practical Implications

Designing Health Messages

The frames found in this study can also facilitate the communication on social media of various aspects of COVID-19 or any future health crisis. They can be used as a starting point for designing effective messages to address people's needs and concerns during future public health crises [18]. For instance, based on the current research, it can be suggested that health messages should be communicated with empathy, as also proposed in the study by Hyland-Wood et al [66]. These frames can support the public in the expression of their feelings and opinions during global crises [21]. The frames can also be used to influence public opinion, behavior, and actions about critical and complex issues related to COVID-19 (see [33]).

Governments, practitioners, organizations, activists, and authorities can take advantage of hashtags to frame their messages to inform the public about the consequences of lack of adherence to public health guidelines. For instance, governments and public health officials need to share actionable guidelines with citizens during public crises and inform them about what is happening. These activities require understanding of how messages should be framed and presented so that risk communications are accepted and adopted by the public [67]. If health communication officers, political officials, and other authorities wish to encourage citizens to follow public health guidelines, stay optimistic, and be supportive during a health crisis, they can frame their messages using the hashtags identified in this research. For instance, a message by the WHO could be framed as follows: "#WeAreInThisTogether: #StayStrong at home and post a video or picture of your dogs or cats in #Quarantine. Use #QuarantineCats or #QuarantineDogs to help others see your posts."

Issues and Their Roots

The results indicated that framing can also be used to identify the roots of the issues discussed by people on social media during public health crises. For instance, framing could be used to understand when, how, and about which topics false information is being distributed. The results indicated that #FilmYourHospital was a hashtag used by people to frame disagreements with evidence and facts about the COVID-19 pandemic. Once such problems and their roots are discovered through frame analysis, officials can find solutions, which, in this case, would be to neutralize and thwart false information dissemination.

Frame analysis can be used to identify what people are panicked about during a public health crisis. Another issue discussed by people was the "shortage panic," referring to people's reactions to the shortage and unavailability of products in the early days of the pandemic in March 2020. This panic could possibly be due to uncertainty in the public about what will happen in the future, lack of real-time communication with the public, or lack of trust between people and government officials. The study by Naeem [68] also indicated that uncertainty about COVID-19 triggered people to buy extra necessary food items, which resulted in the buying panic during the COVID-19 pandemic.

Methodological Contributions

This research contributes to the methodology of framing research on social media in several ways, as explained in the following sections.

Accuracy in Data Collection

In this research, the trending and associated hashtags were used to collect tweets. Using hashtags can increase the accuracy of collecting relevant tweets. The hashtag search approach is more accurate than the keyword-based search approach used in some past studies, such as that by Jang and Hart [69], mainly because

people use hashtags to describe their tweets [70]. Jang and Hart [69] searched "climate change AND real" to find tweets associated with the "real frames" or searched "climate change AND action" to find tweets about "action frames." A major issue with the keyword-based search and analysis is that it may result in retrieving extraneous tweets or excluding relevant ones, as stated by Jang and Hart [69].

Using Trending Hashtags to Identify Frames

Unlike most previous framing studies on Twitter that have solely analyzed tweets to identify frames, this study analyzed trending and associated hashtags along with the tweets containing those hashtags to identify frames. Jang and Hart [69] stated that an effective approach for analyzing frames is "to identify unique components of public rhetoric that clearly represent single frames of a more complex issue." Hashtags are unique components that represent frames of complex issues on social media. Moy and Bosch [30] noted that frames provide "meaning about social phenomena through the highlighting and packaging of information." Hashtags can also be used to give meaning to and highlight social phenomena. In the Literature Review section, the rationale for using (trending) hashtags for identifying frames was discussed.

Measuring Public Attention on Twitter

There is no standard way for measuring public attention on social media [47]. This study contributes to the methodology of framing research by examining the amount of public attention to frames by evaluating public adoption of frames and public engagement with frames [51]. Rarely any previous framing research has used this approach to measure the effect of frames on public attention on social media. This approach can also be used to identify the framing effect of the news media on public attention on social media in future studies.

Study Limitations

The study limitations were mostly related to data collection, some of which were beyond our control. For instance, due to the Twitter API restrictions in collecting historical data, all tweets associated with the trending and associated hashtags could not be collected. We tried to mitigate this limitation by using 2 other software for collecting historical data, as explained in the Data Collection section.

Another limitation is that sampling tweets based on trending hashtags may not represent all Twitter communication. Hashtags may only represent a specific subset of Twitter communication. All Twitter users do not use hashtags in their online communications on social media [71,72].

As mentioned, to identify the frames, the trending hashtags on Twitter in March 2020 were collected. Collecting data in other months may lead to identifying different frames.

Additionally, this research may have missed collecting all trending hashtags about COVID-19 in March 2020 for several reasons. First, Twitter determines emerging and trending topics (topics that are popular now) based on who the users (researchers who collect the data) follow, their interests, their locations, and other criteria (see Twitter trends FAQs). Second, a hashtag may be trending for a couple of hours, a day, or in rare cases, more than a day. A hashtag that is trending today may not be trending tomorrow, but people may still use the hashtag for a short or long period of time. The hashtag may disappear temporarily after a few days, may gain attention again in the future, or may disappear permanently [36].

Future Research

This study answers important questions about the frames in public discourse during the initial phase of the COVID-19 pandemic, but also raises questions to investigate in future research. This research identified 9 frames, which provide useful orientation for future empirical and theoretical research that aims to investigate the frames on social media during global (health) crises. Future studies can expand these frames and apply them to other global crises.

This study did not investigate how different groups of people that create the public, like citizens, officials, researchers, journalists, and organizations, frame COVID-19 differently, which is worth studying in future studies.

Experimental designs should be designed to manipulate the type and category of frames (while keeping other variables constant) to understand to what degree hashtags affect public collective attention (see [73]) on social media.

Future research could also investigate (1) how frames and hashtags emerge, evolve, and operate and (2) how they succeed in achieving sustainability during different phases of a pandemic, such as (1) precrisis, (2) the initial event, (3) maintenance, (4) resolution, and (5) evolution [74].

Additionally, public compliance to health messages and guidelines is different than public attention to frames. Public compliance to COVID-19 can be evaluated by different measures such as "compliance to public health and social measures in preventing the spread of COVID-19" [75]. Future research should investigate how health messages should be designed and framed to increase public compliance to health guidelines during pandemics.

Conclusion

This is one of the first studies to use trending hashtags to analyze and identify frames on social media. It contributes to framing theory and research by showing that frames represent the consequences of a public health emergency such as COVID-19. Additionally, the findings inform framing theory and research by showing that the methodological advantages of using trending and associated hashtags lie not only in their ability to understanding the frames that are the focal point of the public but also in their potential to allow researchers to measure public attention to those frames. The results indicated that some frames are more appealing during a global pandemic than others, such as "call for action," therefore receiving greater public adoption and engagement. It was found that the frequency of a frame on social media does not necessarily mean greater public adoption of or engagement with the frame.

Conflicts of Interest

Abstract

Background: The COVID-19 pandemic has led to unprecedented use of telehealth, including by primary care professionals (PCPs) who serve adolescents.

Objective: To inform future practice and policies, we sought to characterize PCPs' recent experience using adolescent telehealth as well as their support for it after the COVID-19 pandemic is over.

Methods: From February to March 2021, we conducted a web-based survey of 1047 PCPs in the United States. Our national sample included physicians (747/1047, 71%), advanced practice providers (177/1047, 17%), and nurses (123/1047, 12%) who provided primary care to adolescents aged 11-17 years.

Results: Most PCPs reported using telehealth for a low, moderate, or high proportion of their adolescent patients in the three months prior to the survey (424/1047, 40%, 286/1047, 27%, and 219/1047, 21%, respectively); only 11% (118/1047) reported no use. A majority of respondents agreed that adolescent telehealth increases access to care (720/1047, 69%) and enables them to provide high-quality care (560/1047, 53%). Few believed that adolescent telehealth takes too much time (142/1047, 14%) or encourages health care overuse (157/1047, 15%). Most supported giving families the option of adolescent telehealth for primary care after the pandemic is over (683/1047, 65%) and believed that health insurance plans should continue to reimburse for telehealth visits (863/1047, 82%). Approximately two-thirds (702/1047, 67%) wanted to offer adolescent telehealth visits after the pandemic, with intentions being higher among those with recent telehealth experience ($P<.001$).

Conclusions: PCPs in our national sample reported widespread use of and predominantly positive attitudes toward adolescent telehealth. Our findings also suggest broad support among PCPs for continuing to offer adolescent telehealth after the COVID-19 pandemic ends.

KEYWORDS

adolescent health; primary care; telemedicine; health communication; health services; telehealth; adolescent; young adult; teenager; COVID-19; survey; policy; access

Introduction

The COVID-19 pandemic has rapidly transformed health care delivery in the United States; for the first time, telehealth is playing a central role in the delivery of primary care for adolescents. Research conducted prior to the pandemic suggests that telehealth is a promising mode of delivering discrete types of health care for adolescents, including in the areas of mental

health, asthma and diabetes management, and gender-affirming care [1-4]. A small body of research also documents the adolescent medicine community's impressive efforts to rapidly scale up telehealth programs in the first months of the pandemic [5-7]. However, to our knowledge, no published national studies have explored the experience of primary care professionals (PCPs) in delivering care to adolescents in the ensuing period, during which telehealth has presumably become a standard offering for many. To address this gap, we surveyed a national sample of PCPs. Our aims were to characterize PCPs' recent adolescent telehealth use and attitudes as well as their support for continuing to offer adolescent telehealth after the COVID-19 pandemic is over.

Methods

Participants and Procedures

We conducted a web-based survey of PCPs from February to March 2021. We contracted with a survey research company to administer the survey, which we developed, to a standing national panel. The company maintained the panel using a combination of recruitment methods, including web-based registration, referrals, marketing emails, and digital advertisements. As part of the recruitment process, physicians provided licensure information used to verify their identity. For our survey, eligible panel members were US physicians, advanced practitioners (ie, nurse practitioners and physician assistants), and nurses who provided primary care, including vaccinations, to adolescents aged 11-17 years. In compliance with state policies governing PCPs' survey participation, our sample excluded residents of Vermont.

The survey company emailed invitations and up to two reminders to panel members. A total of 1055 panel members responded by accessing the survey. The response rate was 61% among physicians and 41% among advanced practitioners and nurses (American Association for Public Opinion Research response rate 4) [8]. Participants provided informed consent and received up to US $80 for their participation, depending on market rates in their area. Based on survey responses, we excluded 8 PCPs who indicated that they saw no adolescent patients in a typical week, resulting in a final sample size of 1047 participants. The University of North Carolina Institutional Review Board approved the study protocol.

Measures

Our survey began with an introductory statement that defined adolescent telehealth as visits by videoconference or telephone for patients aged 11-17 years. The survey next assessed the extent of PCPs' recent telehealth use with a closed-ended question on the proportion of adolescent patients they saw by telehealth in the 3 months prior to the survey; we recategorized responses as high (51%-75%, 76%-99%, and 100%), moderate (26%-50%), low (1%-25%), or no (0%) use. Among PCPs with any (>0%) use, the survey used 6 closed-ended items to assess telehealth practice. Of these items, 4 used pre-specified lists to assess the type of care provided, perceived advantages, perceived disadvantages, and technological barriers. One item assessed which vaccines PCPs always recommended during telehealth visits for adolescents who were due: seasonal influenza; human papillomavirus (HPV); tetanus, diphtheria, and acellular pertussis (Tdap); and meningococcal ACWY. One item assessed how often PCPs requested confidential time to speak with adolescents during telehealth visits.

Our survey assessed PCPs' perceptions of adolescent telehealth with 7 closed-ended questions that used 5-point response scales, ranging from "strongly disagree" (1) to "strongly agree" (5). Of these items, 4 assessed PCPs' attitudes on whether adolescent telehealth increases access to care, is a way they can provide high-quality care, takes too much time, or encourages health care overuse. A total of 2 items assessed PCPs' support for adolescent telehealth after the COVID-19 pandemic is over in terms of whether families should still have the option to use telehealth for primary care visits and whether health insurance plans should continue to reimburse for visits. One item assessed PCPs' intentions in terms of whether they wanted to offer adolescent telehealth visits once the pandemic is over. For all 7 items, we recategorized responses as disagree ("somewhat" or "strongly"), neither agree or disagree, or agree ("somewhat" or "strongly").

Our survey assessed PCPs' demographic and professional characteristics, including their training, gender, race, number of years in practice, and number of adolescent patients seen in a typical week (Table 1). The survey also assessed characteristics of the clinics in which the PCPs worked. These measures included clinic specialty (family medicine or pediatrics), practice type (solo/group vs other), whether the clinic was part of a health care system or network, the rurality of the area the clinic served, the US census region in which the clinic was located, and the extent to which the clinic experienced financial strain due to the COVID-19 pandemic.

Table 1. Sample characteristics (N=1047).

Characteristic	Value, n (%)
Primary care professional characteristics	
Training	
Physician	747 (71)
Advanced practice provider[a]	177 (17)
Nurse	123 (12)
Gender

COVID-19–related financial strain	
None or a little	360 (34)
Moderate to high	687 (66)

[a]Includes nurse practitioners and physician assistants.

[b]Includes neither woman nor man, prefer to self-describe, and prefer not to say.

[c]Includes hospital- and university-affiliated clinics, Federally Qualified Health Centers, and community, public health, and nonprofit clinics.

Statistical Analysis

We used Pearson chi-square tests to compare the proportions of PCPs who indicated that they always recommended the seasonal influenza vaccine versus each of the other vaccines (HPV, Tdap, meningococcal) during adolescent telehealth visits. We compared the number of advantages and disadvantages that PCPs endorsed for adolescent telehealth using a Wilcoxon signed-rank test. We used bivariate logistic regression to identify correlates of PCPs' intentions to offer adolescent telehealth visits once the COVID-19 pandemic is over, modeling the outcome as yes ("agree") versus no ("neither agree or disagree" and "disagree"). We then simultaneously entered statistically significant correlates into a multivariable model. We conducted analyses using Stata, version 15.1 (StataCorp LLC). Statistical tests were two-tailed with a critical alpha of .05.

Results

Participant Characteristics

Our sample of 1047 respondents comprised physicians (n=747, 71%), advanced practitioners (n=177, 17%), and nurses (n=123, 12%; Table 1). Most had 10 or more years of experience in practice (795/1047, 76%) and saw 10 or more adolescent patients in a typical week (764/1047, 73%). PCPs worked in clinics focusing on family medicine (748/1047, 71%) or pediatrics (299/1047, 29%). The clinics were located in all four US regions; some were in clinical systems or networks (590/1047, 56%), and some served rural areas (159/1047, 15%). Two-thirds (687/1047, 66%) of PCPs reported that their clinics had experienced moderate to high financial strain due to the COVID-19 pandemic.

Telehealth Practice

Almost all PCPs reported using telehealth to see adolescent patients in the 3 months prior to the survey (Table 1). Approximately one-fifth of our sample (219/1047, 21%) indicated high adolescent telehealth use, while others reported more moderate (286/1047, 27%) or low (424/1047, 40%) use. Only 11% of PCPs (118/1047) reported no recent adolescent telehealth use.

The 929 PCPs with recent telehealth visits most often used telehealth for chronic disease management (n=599, 64%), acute care (n=571, 61%), mental and behavioral health (n=561, 60%), or vaccine consultations (n=406, 44%) (Table 2). Most of these 929 PCPs indicated that they always recommended seasonal influenza vaccination during telehealth visits if adolescents were due (n=798, 86%), but somewhat fewer said the same for HPV, Tdap, and meningococcal vaccines (n=715, 77%, n=709, 76%, and n=612, 66%, respectively; all $P<.001$). Approximately one-quarter of these PCPs (263/929, 28%) reported that they "always" or "often" requested time to speak to adolescents confidentially during telehealth visits.

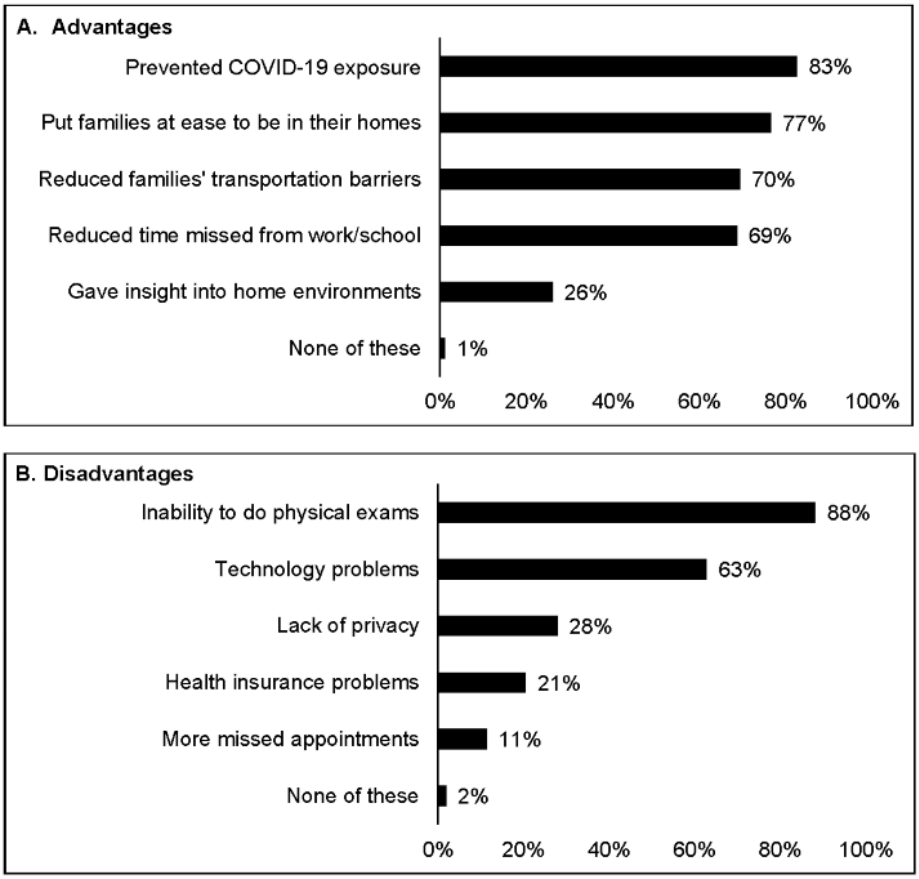
Table 2. Telehealth practice among primary care professionals with recent adolescent telehealth visits (n=929).

	Value, n (%)
Type of adolescent telehealth visits provided	
Chronic disease management	599 (64)
Acute care	571 (61)
Mental and behavioral health	561 (60)
Vaccine consultation	406 (44)
Other well-child care	387 (42)
Sexual health and contraceptive counseling	359 (39)
None of these	14 (2)
Vaccines always recommended if due	
Seasonal influenza	798 (86)
Human papillomavirus	715 (77)
Tetanus, diphtheria, and acellular pertussis	709 (76)
Meningococcal	612 (66)
None of these	48 (5)
Request to speak with adolescent confidentially	
Always or often	263 (28)
Sometimes	356 (38)
Rarely or never	310 (33)
Technology problems[a]	
Poor-quality internet connections	499 (85)
Families' lack of internet-enabled devices	353 (60)
Lack of training for providers and staff	195 (33)
Difficulty working with medical interpreters	128 (22)
None of these	21 (4)

[a]Among the subset of participants who reported technology problems as a disadvantage (n=584).

On average, PCPs reported more advantages than disadvantages of their recent adolescent telehealth use (mean=3.2 of 5 advantages, SD 1.3, vs 2.1 of 5 disadvantages, SD 0.9; $P<.001$). The most common advantages were preventing COVID-19 exposure (768/929, 83%), putting families at ease (712/929, 77%), and reducing families' transportation (646/929, 70%) or time (639/929, 69%) burdens (Figure 1). Only approximately one-quarter of PCPs reported that gaining insight into families' home environments was an advantage (243/929, 26%). The most common disadvantages were the inability to perform physical examinations (820/929, 88%) and technology problems (584/929, 63%). Only a minority of PCPs indicated that a lack of privacy (260/929, 28%), health insurance problems (191/929, 21%), or more missed appointments (106/929, 11%) were disadvantages. Of the 584 PCPs who indicated technology problems as a disadvantage, most reported that poor quality internet connections (n=499, 85%) and families' lack of internet-enabled devices (n=353, 60%) were common barriers (Table 2).

Figure 1. Perceived advantages (A) and disadvantages (B) of adolescent telehealth by primary care providers (n=929).

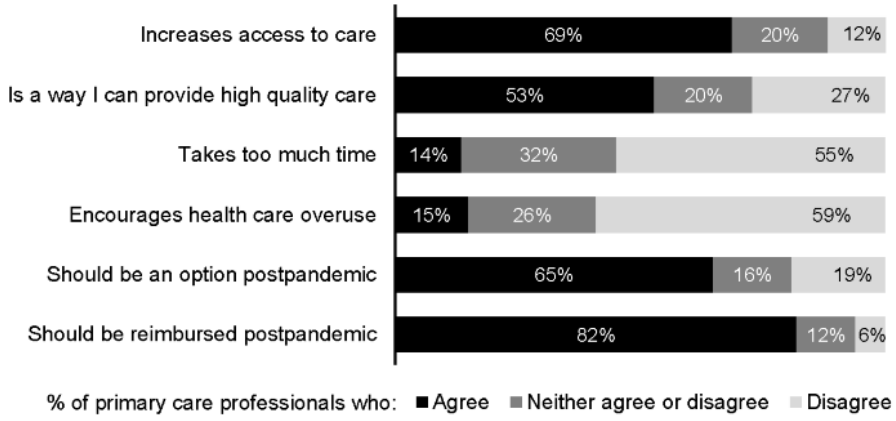


Telehealth Attitudes and Postpandemic Support

Most PCPs reported positive attitudes toward adolescent telehealth. A majority agreed that telehealth increased access to care for adolescents (720/1047, 69%) and was a way they could provide high-quality care (560/1047, 53%, Figure 2). Few agreed that telehealth took too much time (142/1047, 14%) or encouraged families to overuse health care for adolescents (157/1047, 15%).

Most PCPs indicated support for adolescent telehealth after the COVID-19 pandemic is over (Figure 2). Approximately two-thirds (683/1047, 65%) agreed that families should continue to have the option of telehealth for adolescent primary care visits. Approximately four-fifths (863/1047, 82%) agreed that health insurance plans should continue to reimburse for telehealth visits.

Figure 2. Primary care providers' attitudes toward and support for postpandemic adolescent telehealth (n=1047).



Telehealth Intentions

Approximately two-thirds of the 1047 PCPs agreed that they want to offer adolescent telehealth visits once the COVID-19 pandemic is over (n=702, 67%), while the remainder disagreed (n=188, 18%) or neither agreed nor disagreed (n=157, 15%). In multivariable analyses, wanting to offer telehealth was more common among PCPs with high, moderate, and low versus no experience seeing adolescents by telehealth in the 3 months prior to the survey (175/219, 80%, 211/286, 74%, and 280/424, 66%, vs 36/118, 31%, respectively; all $P<.001$) (Table 3). Wanting to offer telehealth was also more common among PCPs who worked in clinics that served urban versus rural areas (258/363, 71%, vs 94/159, 59%, $P=.02$) or that were located in the South or West regions versus the Northeast region (231/333, 69%, and 143/202, 71%, vs 161/265, 61%; $P=.003$ and .047, respectively). Wanting to offer telehealth was less common for PCPs with more years in practice (262/395, 66%, for 10-19 years and 246/400, 62%, for ≥20 years vs 194/252, 77%, for ≤9 years; both $P=.02$). In bivariate analyses, PCPs' adolescent telehealth intentions correlated with working outside of a solo/group practice or within a health care system, but these associations did not retain statistical significance in the multivariable model.

Table 3. Correlates of PCPs' intentions to offer adolescent telehealth after the COVID-19 pandemic (N=1047).

Discussion

Principal Findings

The findings of our national study suggest that adolescent telehealth has achieved widespread adoption in the year since the COVID-19 pandemic began, with most PCPs in our national study reporting that they used adolescent telehealth and wanted to keep using it. The vast majority (89%) of PCPs reported using telehealth to see adolescents in the prior 3 months, including for chronic disease management, acute care, and mental health. This level of adoption is far higher than that reported in prepandemic studies, which found that very few pediatricians or family physicians were using telehealth to deliver care (13% and 15%, respectively) [9,10]. On average, the PCPs in our sample reported that adolescent telehealth offered more advantages than disadvantages, with advantages including increased access to care and reduced time and transportation burdens for families. The most commonly noted disadvantages were the inability to perform physical examinations and technology problems. Despite these limitations, PCPs indicated broad support for adolescent telehealth after the pandemic is over, with approximately two-thirds wanting to offer such visits themselves. This support suggests a pressing need to build on the strengths, address the challenges, and evaluate the quality of adolescent telehealth to ensure it remains a viable option for primary care delivery in the postpandemic era.

Our study provides novel data on two potential challenges for the delivery of adolescent telehealth: vaccine communication and privacy. With regard to vaccine communication, we found that the proportion of PCPs reporting that they "always" recommended vaccines during adolescent telehealth visits was high for seasonal influenza vaccine, perhaps in response to concerns about an influenza–COVID-19 "twindemic." Consistent recommendations were less common for HPV, Tdap, and meningococcal vaccines. In the case of the HPV vaccine, prepandemic studies that used similar measures in the context of traditional primary care documented levels of recommendation consistency that are comparable to or lower than what we observed [11-13]. Although such points of comparison are not available for other adolescent vaccines, our findings suggest that many PCPs are including vaccine counseling in adolescent telehealth visits, and these data can inform interventions to support and further strengthen this communication. For example, PCPs may benefit from electronic health record prompts to remind them to recommend adolescent vaccines during telehealth visits and to counsel families about how to schedule those visits. This care coordination could help to ensure that adolescent telehealth complements rather than competes with the in-person care that is integral to the delivery of vaccinations and other routine preventive health services for adolescents [14].

Consistent with prior studies [5,6], our findings suggest that privacy constitutes an important consideration but may not be a primary barrier to the delivery of adolescent telehealth. Among the PCPs in our sample with recent experience, only approximately one-quarter perceived a lack of privacy as a disadvantage of adolescent telehealth. At the same time, however, only approximately one-quarter routinely offered adolescents confidential time during telehealth visits. Despite being a recommended practice, confidential time is also inconsistently offered during in-person visits [15,16]; therefore, this low level of guideline adherence is perhaps unsurprising. Nevertheless, PCPs may have the opportunity to strengthen their telehealth practice by more consistently offering confidential time and by counseling adolescents to take steps that may help protect their privacy, such as using earphones [5,7,17].

Our study can inform future policy making by documenting PCPs' support for offering adolescent telehealth after the COVID-19 pandemic is over. Telehealth adoption during the pandemic has been possible due to expanded payer reimbursement, which prepandemic studies identified as the single largest barrier to bringing pediatric telehealth programs to scale [9,14,18]. Importantly, most PCPs in our sample believed that health insurance plans should continue to reimburse for adolescent telehealth after the pandemic is over. Furthermore, many PCPs believed that families should have the option of telehealth for adolescent primary care visits and wanted to offer telehealth visits themselves. Wanting to offer adolescent telehealth was more common among PCPs who had recently used it or who worked in the South or West regions of the United States, but it was less common among those serving rural areas. Future research can extend the present study by assessing factors, such as internet connectivity, that might explain these geographic differences.

Strengths and Limitations

This study is, to our knowledge, the first national evaluation of PCPs' experience using adolescent telehealth in the context of the COVID-19 pandemic. Study strengths include the use of data from a large, national sample of PCPs, including physicians, advanced practitioners, and nurses. Although evaluating adolescent telehealth from the perspective of those who deliver it is a study strength, our use of self-reported measures also constitutes a limitation. For example, PCPs may have overestimated the consistency with which they recommended vaccines or offered confidential time during adolescent telehealth visits. Another limitation is the modest response rate among advanced practice providers and nurses. Including nonphysician participants was important for enriching our data with diverse perspectives, but additional research with larger sample sizes may be needed to more fully understand how adolescent telehealth practice and attitudes vary across clinical roles. We acknowledge that other perspectives and data sources are important for understanding the impact of adolescent telehealth. Most notably, PCPs in our sample perceived telehealth as expanding access to care and reducing burden on

their patients, but future research is needed to understand the extent to which adolescents and their families experience telehealth as patient-centered and equitable. Finally, we note that our study examines telehealth broadly as including visits by video and telephone. PCPs' experience of adolescent telehealth may vary between these two delivery modes as well as by health system factors, such as the extent to which telehealth is integrated with electronic health record platforms and patient portals. Future research will be needed to understand the influence of these contextual factors.

Conclusion

One year into the COVID-19 pandemic, our national study finds that PCPs have widely adopted adolescent telehealth and endorse its continued use. In light of this endorsement, health care system leaders, payers, professional organizations, researchers, and other key stakeholders should redouble their efforts to support PCPs in adolescent telehealth delivery, including by further evaluating and fairly reimbursing such services. In this way, we can ensure that telehealth realizes its potential to increase health care access and to serve adolescents in a way that is effective, patient centered, and equitable.

Data Availability Statement

Deidentified individual participant data will not be made available.

Acknowledgments

This project was supported by a Gillings Innovation Laboratory award from the UNC Gillings School of Global Public Health and the Lineberger Comprehensive Cancer Center through a Tier 1 Innovation Award made possible by the University Cancer Research Fund. Abstract

Background: The COVID-19 outbreak has now become a pandemic and has had a serious adverse impact on global public health. The effect of COVID-19 on the lungs can be determined through 2D computed tomography (CT) imaging, which requires a high level of spatial imagination on the part of the medical provider.

Objective: The purpose of this study is to determine whether viewing a 3D hologram with mixed reality techniques can improve medical professionals' understanding of the pulmonary lesions caused by COVID-19.

Methods: The study involved 60 participants, including 20 radiologists, 20 surgeons, and 20 medical students. Each of the three groups was randomly divided into two groups, either the 2D CT group (n=30; mean age 29 years [range 19-38 years]; males=20) or the 3D holographic group (n=30; mean age 30 years [range 20=38 years]; males=20). The two groups completed the same task, which involved identifying lung lesions caused by COVID-19 for 6 cases using a 2D CT or 3D hologram. Finally, an independent radiology professor rated the participants' performance (out of 100). All participants in two groups completed a Likert scale questionnaire regarding the educational utility and efficiency of 3D holograms. The National Aeronautics and Space Administration Task Load Index (NASA-TLX) was completed by all participants.

Results: The mean task score of the 3D hologram group (mean 91.98, SD 2.45) was significantly higher than that of the 2D CT group (mean 74.09, SD 7.59; P<.001). With the help of 3D holograms, surgeons and medical students achieved the same score as radiologists and made obvious progress in identifying pulmonary lesions caused by COVID-19. The Likert scale questionnaire results showed that the 3D hologram group had superior results compared to the 2D CT group (teaching: 2D CT group median 2, IQR 1-2 versus 3D group median 5, IQR 5-5; P<.001; understanding and communicating: 2D CT group median 1, IQR 1-1 versus 3D group median 5, IQR 5-5; P<.001; increasing interest: 2D CT group median 2, IQR 2-2 versus 3D group median 5, IQR 5-5; P<.001; lowering the learning curve: 2D CT group median 2, IQR 1-2 versus 3D group median 4, IQR 4-5; P<.001; spatial awareness: 2D CT group median 2, IQR 1-2 versus 3D group median 5, IQR 5-5; P<.001; learning: 2D CT group median 3, IQR 2-3 versus 3D group median 5, IQR 5-5; P<.001). The 3D group scored significantly lower than the 2D CT group for the "mental," "temporal," "performance," and "frustration" subscales on the NASA-TLX.

Conclusions: A 3D hologram with mixed reality techniques can be used to help medical professionals, especially medical students and newly hired doctors, better identify pulmonary lesions caused by COVID-19. It can be used in medical education to improve spatial awareness, increase interest, improve understandability, and lower the learning curve.

Introduction

The COVID-19 outbreak has now become a pandemic [1]. It has had a serious adverse impact on global public health [2]. Many doctors are on the front line of fighting the epidemic, including orthopedic surgeons, general surgeons, and neurosurgeons. Two-dimensional computed tomography (CT) scanning, which requires high spatial imagination on the part of medical professionals, has been traditionally used to determine the status of a pulmonary infection [3,4]. Often, judging the specific condition of the pulmonary lesions caused by COVID-19 would require the expertise of experienced respiratory, radiology, infectious disease, and intensive care department experts. Doctors who are not specialized in respiratory-related cases, not to mention medical students and the public, may not find it easy to understand the clinical significance of a 2D CT scan.

Both doctors and the public have played a vital role in combating COVID-19. Doctors treat patients with COVID-19 and fight the virus directly. The public's self-protection and isolation efforts help to stop the spread of the virus. However, there are still many members of the public who are not aware of the necessary protective measures. In addition, it is very important for medical students to have a better understanding of COVID-19, as they are the successors in the fight against this virus. This dilemma may be experienced by other countries as well.

Mixed reality techniques can overlap virtual and real worlds. The user can view the real world while manipulating the digital content generated by a device [5]. Mixed reality has been used clinically to help doctors better understand anatomical structures [6-8]. However, the use of 3D holograms to image lungs affected by COVID-19 has not been reported in the literature. Therefore, we present a new method that applies mixed reality techniques to create a 3D hologram of lungs affected by COVID-19.

Methods

Trial Design

The study was a parallel-group randomized controlled trial. It was conducted in Wuhan, China, from March 2020 to September 2020. Participants were randomized into two groups in a 1:1 ratio: (1) a 3D holographic intervention group or (2) a 2D CT control group.

Participants and Recruitment

We randomly selected radiologists, surgeons, and medical students from our institution and asked them to participate in this study. The radiologists, surgeons, and medical students were eligible to participate in this trial if they had not previously seen 3D holograms of lungs affected by COVID-19. The study involved 60 participants, including 20 radiologists, 20 surgeons, and 20 medical students. Each of the three groups was randomly divided into two groups: (1) the 2D CT group and (2) the 3D holographic group (Figure S1 in Multimedia Appendix 1). Exclusion criteria were as follows: surgeons and medical students trained in COVID-19 lung CT imaging, and participants that had previously seen 3D holograms of COVID-19 lungs.

Intervention

For this study, 3D reconstructions of patients' lungs were made using data from CT scans using a StarCloud workstation (a 3D reconstruction software from Visual3D). Polygon mesh files were exported from the StarCloud workstation. These were uploaded into the StarCloud Mixed Reality system (Visual3D). After uploading the data, 3D holographic images were automatically converted as a case-specific computer graphic for mixed reality, referred to as a hologram. The data pertaining to the hologram can be downloaded onto a Microsoft HoloLens (Microsoft Corp).

The two groups completed the same task, which involved identifying lesion areas in the lungs of 6 cases of COVID-19 using a 2D CT or 3D hologram of the lungs. The 6 cases of COVID-19 used for the study involved moderate to severe COVID-19 (Table S1 in Multimedia Appendix 1).

Assessments

An independent radiology professor rated the participants' performance (out of 100). All participants in the two groups completed a Likert scale questionnaire regarding the educational utility and efficiency of 3D holograms. The National Aeronautics and Space Administration Task Load Index (NASA-TLX) was completed by all participants. The NASA-TLX is a multidimensional rating procedure that provides an overall workload score between 0 and 100 based on a weighted average of ratings on 6 subscales [9]: (1) mental demands ("How mentally demanding was the task?"), (2) physical demands ("How physically demanding was the task?"), (3) temporal demands ("How hurried or rushed was the pace of the task?"), (4) own performance ("How successful were you in performing the task?"), (5) effort ("How hard did you have to work to achieve your level of performance?"), and (6) frustration ("How insecure, discouraged, irritated, stressed, and annoyed were you?"). The ethics committee of Wuhan Union Hospital, Tongji Medical College, Huazhong University of Science and Technology approved this study, and all participants provided signed informed consent.

Statistical Analysis

Statistical analyses were performed using SPSS (version 19; IBM Corp). Continuous variables were expressed as means and standard deviations. Results of the NASA-TLX questionnaires were summarized in terms of means and standard deviations.

Data were processed using analysis of variance to determine possible relationships between individual characteristics and workload.

Results

Sample Characteristics

Participant baseline characteristics are described in Table 1. The study involved 60 participants, including 20 radiologists, 20 surgeons, and 20 medical students. Each of the three groups was randomly divided into two groups: (1) the 2D CT group (n=30; mean age 29 years [range 19-38 years]; males=20) and (2) the 3D holographic group (n=30; mean age 30 years [range 20-38 years]; males=20; Figure S1 in Multimedia Appendix 1).

Table 1. Demographic information.

Variables	3D holographic group (n=30)	2D computed tomography group (n=30)
Gender		
Male	20	20
Female	10	10
Age (year), mean (range)	30 (20-38)	29 (19-38)
Participants		
Radiologists, total (male)	10 (5)	10 (5)
Surgeons, total (male)	10 (10)	10 (10)
Medical students, total (male)	10 (5)	10 (5)

Outcomes

Clear 3D visual holographic renderings were obtained for the lungs of patients with COVID-19 (Figure 1). In the 3D holographic (mixed reality) group, the task scores for all participants (mean 91.98, SD 2.45), radiologists (mean 93.60, SD 2.25), surgeons (mean 91.50, SD 2.31), and medical students (mean 91.25, SD 2.18) were significantly higher than that of the conventional (2D) group (all participants: mean 74.09, SD 7.59; radiologists: mean 82.63, SD 2.28; surgeons: mean 74.55, SD 2.52; medical students: mean 65.10, SD 65.10; P<.001). With the help of 3D holograms, surgeons and medical students achieved the same scores as radiologists and made obvious progress in identifying pulmonary lesions caused by COVID-19 (Figure 2, Table 2). The Likert scale questionnaire revealed that the 3D hologram group had superior results compared to the 2D CT group (teaching: 2D CT group median score 2, IQR 1-2 versus 3D group median 5, IQR 5-5; P<.001; understanding and communicating: 2D CT group median score 1, IQR 1-1 versus 3D group median 5, IQR 5-5; P<.001; increasing interest: 2D CT group median score 2, IQR 2-2 versus 3D group median 5, IQR 5-5; P<.001; lowering the learning curve: 2D CT group median score 2, IQR 1-2 versus 3D group median 4, IQR 4-5; P<.001; spatial awareness: 2D CT group median score 2, IQR 1-2 versus 3D group median 5, IQR 5-5; P<.001; learning: 2D CT group median score 3, IQR 2-3 versus 3D group median 5, IQR 5-5; P<.001; Figure 3, Table 2).

The 3D hologram group scored significantly lower than the 2D CT group on the “mental,” “temporal,” “performance,” and “frustration” subscales of the NASA-TLX. Compared with the traditional 2D group, the 3D hologram group reported higher physical demands. The main reason is that participants need to wear a mixed reality headset, but the weight of the mixed reality glasses was acceptable (Figure 4, Table 2).

Figure 1. A 3D hologram of the pulmonary lesions caused by COVID-19. (A) A computed tomography scan of a patient with COVID-19 revealed patchy pure ground-glass opacities (red arrow). (B) A hologram can clearly show the lesion site and lesion range (green color) of the patient's lung infection, allowing stereoscopic viewing from 360 degrees in a physical world. (C) Simultaneous analysis of 2D and 3D images.

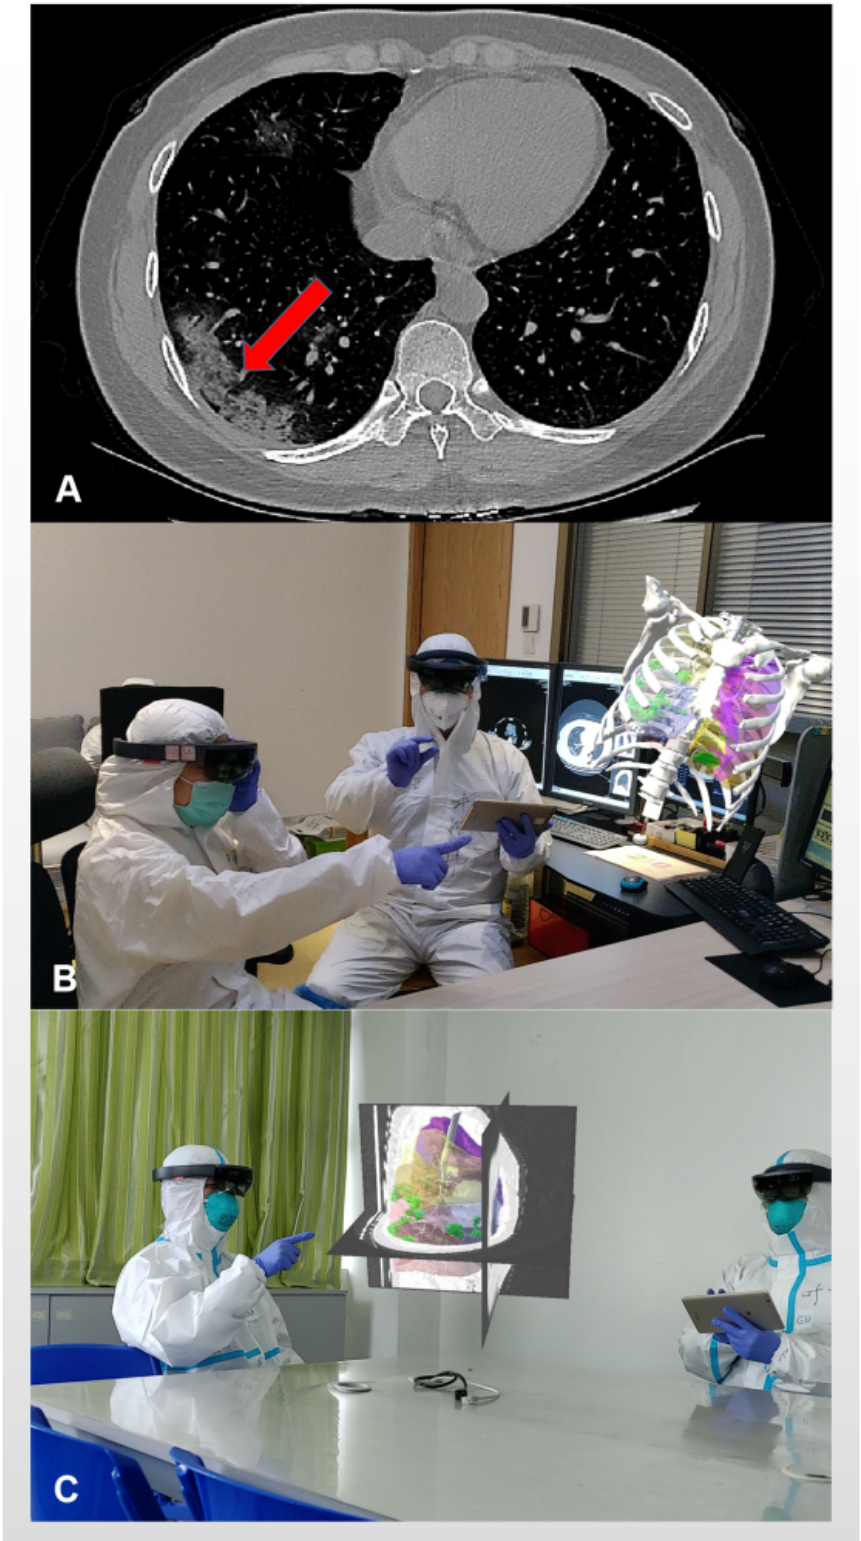

Figure 2. Task scores for identifying COVID-19 lesion areas in lungs. In the mixed reality group, the mean task score was significantly higher than that of the conventional group, with *P*<.001. With the help of 3D holograms, surgeons and medical students achieved the same score as radiologists and made obvious progress in identifying the pulmonary lesions caused by COVID-19.

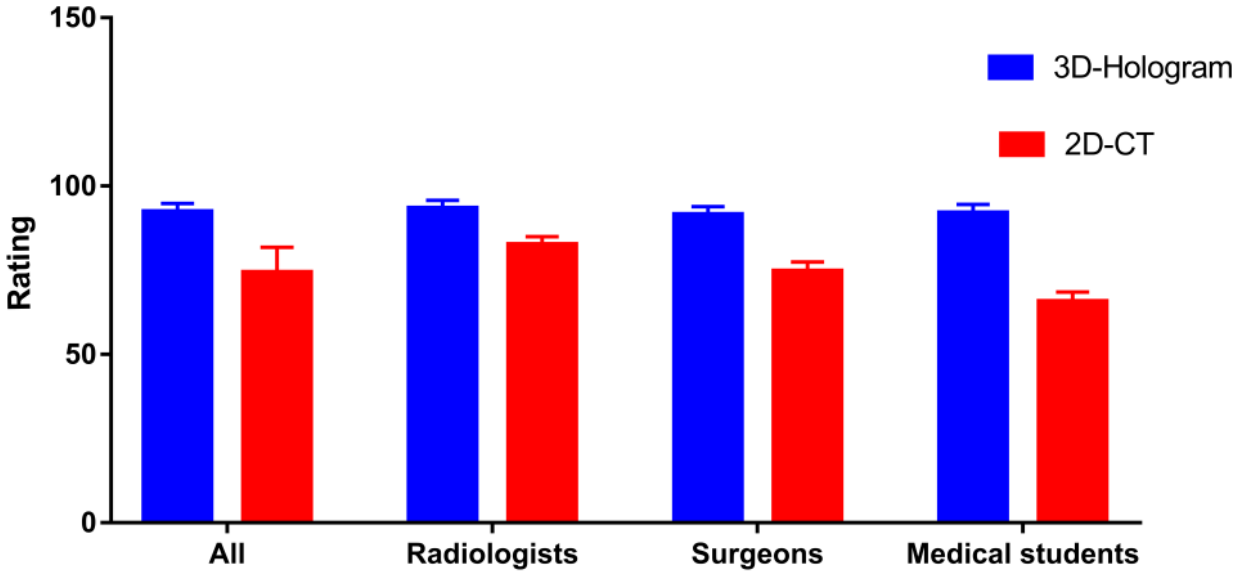

Table 2. Task scores, NASA Task Load Index scores, and Likert scale questionnaire scores.

Category	2D CT[a] group, mean (SD)	2D CT group, median (IQR)	3D holographic group, mean (SD)	3D holographic group, median (IQR)	*P* value
Task score					
All participants	74.09 (7.59)	75 (68-80)	91.98 (2.45)	90 (90-95)	<.001
Radiologists	82.63 (2.28)	83 (80-85)	93.60 (2.25)	95 (90-95)	<.001
Surgeons	74.55 (2.52)	75 (75-75)	91.50 (2.31)	90 (90-95)	<.001
Medical students	65.10 (2.61)	65 (65-68)	91.25 (2.18)	90 (90-94)	<.001
NASA Task Load Index scores					
Mental	47.03 (5.71)	50 (40-50)	20.06 (2.85)	20 (20-20)	<.001
Physical	19.75 (1.09)	20 (20-20)	25.08 (0.64)	25 (25-25)	<.001
Temporal	63.11 (6.45)	60 (60-70)	40.31 (3.04)	40 (40-40)	<.001
Performance	26.17 (6.03)	25 (20-30)	10.08 (0.99)	10 (10-10)	<.001
Effort	69.92 (0.99)	70 (70-70)	69.92 (0.99)	70 (70-70)	.99
Frustration	29.22 (5.95)	30 (25-35)	14.58 (1.39)	15 (15-15)	<.001
Likert-scale questionnaire scores					
Effectiveness as teaching tool	1.73 (0.51)	2 (1-2)	4.8 (0.40)	5 (5-5)	<.001
Better understanding and communication	1.1 (0.30)	1 (1-1)	4.83 (0.37)	5 (5-5)	<.001
Increasing interest	1.8 (0.4)	2 (2-2)	4.9 (0.3)	5 (5-5)	<.001
Lowering the learning curve	1.73 (0.51)	2 (1-2)	4.4 (0.49)	4 (4-5)	<.001
Better spatial awareness	1.6 (0.49)	2 (1-2)	4.93 (0.25)	5 (5-5)	<.001
Learning is easier	2.63 (0.55)	3 (2-3)	4.83 (0.37)	5 (5-5)	<.001

[a]CT: computed tomography.

Figure 3. Responses to a Likert scale questionnaire regarding the educational utility and efficiency of 3D holograms. The 3D hologram group indicated higher educational utility and efficiency than the 2D CT group. CT: computed tomography.

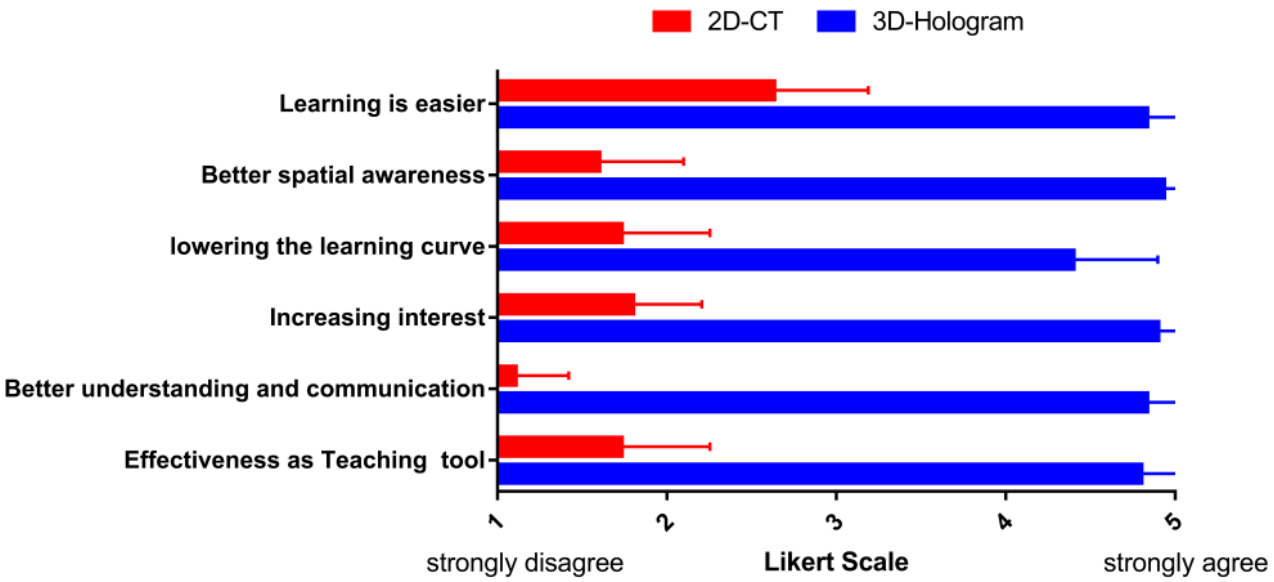

Figure 4. Results from the National Aeronautics and Space Administration (NASA) Task Load Index assessment. The mean rating for each subscale is given. Those that used holograms scored significantly lower than those that used 2D CT scans for task load on the "mental," "temporal," "performance," and "frustration" subscales. CT: computed tomography.

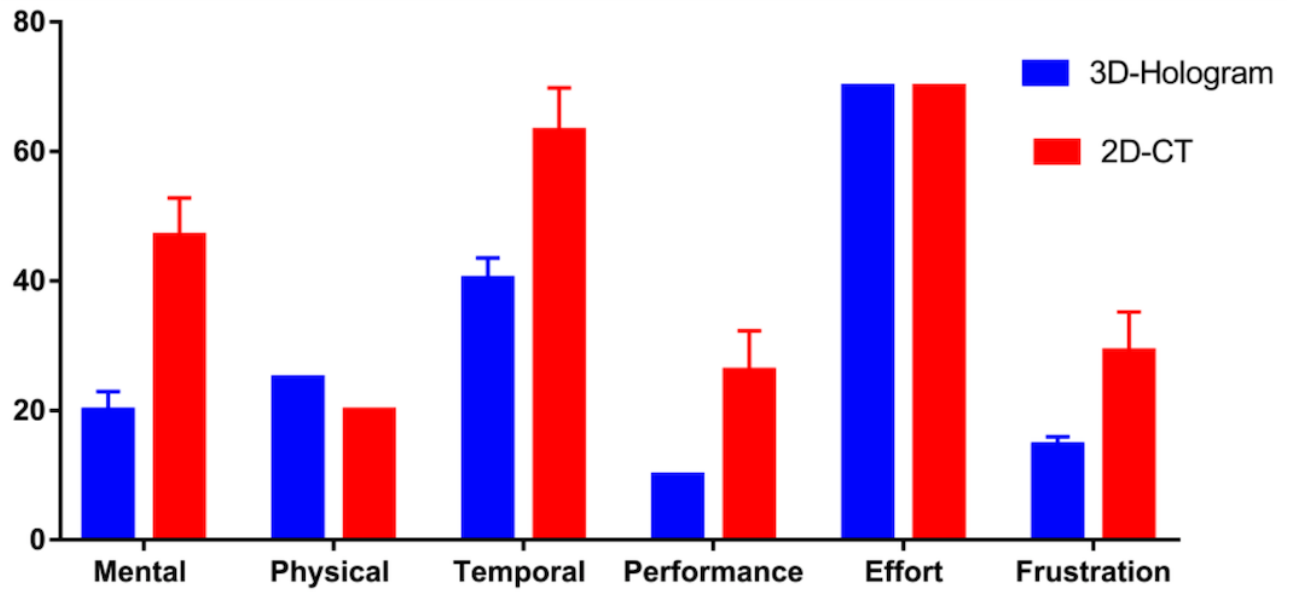

Discussion

A 3D hologram with mixed reality techniques can be used to help medical professionals, especially medical students and newly hired doctors, better identify pulmonary lesions caused by COVID-19. It can be used in medical education to increase interest, improve understandability, improve spatial awareness, and lower the learning curve.

A CT scan of the lungs of patients with COVID-19 revealed patchy pure ground-glass opacities (Figure 1A). We visualized the patients' lungs using mixed-reality technology, which can transform the 2D CT image of the lung into a 3D hologram (Figure 1B) to clearly show the lesion site and lesion range (green color) of the patient's lung infection, allowing stereoscopic viewing from 360 degrees in a physical world. Conversely, a standard 2D CT usually only allows one to see the local area of a certain layer of the lung. The 3D hologram can also analyze 2D and 3D images simultaneously (Figure 1C). As the 3D hologram can clearly show the spatial anatomical neighborhood, it does not require the human brain to mentally transform the complex 2D structure into a complete 3D structure. The results of this study showed that in the 3D hologram group, compared with the traditional 2D CT group, task loads for the "mental," "temporal," and "frustration" subscales were significantly reduced, and better performance was obtained. Thus, this study can help doctors—whether they have just started to practice, are in nonrespiratory specialties, or are in respiratory specialties—better identify and understand the pulmonary lesions caused by COVID-19. In addition, this

can improve medical students' understanding of COVID-19, which is important as they are the successors in the fight against this virus.

This technique of image reconstruction and presentation can also be applied to other anatomical systems throughout the body (Figure 5). It can contribute to a better understanding of normal and abnormal body structure for both medical and nonmedical individuals and could be especially useful for medical students when used in future medical education. In addition, unlike traditional 3D anatomical drawings, mixed reality technology allows multiple people to view the same 3D hologram from 360 degrees during the teaching process.

Figure 5. Images show a 3D holographic mixed reality technology being used to present and teach the digestive system and classification of pelvic fractures.

The COVID-19 outbreak has also created challenges for anatomy education [10]. Cadaver specimens were the standard learning method of anatomy classes in the past [11]. However, substantial financial, ethical, and supervisory constraints on their use and the shortage of cadaver specimens are ongoing problems faced by teaching colleges and universities [12]; in addition, during the COVID-19 epidemic, the use of cadaver specimens has the potential risk of virus transmission [10,13]. Digital anatomical imaging is a feasible alternative solution to the use of cadaver specimens and is more visual, accessible, clean, fun, and inexpensive.

Although this study shows promising results, further studies in more institutions, populations, and locations are needed in the future.

In conclusion, a 3D hologram with mixed reality techniques can provide a better understanding of the pulmonary lesions caused by COVID-19 and will play an important role in future medical education.

Abstract

Background: The COVID-19 pandemic has imposed a large, initially uncontrollable, public health crisis both in the United States and across the world, with experts looking to vaccines as the ultimate mechanism of defense. The development and deployment of COVID-19 vaccines have been rapidly advancing via global efforts. Hence, it is crucial for governments, public health officials, and policy makers to understand public attitudes and opinions towards vaccines, such that effective interventions and educational campaigns can be designed to promote vaccine acceptance.

Objective: The aim of this study was to investigate public opinion and perception on COVID-19 vaccines in the United States. We investigated the spatiotemporal trends of public sentiment and emotion towards COVID-19 vaccines and analyzed how such trends relate to popular topics found on Twitter.

Methods: We collected over 300,000 geotagged tweets in the United States from March 1, 2020 to February 28, 2021. We examined the spatiotemporal patterns of public sentiment and emotion over time at both national and state scales and identified 3 phases along the pandemic timeline with sharp changes in public sentiment and emotion. Using sentiment analysis, emotion analysis (with cloud mapping of keywords), and topic modeling, we further identified 11 key events and major topics as the potential drivers to such changes.

Results: An increasing trend in positive sentiment in conjunction with a decrease in negative sentiment were generally observed in most states, reflecting the rising confidence and anticipation of the public towards vaccines. The overall tendency of the 8 types of emotion implies that the public trusts and anticipates the vaccine. This is accompanied by a mixture of fear, sadness, and anger. Critical social or international events or announcements by political leaders and authorities may have potential impacts on public opinion towards vaccines. These factors help identify underlying themes and validate insights from the analysis.

Conclusions: The analyses of near real-time social media big data benefit public health authorities by enabling them to monitor public attitudes and opinions towards vaccine-related information in a geo-aware manner, address the concerns of vaccine skeptics, and promote the confidence that individuals within a certain region or community have towards vaccines.

KEYWORDS

Twitter; public opinion; COVID-19 vaccines; sentiment analysis; emotion analysis; topic modeling; COVID-19

Introduction

As of May 21, 2021, the COVID-19 pandemic had led to more than 160 million confirmed cases and more than 3 million deaths worldwide [1]. COVID-19 has continued to spread worldwide due to its highly contagious nature, diverse variants, and the mass public's inconsistent adherence to effective public health measures, such as wearing masks and maintaining social distance [2]. Meanwhile, the emergence of asymptomatic cases (which are difficult to detect) has become more frequent, potentially leading to a substantial accumulation in the number of infections over time [3]. As such, it is important to keep COVID-19 vaccines widely available and accessible [4].

Since January 2020, scientists and medical experts around the world have been developing and testing COVID-19 vaccines; 16 vaccines have been approved for emergency use around the world so far, but the progress of vaccination has been subject to hesitancy, distrust, and debate. Vaccine hesitancy was identified by the World Health Organization as one of the top 10 global health threats in 2019 [5]. In many countries, such hesitancy, along with vaccine misinformation, have presented substantial obstacles towards vaccinating a sufficient amount of the population in order to establish herd immunity [6,7].

Therefore, it is crucial for governments, public health officials, and policy makers to understand the potential drivers that affect public opinion towards COVID-19 vaccines [8]. A number of campaigns against antivaccination activists have been made through multiple channels since January 2020. Notably, the accelerated pace of vaccine development has further heightened public anxieties and could compromise the public's acceptance of the vaccine [9]. However, this acceptance varies across geographic contexts and the pandemic timeline. As governments put more effort into developing strategies for promoting vaccine acceptance and uptake, the key questions regarding the willingness to be vaccinated persist — what are the public's opinions and perceptions towards COVID-19 vaccines and what are the potential drivers that affect such opinions?

The internet and social media have provided rich user-generated data sources, in the form of infodemiology studies [10], in real time for performing public health surveillance [11]. Social media, especially Twitter, have been considered as major channels for the distribution of health information and opinion exchange, helping people to make intelligent decisions [12,13]. The analysis of big data derived from Twitter has been an emerging trend in recent COVID-19 vaccine–related studies. Geotagged tweets (hereinafter termed as geotweets) provide a rich volume of cost-effective content, including news, events, public comments, and the locational information of Twitter users. Through sentiment analysis and topic modeling methods that have been widely used in existing studies, qualitative tweet contents can be retrieved to reflect public opinions and attitudes towards COVID-19 vaccines. Additionally, users' location information enables researchers to investigate the spatiotemporal patterns of the public's opinions and attitudes. In general, existing studies have investigated people's reactions towards COVID-19 vaccines, with a geographical emphasis on the United States [14-19]. Some papers have also studied other countries in the world, including China [20], South Africa [21], Australia [22], the United Kingdom [14,23], Canada [24], and Africa [25], and to a global scale [26]. However, the study period of these works is relatively limited to or predominantly focused on the early stage of the pandemic or up to the end of 2020. None of these studies cover early 2021, the period of implementing mass systemic vaccine distribution. Furthermore, although sentiment analysis and topic modeling have been broadly applied, what remains less explored are the potential drivers that induce a change in public sentiment and opinion on vaccines, such as important events and announcements by political leaders (eg, the propaganda of vaccine success or vaccine conspiracy theories). There is a pressing need to investigate public opinion towards COVID-19 vaccines across a longer timeline and to explore the potential drivers that influence the change in such opinion over time.

To address these knowledge gaps, this study aimed to analyze the spatiotemporal patterns of public sentiment and emotion and explore the keywords and major topics of tweets regarding COVID-19 vaccines that were tweeted by Twitter users. Drawing on more than 300,000 geotweets from March 1, 2020 to February 28, 2021 in the United States, we employed sentiment and emotion analysis at both the national and state levels. We identified 3 phases along the pandemic timeline that display sharp changes in public sentiment and emotion. Using cloud mapping of keywords and topic modeling, we identified 11 key events and major topics as the potential drivers that induced such changes. Findings from this study can help governments, policymakers, and public health officials understand factors that motivate and cause hesitance in the public towards vaccination. With this understanding, these entities can better design potential interventions during their vaccination campaigns.

Methods

Data

Using the Twitter streaming Application Programming Interface (API), the Harvard Center for Geographic Analysis collected geotweets from March 1, 2020 to February 28, 2021. Geotweets provide the location information of user-defined places. If users

activate the GPS function in Twitter, their longitude and latitude are provided. We used the keyword "vaccin*" to query vaccine-related tweets, generating a total of 308,755 geotweets. In the results, 1.43% (44,118/308,755) of geotweets' geographic locations are at a state level (ie, Massachusetts, United States), and others are geocoded at a city level (ie, Cambridge, MA) or at a finer geographical level (ie, Uptown Coffee, Oxford, MS). We then conducted a series of data preprocessing of the geotweets' contents. First, we generalized the variations of COVID-related terms to "COVID-19," including "corona," "covid," "covid19," and "coronavirus"; second, we removed unrelated website links from the search results, including links starting with the fragment of "https"; third, we removed punctuation (eg, period, question mark, comma, colon, and ellipsis) and other key symbols (eg, bracket, single and double quotes) and converted capital letters into lower-case letters; fourth, we removed inflectional endings (eg, "ly") and reverted words to their root or dictionary form (eg, "peopl" from people, "dai" from daily, and "viru" from virus), by employing the *word lemmatization* function provided in the Python package Natural Language Toolkit 3.6.2 [27].

Methodology

To explore the spatiotemporal patterns of public sentiment and emotion towards COVID-19 vaccines, we conducted 4 sets of analyses, including sentiment analysis, emotion analysis, topic modeling, and word cloud mapping. For the sentiment analysis, we applied Valence Aware Dictionary for Sentiment Reasoning (VADER), a well-known rule-based model, to estimate sentiment compound scores [28]. The sentiment compound score is computed by summing the score of each word in the lexicon, adjusted according to the rules. The rules embody grammatical and syntactical conventions for expressing and emphasizing sentiment intensity. Then, the score is normalized to be between –1 (most extreme negative) and +1 (most extreme positive). To reclassify sentences as positive, neutral, or negative sentiment, threshold values are set as follows: A tweet with a compound score larger than 0.05 is classified as positive sentiment; a tweet with a compound score smaller than –0.05 is classified as negative sentiment; otherwise, it is classified as neutral sentiment [28]. We then cross-tabulated the 3 types of sentiment on daily and weekly bases with the number of geotweets. We generated line graphs at the national level and in the top 10 states with the largest number of geotweets.

Different from sentiment analysis, which detects positive, neutral, or negative feelings from tweet contents, emotion analysis aims to recognize the types of feelings more specifically through the content expression, such as anger, fear, and happiness. The emotion analysis of this study was performed based on the National Research Council Canada Lexicon (NRCLex) [29]. NRCLex examines 4 pairs of primary bipolar emotions: joy (feeling happy) versus sadness (feeling sad); anger (feeling angry) versus fear (feeling of being afraid); trust (stronger admiration and weaker acceptance) versus disgust (feeling something is wrong or nasty); and surprise (being unprepared for something) versus anticipation (looking forward positively to something). We then examined the temporal patterns of these 8 types of emotion at both national and state levels.

In order to investigate the potential drivers of such changes, we applied the Latent Dirichlet Allocation (LDA) model [30] to detect popular topics based on a certain number of key dates as the turning points of sentiment scores or with a sharp change in the number of geotweets. The LDA model generates automatic summaries of topics in terms of a discrete probability distribution over words for each topic and further infers per-document discrete distributions over topics [31]. Each topic is treated as a cluster, and each document is assigned to a cluster that represents its dominant topic. LDA is an unsupervised algorithm [32], meaning that, prior to running the model, users need to predefine the number of topics. To estimate the optimal number of topics, we used the Python package [33] and pyLDAvis [34] to compare the results with topic numbers from 3 to 10 and found that the smallest overlap among topics occurs when the topic number is 3. We further visualized the topic modeling results in bar graphs with the Y-axis, which indicates the top 10 keywords associated with that topic, and the X-axis, which shows the weight of each keyword (to reveal the extent to which a certain keyword contributes to that topic). Based on the top 10 most relevant keywords to each topic, we generalized and presented the name of each topic at the bottom of each graph.

We then categorized the study period into 3 phases based on 2 iconic events: the results of Phase 1 clinical trials by Moderna that were published in *The New England Journal of Medicine* on July 14, 2020 [35] and the first COVID-19 vaccine shots that were given in the United States on December 14, 2020 [36]. Phase 1, dating from March 1, 2020 to July 13, 2020, is the stage in which the public was waiting for official announcements regarding the effectiveness of COVID-19 vaccines; Phase 2, ranging from July 14, 2020 to December 13, 2020, is when the positive news of COVID-19 vaccine development began to arrive; and Phase 3 starts from December 14, 2020, when the first vaccine shots were given in the United States. We then aggregated sentiment scores at the state level and analyzed the changes in sentiment over the 3 phases in the top 10 states. Finally, we produced word cloud maps over the 3 predefined phases based on the frequency of keywords appearing in Tweet contents, with the size of a keyword reflecting its frequency and popularity.

Results

Sentiment Analysis and Topic Modeling

Figure 1 shows the overall trends in the weekly sentiment scores, unveiling the increased positive attitude towards COVID-19 vaccines within the study period. We identified 11 key dates as turning points in sentiment scores or in the number of geotweets. Correspondingly, a total of 33 topics on these 11 key dates are summarized and presented in Figures 2-4. In Phase 1, changes in the sentiment score were relatively stable, except for a sharp drop on June 21, 2020. This drop could have resulted from the misinformation and conspiracy theories related to Bill Gates. Vaccine-adverse conspiracy related to Gates claimed that the pandemic is a cover for his plan to implant trackable microchips made by Microsoft [37]. Topic modeling suggests that Gates

was referred to as "satan," "terrorist," and "evil" on that day (Figure 2).

In Phase 2, the first stimulus was observed on July 14, 2020, when the results of Phase 1 clinical trials by Moderna were published [35]. However, we did not observe a dramatic change in sentiment score until July 15, 2020, when Donald Trump tweeted "Great News on Vaccines!" [35]. Topic modeling suggests that keywords related to "good," "trial," "promis," and "test" were widely discussed on July 15, 2020 (Figure 2). Speculation suggests that, compared to key events in the development of COVID-19 vaccines, comments from public figures on vaccination could trigger bigger changes in public sentiment.

Figure 1. Sentiment scores and the number of geotweets over the entire study timeline at the national level.

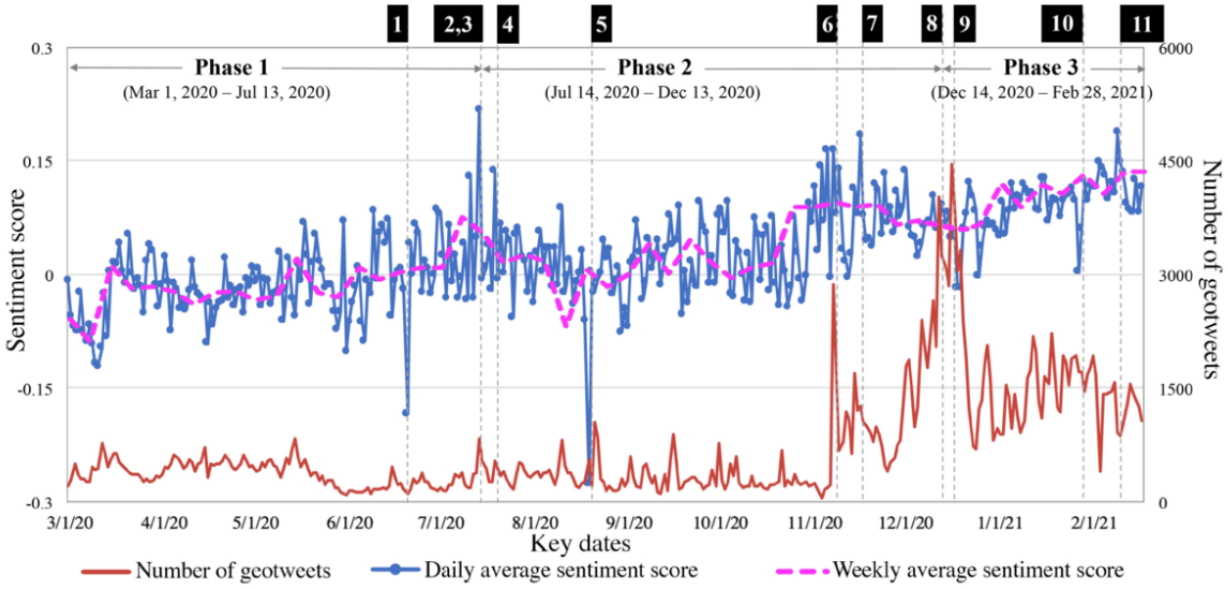

Figure 2. Three topics discussed on each of 3 key dates: June 21, 2020; July 14, 2020; and July 15, 2020.

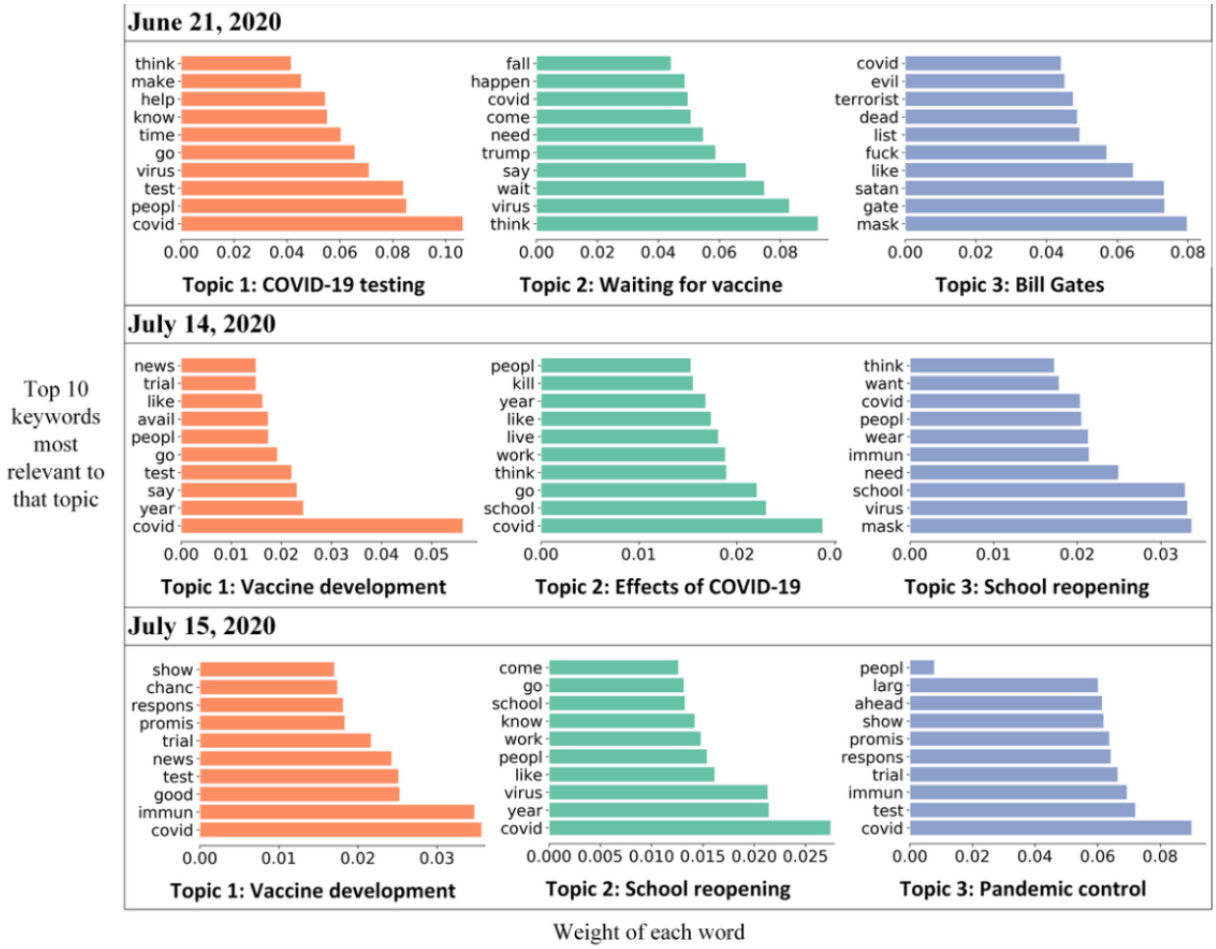
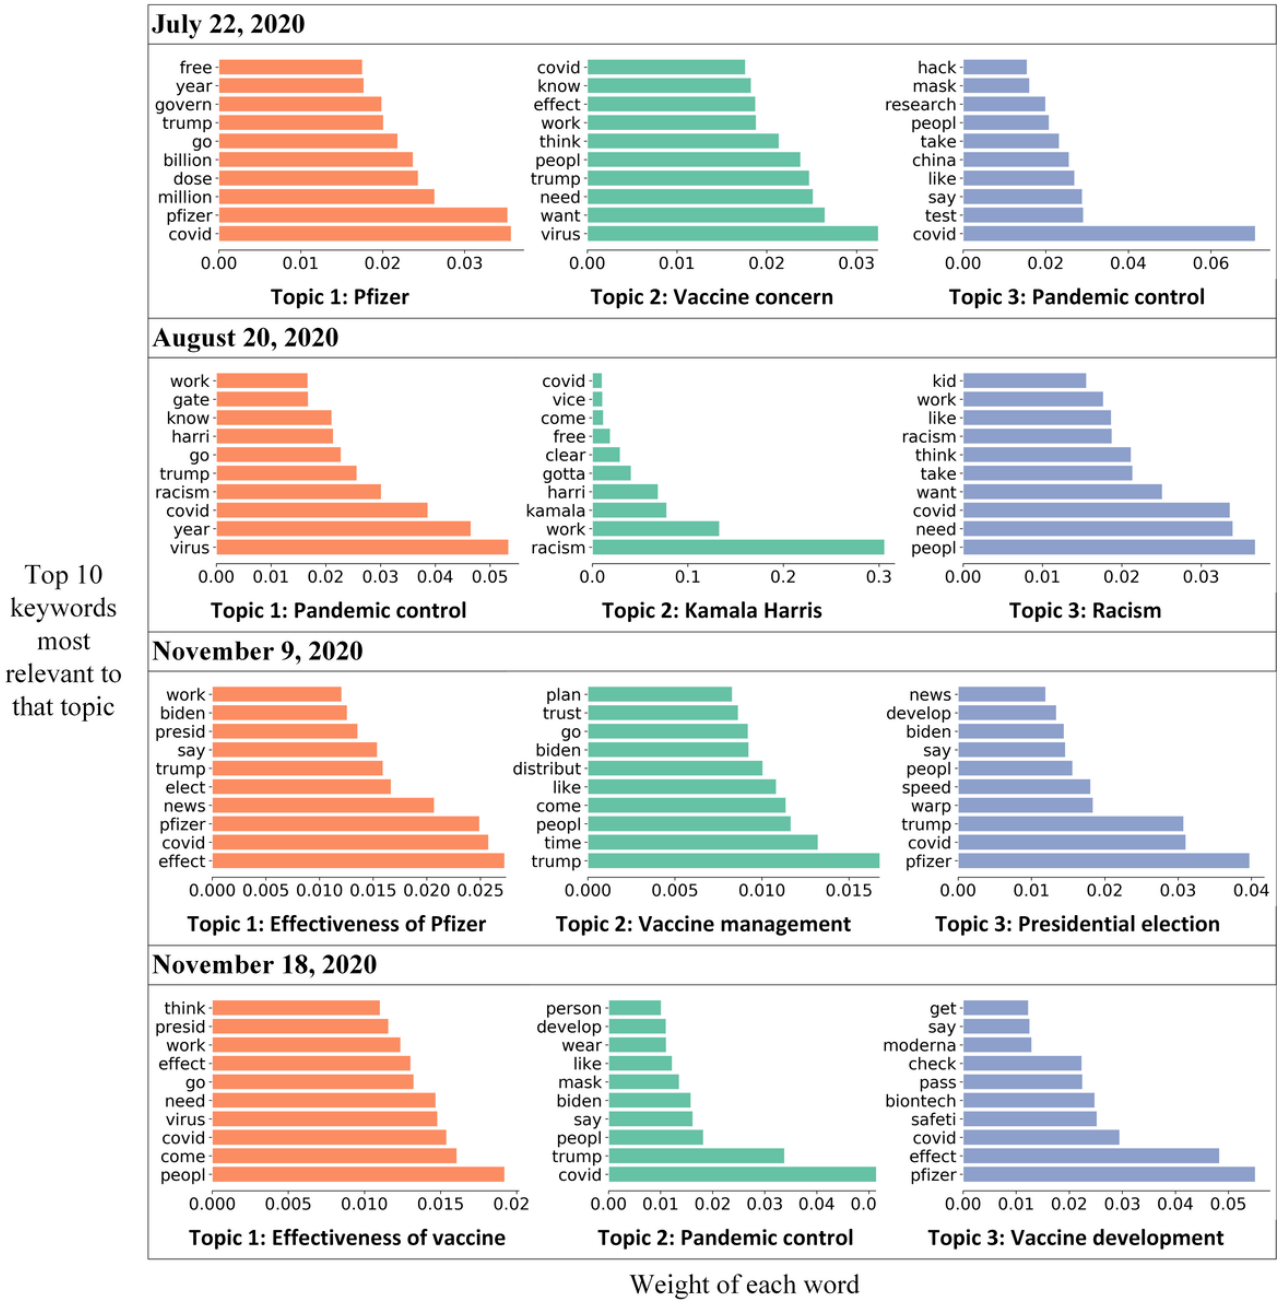


Another sharp increase in sentiment score was observed on July 22, 2020, when the partnership between Pfizer and the US government accelerated the production and delivery of 100 million doses of COVID-19 vaccines [38]. The keywords "pfizer," "govern," and "million" were widely discussed and identified through topic modeling (Figure 3). On August 20, 2020, the sentiment score dropped dramatically after Kamala Harris formally accepted the Democrats' vice-presidential nomination at the 2020 Democratic National Convention. Harris advocated, "There is no vaccine for racism," mentioning the context of the racism protests for George Floyd and Breonna Taylor [39]. Of the keywords, "racism" and "kamala" were observed through topic modeling. Another increase in sentiment score appeared on November 9, 2020, when Pfizer announced that its vaccine is 90% effective (Figure 3) [40]. On the same day, Trump tweeted "STOCK MARKET UP BIG, VACCINE COMING SOON. REPORT 90% EFFECTIVE. SUCH GREAT NEWS!" Amid positive news from Pfizer, people questioned whether Pfizer purposefully released study results after Election Day, though Pfizer's CEO claimed that the release timing had nothing to do with politics [41]. On that day, widely discussed keywords included "trump," "pfizer," and "elect" (Figure 3).

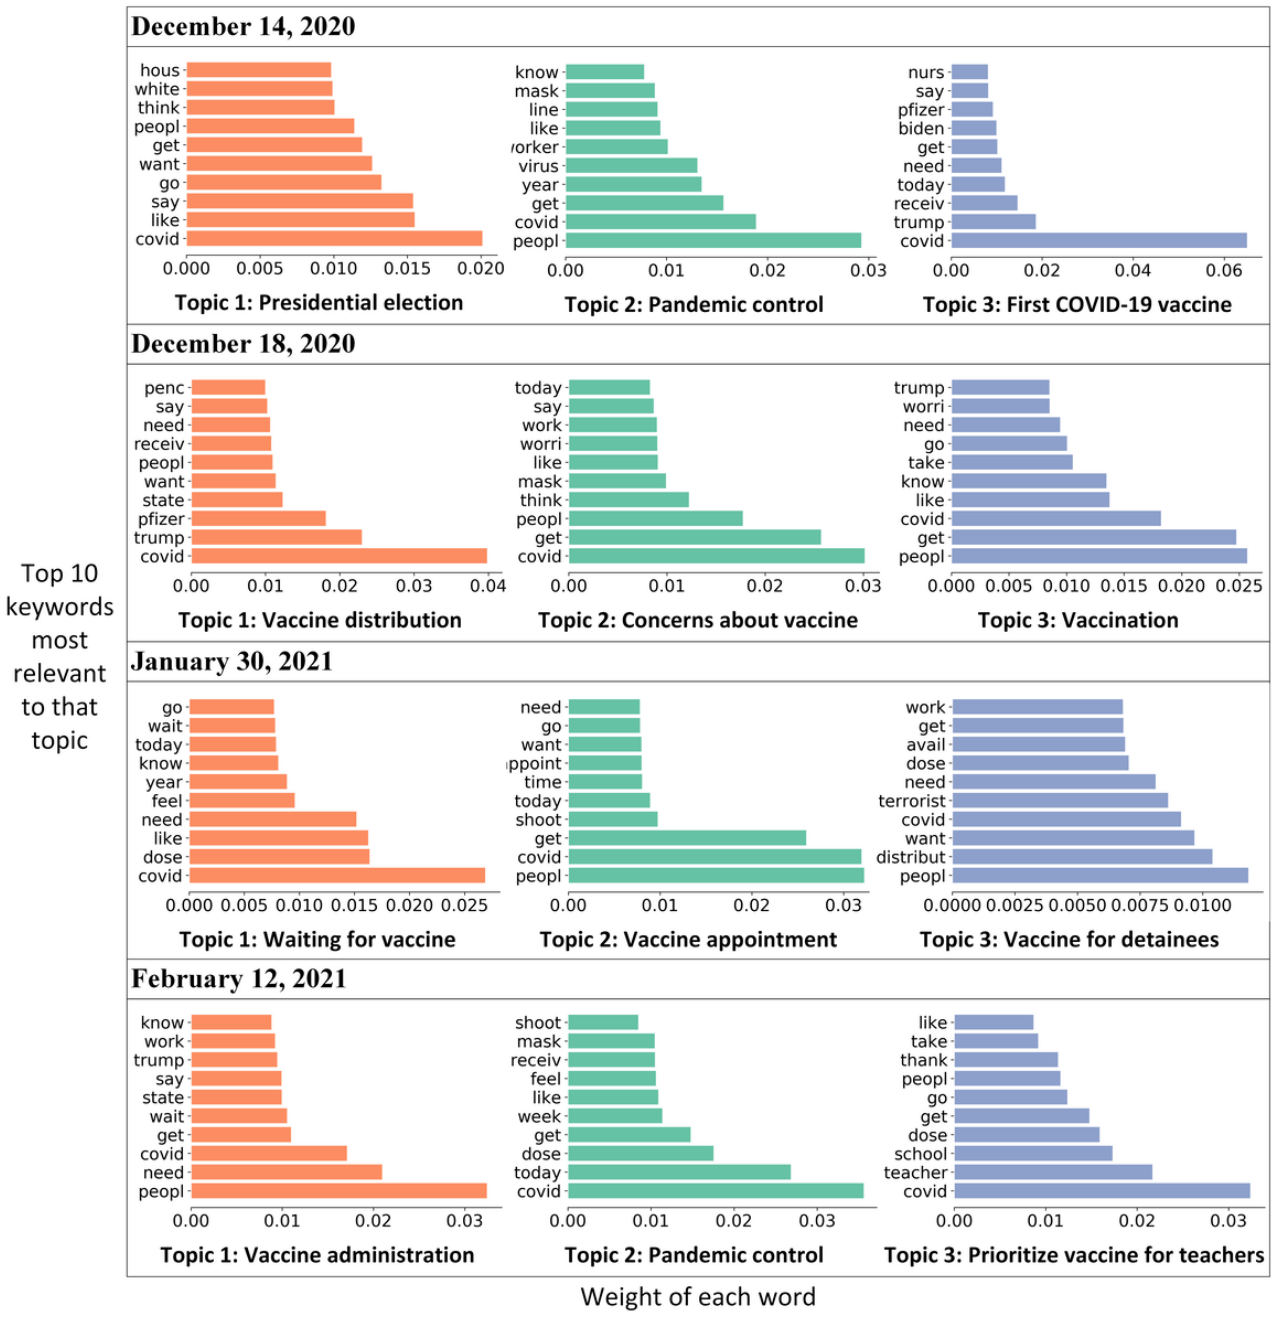
Figure 3. Three topics discussed on each of 4 key dates: July 22, 2020; August 20, 2020; November 9, 2020; and November 18, 2020.



In Phase 3 on December 14, 2020, an increased sentiment score was observed when an intensive care unit nurse received the first COVID-19 vaccine in New York. On the same day, the Electoral College voted to cement Biden's victory over Trump. Discussion regarding COVID-19 vaccines ("pfizer," "nurs," "receive") quickly increased on Twitter, while other related discussions regarding mask wearing ("wear" and "mask") and the presidential election ("house," "trump," "biden") remained popular (Figure 4). By December 18, 2020, the sentiment score remained high as both Pfizer and Moderna were authorized for

emergency use by the US Food and Drug Administration [42]. Trump tweeted "Moderna vaccine overwhelmingly approved. Distribution to start immediately." Additionally, the fact that former Vice President Pence and second lady Karen Pence received a COVID-19 vaccine [43] was widely discussed ("penc" and "receiv"). Expectations for the COVID-19 vaccines were also discussed ("need" and "want"; Figure 4). On January 30, 2021, the Department of Defense paused a plan to give COVID-19 vaccines to detainees in the Guantanamo Bay prison camp [44], which raised queries of COVID-19 vaccine delivery, leading to a moderate decrease in the sentiment score. Keywords were observed, including "terrorist" and "distribut" through topic modeling (Figure 4). On February 12, 2021, an increased sentiment score was observed after the Biden administration announced the purchase of 200 million COVID-19 vaccine doses from Pfizer and Moderna [45]. Discussion surrounding the administration of COVID-19 vaccines was extensive ("wait," "get," "need"; Figure 4). Topic modeling also suggests that complaints were pervasive ("teacher," "school," and "get"; Figure 4) because teachers were not prioritized for vaccination in states despite the Center for Disease Control and Prevention's recommendation.

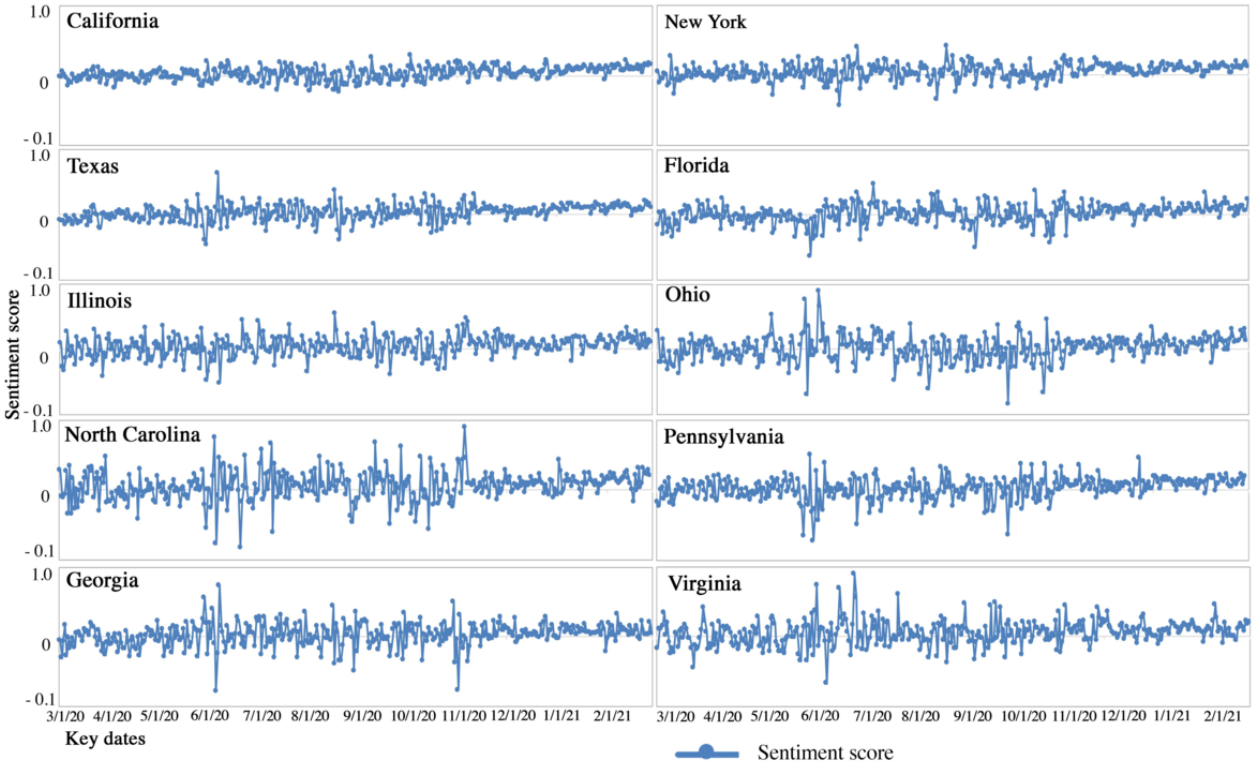
Figure 4. Three topics discussed on each of 4 key dates: December 14, 2020; December 18, 2020; January 30, 2021; and February 12, 2021.



We then broke down the sentiment scores by state in tandem, along with the pandemic timeline. We present the results in the top 10 states with the largest number of geotweets (Figure 5), including California, New York, Texas, Florida, Illinois, Ohio, North Carolina, Pennsylvania, Georgia, and Virginia. The temporal patterns in sentiment scores vary across states, with more obvious fluctuations before November 2020 in Illinois, Ohio, North Carolina, Georgia, Pennsylvania, and Virginia. A

number of sharp decreases in sentiment scores was observed in June 2020 in Illinois, North Carolina, Ohio, Pennsylvania, Georgia, and Virginia, in line with the tendency of sentiment drops at the national level. The states with relatively larger numbers of geotweets (ie, California, New York, Texas, and Florida) had more stable temporal trends and sentiment scores compared with the states with relatively smaller numbers of geotweets (eg, Ohio, North Carolina, Pennsylvania, Georgia, and Virginia).

Figure 5. Sentiment scores in 10 selected states.



We further examined the absolute values of the average positive and negative sentiment scores by states in Figure 6. In the majority of the states, the absolute positive sentiment score was larger than that of the negative sentiment score. The difference between the positive and negative sentiment scores was relatively more obvious in the mainland states of Alabama, Utah, Nebraska, Minnesota, and West Virginia (highlighted in dark grey in Figure 6), as well as in Hawaii and Alaska; the potential drivers triggering such differences across states may either relate to information or news spreading locally or be subject to the variations caused by the different sampling size in each state.

The changes in positive and negative sentiment scores over 2 periods of time (Phase 1 to Phase 2; Phase 2 to Phase 3) were compared and are presented in Figure 7. From Phase 1 to Phase 2, an increase in positive sentiment scores (orange bars) appeared in most states, most obviously in South Dakota, followed by North Dakota and Arkansas; meanwhile, a decrease in negative sentiment scores (dark blue bars) was also observed in the majority of states, most obviously in South Dakota and Rhode Island, followed by Montana, North Dakota, and Arkansas. From Phase 2 to Phase 3, the decrease in negative sentiment scores (light blue bars) appeared in most states, most obviously in Idaho and Rhode Island, followed by North Dakota, Vermont, and New Hampshire. However, the change in positive sentiment scores (red bars) from Phase 2 to Phase 3 varied across states, with a slight increase that is more obviously observed in Idaho, North Dakota, and New Mexico, while a slight decrease is more obviously observed in South Dakota, Rhode Island, and Connecticut. In addition, the magnitude of both positive and negative sentiment scores from Phase 1 to Phase 2 (the height of dark blue and orange bars) was more obvious in most states than that of Phase 2 to Phase 3 (the height of light blue and red bars). This indicates that the fluctuation in people's opinions towards vaccines became less obvious with the gradual development of vaccines and more encouraging news.

Figure 6. Absolute values of negative and positive sentiment scores at the state level.

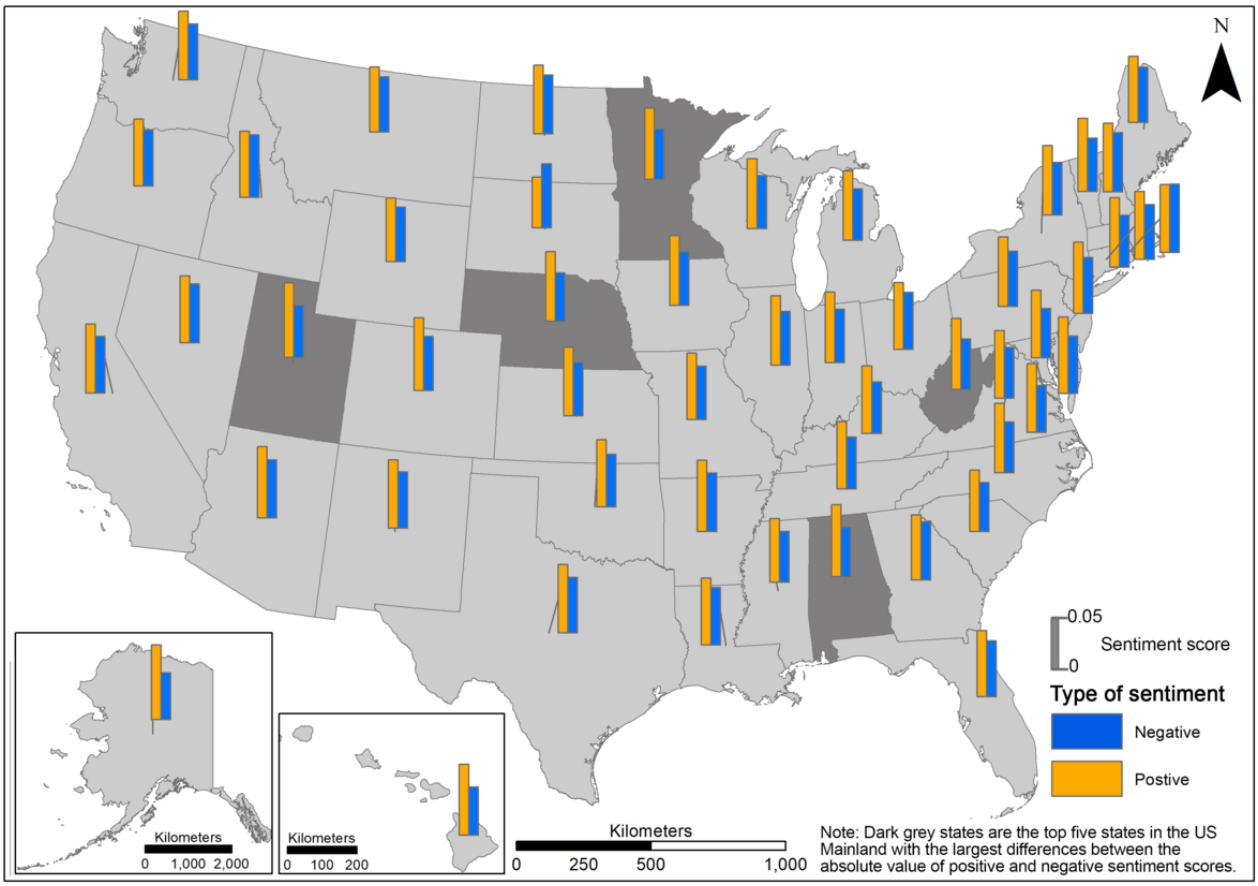


Figure 7. Changes in sentiment scores over the 3 phases at the state level.

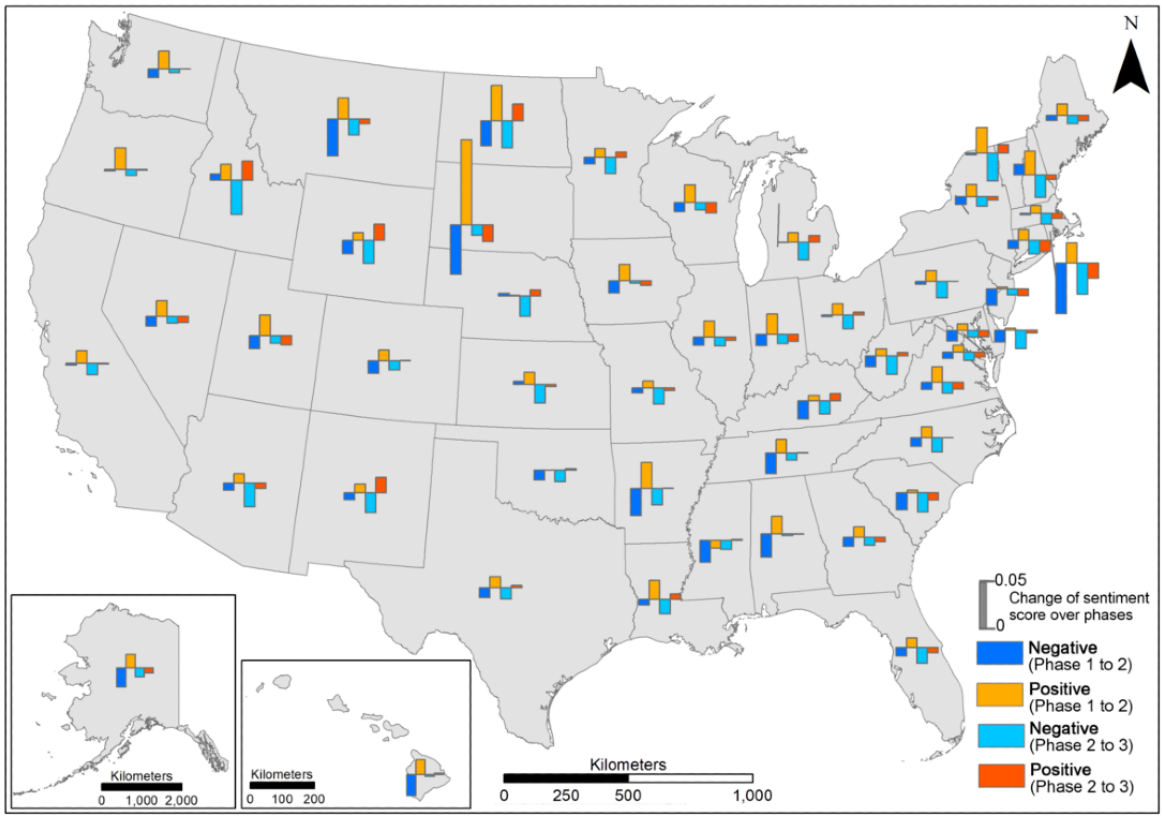
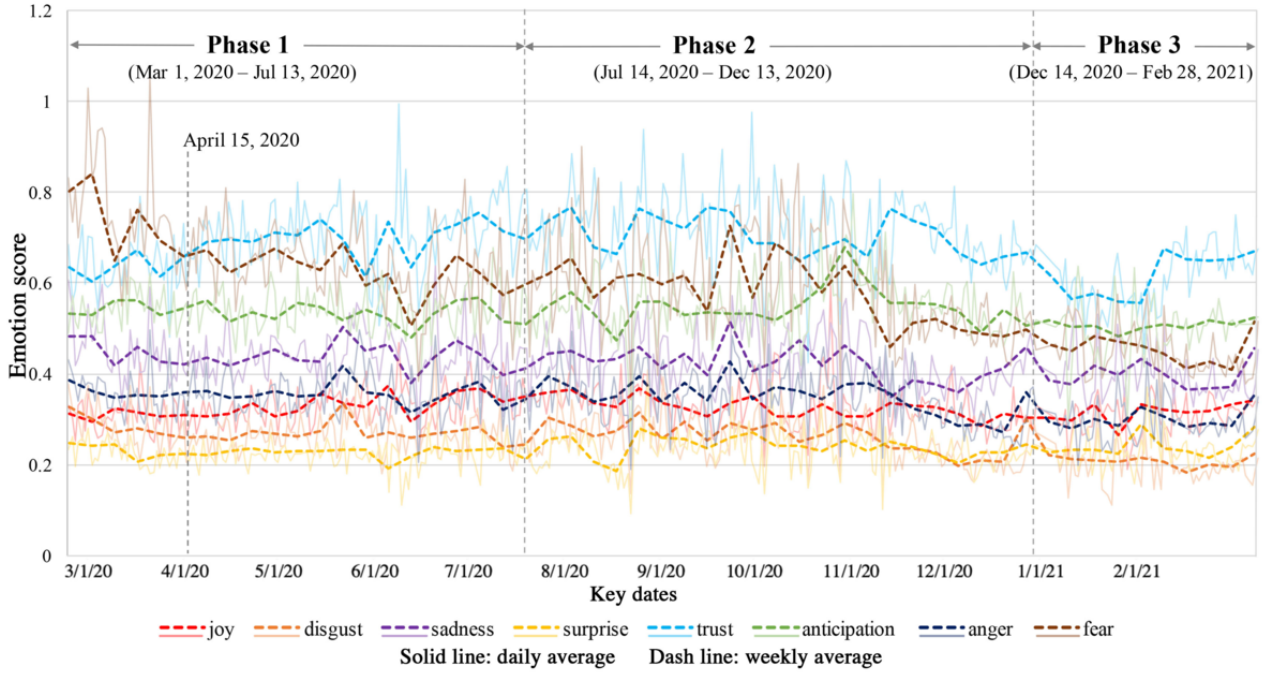


Emotion Analysis

Figure 8 shows the temporal patterns in the 8 types of emotion, including joy, trust, anticipation, trust, surprise, disgust, sadness, and fear. Through the vertical comparison of the weekly average trend lines (dashed lines), we found that the emotion with the highest weekly average scores along the majority of the timeline was trust (blue dashed line), followed by fear, anticipation, sadness, anger, joy, disgust, and surprise. It is worth noting that the weekly average emotion score of fear was higher than that of trust before mid April 2020, possibly due to rapid COVID-19 infection and ineffective control of viral spread at the early stage of the pandemic. These events may have caused fear, uncertainty, or even feelings of panic [46]. Although fluctuations in emotion scores (eg, local peaks and valleys) can be found within each of the 8 emotions, the general trend implies that the public's trust in and anticipation towards vaccination were accompanied by a mixture of fear, sadness, and anger.

Figure 8. Average daily and weekly emotion scores over the entire study timeline at the national level.



We further investigated the relative distributions of 8 emotions in each state, as indicated by the percentage of emotion scores for each type with different colors (Figure 9). The overall patterns of the 8 emotions are consistent across most states. Throughout the entire timeline and in each of the 3 phases of the pandemic, trust was the dominant emotion towards vaccination over the full timeline of the pandemic. It was followed by anticipation, fear, sadness, anger, joy, disgust, and surprise. The state-level patterns largely align with the national pattern as depicted in Figure 9, although there are some exceptions, such as fear outweighing anticipation, joy, and trust (eg, Washington) and with fear, anger, and sadness outweighing other emotions (eg, Maine). As shown in Figures 10 and 11, the emotion of trust stayed consistent over time, while the changes in trends for other types of emotion were distinct across phases and by state.

We further compared the change in the percentage of emotions over 2 periods of time (Phase 1 to Phase 2; Phase 2 to Phase 3). From Phase 1 to Phase 2 (Figure 10), a decrease in fear (dark blue bars) was observed in most states, though its magnitude varied across states. This decrease was most obvious in South Dakota, followed by North Dakota, Arkansas, Mississippi, North Carolina, and South Carolina. The changes in anger, sadness, and disgust varied across states, with a general decrease in most states but sporadic increases in others (eg, Idaho, New Mexico, and New Hampshire). Furthermore, the combination of a decrease in fear and an increase in joy, trust, and anticipation was observed in most states except South Dakota. Throughout the period from Phase 2 to Phase 3 (Figure 11), it is difficult to generalize the pattern of emotion change across states in terms of type and magnitude. An increase in joy, trust, anticipation, and surprise along with a decrease in fear, anger, sadness, and disgust were the most notable (high bars) in Idaho and Rhode Island, followed by Missouri, Vermont, and New Hampshire. On the contrary, some states encountered a decrease in trust and anticipation in tandem with an increase in anger and sadness, including South Dakota, North Dakota, Montana, Kansas, Indiana, Maine, and Delaware. The complexity of emotion changes from Phase 2 to Phase 3 varied across states, reflecting the diversity in people's opinions and psychological reactions to vaccination, which should be subject to an in-depth investigation of causality.

Figure 9. Percentage of 8 emotions expressed at the state level.

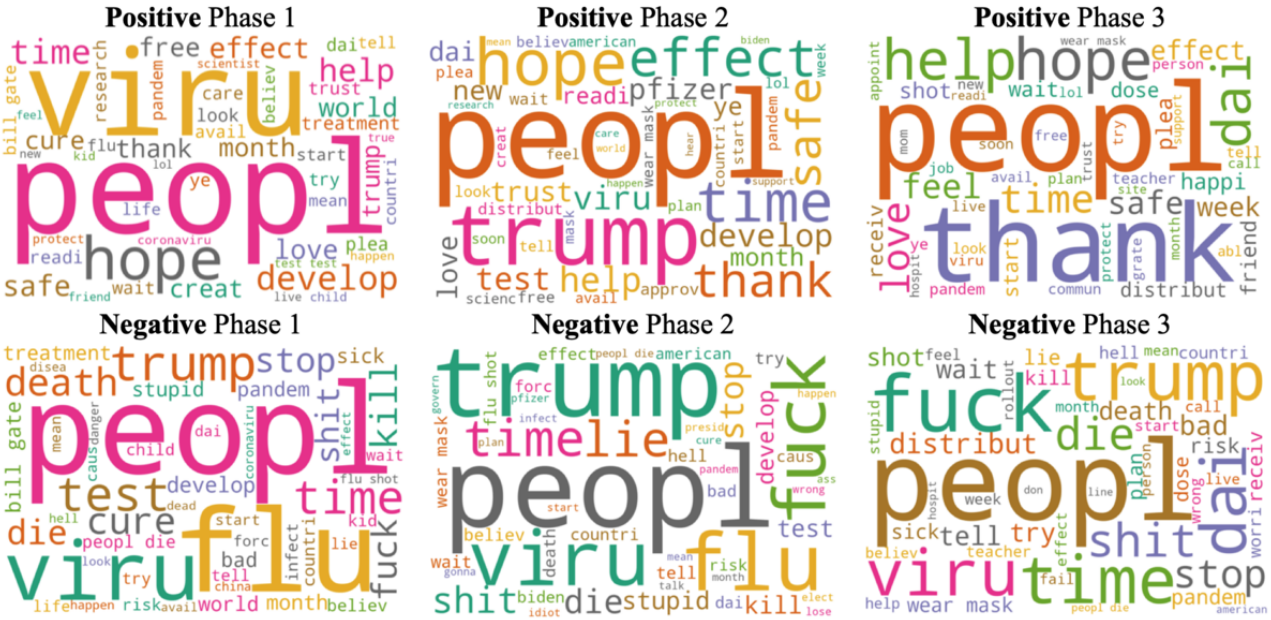
Figure 10. Change in emotions from Phase 1 to Phase 2 at the state level.

Figure 11. Changes in emotion from Phase 2 to Phase 3 at the state level.

Word Cloud Visualization

We produced word cloud mappings of 50 popular words associated with positive and negative sentiments over the 3 phases (Figure 12). The size of a word represents its popularity and the frequency with which it appears in tweets. Among the words associated with positive sentiment, the popular ones were “hope,” “help,” “thank,” “love,” “safe,” “cure,” and “free,” although the word “peopl,” with a more neutral nature, appears to be the most popular. Throughout the 3 phases, “hope,” “safe,” and “thank” grew larger from Phase 1 to Phase 3; in particular, “thank” became the most popular word in Phase 3. On the contrary, “flu,” “death,” “trump,” “fuck,” “lie,” “die,” “kill,” “shit,” and “stupid” were popular words associated with negative sentiment. Over the 3 phases, “flu” became smaller from Phase 1 to Phase 3 whereas “die,” “fuck,” “shit,” and “trump” evolved to be larger from Phase 1 to Phase 3; in particular, “trump” became predominant in Phase 2 possibly due to Trump’s increasing popularity caused by the 2020 Presidential Election. More specifically, while people were waiting for the news of COVID-19 vaccine development during Phase 1, their uncertainties on potential vaccines were reflected in the included keywords, which were related to the coronavirus and public’s frustration of the pandemic (eg, “viru,” “death,” “cure,” and “test”). Some keywords related to the COVID-19 vaccine were also observed, including “hope” and “develop.” Positive news about the development of COVID-19 vaccines appeared in Phase 2, which brought hope as well as misinformation regarding the vaccines to the public. At this stage, more specific information about COVID-19 vaccines was discussed (eg, “Pfizer,” “effect,” “risk,” “develop,” and “approve”), as compared to Phase 1. With Pfizer and Moderna vaccines approved during Phase 3, the public’s attention moved from vaccine development towards vaccine distribution (“distribution,” “wait,” and “free”), effectiveness (“safe” and “risk”), and priority (“teacher”). In all 3 phases, public figures (eg, “Trump,” “Biden,” and “Bill Gates”) contributed to hot topics with impacts on both positive and negative sentiments.

Figure 12. Popular keywords associated with positive and negative sentiments over 3 phases.



Discussion

Principal Findings

Drawing on geotweets from March 1, 2020 to February 28, 2021, this study examined public opinion on COVID-19 vaccines in the United States, by unveiling the spatiotemporal patterns of public sentiment and emotion over time, modeling the popular keywords and topics of Twitter contents, and analyzing the potential drivers of public opinion on vaccines. Our findings indicate that critical social or international events or announcements by political leaders and authorities may have potential impacts on public opinion towards COVID-19 vaccines. Such examples include the vaccine-adverse conspiracy related to Bill Gates on June 21, 2020, the tweet by Donald Trump of "Great News on Vaccines!" on July 14, 2020, Kamala Harris's advocacy of "There is no vaccine for racism" on August 20, 2020, Biden's victory of the presidential election over Trump on December 14, 2020, and the authorized emergent usage of Pfizer and Moderna on December 18, 2020. In the proposed 3 phases over the study timeframe, changes in public opinions on vaccines varied across space and time. More specifically, the fluctuation in people's sentimental response to the vaccine during the earlier stage of the pandemic was more obvious compared to that in the later stage of the pandemic. However, an increase in positive sentiment in parallel with a decrease in negative sentiment were generally observed in most states, reflecting the rising confidence and anticipation of the public towards COVID-19 vaccines. Furthermore, the public's 8 types of emotion towards the COVID-19 vaccine displayed a general trend of a combination of trust and anticipation with a mixture of fear, sadness, and anger. Moreover, the word cloud mapping showed that positive keywords including "hope," "safe," and "thank" grew larger from Phase 1 to Phase 3; in particular, "thank" became the most popular word in Phase 3, indicating the public's increasingly positive response towards vaccination. In all 3 phases, public figures (eg, "Trump," "Biden," and "Bill Gates") contributed to the most popular topics, impacting both positive and negative sentiments. The aforementioned findings reveal the diversity and complexity of people's perception on and their psychological reaction towards COVID-19 vaccines, which indicates a further need to be cautious in the interpretation of analytical outcomes and to initiate an additional in-depth investigation of the causality.

Our findings are partially supported by the current literature. Hussain et al [14] observed a marked increase in positive sentiment toward COVID-19 vaccines in the United States from March 1, 2020 to November 22, 2020. Guntuku et al [18] and Roy and Ghosh [47] found that Republican legislators became more engaged in public discussion on vaccine progress, which may have implications for COVID-19 vaccine uptake among their followers. Germani and Biller-Andorno [17] revealed that antivaccination supporters have been heavily engaged in discussions and dissemination of misinformation and conspiracy theories. Considering the limitations (ie, random sample) inherent in Twitter data, it is important to propose alternative data that provide a complementary understanding of public opinions towards the COVID-19 vaccine to promote vaccination in the United States.

Implications and Recommendations

The emergence of the internet and social media has provided new platforms for persuasion and the rapid spread of (mis)information, which leads to new opportunities for and challenges to the communication of vaccine information [48]. There are over 4.3 billion people using the internet nowadays, with 3.8 billion of these individuals as social media users [49]. The popularity of social media platforms coupled with the advent of digital detection strategies benefit public health authorities by enabling the monitoring of public sentiment towards vaccine-relevant information in a geo-aware, (near) real-time manner. This can inform more effective policymaking and promote participatory dialogue to establish confidence towards vaccines, in order to maximize vaccine uptake. Some of our findings add new value to the current scholarship and

also provide new insights and suggestions for policy implications with regard to safeguarding societal and economic health.

First, our findings indicate that public figures, especially politicians, play a crucial role in impacting the public's opinions on vaccination. Negative opinions expressed by public figures about a vaccine could impact a large population of people, especially those who do not hold an unswayable opinion [48]. People tend to believe public figures' opinions, as they are elected officials who can influence health care systems and are perceived to have more information about a vaccine [50,51]. Thus, public figures have a responsibility to disseminate accurate health information and should be cautious in expressing their opinions in public. This also highlights the necessity of considering the impact that public figures within vaccine campaigns have on upholding the public's confidence towards the concept of vaccination.

Second, our study reveals that vaccine-adverse conspiracy theories led to a sharp decline in sentiment scores. We need to be aware of the fact that social media platforms with a massive number of users, to some degree, "disrupted" traditional vaccine information communication [52], allowing antivaccination advocates to disseminate misleading messages to a certain audience, whose views on vaccination could be susceptible to change. However, it also means that governmental officials should consider using these platforms to communicate with individuals directly about vaccination via geotailored messages to address concerns specific to a certain region.

Third, different states demonstrated various trends in sentimental and emotional scores. Our geospatial analysis and map visualization [53] better portray more aspects of users' attitudes towards COVID-19 vaccines. This helps identify the areas with high negative sentimental and emotional scores that require further research to understand the public's underlying fears and concerns about COVID-19 vaccines. We also recommend government and public health agencies conduct COVID-19 vaccine campaigns in these areas to address people's fears and concerns about COVID-19 vaccines and provide guidance to access available vaccines.

Limitations and Future Work

Our study has several limitations that can be improved in future studies. First, the demographics of Twitter users is typically characterized by younger users who are avid users of mobile phone apps and the internet, and such users may not be able to reflect the opinion and perception of the general public with varying demographics and socioeconomic statuses [54,55]. In addition, the representativeness of Twitter users is not stationary but geographically varying [56,57]. Like other studies that rely on digital devices, the "digital divide" [58] issue needs to be acknowledged. This study only accounts for the reactions from Twitter users to vaccines, which, to some degree, neglect the underprivileged members of society (especially the poor and elderly), inhabitants of rural areas (who do not have access to digital devices), and those who are not willing to share their thoughts on social media platforms. Additionally, the Twitter API that we used allows access to approximately only 1% of the total records [59]. As Padilla et al [60] demonstrated, tweet sentiment can be impacted based on attraction visits throughout the course of a day. Hence, future work needs to increase the sample size to reduce the uncertainties and fluctuations of sentiment scores and emotions. Efforts are also needed to distinguish between local residents and visitors and also conduct investigations under finer temporal scales. In early 2021, Twitter released a new Twitter API (academic research product track) that grants free access to a full-archive search with enhanced features and functionality for researchers to obtain more precise, complete, and unbiased data for analyzing the public conversation [61]. Further efforts can be made to explore the potential of this new API in mining public opinions towards COVID-19 vaccines at a more granular scale. Since emotion is a complex and integrated product of human feelings [62], future research efforts can be put into exploring more diverse dimensions of emotion, on top of the 8 primary types of emotion. Moreover, disaster and crisis management includes 4 phases, namely prevention (capacity building), preparation (early warning), response (search, rescue, and emergency relief), and recovery (rehabilitation) [63]. Management of the COVID-19 pandemic is still in the response phase. For policy and decision-making endeavors that are pertinent to COVID-19 crisis management, it will be highly beneficial if researchers and practitioners continuously monitor emotional and perspective variations throughout the response and also extend the study timeline to the recovery phase or massive vaccination phase in the post-pandemic years. More importantly, to understand the impact of vaccination on countries, the workflow and methodology used in this study can be applied in multiple languages to global-scale geotweets.

Abstract

Background: The COVID-19 pandemic has resulted in a high degree of psychological distress among health care workers (HCWs). There is a need to characterize which HCWs are at an increased risk of developing psychological effects from the pandemic. Given the differences in the response of individuals to stress, an analysis of both the perceived and physiological consequences of stressors can provide a comprehensive evaluation of its impact.

Objective: This study aimed to determine characteristics associated with longitudinal perceived stress in HCWs and to assess whether changes in heart rate variability (HRV), a marker of autonomic nervous system function, are associated with features protective against longitudinal stress.

Methods: HCWs across 7 hospitals in New York City, NY, were prospectively followed in an ongoing observational digital study using the custom Warrior Watch Study app. Participants wore an Apple Watch for the duration of the study to measure HRV throughout the follow-up period. Surveys measuring perceived stress, resilience, emotional support, quality of life, and optimism were collected at baseline and longitudinally.

Results: A total of 361 participants (mean age 36.8, SD 10.1 years; female: n=246, 69.3%) were enrolled. Multivariate analysis found New York City's COVID-19 case count to be associated with increased longitudinal stress (P=.008). Baseline emotional support, quality of life, and resilience were associated with decreased longitudinal stress (P<.001). A significant reduction in stress during the 4-week period after COVID-19 diagnosis was observed in the highest tertial of emotional support (P=.03) and resilience (P=.006). Participants in the highest tertial of baseline emotional support and resilience had a significantly different circadian pattern of longitudinally collected HRV compared to subjects in the low or medium tertial.

Conclusions: High resilience, emotional support, and quality of life place HCWs at reduced risk of longitudinal perceived stress and have a distinct physiological stress profile. Our findings support the use of these characteristics to identify HCWs at risk of the psychological and physiological stress effects of the pandemic.

Introduction

Increasing rates of SARS-CoV-2 infections and hospitalizations, growing workloads, and concern regarding personal protective equipment have resulted in a large psychological burden on health care workers (HCWs) [1]. Prior pandemics have had psychological effects on HCWs, increasing posttraumatic stress, depression, and anxiety [1-3]. However, the scale and duration of the COVID-19 pandemic have further amplified the risk of these adverse outcomes. Cross-sectional studies have demonstrated that frontline HCWs are at a high risk of depression, anxiety, insomnia, and distress compared to the general population [4-6]. HCWs working in wards serving patients with COVID-19 reported higher levels of stress, exhaustion, depressive mood, and burnout [7,8]. However, there is limited longitudinal data on the pandemic's psychological impact on this group and across health care occupations, no means to identify which HCWs are at risk of developing psychological sequela over time, and no objective evaluation of the stress response among HCWs. Identification of at-risk HCWs will allow for the appropriate allocation of mental health resources.

Advances in digital technology provide a means to address these limitations. Smartphone apps can be used to administer surveys and integrate wearable devices, such as the Apple Watch, to monitor the autonomic nervous system (ANS), a primary component of the stress response. ANS function can be ascertained through measurement of heart rate variability (HRV), a measure of the parasympathetic and sympathetic nervous systems' impact on cardiac contractility through calculation of changes in the beat-to-beat intervals [9]. Systems such as the ANS promote adaption to stressors. However, the cumulative burden of stress, or allostatic load, can alter and impair the response of these systems and result in deleterious physical effects on processes ranging from immune function to cardiovascular health. Given the large differences in the response of individuals to stress, an evaluation of both the perceived and physiological consequences of the stressor could provide a more comprehensive overview of its impact and an understanding of who is at risk from the deleterious physical effects of chronic stress [10]. In response to the COVID-19 pandemic, we launched the Warrior Watch Study, comprised of our custom iOS app, which integrates survey metrics with physiological signatures acquired via the Apple Watch. The aim of the study was to understand the longitudinal perceived and physiological stress response among HCWs throughout the course of the pandemic.

Methods

Study Design

This was an observational cohort study. The primary objective of the study was to identify characteristics associated with longitudinal stress in HCWs. The secondary aim was to determine whether changes in HRV were associated with features protective against longitudinal stress development. HCWs across 7 hospitals in New York City (The Mount Sinai Hospital, Morningside Hospital, Mount Sinai West, Mount Sinai Beth Israel, Mount Sinai Queens, New York Eye and Ear Infirmary, and Mount Sinai Brooklyn) were eligible. Participants had to be current employees of one of the participating hospitals, ≥18 years of age, have an iPhone Series 6 or higher, and be willing to wear an Apple Watch Series 4 or higher. An underlying autoimmune disease or the use of medications that interfere with ANS function were exclusionary. This study was approved by the institutional review board at Mount Sinai. Informed consent was obtained from all participants.

Study Procedures

Participants downloaded the custom Warrior Watch Study app to their iPhones and completed eligibility questions prior to signing electronic consent. Through the Warrior Watch Study app, surveys were completed at enrollment and then longitudinally throughout the course of the study. At enrollment, demographic information and whether subjects had a diagnosis of anxiety or depression were collected. Psychological well-being was assessed through structured surveys evaluating perceived stress (Perceived Stress Scale-4 [PSS-4]) [11], resilience (Connor-Davidson Resilience Scale-2 [CD-RISC-2]) [12], emotional support (2-item Patient-Reported Outcomes Measurement Information System [PROMIS] questionnaire) [13], quality of life (2-item Global Health and Quality of Life [QoL]) [14], and optimism (Life Orientation Test) [15] (Table S1, Multimedia Appendix 1). Diagnosis of COVID-19 was defined as a positive SARS-CoV-2 nasal polymerase chain reaction (PCR) swab reported by the study subject.

To longitudinally evaluate subjects, daily surveys were administrated via the study app to collect COVID-19–related symptoms and severity, degree of COVID-19 exposure at work, types of patient care at work, whether participants left their home each day, if public transportation was used, the number of people that participants interacted with each day, the results of any COVID-19 nasal PCR or antibody tests, whether the subject was quarantined, if childcare needs were required, and if the subject was hospitalized. To assess trends in psychological well-being, subjects were prompted to complete the PSS-4 and

2-item General Health and QoL survey weekly. Participants were instructed to wear the Apple Watch for at least 8 hours per day throughout the study period.

Outcome Measures, Instrumentation, and the Wearable Device

HRV, a physiological marker of stress, was collected via the Apple Watch, while subjective outcome measures were assessed through standardized surveys. The Apple Watch Series 4 or 5 was worn by subjects on the wrist to capture HRV and was connected via Bluetooth to the participants' iPhone. A photoplethysmogram sensor on the Apple Watch pairs a green LED (light-emitting diode) light with a light-sensitive photodiode to generate time-series peaks [16]. The Apple Watch and Apple Health app calculates HRV using the standard deviation of NN intervals (SDNN) from the time differences between heart beats, categorized as the interbeat interval. SDNN is a time domain index reflecting sympathetic and parasympathetic nervous system activity [9]. This is recorded by the Apple Watch during approximately 60-second recording periods (ultrashort period). Ultrashort term analyses of HRV can be reliably performed to monitor mental health [17]. In accordance with current HRV guidelines, we did not compare SDNN values obtained from recordings of different duration, and we used one measuring device (Apple Watch) to assure standardization of the equipment [18].

The PSS-4 measures perceived stress. It is a 4-question survey that is scored from 0 to 16. Higher scores correlate with elevated perceived stress. The scale evaluates an individual's confidence in handling problems, whether individuals feel difficulties are piling up, whether things are felt to be going in the way of the individual, and one's sense of control [11].

The CD-RISC-2 measures resilience. It is a 2-question survey, with higher scores correlating to higher resilience. It includes questions about coping, bouncing back from adversity, whether an individual gets discouraged, and adaptation to change [12].

The 2-item emotional support PROMIS questionnaire is a 2-question survey inquiring about whether individuals have someone to listen to them when they need to talk and someone they trust to discuss their feelings with. It is scored on a scale from 2 to 10 points [13].

The 2-item Global Health and QoL questionnaire asks individuals to grade how their health and quality of life are in general, with higher scores correlating with lower health and quality of life [14].

The Life Orientation Test assesses subject optimism. It comprises 6 questions that ask individuals whether he or she expects the best in uncertain times, whether he or she expects things to go wrong, and whether more good is expected to happen compared to bad [15].

Statistical Analysis

Survey Analyses

To account for gaps created by unanswered weekly surveys and allow comparison for each patient, we created a chronological variable called a "period." To account for participants having different time windows between each weekly survey, a period was assigned to each weekly survey according to participants' starting and ending dates. When a participant's survey was completed less than 7 days from their previous survey date, the day after the previous survey date was regarded as the starting window date for the next period. When a participant's survey was done 7 days or more apart from the previous survey date, the starting window date was set to 6 days prior to the current survey date. To integrate weekly psychological metrics and daily risk/health metrics, the results of the daily surveys were summarized by the periods defined by the weekly surveys. Daily survey data were summarized for each period (eg, mean number of risk days per period, mean number of days left home per period). To examine the associations between the COVID-19 case count of New York City and perceived stress, raw case count data were obtained for the city and summarized as a mean case count per period [19].

Occupation Classification

The occupation of each participant was collected at enrollment. Due to the pandemic, the roles and responsibilities of these occupations may have changed compared to nonpandemic job descriptions. We therefore created a new occupation metric to identify which participants were seeing patients during the study. Occupation was calculated as follows:

1. Daily clinical occupation was calculated from the daily survey where participants classified the type of patient or nonpatient care responsibilities that day. Those who reported either (a) exposure to patient areas but without patients diagnosed with or being evaluated for COVID-19, or (b) exposure to areas with patients confirmed to have COVID-19 or being investigated for COVID-19 infection, were assigned as "clinical" for that day. Those who responded they were at work but not caring for patients or those who were working remotely were classified as "nonclinical" for that day.
2. If a participant had one or more clinical days in a period, that participant was assigned as clinical for that period.
3. If a participant had one or more clinical periods over the entire study, then they were deemed as either clinical nontrainee or clinical trainee. To be classified as a clinical trainee, a participant had to be either a resident or fellow. All other occupations were classified as staff.

Statistical Modeling

To model longitudinal changes in stress, we used linear mixed-effect models. Fixed effects included time-invariant covariates (gender, age, occupation, baseline resilience, optimism, and quality of life) and time-variant covariates (COVID-19 diagnosis, SARS-CoV-2/COVID-19 antibody positive test, mobility variables). A continuous first-order autoregressive correlation structure (over period) was found to be suitable for our data, significantly increasing the likelihood function (likelihood ratio test, $P<.001$) and leading to a minimal Akaike information criterion or Bayesian information criterion. Model coefficients were estimated using the restricted maximum likelihood approach via R's *nlme* packages (R Foundation for Statistical Computing). Hypotheses of interest were tested using contrasts through the capabilities of the *emmeans* package.

Univariate models tested the association of each variable with longitudinal stress and identified associated factors. Variables with $P<.10$ in the marginal ANOVA (analysis of variance) test were considered significant and included in the multivariate analysis. Although in univariate models random effects include only the intercept, in multivariate models, a random effect for the case burden in New York City was found to be significant (likelihood ratio test, $P<.001$), indicating heterogeneity in the association of this variable with stress across subjects.

Heart Rate Variability Modeling

HRV captured from the Apple Watch demonstrated a sparse nonuniform sampling and circadian pattern, making it amenable to analysis via a cosinor model. This approach models the daily HRV circadian rhythm over a period of 24 hours, which can be described using the circadian parameters: (1) midline statistic of rhythm (MESOR), a rhythm-adjusted mean; (2) amplitude, a measure of half the extent of variation within a day; and (3) acrophase, a measure of the time of overall high values recurring in each day. This allows testing of the effect that model covariates have on HRV. A cosinor model used the nonlinear function $Y(t)=M + Acos(2\pi t/\tau + \varphi + e_i(t)$, where τ is the period (τ=24 hours), M is the MESOR, *A* is the amplitude, and φ is the acrophase. This can be transformed into the linear model $x=\sin(2\pi t/\tau)$, $z=\sin(2\pi t/\tau)$, with HRV written as $Y(t)=M + \beta x_t + \gamma z_t + e_i(t)$. We identified a subject-specific daily pattern measuring departures from this pattern as a function of emotional support, resilience, and other covariates of interest. Utilizing a mixed-effect cosinor model HRV, the introduction of random effects intrinsically models the correlation due to the longitudinal sampling. Covariates, C, were introduced as fixed effects using the equation $HRV_{it} = M + a_oCi + (\beta + a_2C_i)x_{it} + (\gamma + a_3C_i)z_{it} + W_{it}\theta_i + e_i(t)$. As we have described previously to test if the cosinor curve differs between two populations of interest, we performed the bootstrapping procedure where for each iteration, we (1) fit a linear mixed-effect model using reweighted least squares, (2) estimated the marginal means for each group defined by a covariate, (3) estimated marginal means for each group using the inverse relationship, and (4) defined the bootstrapping statistics as a pairwise difference between groups [20]. Cosinor models were used to estimate HRV MESOR, amplitude, and acrophase for participants based on emotional support and resilience tertials (low, medium, high). Cosinor model covariates included time, gender, age, BMI, baseline emotional support, baseline resilience, optimism, and stress, with the participant serving as a random intercept.

Results

Overview

A total of 361 HCWs were enrolled in this ongoing observational study between April 29 and September 29, 2020, when data were censored for analysis (Table 1). Occupations were classified as (1) clinical nontrainees: participants who reported caring for a patient on any daily survey and was not a resident or fellow, (2) clinical trainee: a resident or fellow, and (3) staff: participants who did not report caring for patients on a daily survey. Participants had a mean age of 37 years, were 69.3% (n=246) female, and were followed for a mean of 60 days (IQR 21-98 days). Clinical trainees had higher baseline resilience compared to clinical nontrainees (P=.03) and staff (P=.01), higher optimism (P=.04) and emotional support (P=.01) compared to staff, and higher emotional support compared to clinical nontrainees (P=.01) (Table S2, Multimedia Appendix 1).

Table 1. Baseline demographic characteristics of the total cohort and by occupation category.

Characteristic	Total cohort (N=361)	Staff (n=65)	Clinical nontrainee (n=217)	Clinical trainee (n=40)
Age (years), mean (SD)	36.8 (10.1)	36.5 (11.0)	37.8 (10.4)	31.1 (3.6)

Factors Associated With Longitudinal Stress

The primary aim of the study was to assess the factors associated with longitudinal perceived stress. Univariate analysis evaluated the relationship between baseline demographics and prospectively collected survey metrics with longitudinal perceived stress (Table 2). Baseline factors including resilience, optimism, emotional support, quality of life, male gender, and age were significantly associated with lower longitudinal stress. Baseline anxiety or depression, BMI, weight, and asthma were significantly associated with increased longitudinal stress. Longitudinal quality of life (P<.001) was associated with reduced longitudinal stress, while the mean number of COVID-19 cases in New York City (P=.004) was positively associated with increased longitudinal stress. Occupation classification (staff vs clinical nontrainee, P=.81; staff vs clinical trainee, P=.15; clinical nontrainee vs clinical trainee, P=.17), mean number of days caring for patients (P=.88), and treatment of patients with COVID-19 (P=.73) were not associated with longitudinal stress. We observed a significant reduction in stress

during the 4-week period following diagnosis (*P*=.01) and over the follow-up period (*P*=.04). Multivariable analysis found only the New York City COVID-19 case count to be significantly associated with increased longitudinal stress (*P*=.008). The drop in stress during the 4-week period following COVID-19 diagnosis was not significant (*P*=.23); however, we noted a borderline significant increase in stress following the 4-week period after a COVID-19 diagnosis (*P*=.05). Baseline emotional support, baseline quality of life, and baseline resilience were associated with decreased longitudinal stress (*P*<.001) (Figure 1).

The COVID-19 case count of New York City and the 4-week period after a COVID-19 diagnosis via nasal PCR were further explored in the context of emotional support and resilience. Participants were stratified into emotional support tertials (low, medium, high). A significant reduction in stress during the 4-week period after COVID-19 diagnosis occurred only in participants in the highest tertial of emotional support (effect estimate –0.97, *P*=.03) but not in the medium (effect estimate –0.62, *P*=.48) and low tertials (effect estimate 0.08, *P*=.93) (Figure S1A, Multimedia Appendix 2). A significant trend between New York City's COVID-19 case count and longitudinal stress was observed only in the high tertial emotional support group (estimate 1.22, *P*=.005), not in the low (estimate –1.45, *P*=.26) or medium (estimate 0.98, *P*=.16) tertials (Figure S1B, Multimedia Appendix 2). Stratification of the cohort into tertials for resilience demonstrated a significant reduction in stress during the 4-week period after COVID-19 diagnosis via nasal PCR in the high (estimate –1.78, *P*=.006) but not medium (estimate 0.33, *P*=.64) and low tertials (estimate –0.60, *P*=.25) (Figure S1C, Multimedia Appendix 2). The impact of New York City's COVID-19 case count demonstrated a borderline significant relationship with stress in the medium (estimate 1.29, *P*=.098) and high (estimate 1.14, *P*=.09) tertials but not in the low resilience group (estimate 0.72, *P*=.21) (Figure S1D, Multimedia Appendix 2).

Table 2. Univariate analysis of factors associated with longitudinal perceived stress.

Factor	Effect estimate	*P* value
Baseline resilience	–0.84	<.001
Baseline optimism	–0.34	<.001
Baseline emotional support	–0.62	<.001
Baseline quality of life	–0.71	<.001
Longitudinal quality of life	–0.80	<.001
Baseline anxiety or depression	1.27	<.001
Baseline BMI	0.07	.001
Male gender	–0.94	.002
Mean New York City case count per period	0.82	.004
No positive COVID-19 nasal PCR[a] at baseline	0.91	.11
2 weeks post positive COVID-19 nasal PCR test	–0.18	.62
4 weeks post positive COVID-19 nasal PCR test	–0.82	.01
2 weeks post positive COVID-19 antibody test	–0.36	.19
4 weeks post positive COVID-19 antibody test	–0.10	.71
Any period post positive COVID-19 nasal PCR test	–0.85	.04
2 weeks post positive COVID-19 PCR or antibody test	–0.25	.28
Any period post positive COVID-19 antibody test	–0.26	.36
Weight	0.02	.04
Age	–0.03	.047
Baseline asthma	0.89	.045
Baseline heart disease	3.37	.19
Baseline hypertension	–0.34	.58
Baseline diabetes	–0.20	.85
Mean symptomatic days per period	0.32	.07
Staff vs clinical nontrainee	–0.03	.81
Staff vs clinical trainee	0.43	.15
Clinical vs clinical trainee	0.60	.17
Any period post positive COVID-19 PCR or antibody test	–0.47	.07
Height	–0.03	.08
Mean days traveled per period	–0.09	.58
Days left home per period	–0.05	.08
No immune-suppressing medication at baseline	–1.80	.17
No childcare needs at baseline	–0.39	.23
Smoking at baseline	0.53	.20
Mean days hospitalized per period	–1.66	.27
Mean days treating COVID-19–positive patients per period	0.22	.28
Number of days left home	–0.02	.30
Asian vs Black	0.02	.97
Asian vs other	–0.34	.47
Black vs other	–0.36	.55
White vs Asian	0.01	.99
White vs Black	0.03	.96

Factor	Effect estimate	*P* value
White vs other	–0.34	.45
No positive COVID-19 antibody test at baseline	0.03	.69
Days caring for patients with COVID-19	0.01	.73
Interacted with 1-3 people outside the home per day	0.01	.97
Interacted with 4-9 people outside the home per day	0.01	.96
Interacted with ≥10 people outside the home per day	–0.11	.64
Mean days quarantined per period	–0.20	.80
Total symptomatic days per period	0.01	.85
Days working weighted based on patient exposure	0.03	.69
Days hospitalized per period	0.07	.88
Days quarantined per period	–0.03	.90
Mean number of days the participant left the house per period	0.03	.90
Mean working days during this period	0.02	.88
Sum of the severity of COVID-19 symptoms per period	–0.001	.96
Mean severity of COVID-19 symptoms this period	0.08	.14

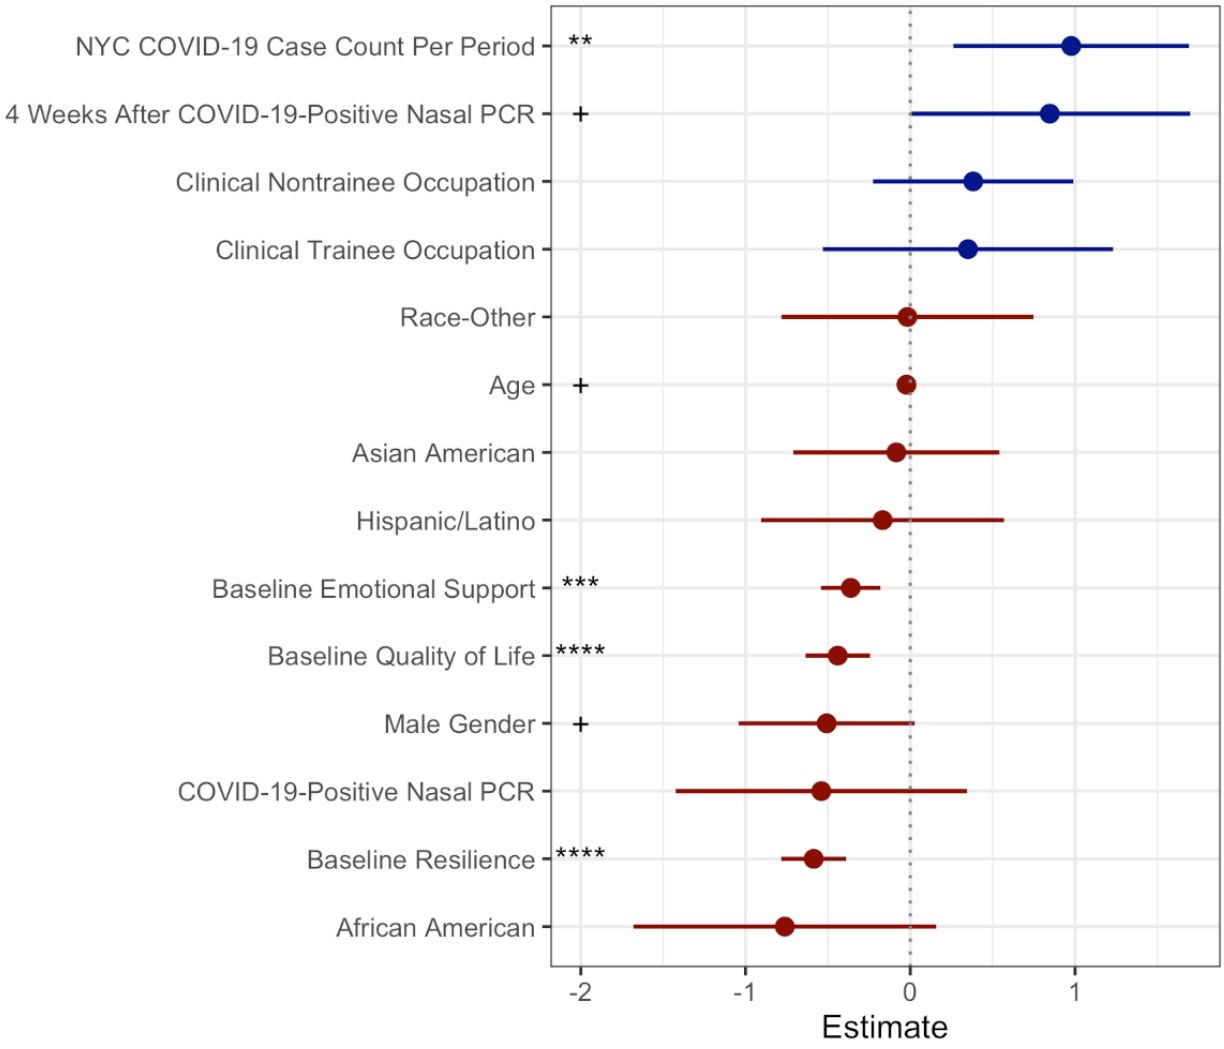
Figure 1. Multivariate analysis of factors associated with longitudinal stress. The scatter plot shows estimated coefficients (CIs) for variables used in the multivariate analysis. Stars indicate that the variable has a significant (*P*<.05) association with longitudinal stress while crosses indicate a borderline significant relationship (*P*<.10). Positive association is indicated in blue and negative association in red. NYC: New York City; PCR: polymerase chain reaction.



Physiological Stress Response

The secondary aim of the study was to evaluate whether features that buffer against perceived stress result in physiological differences in the stress response of HCWs. We fit a cosinor model evaluating differences in HRV (SDNN) (Table S3, Multimedia Appendix 1). A significant reduction in the amplitude of the circadian pattern of SDNN was observed between participants with high compared to medium (*P*<.001) and low (*P*=.008) emotional support (Figure 2A and 2B). There was a significant reduction in the acrophase of the circadian pattern of SDNN in participants with high emotional support compared to those with medium (*P*<.001) and low (*P*=.004) emotional support. Significant changes in the circadian pattern of SDNN were also observed when the cohort was stratified based on baseline resilience (Figure 2C and 2D). The amplitude of the circadian pattern of SDNN was significantly lower in subjects with high resilience compared to those with low (*P*<.001) and medium (*P*<.001) resilience. Similarly, the acrophase of participants with high resilience was significantly reduced compared to those with medium (*P*<.001) and low (*P*=.048) resilience (Table 3).

Figure 2. Exploring the relationship between heart rate variability (HRV), emotional support, and resilience. Plots A and C show mean (95% CIs) HRV midline statistic of rhythm (MESOR), amplitude, and acrophase for participants with low, medium, and high emotional support (A) or resilience (C). Stars indicate significant differences between groups. Plots B and D show average daily circadian HRV rhythm for participants with low, medium, and high emotional support (B) or resilience (D). +*P*<.10, **P*<.05, ***P*<.01, ****P*<.001. SDNN: standard deviation of NN intervals.

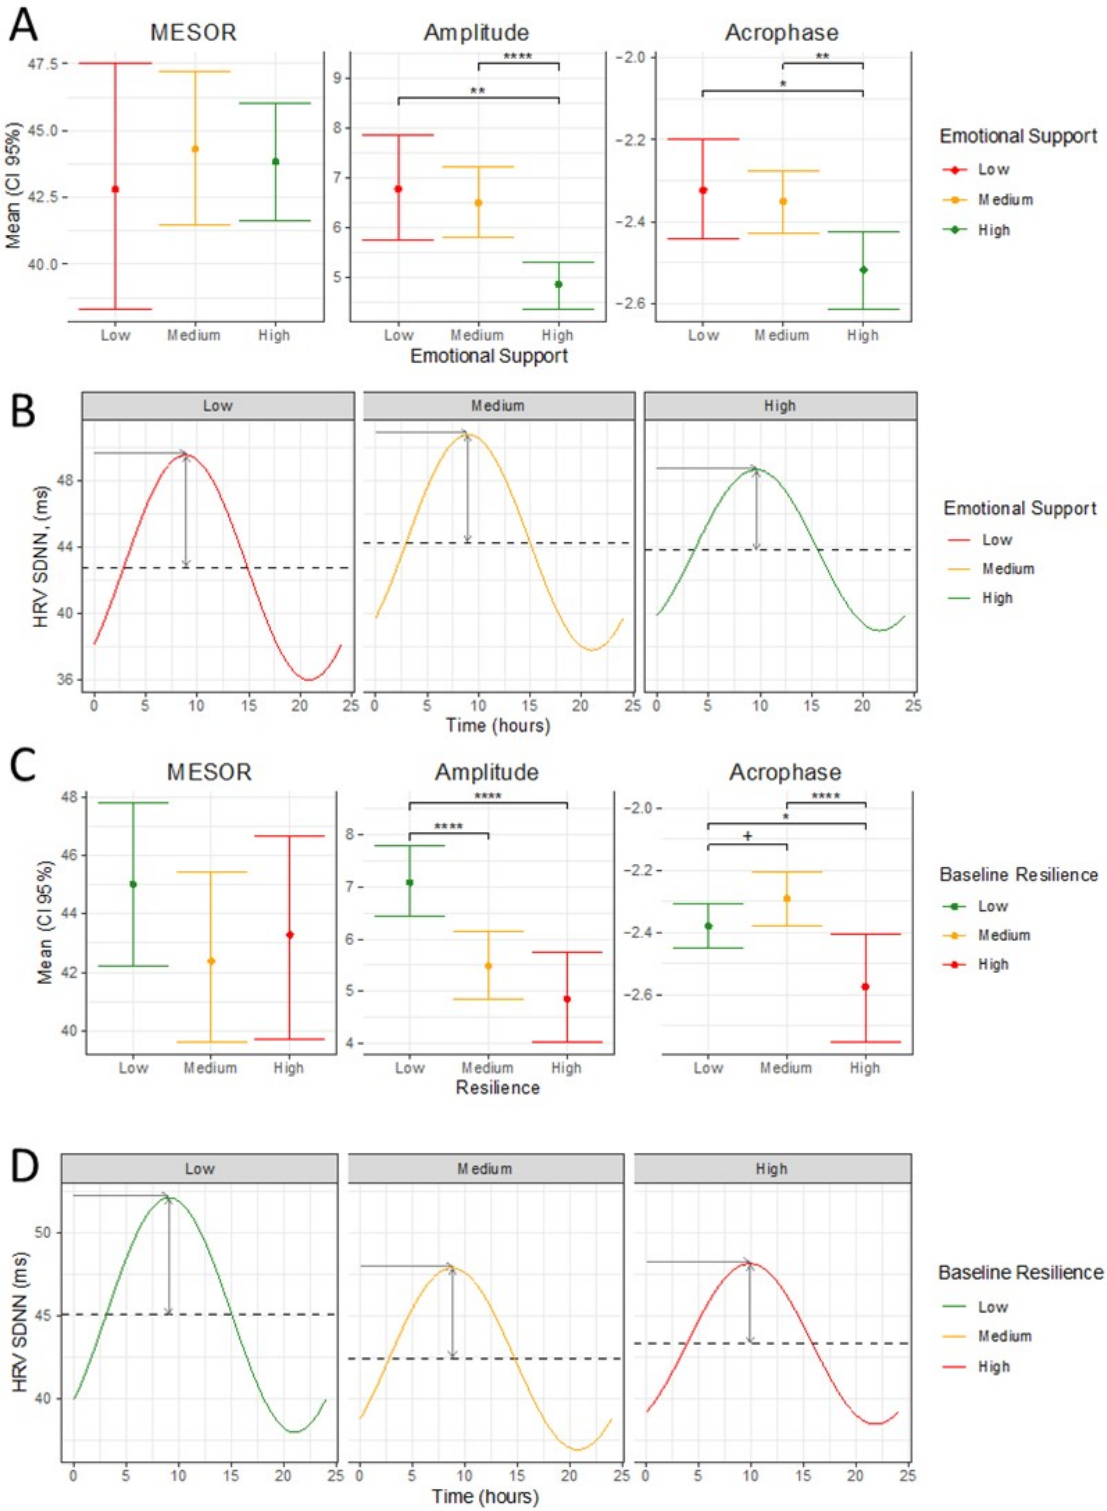


Table 3. Comparison of mean heart rate variability parameters stratified based on emotional support and resilience tertials.

Parameter and tertial comparisons	Emotional support, *P* value	Resilience, *P* value
MESOR[a]		
Low vs medium	.60	.10
Low vs high	.67	.46
Medium vs high	.78	.71
Amplitude		
Low vs medium	.68	<.001
Low vs high	.01	<.001
Medium vs high	<.001	.24
Acrophase		
Low vs medium	.70	.09
Low vs high	.004	.048
Medium vs high	<.001	<.001

Discussion

Principal Results and Comparison With Prior Work

In summary, to the best of our knowledge, we conducted the first study identifying HCW characteristics that correlate with longitudinal stress during the COVID-19 pandemic and identified employees at risk of psychological sequela. We found worsening longitudinal stress to be associated with the number of COVID-19 cases in the community, highlighting the effect of this environmental stressor. Baseline emotional support, resilience, and quality of life, rather than occupation class, defined which HCWs were prone to perceived longitudinal stress and characterized a unique ANS stress profile.

In line with our findings, prior work shows that emotional support and resilience buffer against stress [21,22]. Resilience, defined as a reduced vulnerability to environmental stressors and the ability to overcome difficulty, is crucial to establishing social relationships and is tied to social support, which also acts as an environmental protective factor against adversity [23-25]. In addition to demonstrating their stress protective effect in the multivariate analysis, when we further evaluated the COVID-19 case count of New York City, a factor associated with longitudinal stress over time, we again found that those with lower emotional support or resilience were vulnerable to a dynamic stress response uncoupled from the environmental COVID-19 stressor. Similarly, the transient reduction in stress that occurs after a COVID-19 diagnosis only occurs in those with high emotional support and resilience. Importantly, these latter findings highlight how high resilience or high emotional support can minimize the impact of factors associated with longitudinal stress in HCWs.

A strength of our study is the objective assessment of this observation through longitudinal HRV measurements. HRV is a marker of physiological stress on the ANS. Repeated stressors that are felt to be unmanageable and overwhelming may lead to an impaired stress response characterized by altered autonomic and hypothalamic-pituitary-adrenal axis function [26,27]. Buffers to stress, such as resilience, have also been shown to impact ANS function and are associated with an activation of the sympathetic nervous system that is sufficient to respond to a stressor but not to a degree that results in the development of negative psychological effects [19]. Resilience has been shown to moderate the relationship between perceived stress and the hypothalamic pituitary adrenal axis, which acts as a primary mediator of the physiological stress response [28]. Studies evaluating resilience have demonstrated an associated characteristic ANS profile, with higher vagal indices and with a baseline sympathovagal balance shifted toward parasympathetic predominance [27,29]. Resilience has been associated with the modulation of sympathetic nervous system activation, allowing for an adequate response to a stressor but with moderation of the degree of activation and a rapid return to baseline. This allows for a stable emotional response and reduced chronic anxiety [27,30,31]. Our findings extend these observations into HCWs during the COVID-19 pandemic. We found that buffers of stress, such as high resilience or high emotional support, were characterized by a physiologically distinct ANS profile confirming their impact on how individuals respond to stressors. These findings substantiate the effect these features have on longitudinal stress in HCWs in multiple dimensions, reaffirming their importance not only in the perception of stress but also in how HCWs are physiologically affected by the COVID-19 pandemic stressor.

Our findings have implications for how HCWs can be assessed for the pandemic's detrimental psychological effects, through screening for an individual's degree of resilience and social support. Evaluation of these characteristics will assist health care institutions in allocating often limited psychological support services to at-risk individuals. Importantly, one of these features, resilience, is modifiable through targeted interventions. This provides an opportunity to build resilience in HCWs who are found to have low resilience. While further studies are needed on the impact of such interventions in HCWs, they may mitigate the physiological impact of longitudinal stress. Several resilience

building interventions have demonstrated to be effective in HCWs [32,33]. However, our findings linking HRV alterations with degree of resilience, makes HRV focused resilience building exercises an attractive option [34].

Strengths and Limitations

Strengths of the study are its multicenter, longitudinal study design. Furthermore, the number and type of longitudinal variables we captured allowed for a robust multivariate analysis. Lastly, the incorporation of ANS parameters provided an objective assessment of the stress response. However, there are several limitations to our study. The Apple Watch provides HRV data in one-time dimension (SDNN), limiting evaluation of other metrics with outcomes of interests. The Apple Watch also provides HRV sampling sporadically throughout the day. While our modeling accounts for this, a denser sampling would allow expanded analyses. Additionally, HRV can be impacted by many environmental factors that cannot be fully accounted for in such studies. While we tried to control for relevant covariates, there is the potential for unmeasured factors to impact our results.

Conclusions

We identified features associated with longitudinal perceived stress in HCWs during the COVID-19 pandemic. The COVID-19 case count of New York City was significantly associated with increased longitudinal perceive stress, and baseline emotional support, quality of life, and resilience were associated with decreased longitudinal perceived stress. Furthermore, high resilience and high social support impacted the physiological stress response and were associated with a unique autonomic nervous system profile. This demonstrates the importance of resilience and social support on both perception of stress and its physiological impact.

Abstract

Background: Technologies have been extensively implemented to provide health care services for all types of clinical conditions during the COVID-19 pandemic. While several reviews have been conducted regarding technologies used during the COVID-19 pandemic, they were limited by focusing either on a specific technology (or features) or proposed rather than implemented technologies.

Objective: This review aims to provide an overview of technologies, as reported in the literature, implemented during the first wave of the COVID-19 pandemic.

Methods: We conducted a scoping review using PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-analyses) Extension for Scoping Reviews. Studies were retrieved by searching 8 electronic databases, checking the reference lists of included studies and relevant reviews (backward reference list checking), and checking studies that cited included studies (forward reference list checking). The search terms were chosen based on the target intervention (ie, technologies) and the target disease (ie, COVID-19). We included English publications that focused on technologies or digital tools implemented during the COVID-19 pandemic to provide health-related services regardless of target health condition, user, or setting. Two reviewers independently assessed the eligibility of studies and extracted data from eligible papers. We used a narrative approach to synthesize extracted data.

Results: Of 7374 retrieved papers, 126 were deemed eligible. Telemedicine was the most common type of technology (107/126, 84.9%) implemented in the first wave of the COVID-19 pandemic, and the most common mode of telemedicine was synchronous (100/108, 92.6%). The most common purpose of the technologies was providing consultation (75/126, 59.5%), followed by following up with patients (45/126, 35.7%), and monitoring their health status (22/126, 17.4%). Zoom (22/126, 17.5%) and WhatsApp (12/126, 9.5%) were the most commonly used videoconferencing and social media platforms, respectively. Both health care professionals and health consumers were the most common target users (103/126, 81.7%). The health condition most frequently targeted was COVID-19 (38/126, 30.2%), followed by any physical health conditions (21/126, 16.7%), and mental health conditions (13/126, 10.3%). Technologies were web-based in 84.1% of the studies (106/126). Technologies could be used through 11 modes, and the most common were mobile apps (86/126, 68.3%), desktop apps (73/126, 57.9%), telephone calls (49/126, 38.9%), and websites (45/126, 35.7%).

Conclusions: Technologies played a crucial role in mitigating the challenges faced during the COVID-19 pandemic. We did not find papers describing the implementation of other technologies (eg, contact-tracing apps, drones, blockchain) during the first

wave. Furthermore, technologies in this review were used for other purposes (eg, drugs and vaccines discovery, social distancing, and immunity passport). Future research on studies on these technologies and purposes is recommended, and further reviews are required to investigate technologies implemented in subsequent waves of the pandemic.

technologies; digital tools; COVID-19; novel coronavirus; scoping review; digital health; telemedicine

Introduction

Background

Since late 2019, COVID-19 has spread rapidly across the globe, leading to 175 million infections and nearly 3.8 million deaths worldwide [1]. Health care systems quickly became overwhelmed with the influx of patients, which led to overcrowded or inaccessible hospitals, delayed interventions for time-sensitive conditions and chronic illnesses, and overworked treatment teams that lacked proper personal protective equipment [2].

While developing strategic implementations to eradicate the disease, treatment providers, government entities, and individuals relied on technologies to mitigate some of the disastrous effects of COVID-19. Specifically, technologies have been used by treatment providers working with patients via telehealth; for contact tracing, screening, diagnosing COVID-19, establishing vaccination or immunity passports, and delivering foods, medications, and equipment; for predicting the trend of the pandemic, drug and vaccine discovery, social distancing; and for monitoring quarantined individuals [3]. Technological support played an integral role in guiding these forms of treatment and newly implemented policies likely prevented an even greater global crisis.

Despite the technological advancements introduced as a result of COVID-19, which some researchers have referred to as a "digital revolution," more technologies are still required to alleviate the impact of COVID-19. For instance, hospital-at-home care has yet to be widely introduced, despite many patients who may benefit from this treatment [4]. While less-urgent telehealth visits have played a large role in keeping health care facilities at an appropriate patient capacity, the hospital-at-home model would allow for patients to receive treatment comfortably at home. Patients treated at home would likely not contribute to overcrowding or take up valuable personal protective equipment resources that treatment providers may need for more serious uses. Other researchers have commented that the use of artificial intelligence—which has grown instrumentally throughout the COVID-19 pandemic—has been sparing in assisting surgeons [5]. There is hope that, in the future, artificial intelligence can facilitate patient recovery by something as advanced as implementation in surgery or as simple as patient ventilatory parameter adjustment.

Overall, technologies have played an integral part in keeping communities safe and informed, giving treatment providers innovative ways to effectively perform their duties, and providing government administrations real-time information on the virus' effects.

Research Problem and Aim

Since the first COVID-19 infection was recorded in December 2019 [6], researchers have written extensively on how technology has played a crucial role in the fight against COVID-19—several reviews have been conducted about technologies used during the pandemic. For instance, Davalbhakta et al [7] reviewed mobile apps and assessed their quality, with the primary purpose of mitigating issues related to COVID-19. Gao et al [8] conducted a rapid review about the use of telemedicine for COVID-19 for any purpose. Another review [9] explored the COVID-19–related uses of the Internet of Things, unmanned aerial vehicles, blockchain, artificial intelligence, and 5G.

While these reviews [7-9] play a substantial role in informing how technologies have been used to control the spread of COVID-19, they have been limited by either their topic or their nature. Specifically, most reviews [3,7,8,10] only focused on one or a few technologies at a time, which is an approach that does not allow for gauging the all-encompassing scope of technology use during this pandemic. Moreover, some reviews were literature reviews; therefore, they were not systematic or comprehensive (ie, as systematic reviews and scoping reviews are) [11]. Lastly, some reviews included proposed technologies, rather than technologies that had been implemented [3,10]. In contrast, we aimed to provide an overview of technologies, as reported in the literature, that were implemented during the first wave of the COVID-19 pandemic.

Methods

Overview

To achieve the above-mentioned objective, while ensuring both replicable and transparent methods, we conducted a scoping review using PRISMA ((Preferred Reporting Items for Systematic Reviews and Meta-analyses) Extension for Scoping [12].

Search Strategy

Search Sources

We searched the following electronic databases on August 14, 2020: MEDLINE (via Ovid), EMBASE (via Ovid), PsycInfo (via Ovid), Scopus, Web of Science, IEEE Xplore, ACM Library, and Google Scholar. To account for Google Scholar's vast number of results, only the first 100 citations (sorted by relevance) were screened. To identify additional studies, eligible studies' reference lists were checked, and papers that cited eligible studies were checked.

Search Terms

To develop the search queries (Multimedia Appendix 1), 2 experts in digital health were consulted and other systematic reviews of relevance to the review were checked. Terms were chosen based on the target intervention (ie, technologies) and the target disease (ie, COVID-19).

Study Eligibility Criteria

We included papers that focused on technologies or digital tools implemented during COVID-19 to provide health-related services (eg, consultations, diagnosis, and follow-up) regardless of the target health condition, user, or setting. Studies that only proposed technologies (ie, that did not implement technologies) or focused on technologies for providing non–health-related services (eg, shopping, food delivery) were excluded. Peer-reviewed journal articles were considered, along with conference proceedings, theses, dissertations, preprints, and reports. We restricted our search to studies published between January 1, 2020 to August 14, 2020. Conference abstracts, proposals, editorials, commentaries, and non–English-language papers were excluded. No restrictions related to country of publication, outcome measure, and study design were applied.

Study Selection

We followed 3 steps to identify the relevant papers: (1) duplicates were identified and removed using EndNote (Clarivate Analytics). (2) Reviewers (AH and IA) independently checked the titles and abstracts of all identified studies. (3) The 2 reviewers independently read the full texts of papers included from the second step. Any disagreements between the 2 reviewers were resolved by consulting a third reviewer (AA).

Data Extraction and Synthesis

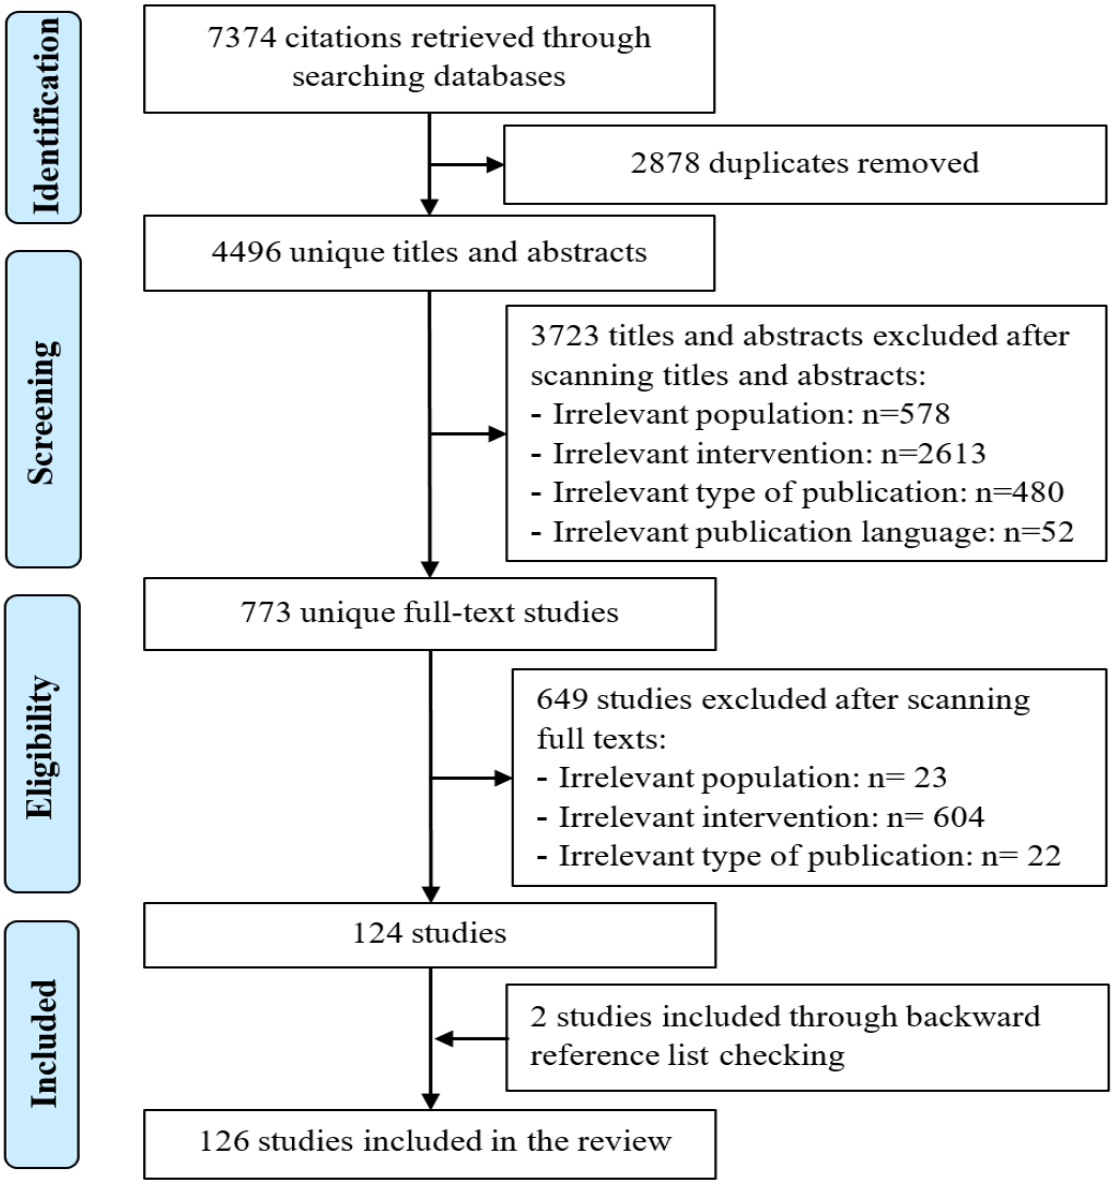
We designed a form to extract the data precisely and systematically (Multimedia Appendix 2). The form was pilot-tested using 10 eligible papers. Given the large number of eligible papers, the list was divided equally into 2 lists. While AA and MA independently extracted the data from the first list, AAA and US independently extracted data from the second list. Any disagreements between the reviewers were resolved by discussion until consensus was reached. A narrative approach was then used to synthesize the extracted data; tables were also used to describe technology types, aims, target users, target health conditions, settings, and modes. Excel (Microsoft Inc) was utilized to manage data extraction and synthesis.

Results

Search Results

Of 7374 citations retrieved through the search (Figure 1), 2878 duplicates were identified and removed. The remaining 4496 citation titles and abstracts were screened, of which 3723 citations were excluded. In total, 126 publications were included in this review [13-138].

Figure 1. Flowchart of the study selection process.



Characteristics of the Included Studies

The first paper [98] was published approximately 2 months after of the emergence of COVID-19. While only 1 paper [98] was published in the first 3 months, there was a sharp increase in the number published in the 5 subsequent months (Table 1); the largest number of studies (n=39) was published in June. The majority of studies (123/126, 97.6%) were papers in peer-reviewed journals, while the remaining studies were reports (n=2) and preprints (n=1). Studies were conducted in 23 different countries—the largest number of studies was carried out in the United States (51/126, 40.5%), followed by China (15/126, 11.9%), Italy (11/126, 8.7%), and India (10/126, 7.9%). Multimedia Appendix 3 shows the characteristics of each study.

Table 1. Characteristics of studies.

Characteristic	Studies (n=126), n (%)	Reference

Characteristics of Technologies

The 126 studies featured 11 different types of technologies used during the first wave of COVID-19 (Table 2). The most common type was telemedicine, which was used in approximately 84.9% of the studies (107/126). The mode of telemedicine was synchronous in 83 studies, asynchronous in 8 studies, and both in 17 studies. Technologies (Multimedia Appendix 4) were used for 20 different purposes. The most common aims of the technologies were providing consultations (75/126, 59.5%), following up with patients (45/126, 35.7%), and monitoring patient health status (22/126, 17.4%).

[a]Numbers do not add to total.

[b]Number of telemedicine studies (n=108) was used to calculate percentages.

[c]We were able to identify the type of technology development in 79 studies; therefore, we used this number to calculate percentages.

The type of technology development was identified in 79 studies (Table 2). Technologies in these 79 studies were designed to provide the respective purpose from the beginning (46/79, 58.2%), or used for other purposes rather than the purpose for which they had been developed (45/79, 57.0%). Studies utilized 8 social media and videoconferencing platforms. The most common platforms were Zoom (22/126, 17.5%) and WhatsApp (12/126, 9.5%). The target users in the studies were health care professionals (15/126, 11.9%), health consumers (5/126, 4%), health care professionals as well as health consumers (103/126, 81.7%), and decision makers (3/126, 2.4%). Technologies in the studies targeted 19 groups of health conditions. The most targeted health condition by the technologies was COVID-19 (38/126, 30.2%), followed by any physical health conditions

(21/126, 16.7%) and mental health conditions (13/126, 10.3%). Multimedia Appendix 5 shows characteristics of the technologies used for COVID-19.

Technologies provided services to individuals in hospitals in 64.3% (81/126), medical clinics in 36.5% (46/126), and the community in 5.6% (7/126) of the studies. Technologies were web-based in 84.1% of the studies (106/126) and non–web-based in half of the included studies. Technologies were used through 11 modes. The most common mode was mobile apps (86/126, 68.3%), followed by desktop apps (73/126, 57.9%), telephone calls (49/126, 38.9%), and websites (45/126, 35.7%).

Discussion

Principal Findings

This review features all technologies utilized in the first efforts to provide health care services for all kinds of clinical conditions during the pandemic, which ideally provides a holistic perspective of technology use during the initial stages of the COVID-19 pandemic. Only 1 paper [98] was published in the first 3 months of the pandemic, whereas the number of the studies significantly increased in subsequent months. This may be attributed to the fact that the process of developing technologies, writing a report on its use, and publishing the report likely require at least 3 months. Furthermore, experts suggest that evidence-based technology adoption is critical for designing, using, and implementing digital tools in the fight against COVID-19 [139]. Most technologies were implemented in the United States. This is expected given that the United States is both the country most infected by COVID-19 [1] as well as highly advanced in technologies.

As evident from the results, telemedicine was the most frequently utilized technology in papers published from January to August 2020. One of the main challenges during the first few months of the pandemic was providing necessary health care services while simultaneously mitigating the risk of infection for patients and health care workers from inadequate supplies of personal protective equipment. The majority of studies included in this review reported the use of synchronous telemedicine, which can improve access to specialized care services at familiar settings (ie, homes) in a more time- and cost-effective manner [140,141]. Similar to earlier reviews, our results showed that telemedicine was used for COVID-19 screening, providing health care advice, and mental health therapy [8]. The remainder of the technologies reported in the studies involved the use of clinical decision support tools, robotic systems, and symptom trackers. While many other technologies were implemented during the first wave of COVID-19 (eg, contact-tracing apps and drones [11]), our review did not report any. This could be attributed to the fact that (1) there are no publications on each technology implemented during COVID-19, (2) only studies published in English were included in this review, and (3) only academic literature was searched.

Several social media and videoconferencing platforms were used in the first wave. Zoom was the most commonly used; this may be attributed to the fact that Zoom is one of the Health Insurance Portability and Accountability Act–compliant teleconferencing platforms and has been integrated into electronic health record systems in many health care settings [31,67,87]. This review also found that most of the implemented technologies targeted both health care providers and health consumers. This is likely because extreme measures (eg, lockdowns; curfews; and closures of many businesses, spaces, and organizations) imposed to prevent the spread of COVID-19 immensely disrupted the routine delivery of health care services to many patients—especially those with chronic conditions—therefore, technologies were required to keep patients and health care providers connected.

COVID-19 was the most targeted health condition by the technologies. This can be attributed to the fact that COVID-19 was given priority over other health conditions in the first wave, when there were extremely large numbers of daily infections, and no treatment or vaccine was available. Mobile apps were the most common venue used to target illness during this time period, as well. This is reasonable given the widespread use of mobile devices over the world [142].

Research and Practical Implications

Modern medicine relies on evidence-based practices and interventions. Many researchers argue that digital health tools and technologies are not exempt and should be evaluated and validated to demonstrate their efficacy [143]. Widespread technology adoption relies heavily upon the availability of evidence regarding technology's effectiveness [144]. While there is a sense of urgency because of the COVID-19 pandemic and its impact on every aspect of daily living, evaluation of digital tools' and technologies' effectiveness remains paramount. However, since the COVID-19 pandemic is still ongoing, there are copious amounts of digital tools and technologies that need to be peer-reviewed, undergo rigorous testing, and be integrated into public health systems [11].

Many digital interventions have failed to be integrated into national systems due to low levels of acceptance at that scale; many digital interventions have been successful at pilot scales only [145,146]. Therefore, it is integral to carefully evaluate digital health tools and technologies by providing validated, documented, and reproducible clinically meaningful evidence [143,147]. There is a need for more peer-reviewed evidence-based research into the effectiveness of these digital tools and technologies.

Overall, there is emerging consensus that digital tools and technologies play a central role in public health interventions during public health outbreaks (eg, the COVID-19 pandemic) by complementing and augmenting traditional or nondigital interventions [11]. However, despite the promise of technologies' benefits, such as alleviating the impact of COVID-19 (such as providing access to health care services during lockdowns through telemedicine), solely relying on these technologies may widen disparities and exacerbate existing vulnerabilities of those who are unable to adopt or afford these technologies [148]. These digital tools and technologies pose the risk of generating informatics-based (or digital) inequalities that disproportionately favor groups with socioeconomic advantages [149]. Therefore, health system leaders,

informaticians, and policy makers need to consider and act upon underlying factors contributing to inequalities in terms of access to resources, digital literacy, and usability [150].

To ensure sustainable investments, use, and adoption in digital tools and technologies after the COVID-19 pandemic has been resolved, issues related to regulating and reimbursing the use of these tools and technologies need to be addressed [151]. Additionally, it is paramount that it is not assumed that digital tools and technologies will naturally become integrated into routine clinical practice post–COVID-19; participatory approaches that include all stakeholders are essential to sustaining the use and adoption of digital tools and technologies [152].

Strengths and Limitations

Strengths

To the best of our knowledge, this paper is the first review to explore all technologies implemented to provide health care services during COVID-19. This review can be considered comprehensive as it does not focus on specific technologies, diseases, users, settings, or countries. Therefore, the review provides a holistic view of the role of technologies during COVID-19 to help decision makers, health care providers, and health care consumers understand the potentials of technologies.

Given that we followed well-recommended guidelines in developing, executing, and reporting this review, it can be considered a robust and high-quality review. The search was sensitive and precise because the most popular databases in health and information technology were searched using a well-developed search query.

The risk of publication bias is minimal in this review because of the strategies that were used, such as searching grey literature databases (ie, Google Scholar) and backward and forward reference list checking. Furthermore, this review has a low risk of selection bias because study selection and data extraction were conducted by 2 reviewers independently.

Limitations

Although the search query consisted of 89 terms related to technologies, it is possible that other terms related to technologies were missed. Therefore, it is likely that several relevant studies were not included. Because of practical constraints, the search was restricted to English studies. Therefore, several studies written in other languages were not included.

This review focused on implemented technologies and excluded proposed technologies, which perhaps could have been subsequently implemented. Thus, several important technologies were not considered in our review. Although this review shows the potential of technologies, it cannot comment on their effectiveness, as it is beyond the scope.

Conclusion

Technologies played a crucial role in mitigating challenges arising from the COVID-19 pandemic, and in the first wave, numerous technologies were used for various purposes. However, we did not find papers on other technologies such as contact-tracing apps, drones, blockchain, unmanned aerial vehicles, wearable devices, and personal protective equipment that were implemented during the first wave of the pandemic. Furthermore, technologies reported in the studies were used for other purposes, such as drug and vaccine discovery, social distancing, and immunity passports. Therefore, it is recommended that researchers conduct studies on these technologies and purposes. Further reviews are required about technologies implemented in subsequent waves of the COVID-19 pandemic. There is also a need for more peer-reviewed evidence-based research into the effectiveness of these digital tools and technologies and users' satisfaction.

Abstract

Background: The COVID-19 pandemic has turned the care model of health systems around the world upside down, causing the abrupt cancellation of face-to-face visits and redirection of the model toward telemedicine. Digital transformation boosts information systems—the more robust they are, the easier it is to monitor the health care system in a highly complex state and allow for more agile and reliable analysis.

Objective: The purpose of this study was to analyze diagnoses from primary care visits and distinguish between those that had higher and lower variations, relative to the 2019 and 2020 periods (roughly before and during COVID-19), to identify clinical profiles that may have been most impaired from the least-used diagnostic codes for visits during the pandemic.

Methods: We used a database from the Primary Care Services Information Technologies Information System of Catalonia. We analyzed the register of visits (n=2,824,185) and their *International Classification of Diseases* (*ICD-10*) diagnostic codes (n=3,921,974; mean 1.38 per visit), as approximations of the reasons for consultations, at 3 different grouping levels. The data were represented by a term frequency matrix and analyzed recursively in different partitions aggregated according to date.

Results: The increase in non–face-to-face visits (+267%) did not counterbalance the decrease in face-to-face visits (–47%), with an overall reduction in the total number of visits of 1.36%, despite the notable increase in nursing visits (10.54%). The largest increases in 2020 were visits with diagnoses related to COVID-19 (*ICD-10* codes Z20-Z29: 2.540%), along with codes related to economic and housing problems (*ICD-10* codes Z55-Z65: 44.40%). Visits with most of the other diagnostic codes decreased in 2020 relative to those in 2019. The largest reductions were chronic pathologies such as arterial hypertension (*ICD-10* codes I10-I16: –32.73%) or diabetes (*ICD-10* codes E08-E13: –21.13%), but also obesity (E65-E68: –48.58%) and bodily injuries (*ICD-10* code T14: –33.70%). Visits with mental health–related diagnostic codes decreased, but the decrease was less than the average decrease. There was a decrease in consultations—for children, adolescents, and adults—for respiratory infections (*ICD-10* codes J00-J06: –40.96%). The results show large year-on-year variations (in absolute terms, an average of 12%), which is representative of the strong shock to the health system.

Conclusions: The disruption in the primary care model in Catalonia has led to an explosive increase in the number of non–face-to-face visits. There has been a reduction in the number of visits for diagnoses related to chronic pathologies, respiratory infections, obesity, and bodily injuries. Instead, visits for diagnoses related to socioeconomic and housing problems have increased, which emphasizes the importance of social determinants of health in the context of this pandemic. Big data analytics with routine care data yield findings that are consistent with those derived from intuition in everyday clinical practice and can help inform decision making by health planners in order to use the next few years to focus on the least-treated diseases during the COVID-19 pandemic.

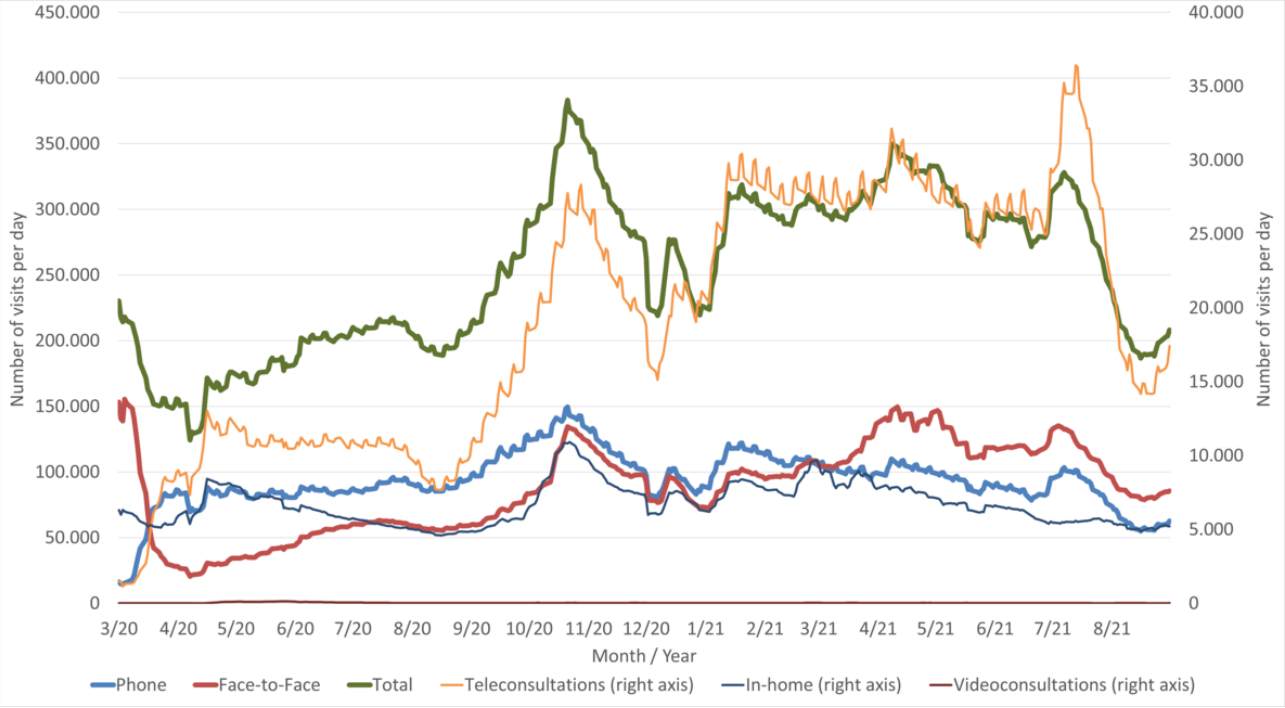
Introduction

The COVID-19 pandemic has turned the care model of health systems around the world upside down, with the abrupt cancellation of face-to-face visits, redirection of the model toward non–face-to-face care, and then the gradual recovery of services, first for priority population sectors and later for the general population [1-4]. Telemedicine in primary care in Catalonia includes provider–patient or provider–provider communications and can take place synchronously (telephone or video calls) or asynchronously (teleconsultations). By the end of February 2021, all face-to-face activity had not yet recovered, although the total number of visits was approximately 15% higher than that at the start of the pandemic (Figure 1), in part because of the increasing use of telemedicine (mostly in the form of telephone consultations).

Figure 1. A 7-day rolling average (with weekends and holidays not included) of primary care daily visits in Catalonia, by type, from March 2020 to August 2021 (unpublished data, Catalan Ministry of Health).



Because of the disruptions, health systems have begun to identify population profiles that may be most adversely affected by changes and underdiagnosed diseases during the pandemic [5-8]. Some patients have had to wait longer than before to receive health care. It has been observed, for example, that cardiac arrests outside hospital have increased, with patients having worse prognoses [9], or that patients with heart failure have had fewer admissions, but when admitted, heart failure has been more severe and admission to the intensive care unit is required more often [10]. It has also been noted that access to telemedicine visits has not been the same for the whole population and that, when this type of care becomes predominant, inequalities in access to care may arise [11,12].

According to a recent study [13], COVID-19 has resulted in loss of years of life over 7 times greater than that in a typical influenza season in Spain. The health emergency has precipitated policy maker decision-making that has often been without any existing evidence and with long delays [14], but it has also highlighted the value of information systems and, more generally, the role of health policy evaluation agencies [15]. Robust information systems make it easier to assess and monitor the health system in a highly complex state and allow for agile and reliable analysis. In this context, we explored the potential for the use of a massive amount of primary care data from the Catalan public health system to inform quick, granular decision making regarding which areas have been most neglected as a

result of the change in the care model. Specifically, we aimed to identify which diagnoses in primary care have increased and decreased from 2019 to 2020 (approximately before and during the COVID-19 pandemic), in order to determine which areas need to be strengthened in view of the gradual recovery of health system activity.

Methods

Ethics

The study was conducted according to the guidelines of the Declaration of Helsinki and in accordance with European General Data Protection Regulations and the Spanish Organic Law on Data Protection and Guarantee of Digital Rights. No ethical approval was required; analyses were conducted only on aggregated data.

Data

The Catalan health system provides universal coverage to 7.6 million inhabitants. Administratively, it is composed of a single public payer and several publicly or privately owned service providers, in an integrated system and with an important role of community and primary health care and the use of information technology. We used a database from the Primary Care Services Information Technologies System of the Health Region of Central Catalonia (Catalonia, Spain) belonging to the Catalan Institute of Health. In this region, the Health Information System is used by the majority (32/37, 86.48%) of Primary Care centers, which facilitated analysis. The variable of interest was primary care visits according to the *International Statistical Classification of Diseases tenth revision* (*ICD-10*) [16] diagnostic codes. These codes were used as a proxy for the reason for the visit.

Data from primary care visits in 2020 (the period covering most of the COVID-19 pandemic) and 2019 (the period used as a comparator)—both face-to-face (at the primary care center or at home) and non–face-to-face (telemedicine tools including telephone and teleconsultations)—were analyzed. One visit could result in several diagnostic codes and not all visits were associated with at least one, as doing so is not mandatory in the Catalan primary care electronic health record. Consequently, the data set was reduced to visits in which at least one diagnosis had been identified.

Statistical Analysis

Diagnostic codes attributed to visits were analyzed at 3 levels of aggregation: aggregation level 1 (21 codes, with format "Neoplasms, C00-D49"), which corresponds to the concept of *chapters* according to the reference *ICD-10* dictionary [16]; aggregation level 2, which was a second, more specific grouping (284 different codes, formatted "Malignant neoplasms of digestive organs, C15-C26"), which corresponded to the concept of *blocks* in the above-mentioned dictionary; and aggregation level 3, which was a third grouping with even more specificity (1532 different codes, with the format "Malignant neoplasm of anus and anal canal, C21").

The variety of diagnostic codes used in clinical practice suggested that there would be a need for the use of big data analysis techniques. Visit data were recursively analyzed in 4 different partitions, and the diagnoses were aggregated according to date. *ICD-10* groupings were represented with a term frequency matrix [17,18], where matrix columns indicated the absolute number of each diagnostic code.

The variation index was used to represent the relative weight of the variation of a diagnostic code over the absolute total interannual variation of all codes. Thus, in addition to the frequency of use of each diagnostic code, this index takes into account the importance of each on a linear scale to allow visualization of the diagnoses on 2 scales (code frequency and variation index). Data were analyzed using R (version 3.4.3; R Foundation for Statistical Computing).

Results

There were 3,555,799 primary care visits for 376,486 citizens (a total of 404,245 citizens are in the reference population of this health region) in 2019 and 2020, and at least one diagnosis was identified in 79.43% of visits (2824371/3,555,799). The degree of coding is slightly higher in the face-to-face visits compared to the non-face-to-face visits Regarding the effects of the pandemic on missing data, during 2019, 18.46% (262,460/1,421,779) of visits had no associated diagnoses, while in 2020, missing instances reached 22.50% (315,541/1,402,406), representing a limited impact on reported outcomes. The final database was composed of 2,824,185 visits for 358,419 different citizens, with 3,921,974 diagnostic visit codes (1.38 codes per visit on average; 3.5% of visits had more than 3 associated codes; Figure 2 and Figure 3).

Figure 2. Aggregation level 1 cumulative frequency of the 21 most used *International Statistical Classification of Diseases, tenth revision*, diagnostic codes (2019 and 2020). behav: behavioral, endoc: endocrine, malf: malformation, metabol: metabolic, nutrit: nutritional.

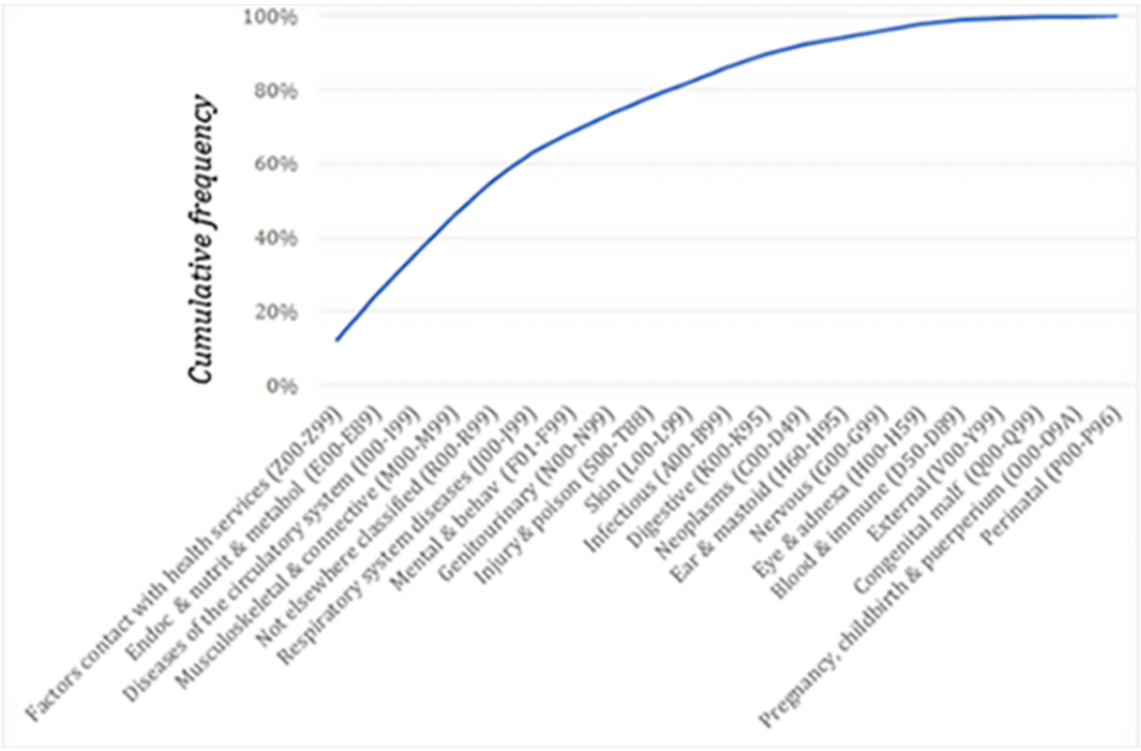


Figure 3. Aggregation level 2 cumulative frequency of the 21 most used *International Statistical Classification of Diseases, tenth revision*, diagnostic codes (2019 and 2020). dis: disease, resp/respirat: respiratory.

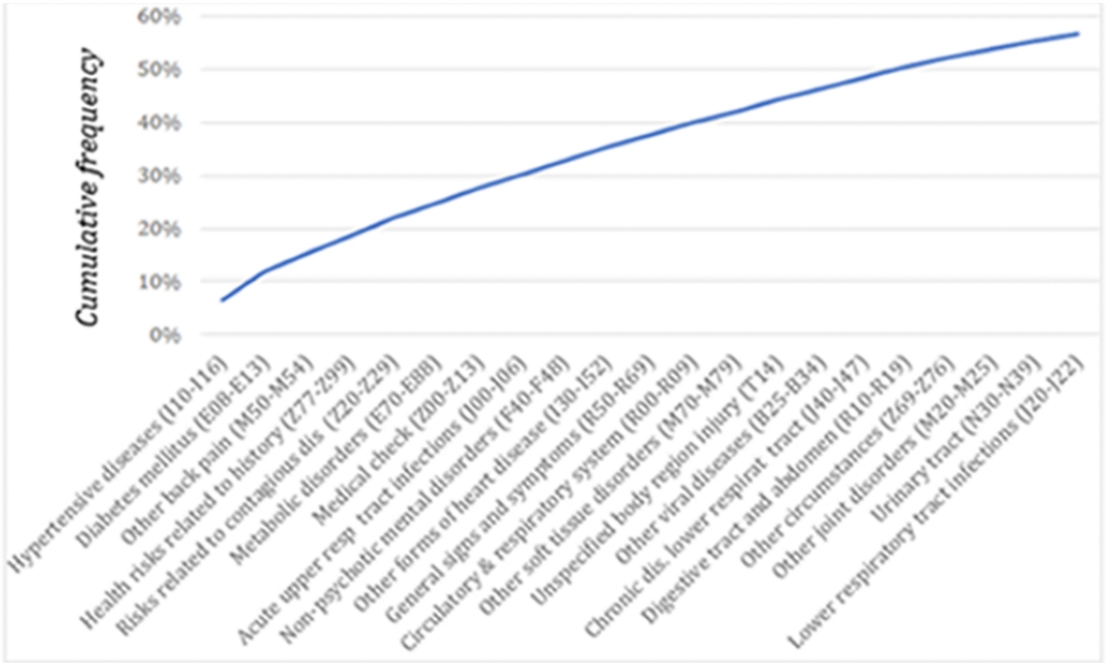

The total number of visits in 2020 decreased slightly (–1.36%) compared to those in 2019; if COVID-19–related visits are excluded, this figure is even lower (–7.56%). The type of visit changed markedly (Table 1). In 2019, most visits (1,212,800/1,421,779, 85.30%) were face-to-face, while in 2020 more than half of visits (768,548/1,402,406, 54.80%) were telemedicine. The increase in this type of visit, therefore, has not been able to compensate for the decrease in face-to-face visits.

Table 1. Evolution of visits.

Characteristic	2019	2020	Difference, %
Total patients attended	287,936	287,965	0.01
Total visits, n	1,421,779	1,402,406	–1.36
Face-to-face, n (%)	1,212,800 (85.30)	633,858 (45.20)	–47.74
Telemedicine, n (%)	208,979 (14.70)	768,548 (54.80)	267.76
General medicine, n (%)	859,153 (60.43)	822,433 (58.64)	–4.27
Nursing, n (%)	427,959 (30.10)	473,051 (33.73)	10.54
Pediatrics, n (%)	134,667 (9.47)	106,922 (7.62)	–20.60
Early childhood[a], n (%)	95,098 (6.69)	76,460 (5.45)	–24.38
Childhood[b], n (%)	57,436 (4.04)	52,101 (3.72)	–10.24
Adolescence[c], n (%)	55,768 (3.92)	61,693 (4.40)	9.60
Youth[d], n (%)	55,943 (3.93)	69,287 (4.94)	19.26
Adulthood[e], n (%)	475,366 (33.43)	514,327 (36.67)	7.58
Older adult[f], n (%)	682,168 (47.98)	628,538 (44.82)	–8.53
Total diagnostic codes, n	2,079,680	1,912,342	–10.57
Diagnostic codes per visit, mean (SD)	1.46 (1.00)	1.36 (0.89)	–6.84
Sex, n (%)			
Male	641,602 (45.13)	627,806(44.77)	–2.15
Female	780,074 (54.87)	774,486 (55.23)	–0.72
Age of visits, mean (SD)	53.54 (26.25)	52.89 (25.72)	–1.21

[a]Early childhood: 0 to 5 years old.

[b]Childhood: infancy to 11 years old.

[c]Adolescence: 12 to 18 years old.

[d]Youth: 14-26 years old.

[e]Adulthood: 27 to 59 years old.

[f]Older adult: over 60 years old.

In relation to the specialty, the number of visits with doctors decreased slightly (–4.27%), the number of visits with nurses increased (10.54%), and the number of pediatric visits decreased (–20.60%). Despite this decrease, the mean age of patients decreased by approximately 1 year (from 53.54 in 2019 to 52.89 years in 2020). There was a variation in visits according to age groups: there was a decrease in visits for patients in early childhood and infancy (from 0 to 5 years old), an increase in patients in adolescence (12 to 18 years old) to adulthood (27 to 59 years old), and a decrease in older adult patients. The proportion of visits made by women was 55.04% (1,554,560/2,824,185); the magnitude remained fairly unchanged between 2019 and 2020.

The cumulative frequency of the 21 most used diagnostic codes for the 2 first levels of grouping were analyzed (Figure 3). In the case of aggregation level 1, the 5 code groupings comprised more than half of the total number of codes (Factors influencing health status and contact with health services; Endocrine, nutritional, and metabolic diseases; Diseases of the circulatory system; Diseases of the musculoskeletal system and connective tissue; Signs, symptoms, and abnormal test results not classified elsewhere). For aggregation level 2, the 5 most-used codes comprised approximately one-quarter of the total (Hypertensive diseases; Diabetes mellitus; Other back disorders; Persons with potential health risks related to personal and family history and certain conditions influencing health status; Persons with potential health risks related to communicable diseases).

For aggregation level 1, large interannual variations were observed (Table 2), especially for diagnostic codes related to *factors influencing health status and contact with health services* (*ICD-10* codes Z00-Z99), codes that were initially used for diagnoses related to COVID-19, and the diagnosis of *certain infectious and parasitic diseases*, which nearly doubled in 2020. The rest of the codes decreased in 2020 compared to 2019; however, those related to mental health decreased less than the rest (*ICD-10* codes F01-F99: –3.39%). Diagnostic codes related to injuries were reduced by almost one-quarter (*ICD-10* codes S00-T88: –26.85%), possibly due to a drastic reduction in accidents resulting from people engaging in less activity during confinement. The variation index shows the weight of each of these variations on overall disruption (Table 3).

Table 2. Use of *International Statistical Classification of Diseases, tenth revision*, diagnostic codes (aggregation level 1).

Diagnostic code	Total, n (%)	2019, n (%)	2020, n (%)	Interannual variation, %	Variation index
Factors influencing health status and contact with health services (Z00-Z99)	483,368 (12.32)	186,604 (9.06)	296,764 (15.93)	59.03	0.22
Endocrine, nutritional, and metabolic diseases (E00-E89)	464,009 (11.83)	261,076 (12.68)	202,933 (10.90)	–22.27	0.11
Diseases of the circulatory system (I00-I99)	440,256 (11.23)	252,555 (12.26)	187,701 (10.08)	–25.68	0.13
Diseases of the musculoskeletal system and connective tissue (M00-M99)	405,813 (10.35)	224,901 (10.92)	180,912 (9.71)	–19.56	0.09
Signs, symptoms, and abnormal test results not elsewhere classified (R00-R99)	385,121 (9.82)	200,711 (9.75)	184,410 (9.90)	–8.12	0.03
Diseases of the respiratory system (J00-J99)	297,074 (7.57)	176,405 (8.57)	120,669 (6.48)	–31.60	0.11
Mental, behavioral, and neurodevelopmental disorders (F01-F99)	214,709 (5.47)	109,203 (5.30)	105,506 (5.66)	–3.39	0.01
Diseases of the genitourinary system (N00-N99)	182,642 (4.66)	96,692 (4.70)	85,950 (4.61)	–11.11	0.02
Injuries, poisonings, and other consequences of external causes (S00-T88)	182,045 (4.64)	105,135 (5.11)	76,910 (4.13)	–26.85	0.06
Diseases of the skin and subcutaneous tissue (L00-L99)	164,759 (4.20)	89,119 (4.33)	75,640 (4.06)	–15.12	0.03
Certain infectious and parasitic diseases (A00-B99)	151,999 (3.88)	52,220 (2.54)	99,779 (5.36)	91.07	0.09
Diseases of the digestive system (K00-K95)	143,793 (3.67)	78,968 (3.83)	64,825 (3.48)	–17.91	0.03
Neoplasms (C00-D49)	102,910 (2.62)	55,201 (2.68)	47,709 (2.56)	–13.57	0.01
Diseases of the ear and mastoid process (H60-H95)	81,495 (2.08)	47,699 (2.32)	33,796 (1.81)	–29.15	0.03
Diseases of the nervous system (G00-G99)	72,150 (1.84)	38,057 (1.85)	34,093 (1.83)	–10.42	0.01
Diseases of the eye and adnexa (H00-H59)	61,810 (1.58)	36,837 (1.79)	24,973 (1.34)	–32.21	0.02
Diseases of the blood and blood-forming organs and disorders affecting the immune mechanism (D50-D89)	45,551 (1.16)	25,305 (1.23)	20,246 (1.09)	–19.99	0.01
External causes of morbidity (V00-Y99)	23,659 (0.60)	12,481 (0.61)	11,178 (0.60)	–10.44	0.00
Congenital malformations. congenital deformities, and congenital chromosomal anomalies (Q00-Q99)	10,034 (0.26)	5493 (0.27)	4541 (0.24)	–17.33	0.00
Pregnancy. childbirth, and puerperium (O00-O9A)	7023 (0.18)	3788 (0.18)	3235 (0.17)	–14.60	0.00
Certain conditions originating in the perinatal period (P00-P96)	1754 (0.04)	991 (0.05)	763 (0.04)	–23.01	0.00

Table 3. Top 10 *International Statistical Classification of Diseases, tenth revision*, diagnostic codes according to the variation index.

Diagnostic code	Variation index
Aggregation level 2	
Persons with potential health risks related to communicable diseases (Z20-Z29)	0.20
Other viral diseases (B25-B34)	0.10
Hypertensive diseases (I10-I16)	0.09
Acute upper respiratory infections (J00-J06)	0.05
Diabetes mellitus (E08-E13)	0.04
Metabolic disorders (E70-E88)	0.03
Injury to unspecified body region (T14)	0.03
Other acute lower respiratory tract infections (J20-J22)	0.03
Other soft tissue disorders (M70-M79)	0.03
Other back disorders (M50-M54)	0.02
Aggregation level 3	
Contact and exposure (suspected): communicable diseases (Z20)	0.17
Viral infection of unspecified location (B34)	0.08
Essential (primary) hypertension (I10)	0.07
COVID (U07)	0.05
Diabetes mellitus type 2 (E11)	0.03
Injury to unspecified body region (T14)	0.03
Disorders of lipoprotein metabolism and other hyperlipidemias (E78)	0.02
Acute rhinopharyngitis (J00)	0.02
Dorsalgia (M54)	0.02
Overweight and obesity (E66)	0.02

The number of diagnostic codes decreased slightly (Figure 4), and those for telemedicine and face-to-face visits increased and decreased, respectively. Aggregation level 2 analysis shows that the diagnostic codes with the largest increase in 2020 were those related to COVID-19 (*ICD-10* codes Z20-Z29: 2.540%), along with codes related to economic and housing problems (*ICD-10* codes Z55-Z65: 44.40%). Visits with most of the other diagnostic codes decreased in 2020 relative to those in 2019. Visits for chronic pathologies such as arterial hypertension (*ICD-10* codes I10-I16: –32.73%) or diabetes (*ICD-10* codes E08-E13: –21.13%), but also those for obesity (*ICD-10* codes E65-E68: –48.58%) and bodily injuries (T14: –33.70%) were reduced. The results show year-on-year variations (in absolute terms, an average of 12%).

The frequencies of diagnoses (listed according to the highest variation index) in face-to-face and non–face-to-face visits were systematically negative (Table 4) and positive (Table 5), respectively. It should also be noted that none of the face-to-face visit code groups were offset by those of the non–face-to-face group (ie, the largest reductions in the former were not offset by the largest increases in the latter).

Figure 4. Primary care consultations before (in 2019) vs during (in 2020) COVID-19 (absolute frequency, log scale) according to *International Statistical Classification of Diseases, tenth revision*, codes. Each point corresponds to an *International Statistical Classification of Diseases, tenth revision*, diagnostic code. The 45° line indicates the identical frequency of diagnostic code use between periods; points above indicate the set of diagnostic codes that have been visited relatively more in 2020 and vice versa. The color of the dot indicates the value of the variation index (the higher, the more important the year-on-year variation).

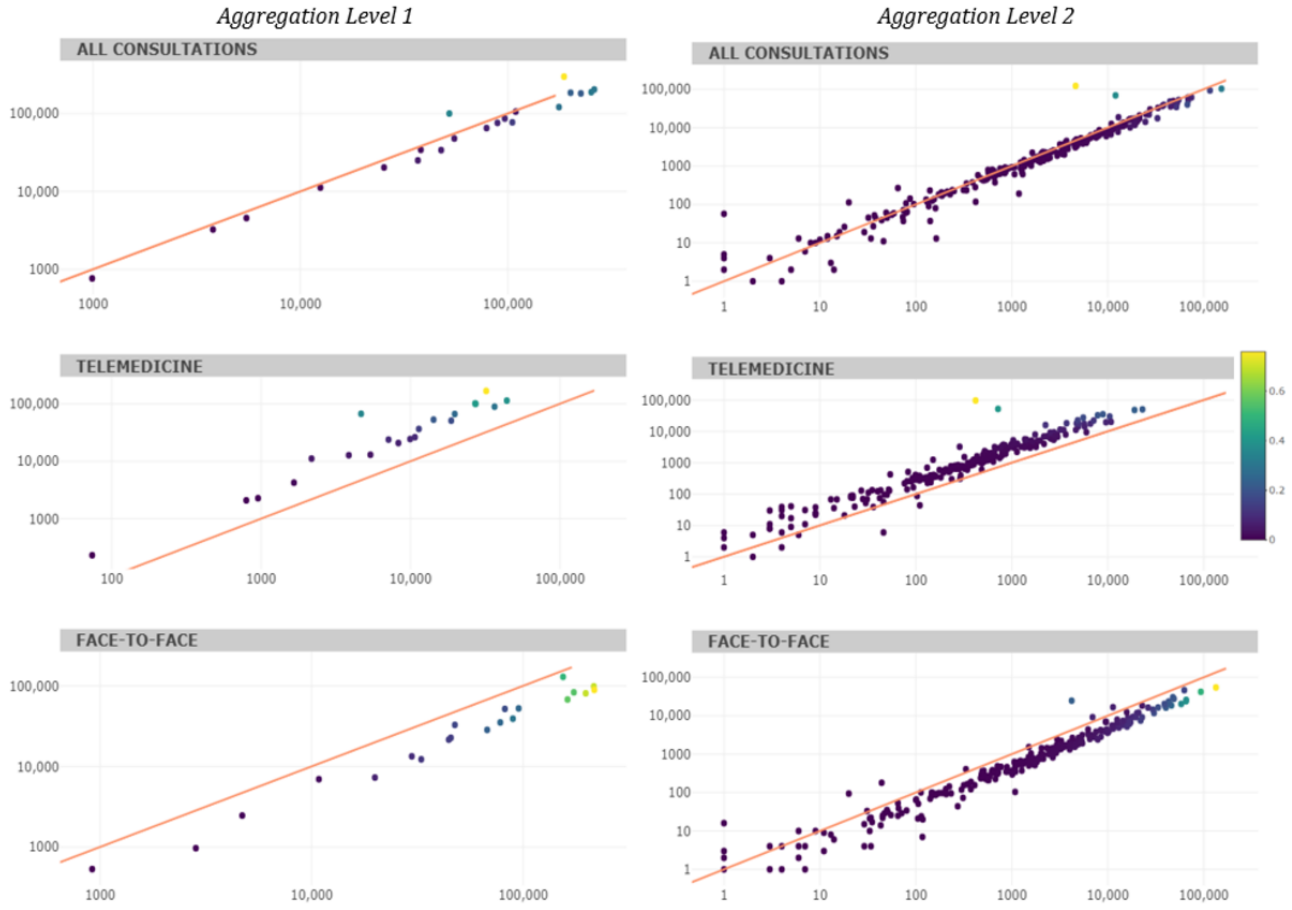

Table 4. Top 5 in variation index of diagnostic use in face-to-face visits (aggregation level 2).

ICD-10[a] diagnostic code	Total, n (%)	2019, n (%)	2020, n (%)	Interannual variation, %	Variation index
Diseases of the blood and blood-forming organs and disorders of the immune mechanism (D50-D89)	27,197 (1.03)	19,912 (1.12)	7285 (0.83)	–63.41	0.14
Mental, behavioral, and neurodevelopmental disorders (F01-F99)	128,611 (4.85)	89,415 (5.05)	39,196 (4.47)	–56.16	0.13
Diseases of the ear and mastoid process (H60-H95)	68,215 (2.57)	45,515 (2.57)	22,700 (2.59)	–50.13	0.13
Diseases of the digestive system (K00-K95)	96,028 (3.62)	67,589 (3.81)	28,439 (3.24)	–57.92	0.11
Congenital malformations, congenital deformities, and congenital chromosomal anomalies (Q00-Q99)	7107 (0.27)	4668 (0.26)	2439 (0.28)	–47.75	0.10

[a]*ICD-10*: *International Statistical Classification of Diseases, tenth revision*

Table 5. Top 5 in variation index of diagnostic use in non–face-to-face visits (aggregation level 1).

ICD-10[a] diagnostic code	Total, n (%)	2019, n (%)	2020, n (%)	Interannual variation, %	Variation index
Factors influencing health status and contact with health services (Z00-Z99)	199,464 (15.68)	32,146 (11.20)	167,318 (16.99)	420.49	0.19
Signs, symptoms, and abnormal test results not elsewhere classified (R00-R99)	128,214 (10.08)	27,092 (9.44)	101,122 (10.27)	273.25	0.11
Diseases of the musculoskeletal system and connective tissue (M00-M99)	127,293 (10.01)	27,328 (9.52)	99,965 (10.15)	265.80	0.10
Endocrine, nutritional, and metabolic diseases (E00-E89)	157,663 (12.40)	44,155 (15.38)	113,508 (11.53)	157.07	0.10
Certain infectious and parasitic diseases (A00-B99)	71,620 (5.63)	4670 (1.63)	167,318 (16.99)	1333.62	0.09

[a]*ICD-10*: *International Statistical Classification of Diseases, tenth revision*

Finally, for children, adolescents, and adults, there were decreases in consultations for respiratory infections; ear, nose and throat pathologies; and skin problems. In adults and older adults, there were overall decreases in visits for chronic pathologies, especially those for arterial hypertension and diabetes. Decreases in visits for some pathologies were counterbalanced by an increase in telemedicine visits—among adults, for back disorders, soft tissue disorders, upper respiratory tract infections, and anxiety, and among older adults, different types of neoplasms. By sex, no differences were observed in the frequency of diagnoses (Multimedia Appendices 1-3).

Discussion

Principal Findings

We analyzed the differences in distinctive characteristics of care before and after the outbreak of the COVID-19 pandemic in the context of primary care in Catalonia. As expected, the increase in the frequency of visits with diagnostic codes related to *contact with or suspected exposure to SARS-CoV-2* stands out, but those related to *housing, employment and psychosocial factors* (*ICD-10* codes Z55-Z65) are also noteworthy. On the eve of a foreseeable economic crisis, this fact underlines the importance of social determinants of health and population health management when planning reconstruction policy for the period after the pandemic, as it is well known that vulnerable population groups were the worst affected by the economic crisis [19]. The change in the pattern of visits is also visible in 2 other aspects. First, the number of visits in the nursing service increased (10.54%), while those in general medicine visits decreased (–4.27%). Second, the increasing use of non–face-to-face care tools since the start of the pandemic has served a wider and more representative cross-section of the population (traditionally underrepresented groups, including low-income individuals and patients residing in the poorest areas of the country, ie, rural areas) [12]. For this reason, since the outbreak of COVID-19, and due to the role of primary care in the management of sick leave, there seems to have been a reduction in the clinical complexity of patients seen, while patients with socioeconomic problems (eg, unemployment) have increased. Visits associated with diagnostic codes for chronic pathologies (mainly endocrine and cardiovascular diseases) have been the most affected, with a decrease in frequency that has not been counterbalanced by the increase in telemedicine.

Opportunities abound for quantifying the impact of the pandemic, in addition to analyses presented herein, on service delivery and citizens' health in order to anticipate and plan for changes in demand for health services in the coming months or years. It would be necessary to study whether, due to the lack of testing (eg, routine analysis), prescriptions performed by clinicians have been more pharmacological; which visits that were previously made in person are now conducted using telemedicine; to what extent the reduced intensity of care for chronic disease management has affected the health of citizens [6]; and whether mental health (note that the amount of this type of visit have been reduced less than the rest) will be the next pandemic [20] in order to reprioritize a care model in Catalonia which, in the opinion of the authors, was already suffering a lot of health care pressure before COVID-19.

Despite the crisis caused by the pandemic, the changes that have been made to address the crisis may improve future health systems. Big data analysis tools allow exhaustive, systematic, agile evaluation. Given the preeminence and role of primary care as the gateway to the public health system in Catalonia, the information derived from primary care information registers is very appropriate for monitoring variations in the provision of health services. This is demonstrated by the fact that the results of this study quantify reductions in the intensity of some types of visits that are consistent with our expectations. Future avenues of research are the sensitivity of information system records in predicting the severity of the situation.

Limitations

It is worth mentioning that the 2 samples that were compared were not perfectly symmetric, insofar as the start of the COVID-19 outbreak did not coincide exactly with end and beginning of calendar years. Thus, 2020 data reflect, in part, some weeks or months of normal health care, showing some bias in favor of non–COVID-19 visits. In addition, we used *ICD-10* diagnostic codes as a proxy for the reason for visits; though it is a useful variable due to its systematic collection, it is not perfect. Moreover, while it is true that in hospitals there is a fairly exhaustive control in the coding of these variables due to the implications for billing, this is not the case in primary care, so these data may be less well coded. The circumstances

caused by the pandemic may also have affected the overall quality of the data (eg, due to newly established teleworking tools among health professionals).

Conclusions

The disruption in the primary care model in Catalonia has led to an explosive increase in the number of non–face-to-face visits. There has been a reduction in the number of visits for diagnoses related to chronic pathologies, obesity, bodily injuries, and respiratory infections, possibly as an indirect effect of COVID-19 prevention measures. Instead, diagnostic visits for socioeconomic and housing problems have increased, which emphasizes the importance of social determinants of health in a pandemic context.

Big data analysis can help to inform health planners in their decision making to focus on the least treated diseases during the pandemic. The availability of information enables comprehensive and reliable monitoring of the health system to be undertaken. In extraordinary situations, such as those created by the COVID-19 pandemic, and in view of the necessary emergency plan that will have to be carried out to compensate for the onslaught of clinical activity caused by COVID-19, big data analysis is even more relevant.

Abstract

Background: Digital contact tracing is employed to monitor and manage the spread of COVID-19. However, to be effective the system must be adopted by a substantial proportion of the population. Studies of mostly hypothetical contact tracing apps show generally high acceptance, but little is known about the drivers and barriers to adoption of deployed systems.

Objective: The aim of this study was to investigate adoption of and attitudes toward the NHS (National Health Service) COVID-19 smartphone app, the digital contact tracing solution in the United Kingdom.

Methods: An online survey based on the extended Technology Acceptance Model with the added factor of trust was carried out with a representative sample of the UK population. Statistical analysis showed adoption rates, attitudes toward and trust in the app, and compliance with self-isolation advice and highlighted differences for vulnerable populations (ie, older adults aged 65 years and over and members of Black, Asian, and minority ethnic [BAME] communities).

Results: A total of 1001 participants took part in the study. Around half of the participants who had heard of the NHS COVID-19 mobile phone app (490/963, 50.9%; 95% CI 47.8%-54.0%) had downloaded and kept the app, but more than one-third (345/963, 35.8%; 95% CI 32.8%-38.8%) either did not intend to download it or had deleted it. Significantly more BAME respondents than White respondents had deleted the app (16/115, 13.9%; 95% CI 11.8%-16.0%, vs 65/876, 7.4%; 95% CI 5.8%-9.0%), and significantly more older adults 65 years and over than those under 65 years did not intend to download it (44/127, 34.6%; 95% CI 31.7%-37.5%, vs 220/874, 25.2%; 95% CI 22.5%-27.9%). Broadly, one of the reasons for uptake was to help the NHS and other people, especially among older adults, although significantly fewer BAME participants agreed that they did so to help the NHS. Reported compliance with received notifications to self-isolate was high but was significantly lower than reported intended compliance without received notifications. Only one-fifth (136/699, 19.5%; 95% CI 17.0%-22.0%) of participants understood that the decision to send self-isolation notifications was automated by the app. There were a range of significantly more negative views among BAME participants, including lower trust in the NHS, while older adults were often significantly more positive. Respondents without the app reported significantly lower trust and more negative views toward the app and were less likely to report that they understood how the app works.

Conclusions: While compliance on the part of the approximately 50% of participants who had the app was fairly high, there were issues surrounding trust and understanding that hindered adoption and, therefore, the effectiveness of digital contact tracing,

particularly among BAME communities. This study highlights that more needs to be done to improve adoption among groups who are more vulnerable to the effects of the virus in order to enhance uptake and acceptance of contact tracing apps.

Introduction

Digital contact tracing solutions are employed to monitor and manage the spread of disease during pandemics [1]. Public acceptance of app-based contact tracing in the United Kingdom, the European Union, and the United States is high [2-4]; however, to make a difference they must be adopted by a substantial proportion of the population [5,6]. Engaging users in the development, implementation, and evaluation of contact tracing can help maximize engagement and technology acceptance, according to the Responsible Research and Innovation (RRI) framework [7,8]. Therefore, this paper reports on research to understand the drivers and barriers to adoption of a COVID-19 contact tracing app in the United Kingdom to help increase the effectiveness of such systems and inform future design.

An earlier study of hypothetical digital contact tracing in the United Kingdom suggested that people would adopt it to protect family, friends, and the community as well as to stop the pandemic, while potential barriers were reported risks of postpandemic surveillance, increasing anxiety, and fear of hacking [2,4]. In a study by Velicia-Martin et al, the Technology Acceptance Model (TAM) was used to show that the intention to use a contact tracing app was determined by how useful it was perceived to be; the study also showed that concern about privacy would be overridden by concerns about health [9]. Similarly, a study in Germany looked at the difference between the perceived utility of a contact tracing app and a data donation app. Motivations for using and accepting a contact tracing app were higher, and the data donation app was perceived as having less utility for the user [10]. However, there may also be wider social implications, such as having no choice but to download the app for work or venue check-ins, and real-world uptake might differ from usage within a trial.

Trust may also significantly impact the adoption of contact tracing apps, [11]; for example, a study conducted in Switzerland suggested that higher levels of trust in government and health authorities may also lead to increased uptake [12]—perceived effectiveness of a contact tracing app and the overall app user experience depended on the app being embedded within the health system. In the UK context, this may mean that trust or confidence in the National Health Service (NHS) might influence people's attitudes toward and usage of the app. In Germany, it was also shown that general trust in official app providers as well as social trust played important roles, highlighting the importance of both data-securing issues and interpersonal solidarity [10]. A study across five countries—France, Germany, Italy, the United Kingdom, and the United States—also found that a lack of trust was one of the main barriers for adoption of a hypothetical contact tracing app [4].

Security and privacy have also been shown to be important. In the Netherlands, a study designed to determine the potential uptake of a contact tracing app in the Dutch population showed an adoption rate as high as 64% for apps that had a higher number of security and privacy-respecting features [13]. In Ireland, there was shown to be a high level of willingness to download a public health–backed app to augment contact tracing, with 54% of respondents definitely willing to download an app and 30% who would consider downloading it [14]. The most common reason to download the app was linked to social altruism: helping family and friends and a sense of responsibility to the wider community. The most common reason not to download the app was linked to issues of trust, privacy and data security, and fear that technology companies or the government might use the app technology for greater surveillance after the pandemic. Another study across five countries—France, Germany, Italy, the United Kingdom, and the United States—found that there was strong support for an app, whether it was subject to voluntary or automatic installation, but the study identified concerns once more about cybersecurity and privacy [4]. In Australia, 37.3% of participants in a study of 1500 citizens had downloaded the COVIDSafe app, and 27.7% refused to do so [15]. Reasons for not downloading the app included privacy and technical concerns, the belief that that app was unnecessary due to social distancing, distrust in the government, and apathy. This study also highlighted the importance of public health messages for increasing the acceptability of apps and their correct use, while also addressing concerns around privacy, data storage, and technical ability needed to operate the app; it also emphasized the importance of identifying and understanding specific barriers to the use of contact tracing apps to improve their design.

Data suggest that specific groups of the population are more at risk of dying of COVID-19, including older adults [16-18] as well as those in Black, Asian, and minority ethnic (BAME) communities [19,20]. The main challenge among the Dutch population was to increase the uptake among older adults, who were least inclined to install and use a COVID-19 contact tracing app [13]. In line with this, in Germany, age was negatively associated with the motivation for using a data donation app [10]. The risk for BAME communities, in particular, has been linked to socioeconomic factors [21,22]. Furthermore, recent studies have shown increased COVID-19 vaccine hesitancy in certain BAME communities [23-25]; however, little is known about whether hesitancy also extends to attitudes toward digital contact tracing.

At the time the study reported in this paper closed on December 21, 2020, 2,183,506 people in the United Kingdom had tested positive for COVID-19, approximately 3.2% of the population [26]. The UK government released the NHS COVID-19 app on September 24, 2020. The app is entirely automated and decentralized, and it relies on Bluetooth proximity as well as self-reporting of symptoms and test results [27,28]. The app has been downloaded more than 21 million times, suggesting a 56% uptake among the population aged 16 years and older who own a smartphone [29,30]. A recent study also showed that the app has been effective in reducing the number of positive cases of COVID-19 in the United Kingdom; 1.7 million users were contact-traced by the app, with an estimated reduction in cases during the second wave of COVID-19 by one-quarter. However, only 28% of people had actively used the app in the period leading up to this study [31]. Little is known about the views driving or hindering adoption of the app; our research addresses this gap. The study surveys public trust in and adoption of digital contact tracing in the United Kingdom, in terms of reported reasons, compliance, and understanding of the app, especially highlighting significant differences for vulnerable groups.

Methods

Recruitment

Ethical approval was granted for the study by the Research Ethics Committee of the authors' institution. The recruitment was carried out by Ipsos MORI via email to a nationally representative sample, based on age, gender, and region, drawn from a randomly selected pool of participants who met the relevant criteria. There was also a 10% to 15% quota for BAME respondents, with the same process applied to ensure hitting the minimum required quota. As fieldwork progressed, they specifically targeted any quota groups that were still required to meet the final profile that was needed, again randomly selecting within those groups. Participants were incentivized for survey participation through monetary compensation paid into their panel account. As a market research agency, Ipsos MORI operates under the Market Research Society code of conduct and is General Data Protection Regulation compliant, so participants' privacy was guaranteed. Data were only received via their survey platform in an anonymized form, so no personally identifiable information on the participants was received. A total of 2575 invitations to take part in the study were sent out.

A representative sample of 1001 members of the UK population aged 16 to 75 years took part, weighted to the known offline proportions for age within gender, region, working status, and ethnicity. Participants were asked a series of demographic questions, the full details of which are provided in Table S1 in Multimedia Appendix 1. A summary of the main self-reported characteristics is provided in Table 1.

Table 1. Summary characteristics of participants.

Characteristic	Participants (N=1001), n (%)
Age (years)	
Under 65	874 (87.3)
65 and over	127 (12.7)
Gender	
Male	501 (50.0)
Female	500 (50.0)
Employment status	
Working	666 (66.5)
Not working	335 (33.5)
Education	
Up to General Certificate of Secondary Education (GSCE)	307 (30.7)
Post-GSCE	694 (69.3)
Ethnicity	
White	876 (87.5)
Black, Asian, and minority ethnic	115 (11.5)
Not stated	10 (1.0)
Country of residence	
England	847 (84.6)
Wales	48 (4.8)
Scotland	85 (8.5)
Northern Ireland	21 (2.1)

Materials and Procedure

An online survey was carried out between December 11 and 21, 2020, when the United Kingdom was between "lockdown 2" and "lockdown 3" and subject to a regional tier system. Questionnaire development was carried out in several stages. First, in the summer of 2020, a series of interviews were carried out with members of the public with regard to their opinions of, and intention to use, the United Kingdom's test and trace app when it would be released (paper forthcoming). From these interviews, a series of themes were identified, which led to the survey being based on the extended TAM (TAM2) [32]. The TAM2 identifies several key factors in the adoption of new technology and has been applied to explore acceptance of various technologies, including hypothetical COVID-19 tracing apps [9]. The conceptual model is extended with "trust" as a factor for acceptance, as it may significantly impact the adoption of contact tracing apps [11]. A list of pertinent questions was developed among the author team; the questions were tested and refined involving experts in questionnaire development from Ipsos MORI. Figure 1 illustrates how these questions relate to and extend the TAM2 framework.

Recruitment and data collection were carried out by Ipsos MORI, who also carried out piloting of the questionnaire. The questionnaire had an initial data review on Day 1 with 61 respondents; it was thoroughly checked to make sure that all data were being collected correctly (eg, checking routing and displaying of correct answer options) and was checked for anomalies and understanding. The data were reviewed again when 213 respondents had completed it to ensure data quality.

Participants were provided with information and privacy notices and gave informed consent to take part. All questions were closed-ended, either multiple choice or rated on Likert or Likert-like scales from 1 ("strongly disagree" or "not at all") to 5 ("strongly agree" or "entirely"), except for a single open-ended question that was included for further comments; participants were routed to appropriate questions based on previous answers.

Figure 1. The extended Technology Acceptance Model (TAM2) and its relation to the this questionnaire study. Items in bold in white boxes are existing factors in the TAM2 [8], followed by examples, as bullet points, from the questionnaire. Trust was added as an additional factor (peach box) affecting intention to use and includes examples from the questionnaire.

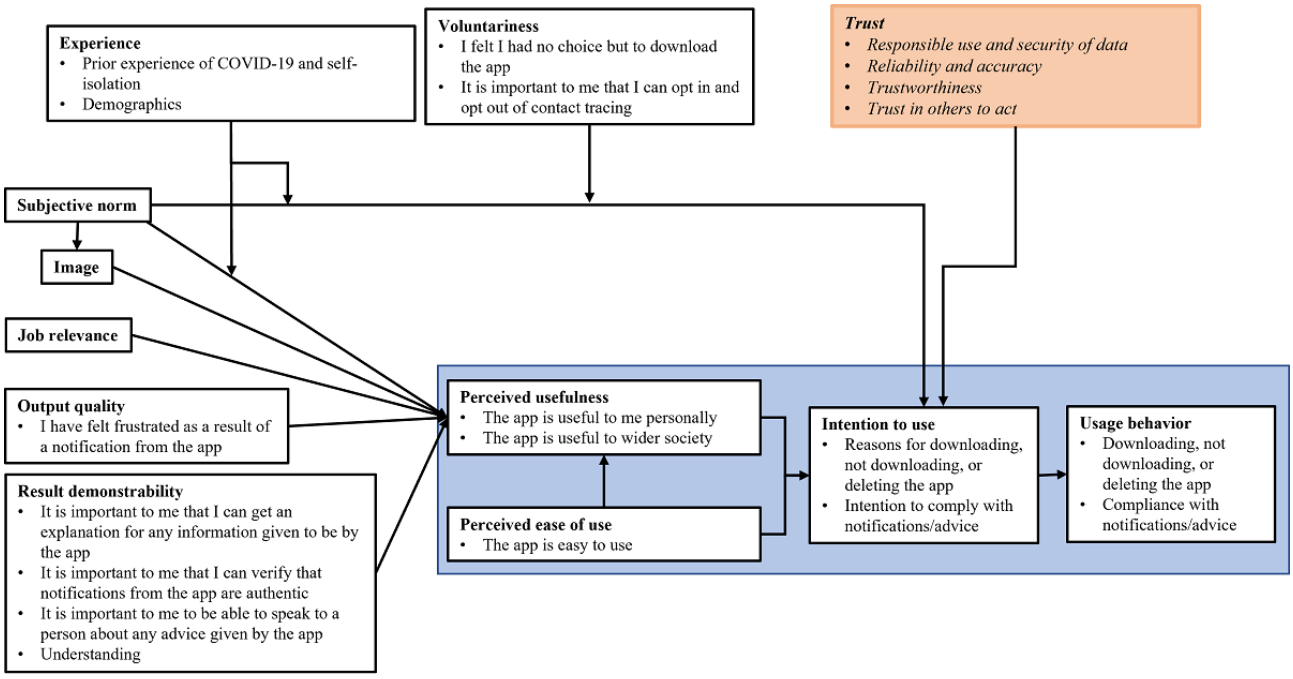

Figure 2 shows the survey flow and resulting major subpopulations that were used for branching. Section 1 of the survey asked participants to indicate what knowledge and experiences they had of COVID-19 and the NHS Test and Trace app; for example, if they had been asked to self-isolate and the extent to which they complied, whether they had downloaded the app, and if not, why not. Section 2 focused on those with the app and collected reasons for downloading and experiences of using the app. Section 3 asked about app functionality and the technology involved, including whether the app was useful, easy to use, or beneficial; understanding of how it worked; and the importance of features such as opting in and out of contact tracing. Section 4 asked about levels of trust in distinct aspects of the app, including responsibility, security, reliability, functionality, data use, and stakeholders and wider society.

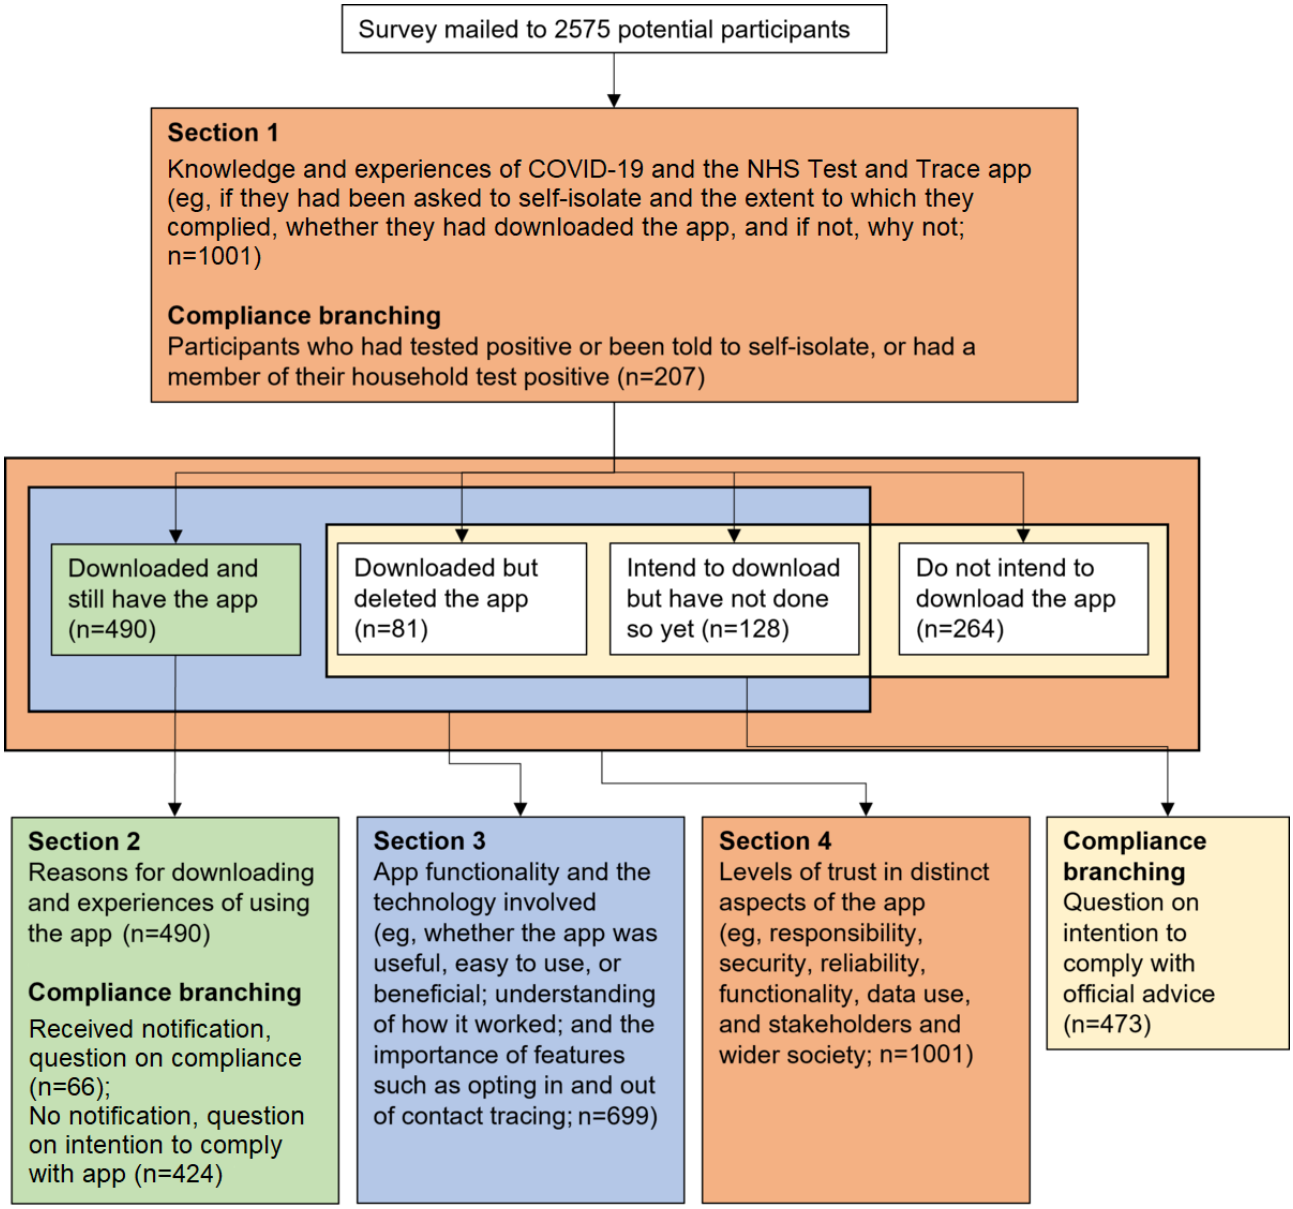
Figure 2. Illustration of major sections of the survey and subgroups identified for branching. NHS: National Health Service.



Statistical Analysis

Responses were analyzed using SPSS software (version 26; IBM Corp) and Excel (Microsoft 365). Summary statistics (ie, mean, median, SD, and IQR) or frequencies were extracted for all questions. Confidence intervals for proportions are given at the 95% level. Most questions were significantly nonnormal as shown by skewness and kurtosis, so nonparametric tests are appropriate. In the text, we report the sample mean, given with statistical test results, and the median response on a Likert-like scale. All inferential statistical analysis was carried out with $P<.05$ as the threshold for statistical significance. Missing data were reported as "no response" and were included in frequency calculations; missing data for inferential statistical analysis and the calculation of means were excluded.

Subgroup analyses using independent-samples Mann-Whitney *U* or chi-square tests were used to compare those who had been told to self-isolate with those who had not, White participants with BAME participants, and participants under 65 years with participants 65 years and over. Independent-samples Kruskal-Wallis tests were used to compare those who had the app, did not have the app, had deleted the app, or intended to download the app but had not yet done so. Post hoc tests were carried out to identify which groups had significant differences between them, with Bonferroni corrections to account for multiple testing. Due to use of the nonparametric versions of inferential statistics, and because the weighted values for the data all rounded to 1, weighting was not used. However, exploratory analysis revealed no difference in significance when using the parametric versions of tests.

Results

Adoption of the Test and Trace App

A total of 1001 participants took part in the study. Most participants (n=963, 96.2%; 95% CI 95.0%-97.4%) had heard of the NHS COVID-19 mobile phone app, of which 50.9% (490/963; 95% CI 47.8%-54.0%) had downloaded the app and still had it on their phone. A further 13.3% (128/963; 95% CI

11.2%-15.4%) had not yet downloaded it but intended to, 27.4% (264/963; 95% CI 24.6%-30.2%) did not intend to download it, and 8.4% (81/963; 95% CI 6.7%-10.1%) had downloaded it but since deleted it.

Among the 27.4% (264/963) of participants who did not intend to download the app, the most common reasons were a desire not to be tracked, not thinking it would be effective, not wanting to take part in contact tracing in that way, and lack of trust in those who built the app (Table 2). Of the 8.4% (81/963) who had decided to delete the app, this was mostly because they did not think it was effective or did not want to be tracked. Reasons given by the 13.3% (128/963) of participants who intended to download the app were mostly to help the NHS or to help protect their friends and family or themselves, as well as to reduce the spread of the virus and to help protect broader society (Table 3).

Of the 50.9% (490/963) of participants who had downloaded the app, 92.0% (451/490; 95% CI 90.3%-93.7%) had opened the app and had a look around, 66.7% (327/490; 95% CI 63.8%-69.6%) had used it for a venue check-in, 58.4% (286/490; 95% CI 55.3%-61.5%) had made use of the “check symptoms” section, 71.2% (349/490; 95% CI 68.4%-74.0%) had contact tracing always switched on, 20.4% (100/490; 95% CI 17.9%-22.9%) sometimes had contact tracing switched on, 1.8% (9/490; 95% CI 1.0%-2.6%) never turned contact tracing on, and 6.5% (32/490; 95% CI 5.0%-8.0%) did not know if contact tracing was enabled or not. The strongest reasons given for downloading the app were helping the NHS and protecting friends and family (Table 3).

Table 2. Reasons for not having the NHS Test and Trace app for those who do not intend to download it and those who downloaded but deleted the app.

Reasons for not having the app[a]	Participants who do not intend to download the app (n=264)		Participants who downloaded but deleted the app (n=81)	
	n (%)	95% CI	n (%)	95% CI
I don’t want to be tracked	105 (39.8)	36.8-42.8	22 (27.2)	24.4-30.0
I don’t think it will be effective	80 (30.3)	27.5-33.1	28 (34.6)	31.7-37.5
I choose/chose not to take part in contact tracing in this way	78 (29.5)	26.7-32.3	12 (14.8)	12.6-17.0
I don’t trust the people who built the app	72 (27.3)	24.5-30.1	14 (17.3)	15.0-19.6
The app doesn’t/didn’t work on my mobile phone	28 (10.6)	8.7-12.5	14 (17.3)	15.0-19.6
I don’t have a smartphone	27 (10.2)	8.3-12.1	N/A[b]	N/A
I don’t want to be told to self-isolate	16 (6.1)	4.9-7.6	9 (11.1)	9.2-13.0
None of the above	25 (9.5)	7.7-11.3	7 (8.6)	6.9-10.3
I wouldn’t/didn’t know how to use it	12 (4.5)	3.2-5.8	12 (14.8)	12.6-17.0
Don’t know	1 (0.1)	0-0.3	0 (0)	__[c]

[a]Multiple answers were allowed.

[b]N/A: not applicable, because participants do not have a smartphone, which is needed to download the app.

[c]The 95% CI value could not be calculated since there were no participants.

Table 3. Reasons for intention to download and for downloading the NHS COVID-19 app.

Reasons for intention to download and for downloading the app	Participants who intended to download the app[a] (n=128)		The extent to which each reason was a motivation for downloading the app[b] (n=490)	
	n (%)	95% CI	Mean (SD)	Median (IQR)
To help the National Health Service	84 (65.6)	62.7-68.5	4.42 (0.753)	5 (1)
To help protect my friends and family	80 (62.5)	59.5-65.5	4.36 (0.792)	5 (1)
To help protect myself	70 (54.7)	51.6-57.8	4.27 (0.883)	4 (1)
Because it will reduce the spread of the virus	55 (43.0)	39.9-46.1	4.11 (0.966)	4 (1)
To help protect broader society	46 (35.9)	32.9-46.1	4.2 (0.897)	4 (1)
Because I need it to check into venues	24 (18.8)	16.4-21.2	3.54 (1.179)	4 (1)
Because the government told me to	15 (11.7)	9.7-13.7	3.46 (1.177)	4 (1)
Because everyone else is	12 (9.4)	7.6-11.2	3.14 (1.177)	3 (2)
Because it is a requirement for my job	7 (5.5)	4.1-6.9	2.53 (1.361)	2 (3)
None of the above	2 (1.6)	0.8-2.4	N/A[c]	N/A

[a]Participants who intended to download the app were asked to select all reasons that applied.

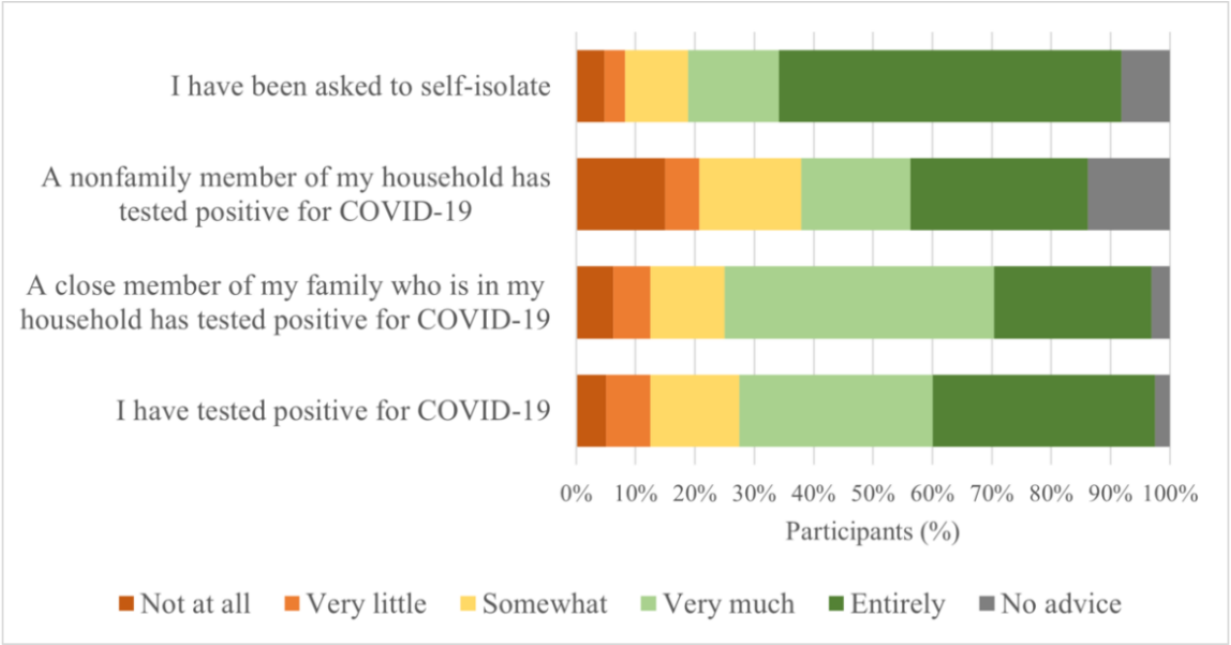
[b]Participants who had the app were asked to what extent each reason was a motivation for downloading the app; responses were rated on a 5-point Likert scale from 1 (“strongly disagree”) to 5 (“strongly agree”).

[c]N/A: not applicable; this entry was not rated.

Compliance With Official Advice and Self-isolation

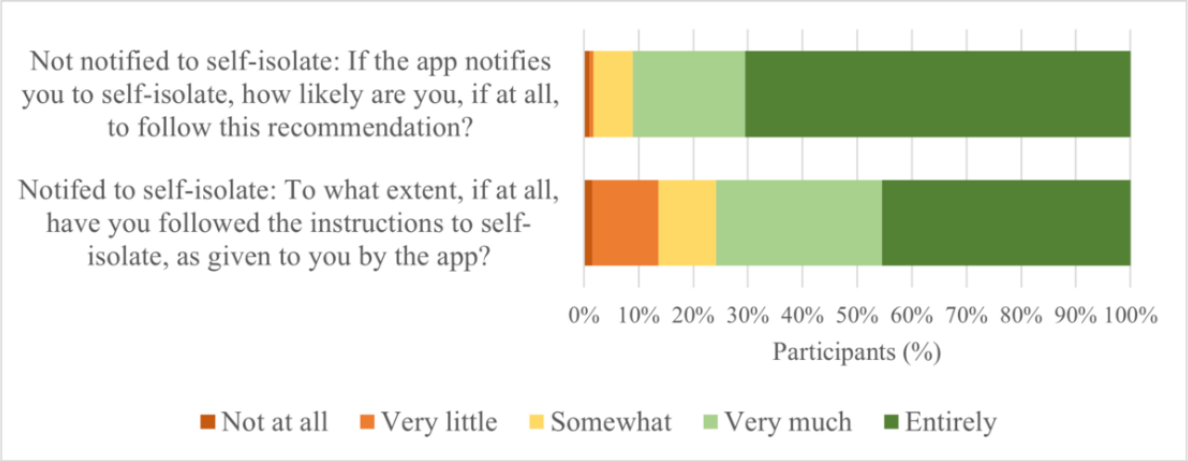
Out of 1001 participants, nearly half (n=434, 43.4%; 95% CI 40.3%-46.5%) had at least one of the following experiences: 4.0% (n=40; 95% CI 2.8%-5.2%) had tested positive for COVID-19, 14.1% (n=141; 95% CI 11.9%-16.3%) had a member of their household test positive, 27.9% (n=279; 95% CI 25.1%-30.7%) had another person close to them test positive, and 8.5% (n=85; 95% CI 6.8%-10.2%) had been asked to self-isolate in any form, whether via app or other means. Participants who had been affected or asked to self-isolate, or who had a member of their household who had (207/1001, 20.7%), were asked to indicate how much they had complied with any official advice they received, regardless of whether it was through the app or another source; the average response across all four experiences was “very much” (mean 3.88, SD 1.292). However, 10.6% (22/207; 95% CI 7.9%-11.5%) stated they did not receive any official advice at all, most often when a nonfamily member of their household had tested positive (12/87, 14%; 95% CI 11.7%-15.9%) (Figure 3). Note that this implies that some participants, therefore, did not consider being asked to self-isolate as “official advice.”

Figure 3. Compliance with official advice, dependent on the circumstances. Participants were asked "To what extent, if at all, did you follow any advice given to you?".



Of the 47.3% (473/1001) of participants who did not currently have the app, most stated they would either very much or entirely follow advice to self-isolate if they received a call (352/473, 74.4%; 95% CI 71.7%-77.1%). Of participants with the app (490/963, 50.9%), 13.5% (66/490; 95% CI 11.4%-15.6%) had been notified to self-isolate, and 45% (30/66; 95% CI 42.4%-48.6%) of those said that they had entirely followed the recommendation. However, of the 85.3% (418/490; 95% CI 83.1%-87.5%) who stated that they had not been notified by the app to self-isolate, 70.6% (295/418; 95% CI 73.4%-78.6%) said they would entirely follow a recommendation from the app if they received one (Figure 4). An independent-samples Mann-Whitney *U* test comparing those who had received advice to self-isolate from the app (66/490, 13.5%) to those who had not (418/490, 85.3%) shows that reported intention to comply with advice is significantly stronger than reported actual compliance ($mean_{intention}$ 4.59, SD 0.738; $mean_{actual}$ 4.06, SD 1.094; U=17673.0; P<.001).

Figure 4. Compliance and intention to comply with app notifications to self-isolate. An independent-samples Mann-Whitney *U* test comparing those who had received advice to self-isolate (n=66) from the app to those who had not (n=418) shows that reported intention to comply with advice is significantly stronger than reported actual compliance (mean intention 4.59, SD 0.738; mean actual 4.06, SD 1.094; U=17673.0; P<.001).



Understanding and Attitudes Toward the App

Of participants who currently have the app, have deleted it, or intended to download it (699/963, 72.6%), most stated that they thought that decisions to send a notification to self-isolate were made by both humans and the app (379/699, 54.2%; 95% CI 51.1%-57.3%); only 19.5% (136/699; 95% CI 17.0%-22.0%) thought they were made by the app only. Participants with the app agreed that they knew how the app worked, that it was easy to use, that it was useful to them and to wider society, that the regulations surrounding the app were sufficient, that it was important that they could get explanations and verify information from the app, that they could speak to a person about any advice they receive, and that they have the option to opt out of contact tracing if they chose to. They were neutral about data concerns and about whether they had a choice in downloading the app. They tended to disagree that they had been frustrated by a notification from the app. Independent-samples Kruskal-Wallis tests showed that participants who had deleted the app (81/963, 8.4%) felt significantly less than those who still have the app (490/963, 50.9%) that they understood the app (χ^2_2=16.1, P=.003), that it was useful to them (χ^2_2=26.2, P<.001) or wider society (χ^2_2=29.7, P<.001), that regulations were sufficient (χ^2_2=12.9, P=.003), or that it was easy to use (χ^2_1=41.2, P<.001). It was also significantly less important to them that they could verify app notifications (χ^2_2=18.3, P<.001). However, they showed significantly more concern about how their data were used (χ^2_2=25.7, P<.001) and were more likely to have been frustrated by a notification from the app (χ^2_1=18.3, P<.001). None of the other statements (Table 4) were significantly different.

Table 4. Levels of agreement with statements related to the technology and ecosystem surrounding the NHS COVID-19 app.

Statements[a]	Participants who still have the app (n=490)		Participants who deleted the app (n=81)		*P* value[b]
	Mean (SD)	Median (IQR)	Mean (SD)	Median (IQR)	
I understand how the NHS COVID-19 app works	3.99 (0.850)	4 (1)	3.57 (1.036)	4 (1)	.003
I am concerned about how my data will be used by the app	3.04 (1.250)	3 (2)	3.73 (1.037)	4 (1)	<.001
The app is useful to me personally	3.84 (0.944)	4 (2)	3.19 (1.174)	3 (2)	<.001
The app is useful to wider society	4.11 (0.874)	4 (1)	3.47 (1.096)	4 (1)	<.001
It is important to me that I can get an explanation for any information given to me by the app	4.01 (0.801)	4 (1)	3.72 (1.028)	4 (2)	.052
It is important to me that I can verify that notifications from the app are authentic	4.14 (0.823)	4 (1)	3.60 (1.137)	4 (1)	<.001
The regulations governing the creation of the app are sufficient	3.72 (0.934)	4 (1)	3.37 (1.089)	3 (1)	.003
It is important to me to be able to speak to a person about any advice given by the app	3.71 (0.982)	4 (1)	3.64 (1.099)	4 (1)	>.99
It is important to me that I can opt in and opt out of contact tracing	3.50 (1.166)	4 (1)	3.58 (0.947)	4 (1)	>.99
The app is easy to use	4.18 (0.815)	4 (1)	3.42 (1.082)	4 (1)	<.001
I felt that I had no choice but to download the app	2.98 (1.273)	3 (2)	3.27 (1.162)	3 (2)	.06
I have felt frustrated as a result of a notification from the app	2.59 (1.279)	2 (2)	3.28 (1.154)	3 (2)	<.001

[a]Statements were rated on a 5-point Likert scale from 1 (“strongly disagree”) to 5 (“strongly agree”).

[b]Independent-samples Kruskal-Wallis tests were carried out with a significance level of $P<.05$ and post hoc tests to indicate which groups had significant differences between them, with Bonferroni correction to account for multiple tests. Additional differences, including participants who downloaded and still have the app and those who intend to download the app, are in Table S2 in Multimedia Appendix 1.

Trust in Test and Trace

While those who still have the app (490/963, 50.9%) tended to agree that they had trust in various aspects of the app (Table 5), independent-samples Kruskal-Wallis tests showed that those who chose not to download the app (264/963, 27.4%) had significantly less trust, feeling neutral regarding trusting that the data were used responsibly (χ^2_3=222.2, $P<.001$) and stored securely (χ^2_3=236.3, $P<.001$), that the app does what it is supposed to do (χ^2_3=273.9, $P<.001$), and that the app is basically trustworthy (χ^2_3=243.1, $P<.001$). They were also significantly less trusting of others, feeling neutral about whether they trusted others to download the app (χ^2_3= 128.8, $P<.001$) or to self-isolate if they were told to (χ^2_3=74.1, $P<.001$). Participants who chose not to download the app were also significantly more likely not to trust that their data would be deleted when the app said it would be (χ^2_3=251.1, $P<.001$) or that the app was reliable (χ^2_3=277.7, $P<.001$). Trust was thought to be important for all participants to feel comfortable using the app, although significantly less so for those who chose not to download it (χ^2_3=24.0, $P<.001$).

Table 5. Levels of agreement with statements related to trust in the NHS COVID-19 app.

Statements[a]	Participants who have the app (n=490)		Participants who do not intend to download the app (n=264)		*P* value[b]
	Mean (SD)	Median (IQR)	Mean (SD)	Median (IQR)	
I trust that the data collected by the app are used responsibly	3.98 (0.888)	4 (1)	2.63 (1.224)	3 (2)	<.001
I trust that the data collected by the app are stored securely	3.93 (0.916)	4 (2)	2.56 (1.149)	3 (1)	<.001
I feel that the app is reliable	3.89 (0.919)	4 (2)	2.42 (1.062)	2 (1)	<.001
I trust that the app will do what it is supposed to do	3.97 (0.880)	4 (1)	2.53 (1.136)	3 (1)	<.001
I think the NHS COVID-19 app is basically trustworthy	4.03 (0.875)	4 (1)	2.73 (1.129)	3 (1)	<.001
I think that most other people will download the app	3.58 (1.026)	4 (1)	2.65 (1.086)	3 (1)	<.001
I trust that most other people will self-isolate if told to do so by the app	3.54 (1.113)	4 (1)	2.80 (1.106)	3 (2)	<.001
I trust that my data will be deleted when the app says they will be	3.93 (0.892)	4 (2)	2.48 (1.196)	2 (2)	<.001
It is important to me that I trust the app in order to use it	4.15 (0.736)	4 (1)	3.86 (1.145)	4 (2)	<.001

[a]Statements were rated on a scale from 1 (“strongly disagree”) to 5 (“strongly agree”).

[b]Independent-samples Kruskal-Wallis tests were carried out with a significance level of $P<.05$ and post hoc tests to indicate which groups had significant differences between them, with Bonferroni correction to account for multiple tests. Additional differences, including participants who deleted or intended to download the app, are in Table S3 in Multimedia Appendix 1.

While those who still had the app (490/963, 50.9%) agreed that they trusted most of the stakeholders involved in the NHS Test and Trace system (Table 6), independent-samples Kruskal-Wallis tests showed that those who chose not to download the app (264/963, 27.4%) were significantly more neutral about big tech companies ($\chi^2_3=82.1$, $P<.001$), small hospitality venues ($\chi^2_3=34.8$, $P<.001$), large hospitality venues ($\chi^2_3=56.1$, $P<.001$), and their local council ($\chi^2_3=61.7$, $P<.001$), and significantly more negative about their trust in the UK government ($\chi^2_3=61.7$, $P<.001$). Those with the app were neutral about their trust in private contractors, while those without the app were significantly more negative ($\chi^2_3=85.6$, $P<.001$). Finally, both groups tended to agree that they trusted the NHS, but those without the app significantly less so ($\chi^2_3=78.9$, $P<.001$).

Table 6. Levels of trust in stakeholders involved in the NHS Test and Trace system among participants.

Statements[a]	Participants who have the app (n=490)		Participants who do not intend to download the app (n=264)		*P* value[b]
	Mean (SD)	Median (IQR)	Mean (SD)	Median (IQR)	
I trust the big tech companies, such as Google and Apple	3.42 (0.996)	4 (1)	2.65 (1.134)	3 (1)	<.001
I trust private contractors, such as Serco	3.07 (1.086)	3 (2)	2.29 (1.021)	2 (2)	<.001
I trust small hospitality venues, such as independent pubs and cafés	3.62 (0.864)	4 (1)	3.13 (1.125)	3 (2)	<.001
I trust larger hospitality venues, such as chain restaurants	3.52 (0.923)	4 (1)	2.91 (1.068)	3 (2)	<.001
I trust the UK Government	3.32 (1.213)	4 (2)	2.39 (1.181)	2 (2)	<.001
I trust my local council	3.51 (0.968)	4 (1)	2.86 (1.096)	3 (2)	<.001
I trust the National Health Service	4.33 (0.774)	4 (1)	3.72 (1.102)	4 (2)	<.001

[a]Statements were rated on a 5-point Likert scale from 1 (“strongly disagree”) to 5 (“strongly agree”).

[b]Independent-samples Kruskal-Wallis tests were carried out with a significance level of $P<.05$ and post hoc tests to indicate which groups had significant differences between them, with Bonferroni correction to account for multiple tests. Additional differences, including participants who deleted or intended to download the app, are in Table S4 in Multimedia Appendix 1.

Vulnerable Groups

Of the 11.5% (115/1001) of participants who identified as BAME, 53.0% (61/115; 95% CI 49.9%-56.1%) had any close experience of COVID-19, including friends and family receiving diagnoses, compared to 42.3% (371/876; 95% CI 39.2%-45.4%) of White participants (Table 7). Chi-square tests showed that significantly more BAME participants had a member of their household test positive, (χ^2_1=10.0, *P*<.05). While more BAME participants had tested positive or had another person close to them test positive than White participants, the differences were not significant; a similar proportion had been asked to self-isolate. Significantly fewer BAME participants than White participants had downloaded the app (χ^2_1=4.7, *P*<.05) and more had deleted the app (χ^2_1=4.5, *P*<.05); while fewer BAME participants did not intend to download the app and more intended to download it, neither difference was significant (Table 8). BAME participants agreed significantly less that they downloaded the app to help the NHS ($mean_{BAME}$ 4.02, SD 1.000; $mean_{White}$4.46, SD 0.710; *U*=7803.5; *P*=.001) and significantly more that it was a requirement for their job ($mean_{BAME}$ 3.19, SD 1.437; $mean_{White}$ 2.45, SD 1.341; *U*=13734.0; *P*<.001); no other reasons showed a difference.

Table 7. Experiences of COVID-19 among vulnerable populations (BAME participants and those 65 years and over) compared to other populations (White participants and those under 65 years).

Experiences of COVID-19	White participants (n=876)		BAME[a] participants (n=115)		Participants under 65 years (n=874)		Participants 65 years and over (n=127)	
	n (%)	95% CI	n (%)	95% CI	n (%)	95% CI	n (%)	95% CI
Any close experience of COVID-19	371 (42.3)	39.2-45.4	61 (53.0)	49.9-56.1	407 (46.6)	43.5-49.7	28 (22.0)	19.4-24.6
Tested positive	32 (3.7)	2.5-4.9	8 (7.0)	5.4-8.6	39 (4.5)	3.2-5.8	1 (0.9)	0.3-1.5
Member of household tested positive	112 (12.7)	10.6-14.8	29 (25.2)	22.5-27.9	136 (15.6)	13.4-17.8	5 (3.9)	2.7-5.1
Another close person tested positive	241 (27.5)	24.7-30.3	36 (31.3)	28.4-34.2	265 (30.3)	27.5-33.1	14 (11.0)	9.1-12.9
Asked to self-isolate	76 (8.7)	7.0-10.4	7 (7.0)	5.4-8.6	74 (8.5)	6.8-10.2	11 (8.8)	7.0-10.4

[a]BAME: Black, Asian, and minority ethnic.

Table 8. Downloads of the NHS COVID-19 app among vulnerable populations (BAME participants and those 65 years and over) compared to other populations (White participants and those under 65 years).

Download status	White participants (n=876)		BAME[a] participants (n=115)		Participants under 65 years (n=874)		Participants 65 years and over (n=127)	
	n (%)	95% CI	n (%)	95% CI	n (%)	95% CI	n (%)	95% CI
Downloaded	440 (50.2)	47.1-53.3	48 (41.7)	38.6-44.8	424 (48.5)	45.4-51.6	66 (52.0)	48.9-55.1
Downloaded then deleted	65 (7.4)	5.8-9.0	16 (13.9)	11.8-16.0	79 (9.0)	7.2-10.8	2 (1.6)	0.8-2.4
Not downloaded but intend to	105 (12.0)	10.0-14.0	19 (16.5)	14.2-18.8	115 (13.2)	11.1-15.3	13 (10.2)	8.3-12.1
Do not intend to download	236 (26.9)	24.2-29.6	24 (20.9)	18.4-23.4	220 (25.2)	22.5-27.9	44 (34.6)	32.6-38.6

[a]BAME: Black, Asian, and minority ethnic.

Of the 12.7% (127/1001) of participants who were 65 years of age or over, only 22.0% (28/127; 95% CI 19.4%-24.6%) had any close experience of COVID-19 compared to 46.6% (407/874; 95% CI 43.5%-49.7%) of participants under 65 years. Chi-square tests showed that significantly more participants under 65 years than those 65 years and over had a member of their household test positive (χ^2_1=10.4, *P*<.05) or another person close to them (χ^2_1=4.7, *P*<.05), with no significant difference in testing positive for COVID-19 or being asked to self-isolate. Significantly more participants 65 years and over had downloaded the app (χ^2_1=7.0, *P*<.05), fewer participants 65 years and over had deleted it (χ^2_1=8.2, *P*<.05), but significantly more participants 65 years and over, compared to those under 65 years, did not intend to download the app (χ^2_1=13.5, *P*<.05); similar proportions intended to download the app. Participants 65 years and over agreed significantly more that they downloaded the app to help the NHS ($mean_{\geq 65}$ 4.59, SD 0.656; $mean_{<65}$ 4.39, SD 0.764; *U*=16164.0; *P*=.02) and to help protect their friends and family ($mean_{\geq 65}$ 4.50, SD 0.846; $mean_{<65}$ 4.34, SD 0.782; *U*=16220.0; *P*=.02) or broader society ($mean_{\geq 65}$ 4.45, SD 0.786; $mean_{<65}$ 4.16, SD 0.910; *U*=16630.5; *P*=.008); however, they were less likely to agree that it was needed for them to check into venues ($mean_{\geq 65}$ 3.15, SD 1.256; $mean_{<65}$ 3.60, SD 1.157; *U*=11089.5; *P*=.005) or for their job ($mean_{\geq 65}$ 1.94, SD 1.188; $mean_{<65}$ 2.63, SD 1.364; *U*=9874.0; *P*<.001); no other reasons showed a difference.

Of participants who did not have the app, intention to comply with a phone call asking them to self-isolate was the same between both BAME and White participants ($mean_{BAME}$ 3.93, SD 1.201; $mean_{White}$ 4.14, SD 1.192; *U*=13909.0; *P*=.06) and between participants 65 years and over and those under 65 years ($mean_{\geq 65}$ 4.39, SD 1.000; $mean_{<65}$ 4.08, SD 1.207; *U*=10573.0;

P=.11). Of those with the app who had been notified to self-isolate, there was no significant difference in compliance between populations ($mean_{BAME}$ 3.67, SD 1.234; $mean_{White}$ 4.18, SD 1.034; *U*=291.5; *P*=.14; $mean_{\geq 65}$ 4.25, SD 1.500; $mean_{<65}$ 4.05, SD 1.078; *U*=150.0; *P*=.51), but of those who had not been notified, White participants reported a significantly higher intention to comply ($mean_{BAME}$ 4.26, SD 0.855; $mean_{White}$ 4.63, SD 0.700; *U*=4544.5; *P*=.006), as did participants 65 years and over ($mean_{\geq 65}$ 4.90, SD 0.349; $mean_{<65}$ 4.54, SD 0.774; *U*=13838.5; *P*<.001).

BAME participants had a significantly lower understanding of how decisions were made by the app (χ^2_2=9.2, *P*<.05) (Table 9); more participants thought it was either humans only or humans and the app, while far fewer understood that it was only the app. While more participants 65 years and over than those under 65 years also felt that decisions were made entirely by humans, fewer felt decisions were made by both humans and the app, and more of them correctly identified that decisions were made entirely by the app; there was no significant difference between the age groups (Table 9).

Table 9. Beliefs about how decisions are made by the NHS COVID-19 app among vulnerable populations (BAME participants and those 65 years and over) compared to other populations (White participants and those under 65 years).

Beliefs about how decisions are made by the app	White participants (n=876)		BAME[a] participants (n=115)		Participants under 65 years (n=874)		Participants 65 years and over (n=127)	
	n (%)	95% CI	n (%)	95% CI	n (%)	95% CI	n (%)	95% CI
Humans only	156 (17.8)	15.4-20.2	26 (22.6)	20.0-25.2	159 (18.2)	15.8-20.6	25 (19.7)	17.2-22.2
Both humans and the app	324 (37.0)	34.0-40.0	51 (44.3)	41.2-47.4	343 (39.2)	36.2-42.2	36 (28.3)	25.5-31.1
App only	130 (14.8)	12.6-17.0	6 (5.2)	3.8-6.6	116 (13.3)	11.2-15.4	20 (15.7)	13.4-18.0

[a]BAME: Black, Asian, and minority ethnic.

BAME participants were more concerned about how their data would be used ($mean_{White}$ 3.07, SD 1.232; $mean_{BAME}$ 3.58, SD 1.091; *U*=31052.5; *P*=.001), felt more strongly that they had no choice but to download the app ($mean_{White}$ 2.95, SD 1.267; $mean_{BAME}$ 3.59, SD 1.065; *U*=20857.0; *P*<.001), and felt frustrated as a result of a notification from the app ($mean_{White}$ 2.59, SD 1.263; $mean_{BAME}$ 3.42, SD 1.219; *U*=21961.5; *P*<.001). They felt less strongly that the app was easy to use ($mean_{White}$ 4.11, SD 0.871; $mean_{BAME}$ 3.75, SD 1.039; *U*=12844.5; *P*=.004) or that it was useful to wider society ($mean_{White}$ 4.05, SD 0.885; $mean_{BAME}$ 3.75, SD 0.960; *U*=21371.5; *P*=.01). Participants 65 years and over were less concerned about how their data would be used ($mean_{\geq 65}$ 2.72, SD 1.269; $mean_{<65}$ 3.20, SD 1.216; *U*=20663.0; *P*=.009), less likely to feel that they had no choice but to download the app ($mean_{\geq 65}$ 2.68, SD 1.215; $mean_{<65}$ 3.07, SD 1.260; *U*=14010.0; *P*=.01), and less likely to feel frustrated as a result of a notification from the app ($mean_{\geq 65}$ 2.09, SD 1.129; $mean_{<65}$ 2.77, SD 1.283; *U*=11854.5; *P*<.001). It was also less important to them that they could opt in and opt out of contact tracing ($mean_{\geq 65}$ 3.18, SD 1.119; $mean_{<65}$ 3.56, SD 1.101; *U*=19243.0; *P*<.001). There were no other significant differences in attitudes.

BAME participants felt it was less important that they trusted the app ($mean_{White}$ 4.04, SD 0.898; $mean_{BAME}$ 3.79, SD 0.996; *U*=43247.5; *P*=.008). They had more trust in the big tech companies ($mean_{White}$ 3.14, SD 1.106; $mean_{BAME}$ 3.43, SD 1.109; *U*=57731.5; *P*=.008) and private contractors ($mean_{White}$ 2.78, SD 1.099; $mean_{BAME}$ 3.24, SD 1.081; *U*=61597.5; *P*<.001), but less trust in the NHS ($mean_{White}$ 4.12, SD 0.954; $mean_{BAME}$ 3.97, SD 0.912; *U*=44705.5; *P*=.04). Conversely, participants 65 years and over had less trust in the big tech companies ($mean_{\geq 65}$ 2.97, SD 1.133; $mean_{<65}$ 3.21, SD 1.100; *U*=49432.0; *P*=.04) and private contractors ($mean_{\geq 65}$ 2.53, SD 1.133; $mean_{<65}$ 2.88, SD 1.092; *U*=46020.0; *P*=.001), but more trust in the UK government ($mean_{\geq 65}$ 3.24, SD 1.269; $mean_{<65}$ 2.97, SD 0.945; *U*=62275.5; *P*=.02). There were no other significant differences in trust.

Discussion

Principal Findings and Comparison With Prior Work

Just over half of those surveyed had downloaded the app, agreeing with other estimates for the United Kingdom [29]. Reasons for app uptake were predominantly to help the NHS, protect others, and reduce the spread of the virus, broadly agreeing with previous research [2,4]. Older adults had more community-minded and altruistic attitudes, being more likely to download the app to help the NHS, friends, family, and society, but they also had less intention to download the app. However, almost 1 in 9 of those who initially downloaded the app eventually deleted it, especially BAME participants, although the number of these participants who had downloaded and kept the app was similar to that of White participants. However, this increased deletion is a particular concern, as their vulnerability is reflected in the finding that twice as many BAME participants had tested positive or had a household member test positive for COVID-19.

In line with previous studies [4,10,13-15], reasons for not downloading or deleting the app were related to not wanting to be tracked, a feeling that it would be ineffective, and a lack of trust in the people who built the app. People who decided to delete the app were more likely than those who kept it to feel that it was not useful or easy to use, as expected from the TAM2 [32]; they also felt they understood less about how it worked, were more concerned about how their data would be used, and were more likely to have been frustrated by a notification from the app. This shows how important a trustworthy user experience

is for the adoption of contact tracing apps. BAME participants who had the app also had higher levels of concern about their data, felt the app was less easy to use and was less useful to society, and were more likely to have been frustrated by the app; this could lead to them deleting the app in the future. Those involved in the design of contact tracing should pay particular attention to the needs of BAME app users. On the other hand, older adults had less concern about their data and less frustration. Engaging users in the development, implementation, and evaluation of contact tracing can help to maximize engagement and technology acceptance, according to the RRI framework [7,8], helping designers to consider wider social implications of a technology and how real-world use might differ from usage within a trial or with a prototype. Working together with users to anticipate concerns and develop solutions can be an effective mechanism to achieve the adoption of digital solutions.

The feeling that there was a lack of choice in using the app was stronger among BAME participants and lowest among older adults; BAME participants were also more likely to state that they had to download the app for their job. Participants required a level of control over the app, feeling that it was important to get explanations, verify and speak to people about notifications, and be able to opt out of contact tracing; interestingly, the latter was less important for older adults. Most people stated that they would be or had been highly compliant with advice to self-isolate, although intention was significantly higher than actual reported compliance, especially among older adults. Actual reported compliance was similar across the different groups, although our findings suggest that White people tended to overstate their intention to comply. This finding may be impacted by the reduced trust in the government, as previously discussed, as well as a perceived lack of incentives offered for compliance [33]. It is also interesting that when asked how much they complied with "official advice," some participants who had been asked to self-isolate, by the app or otherwise, occasionally answered that they had not received any official advice. This implies that the instruction to self-isolate was perceived as being a suggestion rather than holding any authority, which may, in turn, have led to participants not taking the same precautions as they would have if they felt that the instruction to self-isolate was an official request.

Trust in the app was moderate. Participants who did not download the app had significantly lower trust in the app, especially in whether their data would be deleted and whether the app was reliable. They also had significantly lower trust in other users and in stakeholders surrounding the app, suggesting that trust is an important consideration in the design of contact tracing apps. Trust in the government was particularly low and may be a factor in adoption of app-based contact tracing [2,4,34,35], although it was higher among older adults, who were more concerned about big tech and private contractors. The BAME population had more trust in the big tech companies and private contractors but less trust in the NHS. BAME participants were also significantly less likely to download the app to help the NHS. A recent study on health-related quality of life revealed inequalities within English ethnic minorities [36], including poor primary care experiences, inadequate support from local services, and low patient self-confidence. This indicates that government slogans like "protect the NHS" may not have the intended effect on BAME communities and should be rethought to be more inclusive. However, reasons for a lack of trust on the part of BAME people in the governments and institutions in the United Kingdom are likely linked to persistent issues of structural racism [37] and, thus, are unlikely to be changed through singular measures alone, such as government messaging.

Finally, although participants felt they understood how the app worked, the results show that most people do not know that decisions about notifications are entirely made by the app [27,29], without human involvement. Understanding was particularly low in BAME communities. This lack of understanding may affect uptake and continued use, as it may negatively impact trust and, consequently, the app's popularity, perceived validity, and reliability [38]. At the same time, perceived human intervention may falsely increase trust in the app, as a completely automated system is likely to be recognized as having an unfair impact on the population, limiting freedom without taking into consideration personal circumstances [39].

Limitations and Future Work

While the sample was representative of the UK population in terms of age, gender, region, and ethnicity, some demographics that were not measured, such as income and political leaning, may have affected the results. Additionally, this representativeness means that the sample sizes for the vulnerable populations, although proportionate to population, were small compared to the overall sample. Future work should consider enriching the sample with greater numbers of participants from minority populations in order to capture their views more thoroughly. Additionally, while the sample was drawn from an online panel, this bias toward the online population was considered acceptable for this study, as the focus was on use of a smartphone app, which implied internet access. Recent estimates suggest that 92% of adults in the United Kingdom are recent internet users, including 54% of those over 75 years of age and 81% of disabled adults; only 6.3% of adults had never used the internet [40]. However, this does mean that potential respondents who do not have access to, or the ability to use, the internet—as were individuals who were not part of the online panel—were unable to take part in this study. While out of scope for this paper, this should be examined in future studies, as such issues could disproportionately affect vulnerable communities.

Future work should also consider multivariable analyses to account for the demographics of participants, to aid in explaining the differences found between vulnerable subgroups. For example, it is possible that lower trust in the government or the NHS might be driven by factors such as age, gender, or education. Similarly, further investigation of other groups could be beneficial, for example, to test the effects of having tested positive on their opinions or behaviors. There was a slightly higher proportion of participants who had tested positive than the national proportion (4% vs 3%), and quite a few participants reported they had been otherwise affected by the virus; it is possible that some participants were drawn to the study for this reason. However, this group was not excluded or highlighted

in this paper due to the overall low numbers of self-reported positive cases among respondents.

Finally, as with all self-report studies, in addition to the potential oversubscription of closely affected participants, there is a possibility of other reporting biases in this study; for example, social desirability bias and overreporting of compliance to self-isolation advice. However, as described above, a nontrivial number of participants did report not complying at all or not intending to comply, although it does seem there is a tendency to overstate intentions. It would be interesting to relate this to actual recorded behavior with regard to self-isolation.

Conclusions

This paper adds to the existing evidence surrounding digital contact tracing by reporting on an investigation of acceptance of a live app, which had been available to download for almost 3 months at the time of the study. Based on the TAM with the added factor of trust, an online survey was carried out looking at use of and attitudes toward the United Kingdom's NHS Test and Trace app, NHS COVID-19, among a representative sample of participants, including subgroup analysis of participants 65 years and over and members of the BAME community as potentially vulnerable users. Results indicate that uptake was limited to around 1 in 2 persons. Stated reasons for adoption predominantly surrounded a desire to help the NHS, friends and family, and society, especially among older adults, although BAME respondents agreed significantly less that their reason was to help the NHS. However, of those with the app, only one-fifth understood that the decision to send self-isolation notifications was made by the app without human involvement; in addition, there were a range of significantly more negative views among BAME participants. Respondents without the app reported significantly lower trust and more negative views toward the app. In cohort with other studies, the evidence shows that there are considerable barriers to the uptake of digital contact tracing apps, and these differ across different populations. It is important to consider especially potentially vulnerable groups to ensure that interventions such as these are effective. Potential users must be engaged in the design to enhance uptake and acceptance of test and trace apps, focusing particularly on groups that might be hard to reach or may have different attitudes toward acceptance.

Acknowledgments

This research was supported by the Engineering and Physical Sciences Research Council (grants EP/V00784X/1, EP/M02315X/1, and EP/T022493/1). EPV also acknowledges the resources of the National Institute for Health Research, Nottingham Biomedical Research Centre. We are also grateful for the support of Ipsos MORI in conducting this study. While the questionnaire was designed by the authors, Ipsos MORI was contracted to recruit participants and carry out the survey.

Authors' Contributions

All authors were involved in the conceptualization and the methodology of the study. LD conducted the formal analysis of the data for the study, conducted the visualization of results, and wrote the original draft. LD and JF performed data curation and verified the underlying data. JF and DM supported funding acquisition for the study and conducted project administration. Investigation was carried out by Ipsos MORI, who also verified the underlying data. LD, JF, EPV, VP, MG, and EN contributed to reviewing and editing of the paper.

Abstract

Background: The COVID-19 global health crisis has led to an exponential surge in published scientific literature. In an attempt to tackle the pandemic, extremely large COVID-19–related corpora are being created, sometimes with inaccurate information, which is no longer at scale of human analyses.

Objective: In the context of searching for scientific evidence in the deluge of COVID-19–related literature, we present an information retrieval methodology for effective identification of relevant sources to answer biomedical queries posed using natural language.

Methods: Our multistage retrieval methodology combines probabilistic weighting models and reranking algorithms based on deep neural architectures to boost the ranking of relevant documents. Similarity of COVID-19 queries is compared to documents, and a series of postprocessing methods is applied to the initial ranking list to improve the match between the query and the biomedical information source and boost the position of relevant documents.

Results: The methodology was evaluated in the context of the TREC-COVID challenge, achieving competitive results with the top-ranking teams participating in the competition. Particularly, the combination of bag-of-words and deep neural language models significantly outperformed an Okapi Best Match 25–based baseline, retrieving on average, 83% of relevant documents in the top 20.

Conclusions: These results indicate that multistage retrieval supported by deep learning could enhance identification of literature for COVID-19–related questions posed using natural language.

Introduction

Background

In parallel with its public health crisis with vast social and economic impacts, the COVID-19 pandemic has resulted in an explosive surge of activities within scientific communities and across many disciplines [1]. In turn, it has led to an overabundance of information online and offline — a phenomenon described as an infodemic [2-4] — with often negative impacts on the population [5]. Since early 2020 when the pandemic was officially announced, the number of publications related to COVID-19 has had exponential growth [6]. In addition to the volume and velocity of the generated data, the heterogeneity as a result of the typical variety of concept naming found in the biomedical field, spelling mistakes, and the different source types [7] make searching and discovery of relevant literature within the COVID-19 corpora an important challenge [2].

With the sheer quantity of COVID-19 information continuously produced, researchers, policy makers, journalists, and ordinary citizens, among others, are unable to keep up with the fast-evolving body of knowledge disseminated. As knowledge about the pandemic evolves, study results and conclusions may be improved, contradicted, or even proven wrong [3]. Combined with relentless media coverage and social media interactions, this fast-changing and massive amount of information leads to confusion and desensitization among audiences (eg, as in the case of school opening guidelines and mask-wearing and social distancing recommendations) [5,8]. They also fuel deliberate attempts to create information disorders, such as misinformation, disinformation, malinformation, and fake news [9], reducing the effectiveness of public health measures and endangering countries' ability to stop the pandemic, ultimately having a negative impact on live costs [10,11].

To support states and relevant actors of society to manage the COVID-19 infodemic, the World Health Organization (WHO) has published a framework containing 50 recommendations, of which more than 20% are related to strengthening the scanning, review, and verification of evidence and information [2]. To help actors involved with the pandemic find the most relevant information for their needs, effective information retrieval models for the COVID-19–related corpora became thus a prominent necessity [12]. The information retrieval community, in turn, has responded actively and quickly to this extraordinary situation and has been aiming to address these challenges. To foster research for the scientific communities involved with the pandemic, the COVID-19 Open Research Dataset (CORD-19) [13] collection was built to maintain all the related publications for the family of coronaviruses. This dataset helped research in various directions, and several tasks are built around it, including natural language processing (NLP)–related tasks, like question answering [14] and language model pretraining [15], and information retrieval challenges in Kaggle [16] as well as the TREC-COVID [17,18].

The TREC-COVID [18-20] challenge ran in 5 rounds, each asking for an incremental set of information needs to be retrieved from publications of the CORD-19 collection. In a TREC-COVID round, participants were asked to rank documents of the CORD-19 corpus in decreasing order of likelihood of containing answers to a set of query topics. At the end of the round, experts provided relevance judgments for the top-ranking documents submitted by different participants using a pooling strategy [21]. Although limited to the first several top submissions of the participating teams, these relevance judgments enable the evaluation of the different models and are valuable examples to train retrieval models for the subsequent rounds of the challenge.

To improve search and discovery of COVID-19 scientific literature, in this work we aimed to investigate an information retrieval model supported by deep language models to enhance findability of relevant documents in fast-evolving corpora.

More than 50 teams participated in the TREC-COVID challenge worldwide, developing new information retrieval and NLP methodologies to tackle this complex task [22-27]. Having participated in the TREC-COVID challenge, in this paper we detail our retrieval methodology, which brought us competitive results with the top-ranking teams. Particularly, we used a multistage retrieval pipeline, combining classic probabilistic weighting models with novel learning to rank approaches made by ensemble of deep masked language models. We present our results and analyze how the different components of the pipeline contribute to providing the best answers to the query topics.

Related Work

Two-Stage Information Retrieval

Currently, 2 main methodologies are used to rank documents in information retrieval systems: (1) the classic query-document probabilistic approaches, such as Okapi Best Match 25 (BM25) [28] and probabilistic language models [29], and (2) the learning-to-rank approaches, which usually postprocess results provided by classic systems to improve the original ranked list [30,31]. When there are sufficient training data (ie, queries with relevance judgments for the case of information retrieval), learning-to-rank models often outperform classic one-stage retrieval systems [30,32]. Nevertheless, empiric results have also shown that the reranking step may degrade the performance of the original rank [33]. Progress on learning-to-rank algorithms has been fostered thanks to the public release of annotated benchmark datasets, such as the LETOR [34] and Microsoft Machine Reading Comprehension (MS MARCO) [35].

Learning-to-rank approaches can be categorized into 3 main classes of algorithms — pointwise, pairwise, and listwise — based on whether they consider 1 document, a pair of documents, or the whole ranking list in the learning loss function, respectively [30-32,36]. Variations of these learning-to-rank algorithms are available based on neural networks [31,36] and other learning algorithms, such as boosting trees [37]. More recently, pointwise methods leveraging the power of neural-based masked language models have attracted great attention [38,39]. These learning-to-rank models use the query and document learning representations provided by the masked language model to classify whether a document in the ranked list is relevant to the query. While these two-stage retrieval methods based on neural rerankers provide interesting

features, such as learned word proximity, in practice, the first stage based on classic probabilistic retrieval algorithms is indispensable, as the algorithmic complexity of the reranking methods makes them often prohibitive to classify the whole collection [32].

Recent advances in text analytics, including question answering, text classification, and information retrieval, have indeed mostly been driven by neural-based masked language models. A seminal effort in this direction is the Bidirectional Encoder Representations from Transformers (BERT) model [38], which shows significant success in a wide range of NLP tasks. BERT uses a bidirectional learning approach based on the transformer architecture [40] and is trained to predict masked words in context. Since the introduction of BERT, several works tried to augment its performance. A successful work in this direction is the robustly optimized BERT approach (RoBERTa) [41], using larger and more diverse corpora for training as well as a different tokenizer. While RoBERTa needs larger computing power, it often improves the performance of BERT across different downstream tasks. Another similar effort is the XLNet model [42], which uses a permutation-based masking, showing also consistent improvement over BERT.

TREC-COVID Retrieval Efforts

Recently, the specific case of retrieval of COVID-related scientific publications has been addressed in several efforts [22-27]. These works follow mostly the aforementioned two-stage retrieval process. Among the first efforts is the SLEDGE system [22], where the authors detailed their solutions for the first round of the TREC-COVID challenge using a BM25-based ranking method followed by a neural reranker. An important difficulty for the first round of the challenge is the absence of labelled data. To overcome this limitation, the authors lightly tuned the hyperparameters of the first-stage ranking model using minimal human judgments on a subset of the topics. As for the second stage, they used the SciBERT model [43], which is pretrained on biomedical texts, and fine-tuned on the general MS MARCO set [35] with a simple cross-entropy loss. CO-Search [24] uses a slightly different approach, wherein they incorporated semantic information, as captured by Sentence-BERT [44], also within the initial retrieval stage. Moreover, they used the citation information of publications in their ranking pipeline. In the work of Covidex [23], the authors provided a full-stack search engine implementing a multistage ranking pipeline, where their first stage is based on the Anserini information retrieval toolkit [45], complemented by different neural reranking strategies. They addressed the issue of length variability among documents with an atomic document representation using, for example, paragraph-level indexing.

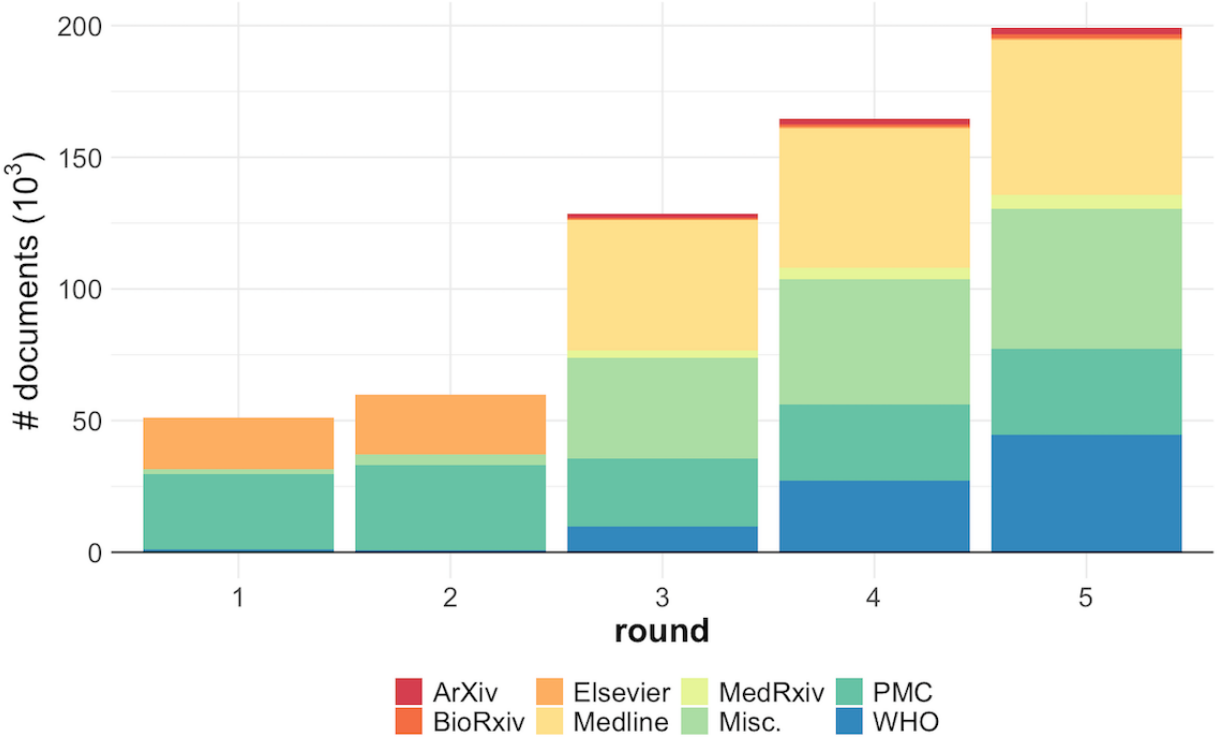
Methods

In this section, we describe the corpus and query set and our methodology for searching COVID-19–related literature in the context of the TREC-COVID challenge. We start by introducing the CORD-19 dataset, which is the corpus used in the competition. We then describe the challenge organization and assessment queries. Then, we detail our searching methodology, based on a multistage retrieval approach. Finally, we present the evaluation criteria used to score the participants' submissions. For further details on the TREC-COVID challenge, see [19,20].

The CORD-19 Dataset

A prominent effort to gather publications, preprints, and reports related to the coronaviruses and acute respiratory syndromes (COVID-19, Middle East respiratory syndrome [MERS], and severe acute respiratory syndrome [SARS]) is the CORD-19 collection of the Allen Institute for Artificial Intelligence (in collaboration with other partners) [13]. Figure 1 describes the size and content origin of the corpus for the different TREC-COVID rounds. As we can see, this is a large and dynamically growing semistructured dataset from various sources like PubMed, PubMed Central (PMC), WHO, and preprint servers like bioRxiv, medRxiv, and arXiv. The dataset contains document metadata, including title, abstract, and authors, among others, but also the full text or link to full-text files when available. A diverse set of related disciplines (eg, from virology and immunology to genetics) are represented in the collection. Throughout the challenge, the dataset was updated daily, and snapshot versions representing its status at a certain time were provided to the participants for each round. In the last round of the TREC-COVID challenge, the corpus contained around 200,000 documents, coming mostly from Medline, PMC, and WHO sources.

Figure 1. Evolution of the CORD-19 corpus across the TREC-COVID rounds stratified by source. PMC: PubMed Central; WHO: World Health Organization.



The TREC-COVID Challenge

To assess the different information retrieval models, the TREC-COVID challenge provided a query set capturing relevant search questions of researchers during the pandemic. These needs are stated in query topics, consisting of 3 free-text fields — query, question, and narrative — with an increasing level of context, as shown in the examples in Table 1. The challenge started with 30 topics in round 1 and added 5 new topics in each new round, thus reaching 50 topics in round 5.

In each round, the participants provided ranked lists of candidate publications of the CORD-19 collection that best answered the query topics. Each list was generated by a different information retrieval model, so called *run*, with up to 5 runs in the first 4 rounds and 7 runs in the last round per team. At the end of the round, domain experts examined the top k candidate publications (where k is defined by the organizers) from the priority runs of the teams and judged them as "highly relevant," "somehow relevant," or "irrelevant." Then, based on the consolidated relevance judgments, the participants were evaluated using standard information retrieval metrics (eg, normalized discounted cumulative gain [NDCG], precision). Judged documents for a specific topic from previous rounds were excluded from the relevance judgment list.

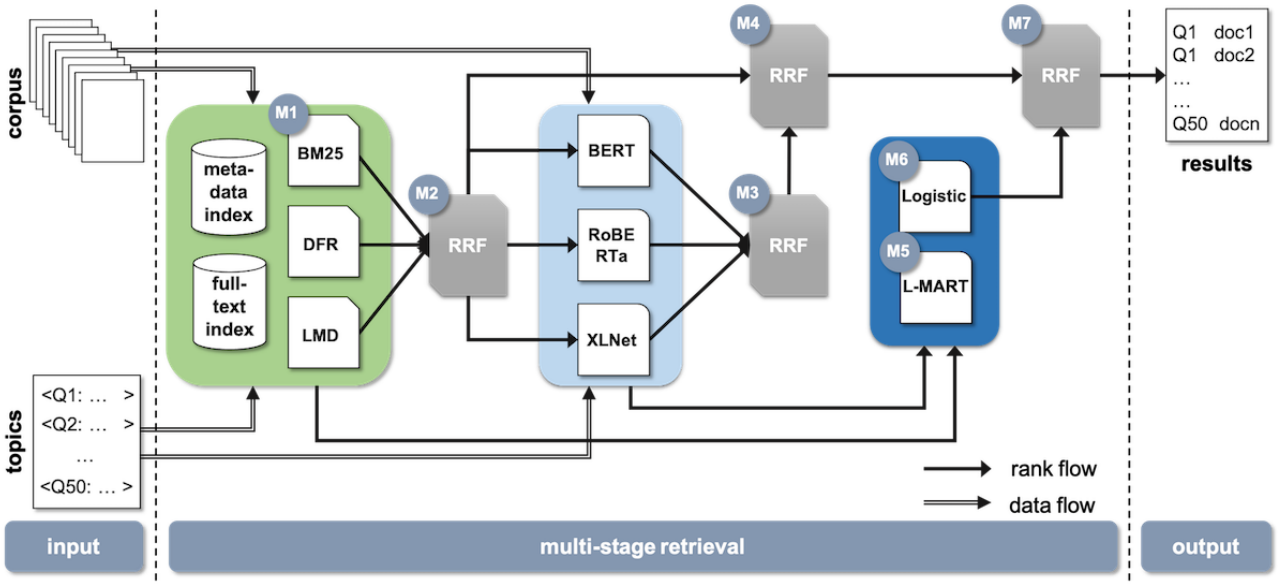
Table 1. Examples of TREC-COVID topics with the fields query, question, and narrative.

Topic	Query	Question	Narrative
1	Coronavirus origin	What is the origin of COVID-19?	Seeking a range of information about the SARS-CoV-2 virus's origin, including its evolution, animal source, and first transmission into humans
25	Coronavirus biomarkers	Which biomarkers predict the severe clinical course of 2019-nCOV infection?	Looking for information on biomarkers that predict disease outcomes in people infected with coronavirus, specifically those that predict severe and fatal outcomes
50	mRNA vaccine coronavirus	What is known about an mRNA vaccine for the SARS-CoV-2 virus?	Looking for studies specifically focusing on mRNA vaccines for COVID-19, including how mRNA vaccines work, why they are promising, and any results from actual clinical studies

Proposed Multistage Retrieval Methodology

Figure 2 shows the different components of our information retrieval pipeline for the COVID-related literature. These components can be divided into 3 main categories: (1) first-stage retrieval using classic probabilistic methods, (2) second-stage (neural) reranking models, and (3) rank fusion algorithms. Given a corpus containing metadata information, such as title and abstract, and full text, when available, documents are stored using directed and inverted indexes. Then, transformer-based and classic learning-to-rank models trained using relevance judgments are used to classify and rerank pairs of query-document answers. The ranked list obtained from the different models are further combined using the reciprocal rank fusion (RRF) algorithm.

Figure 2. Multistage retrieval pipeline, where light green indicates first-stage retrieval, light and dark blue indicate second-stage retrieval, and M1-M7 denote the different models used to create the respective runs 1-7 in round 5. BERT: Bidirectional Encoder Representations from Transformers; BM25: Okapi Best Match 25; DFR: divergence from randomness; L-MART: LambdaMART model; LMD: language model Dirichlet; Logistic: logistic regression model; RoBERTa: robustly optimized BERT approach; RRF: reciprocal rank fusion.



First-Stage Retrieval

For the first-stage retrieval, we assessed 3 variations of the classic query-document probabilistic weighting models: BM25 [46], divergence from randomness (DFR) [47], and language model Dirichlet (LMD) [48].

Our first classical model, Okapi BM25 [28], is based on the popular term frequency-inverse document frequency (tf-idf) framework. In the tf-idf framework, term-weights are calculated using the product of within term-frequency *tf* and the inverse document frequency *idf* statistics. Denote *f(t,d)* as the number of times a term *t* appears in a document *d* within a collection *D*, BM25 calculates the term-weight *w* as:

where $|d|$ is the length of the document, $|D|$ is the size of the collection, avg_l is the average length of the documents in the collection, n_t is the number of documents containing the term *t*, and k_1 and *b* are parameters of the model associated with the term frequency and the document size normalization, respectively.

The second model, DFR, extends the basic tf-idf concept by considering that the more the divergence of the term frequency *tf* from its collection frequency *cf* (*cf* ≈ *df*), the more the information carried by the term in the document [47]. Thus, for a given model of randomness *M*, in the DFR framework, the term-weight is inversely proportional to the probability of term-frequency within the document obtained by *M* for the collection *D*:

$$w(t,d,D) = k \cdot \log p_M (t \quad d|D),$$

where p_M is a probabilistic model, such as binomial or geometric distributions, and *k* is a parameter of the probabilistic model.

The third model, LMD, uses a language model that assigns probabilities to word sequences with a Dirichlet-prior smoothing to measure the similarity between a query and a document [48]. In a retrieval context, a language model specifies the probability that a document is generated by a query, and smoothing is used to avoid zero probabilities to unseen words and improves the overall word probability accuracy. In the LMD algorithm, term-weight is calculated using the following equation:

where $p(t|d)$ denotes the probability of a term in a document, $p(t|D)$ is the probability of a term in the collection, and μ is the Dirichlet parameter to control the amount of smoothing.

In our pipeline, the BM25, DFR, and LMD implementations are based on the Elasticsearch framework. The model parameters were trained using the queries and relevance judgments of round 4 in a 5-fold cross-validation setup.

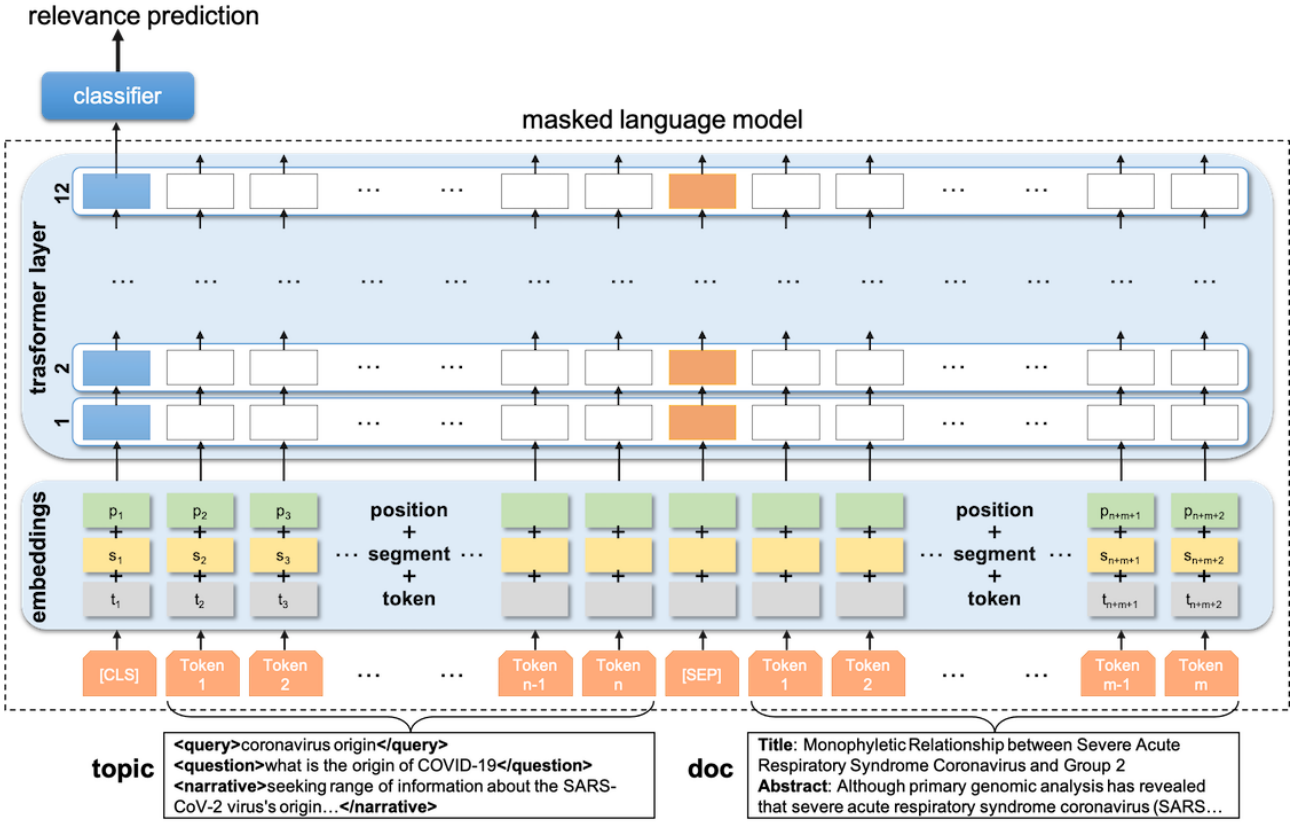
Second-Stage Reranking

The models used in the first-stage ranking were based on the bag-of-words statistics, where essentially we looked at the histogram of query terms and their document and collection statistics but neglected the sequential nature of text and word relations. To mitigate these limitations and improve the initial rankings, after the first-stage retrieval, we used neural masked language models trained on the relevance judgments from previous rounds so that syntactic and semantic relations can be better captured [49,50]. As shown in Figure 2, we assessed 3 masked language models based on the transformer architecture: BERT, RoBERTa, and XLNet.

Figure 3 shows the general idea of how we used the BERT language model to match documents to a query topic. Given a topic and a document associated with it as input and a relevance judgment as the label for the query-document association (relevant or not), the model was trained or fine-tuned in the

BERTology parlance, as it had been previously pretrained on a large corpus, to predict whether the document is relevant to the query. In the input layer of the pretrained model, the topic and candidate publication were tokenized and separated by the language model *[SEP]* token (stands for sentence separation). Moreover, to enforce the sequential structure of text, positional embedding as well as sentence embeddings were added to the main embeddings for each token. These embeddings were then fed to the transformer layers of BERT, which were updated during the fine-tuning step. Finally, the output of the special *[CLS]* token (stands for classification) was used to determine the relevance of the candidate publication to the queried information topic.

Figure 3. Neural masked language model for document relevance classification. As inputs to the pre-trained masked language model, the topics and candidate publications are separated by the [SEP] tag. Inputs are tokenized using subword tokenization methods (grey boxes); segment embeddings (yellow boxes) represent the difference between a topic and a document input; position embeddings (green boxes) enforce the sequential structure of text; the transformer and classification layers are updated in the training phase using the relevance judgments; and the output of the special [CLS] token is finally used to determine the relevance of the candidate publication to the queried information topic.



Using the query topics from a preceding round (round 4 for the results presented here) and their respective list of relevance judgments, we fine-tuned the BERT model to rescore the initial association of the query-document pair between (not relevant) and (very relevant). For this, we used the score associated with the *[CLS]* token position. We limited the input size of the query and document to 512 tokens (or subwords). Then, at the second-stage re-ranking step, we classified the top *k* publications retrieved by the first stage models using the fine-tuned BERT model (we set *k*=5000 in our experiments).

Identical training strategies were used for the RoBERTa and XLNet language models. The main difference for the RoBERTa model is that it was originally pretrained on a corpus with an order of magnitude bigger than that of BERT (160 GB vs 16 GB). Moreover, it uses dynamic masking during the training process, that is, at each training epoch, the model sees different versions of the same sentence with masks on different positions, compared to a static mask algorithm for BERT. Last, RoBERTa uses a byte-level Byte-Pair-Encoding tokenizer compared to BERT's WordPiece. As BERT and its variants (eg, RoBERTa) neglect the dependency between the masked positions and suffer from a pretrain-finetune discrepancy, XLNet adopts a permutation language model instead of masked language model to solve the discrepancy problem. For downstream tasks, the fine-tuning procedure of XLNet is similar to that of BERT and RoBERTa.

We used the BERT (base - 12 layers), RoBERTa, and XLNet model implementations available from the Hugging Face framework. The models were trained using the Adam optimizer [51] with an initial learning rate of 1.5e–5, weight decay of 0.01, and early stopping with a patience of 5 epochs.

Combining Model Results

We used the RRF algorithm [52] to combine the results of different retrieval runs. RRF is a simple, yet powerful technique to rescore a retrieval list based on the scores of multiple retrieval lists. Given a set of documents D to be sorted and a set of ranking files $R = \{r_1 \ldots r_n\}$, each with a permutation on $1 \ldots |D|$, RRF computes the aggregated score using the following equation:

where $r(q,d)$ is the rank of document d for the query q in the ranking file r_i and k is a threshold parameter, which was tuned to k=60 using data from previous rounds.

Second-Step Learning-to-Rank

To exploit the features (relevance score) created by the different bag-of-words and masked language models, we added a second-step learning-to-rank pass to our pipeline. Using the similarity scores s computed by the BM25, DFR, LMD, BERT, RoBERTa, and XLNet as input features and the relevance judgments of previous rounds as labels, we trained 2 learning-to-rank models: LambdaMART and a logistic regression classifier. While the language models exploit the sequential nature of text, they completely neglect the ranking provided by the bag-of-words models. Thus, we investigated the use of the LambdaMART [31] algorithm, which uses a pairwise loss that compares pairs of documents and tells which document is better in the given pair. Moreover, we trained a simple pointwise logistic regression to consider the similarity measures computed by the first- and second-stage retrieval models. We used the pyltr and scikit-learn implementations for the LambdaMART and logistic regression, respectively. For the LambdaMART model, we trained the learning rate and the number of estimators, and for the logistic regression model, we trained the solver and regularization strength parameters.

First-Stage Retrieval: Preprocessing, Querying Strategies, and Parameter Tuning

In the first-stage retrieval step, we applied a classical NLP preprocessing pipeline to the publications (indexing phase) and topics (search phase): lower-casing, removal of nonalphanumerical characters (apart from "-"), and Porter stemming. Additionally, a minimal set of COVID-related synonyms, such as "covid-19" and "sars-cov-2," were created and used for query expansion.

The queries were then submitted to the index in a combinatorial way using the different topic fields and document sections. This means that, for each *query*, *question*, and *narrative* field of a topic, we submitted a query against the index for each of the *title* and *abstract* sections of the publications (abstract + full text in case of the full-text index). Additionally, the whole topic (query + question + narrative) was queried against the whole document. This querying strategy led to 7 queries for each topic, and the final score was computed by summing up the individual scores. Moreover, as the first public announcement of a coronavirus-related pneumonia was made in January 2020, we filtered out all publications before December 2019.

We defined the best query strategy and fine-tuned the basic parameters of the bag-of-words models using the relevance judgments of the previous round in a 5-fold cross-validation approach. As an example, to tune the b and k parameters of the BM25 model in round 5, we took the topics and relevance judgment from round 4 and submitted them to the index in round 5, optimizing the P@10 metric. For round 1, we used default parameter values.

Evaluation Criteria

We used the official metrics of the TREC-COVID challenge to report our results: precision at K documents (P@K), NDCG at K documents (NDCG@K), mean average precision (MAP), and binary preference (Bpref) [19]. For all these metrics, the closest the result is to 1, the better the retrieval model. They were obtained using the *trec_eval* information retrieval evaluation toolkit.

Results

We used 7 models from our pipeline to create the 7 runs submitted for the official evaluation of the TREC-COVID challenge (labels M1 to M7 in Figure 2). Our first model — *bm25* — based on the BM25 weighting model against the metadata index provided the baseline run. Our second model — *bow + rrf* — was a fusion of the BM25, DFR, and LMD weighting models computed against the metadata and full-text indices and combined using the RRF algorithm. Model 3 — *mlm + rrf* — used the RRF combination of the BERT, RoBERTa, and XLNet models applied to the top 5000 documents retrieved by model 2. Model 4 — *bow + mlm + rrf* — combined the results of models 2 and 3 using the RRF algorithm. Then, model 5 — *bow + mlm + lm* — reranked the results of runs 2 and 3 using the LambdaMART algorithm trained using the similarity scores of the individual models 2 and 3. Similarly, model 6 — *bow + mlm + lr* — was based on a logistic regression classifier that uses as features the similarity scores of runs 2 and 3 to classify the relevance of the query-document pairs. Finally, model 7 — *bow + mlm + lr + rrf* — combined runs 2, 3, and 6 using the RRF algorithm. For all RRF combinations, the parameter k was set to 60. All models and parameters were trained using round 4 relevance judgments. Table 2 summarizes the submitted runs.

Table 2. Summary of the submitted runs. Refer to Figure 2 for a pictorial description.

Run	Name	Description
1	bm25	Run based on the baseline BM25[a] model using the metadata index
2	bow + rrf	An RRF[b] combination of BM25, DFR[c], and LMD[d] models computed against the metadata and full-text indices
3	mlm + rrf	An RRF combination of BERT, RoBERTa[e], and XLNet models applied to run 2
4	bow + mlm + rrf	An RRF combination of runs 2 and 3
5	bow + mlm + lm	A LambdaMART-based model using features from the individual models used to create runs 2 and 3
6	bow + mlm + lr	A logistic regression model using features from the individual models used to create runs 2 and 3
7	bow + mlm + lr + rrf	An RRF combination of runs 2, 3, and 6

[a]BM25: Okapi Best Match 25.

[b]RRF: reciprocal rank fusion.

[c]DFR: divergence from randomness.

[d]LMD: language model Dirichlet.

[e]RoBERTa: robustly optimized BERT approach.

Official Evaluation Results

Table 3 shows the official results of the TREC-COVID challenge for the 7 submitted runs. As we can see, the best results are provided by model 7 (bow + mlm + lr + rrf), apart from the metric Bpref, which is the highest for model 5 (bow + mlm + lm). Comparing the NDCG@20 metric, model 7 improved 16.4 percentage points against the baseline model (26.0% relative improvement). On average, almost 17 of the top 20 documents retrieved by model 7 were pertinent to the query. Model 3 was able to retrieve 6.6% more relevant documents compared to the baseline model (6963 vs 6533 of a total of 10,910 documents judged relevant for the 50 queries). On the other hand, it showed a relative improvement in precision of 22.1% for the top 20 documents. Therefore, it not only improved the recall but also brought relevant documents higher in the ranking list. These results show that the use of the masked language models had a significant positive impact in the ranking.

Table 3. Performance of our models in round 5 of the TREC-COVID challenge.

Model	NDCG@20[a]	P@20[b]	Bpref[c]	MAP[d]	# rel[e]

Table 4 shows the official best results for the different metrics for the top 10 teams participating in round 5 of TREC-COVID (NDCG@20 metric taken as reference). Comparing the NDCG@20 metric, the best model submitted by our team (risklick) was ranked 4 of the 28 teams participating in round 5, 5.4 percentage points below the top-performing team (Unique-ptr). For reference, the best-performing model in the challenge retrieves on average 17.5 relevant documents per query in the top 20 retrieved documents compared to 16.5 for our model. If we consider a reference baseline made by the median of the participating teams' best values, our pipeline outperforms the baseline by 11.7%, 14.6%, 16.7%, and 25.0% for the MAP, P@20, NDCG@20, and Bpref metrics, respectively. All data and results of the TREC-COVID challenge can be found here: [17].

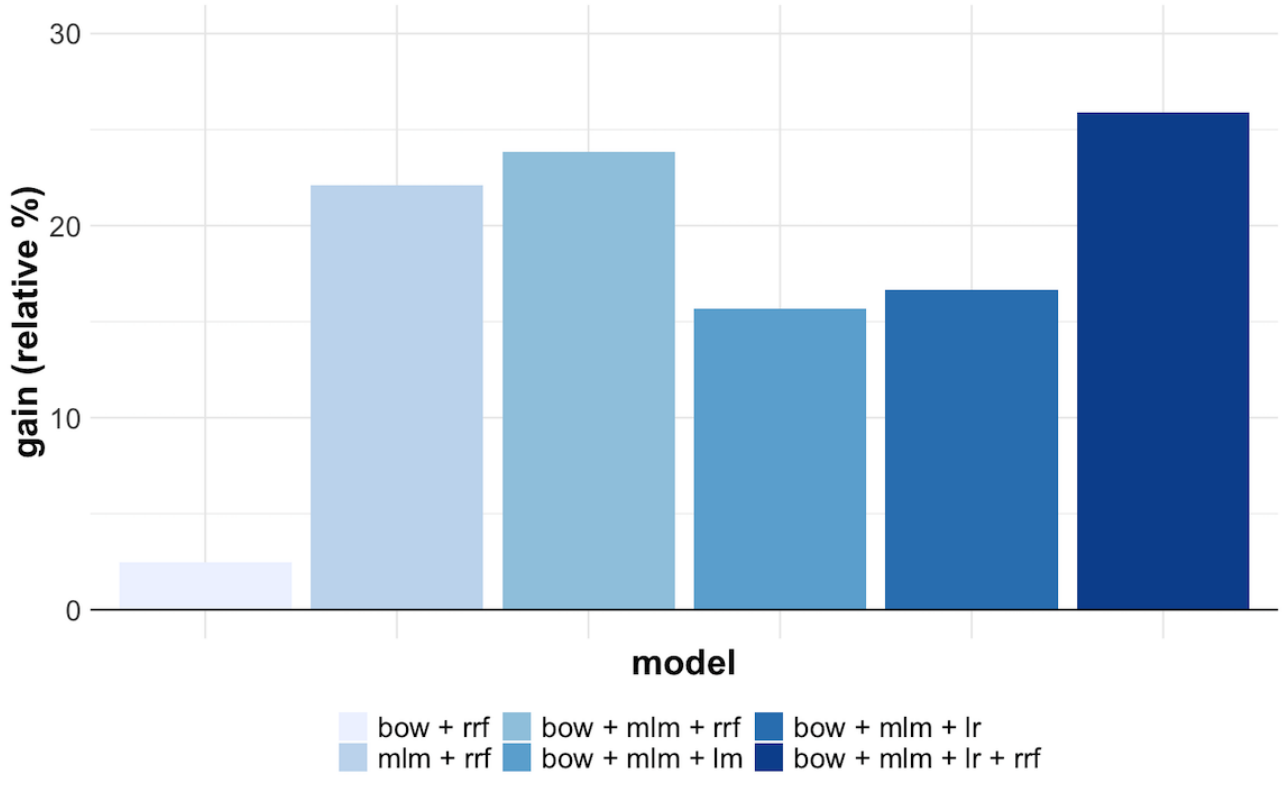
Model Performance Analyses

Figure 4 shows the relative improvement of the different models in the pipeline in relation to the baseline (model 1 – bm25) according to the NDCG@20 metric. The most significant contribution to the final performance came from the inclusion of the masked language models in the pipeline — model 3: mlm + rrf and model 4: bow + mlm + rrf — adding a relative performance gain to the results of 22.1% and 23.8%, respectively. The classic learning-to-rank models — model 5 and model 6 — actually jeopardized the performance when compared to their previous model in the pipeline (model 4). However, when model 6 was combined with model 4, a 2.1 percentage point gain was achieved on top of model 4, leading to the best model (model 7: bow + mlm + lr + rrf). Indeed, it is important to notice the consistent benefit of combining models using the RRF algorithm. Interestingly, the effect of LambdaMART seemed to be significantly detrimental for P@20, NDCG@20, and MAP, but marginally beneficial for Bpref, for which it is the best model.

Figure 4. Relative contribution of each model for the normalized discounted cumulative gain at document 20 (NDCG@20) metric compared to the baseline model bm25.



The performance of the individual masked language models is shown in Table 5. Surprisingly, they are similar to the baseline model, with small performance reductions for BERT and RoBERTa models and a small performance gain for the XLNet model. However, when combined, they provide the significant performance improvement shown in Figure 4. Our assumption is that they retrieve different documents as relevant and their combination using RRF ends up aligning these documents in the top rank. Indeed, looking at the top 3 documents for query 1 retrieved by these models, for example, there is no overlap between the documents, with 8 relevant and 1 unjudged (out of the 9 documents). This result clearly shows the beneficial effect of using an ensemble of masked language models, as well as the success of RRF in fusing their retrievals.

Table 5. Performance of the individual masked language models and their combination using reciprocal rank fusion (RRF).

Model	NDCG@20[a]	P@20[b]	Bpref[c]	MAP[d]	# rel[e]
BERT[f]	0.6209	0.6430	0.5588	0.2897	6879
RoBERTa[g]	0.6261	0.6440	0.5530	0.2946	6945
XLNet	0.6436	0.6570	0.5644	0.3064	6926
mlm + rrf	0.7716	0.7880	0.5680	0.3468	6963

[f]BERT: Bidirectional Encoder Representations from Transformers.

[g]RoBERTa: robustly optimized BERT approach.

Topic Performance Analyses

The performance analyses for the individual topics shows that our best model had a median value of 0.9000 for the P@20 metric (max=1.0000, min=0.3000), which demonstrates successful overall performance. However, as shown in Figure 5, for some topics, notably 11, 12, 19, 33, and 50, less than 50% of documents in the top 20 retrieved are relevant. For topics 11, 12, and 19, which searched for “coronavirus hospital rationing,” “coronavirus quarantine,” and “what alcohol sanitizer kills coronavirus” information, respectively, all our models have poor performance, and indeed, the combination of the different models in the pipeline managed to boost the results. On the other hand, for topics 33 and 50, which searched for “coronavirus vaccine candidates” and “mRNA vaccine coronavirus” information, respectively, it was the combination with the logistic regression model that lowered the performance (notice in Figure 5 that model 4: bow + mlm + rrf has a significantly better performance compared to model 7 for those queries).

The difference in performance per topic between our best model and the median of the submitted runs in round 5 for all teams for the P@20 metric is shown in Figure 6. Indeed, topics 11, 12, and 19 seemed hard for all the models participating in the TREC-COVID challenge to retrieve the correct documents. Even if our best model had poor performance for those topics, it still outperformed most of the runs submitted to the official evaluation. In particular, topic 19 had only 9 relevant or somewhat relevant documents in the official relevance judgments, which means that its max performance can be at most around 50% for the P@20 metric. For our worst performing topics compared to the other participants — topics 33 and 50 — better tuning between the ranking weights of the bag-of-words, masked language, and logistic regression models could have boosted the results.

Figure 5. Per topic precision at rank 20 (P@20) in round 5 of TREC-COVID per each run. The baseline run1 and the best-performing run7, which benefits from neural language models, are highlighted with dashed lines. Note that for most topics, the transformer-based runs have significantly improved performance.

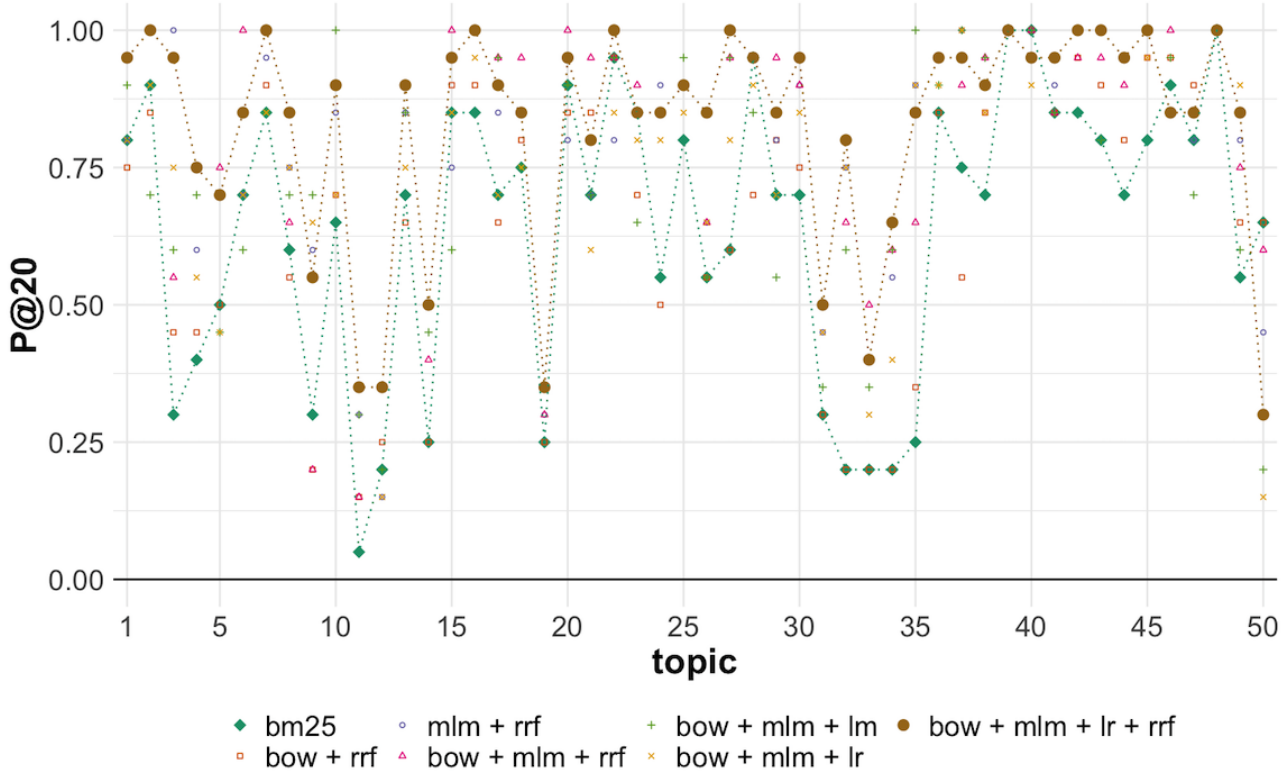

Figure 6. Per topic performance difference between our best model (model 7) and the median of all official submissions for the precision at document 20 (P@20) metric in round 5.

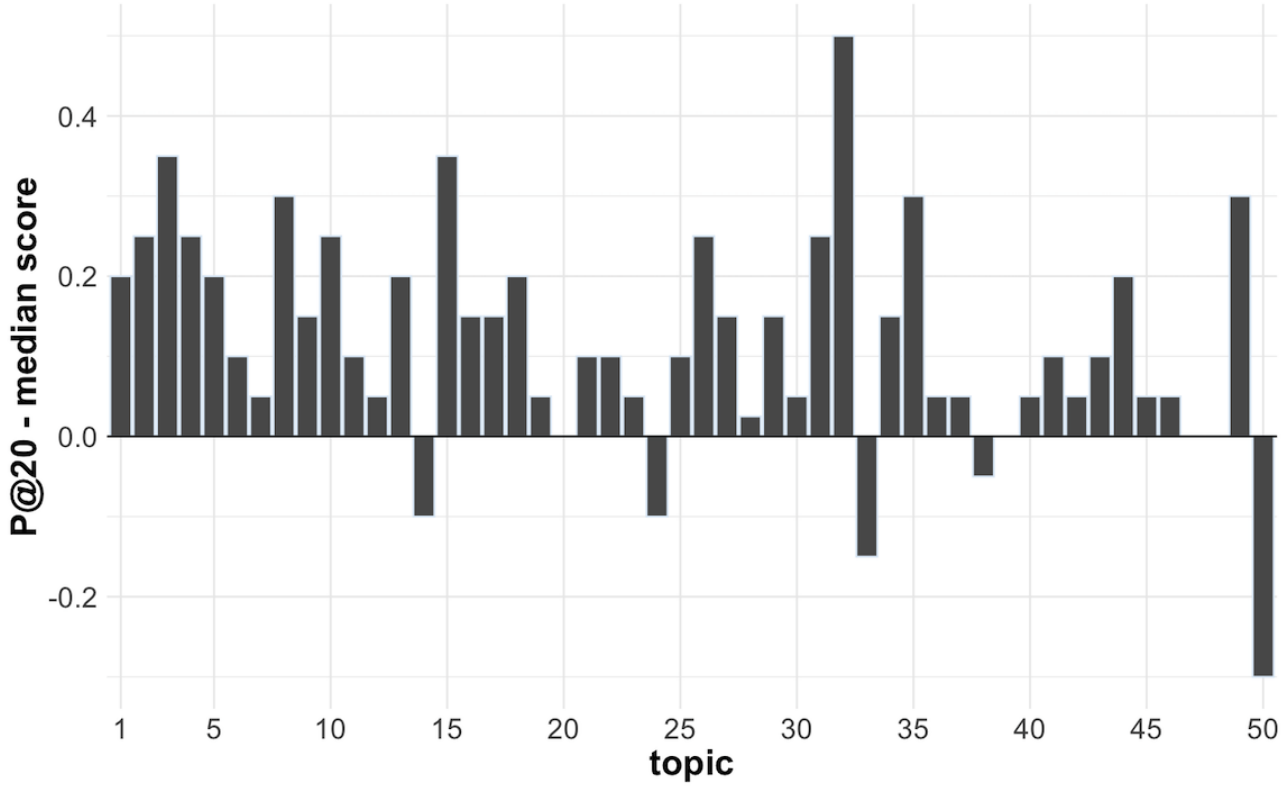
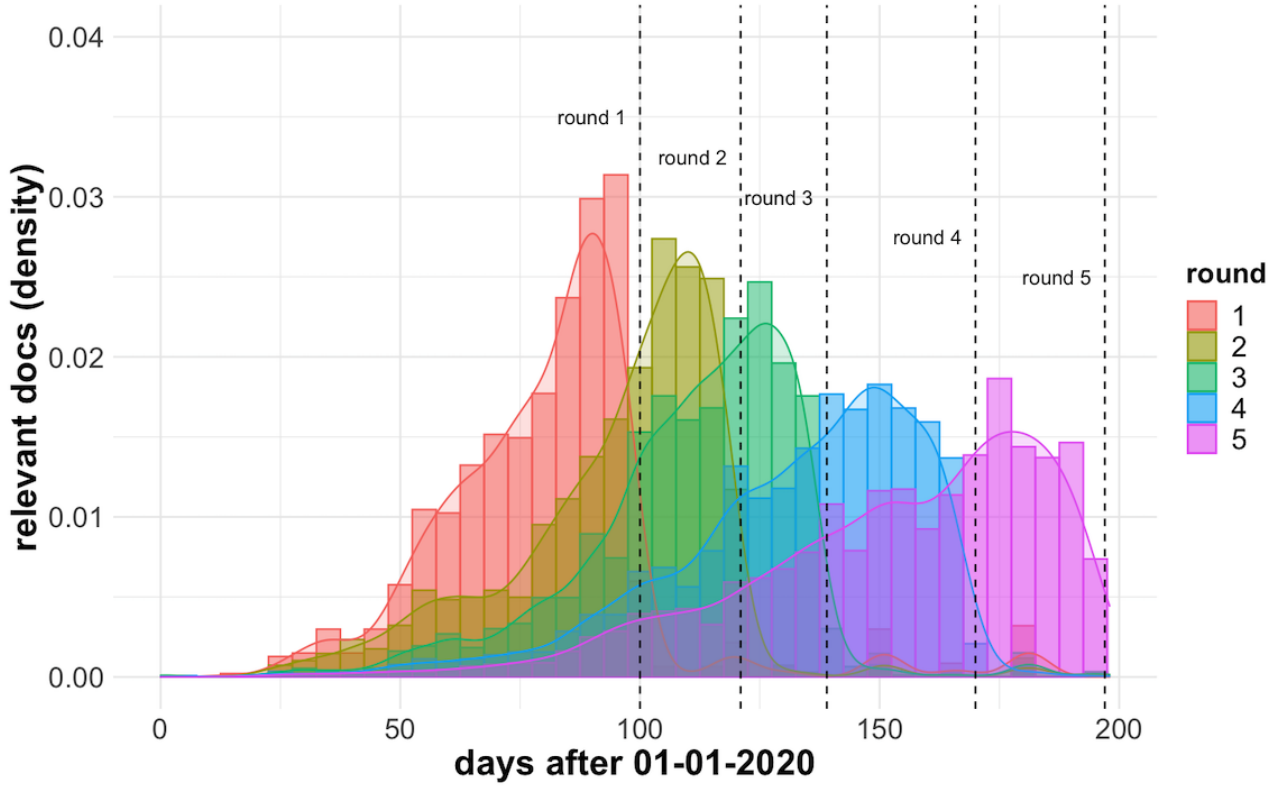


Time-Dependent Relevance Analyses

Given the dynamics of the COVID-19 pandemic, with a relatively well-defined starting period, a particularly effective technique to remove noise from the results, also adopted by some other participating teams [22], is filtering documents based on their publication dates. For our first-stage retrieval models, we filtered out publications before December 2019 when the outbreak was first detected. This led to a small negative impact on recall but highly improved the precision of our models.

To better understand how the document relevance varied over time, we analyzed the publication date of the official relevance judgments for the 5 rounds of TREC-COVID. As we can see in Figure 7, there is a clear exponential decay pattern in the number of relevant articles over time for all the rounds, with a faster decay in the first rounds and a longer tail for the later ones. We noticed that more recent publications closer to the round start, when the snapshot of the collection was created and queries were submitted, tended to have a higher probability of being relevant to the information need, with a half-life of around 20 days for round 1. This is somehow expected. First, as the documents found in previous query rounds were explored and are no longer relevant, only the most recent data are interesting, particularly in the gap between rounds. A second explanation is that in the case of a pandemic, new evidence arrives at an explosive rate, possibly refuting older knowledge.

Figure 7. Distribution of the publication dates of the "highly relevant" articles for each of the TREC-COVID rounds.



Discussion

To support effective search and discovery of COVID-19–related relevant literature in the COVID-19 infodemic, we explored the use of a multistage retrieval pipeline supported by bag-of-words models, masked language models, and classic learning-to-rank methods. The proposed methodology was evaluated in the context of the TREC-COVID challenge and achieved competitive results, being ranked in the top 4 of 126 runs among 28 teams participating in the challenge. The use of the multistage retrieval approach significantly improved the search results of COVID-related literature, leading to a gain in performance of 25.9% in terms of the NDCG@20 metric compared to a bag-of-words baseline. Particularly, the ensemble of masked language models brought the highest performance gain to the search pipeline. Indeed, ensembles of language models have proved to be a robust methodology to improve predictive performance [53-55].

The COVID-19 pandemic has led to a huge amount of literature being published in the most diverse sources, including scientific journals, grey repositories, and white reports, among others. As the pandemic continues, the number of scientific publications grows at an unprecedented rate causing an infodemic within many of the different disciplines involved [3]. Finding the most relevant information sources to answer different information needs within the huge volume of data created had become of utmost necessity [2]. By enabling the discovery of relevant information sources to complex user queries, effective retrieval models as proposed in this work may help to tackle the spread of misinformation. Such models empower experts with a minimal cost to search and discover information sources within a massive and fast-evolving corpus. Indeed, our model provides relevant information sources for more than 8 documents in the top-10 rank. Thus, continuous active search methods could be put in place to monitor and discover sources of evidence to certain query topics of relevant public health interest (eg, "coronavirus origin") in a timely manner. This in turn, would

enable experts to analyze, identify, and curate both sources of the best evidence at the time and sources of misinformation. The former would foster the creation among others of living systematic reviews [56,57], which is one of the recommendations of the WHO to tackle the COVID infodemic [2]. On the other hand, the latter could help fight, for example, the spread of scientific fake news by early retraction of misinforming articles, particularly in preprint servers, and thus limiting their exposition.

Looking at the boost in performance of model 3 (mlm + rrf) alone, one could be tempted to argue that masked language models could be the main component in a retrieval system. However, 2 issues may arise: algorithmic complexity and search effectiveness. The former is related to the high complexity of masked language models $(O(n^2 \cdot h)$, where n is the sentence length and h is the number of attention heads), which makes it prohibitive to classify a whole collection, often containing millions of documents, for every given query. The latter is related to the effectiveness of the individual models themselves. As shown in Table 5, individually, the performance of the language models is not significantly different from the baseline BM25 model. Thus, we believe it is the combination of models with different properties that can provide a successful search strategy in complex corpora, such as the one that originated from the COVID-19 infodemic.

In terms of practical implications, by effectively processing natural language, the methodology proposed can help biomedical researchers and clinicians to find the COVID-19 papers that they need. The efficient literature discovery process fostered by our methods may lead to faster publication cycles when required, for example reducing from weeks to days the drafting time of COVID-19 reviews [58], but also to less costly creation of curated living evidence portals, which will inform clinicians and public health officers with the best available evidence [59]. Indeed, as shown in [27,60], these methodologies outperform commercially available tools for searching and discovering COVID-19–related literature. Moreover, as they are data-driven, it is expected that they can be extrapolated to other types of corpora, such as clinical trial protocols and biomedical metadata datasets [60,61], enabling thus a more comprehensive identification of scientific evidence. Equally important, as the COVID-19 infodemic is not the first and unlikely the last [62,63], our methodology and findings could be extended to help tackling future epi-, pan-, and infodemics by supporting relevant actors to scan large and fast-changing collections to create timely reviews and curated evidence and apply localized infodemic management approaches.

With the rapid surge of published information and the variety of topics and sources related to COVID-19, it became hard for professionals dealing with the pandemic to find the correct information for their needs. While the automation discussed in this work can support more effective search and discovery, some high-level topics are still challenging. Indeed, some topics assessed in the TREC-COVID challenge were shown to be particularly hard for the retrieval models. For example, for topic 11, which searched for documents providing information on "guidelines for triaging patients infected with coronavirus," our best model prioritized documents providing information about indicators for diagnosis (eg, "early recognition of coronavirus," "RT-PCR testing of SARS-CoV-2 for hospitalized patients clinically diagnosed"). On the other hand, it missed documents including passages such as "telephone triage of patients with respiratory complaints." Similarly, for topic 12, which searched information about the "best practices in hospitals and at home in maintaining quarantine," our model prioritized documents providing information about "hospital preparedness" (eg, "improving preparedness for," "preparedness among hospitals") and missed documents containing information about "home-based exercise note in Covid-19 quarantine situation."

The methodology proposed has some limitations. First, it fails to explore transfer learning of learning-to-rank datasets. While the top-ranked teams all used multistage retrieval approaches, confirming the value of such methodology in modern retrieval models [18,23], the reranking strategy within the different pipelines varied slightly among the participants. For example, the top-ranked team used transfer learning from the MS MARCO learning-to-rank dataset and from a zero-shot learning approach. Other teams in the top 3 used transfer learning from a silver collection, based on the known item search technique [64]. Second, while we explored the combination of different topic items to build our queries, we failed to work on the document indexing unit, leaving all the normalization work to the probabilistic weighting models. As the COVID-19 literature comes from heterogeneous collections, containing sometimes only title and sometimes large full text, even with good finetuning of the model parameters, such variation in size and content poses a challenge to the first-stage retrieval model. Indeed, some strategies that explored decomposing the indexing unit into small structures, such as sentences and paragraphs, have achieved more competitive results [23].

Another limitation of our work was the ability to explore the freshness of the corpus. The TREC-COVID challenge dynamics, running throughout a sequence of rounds with new incremental search topics added on each round, provides an interesting setting for evaluating retrieval models in an infodemic context. It simulates typical search and discovery workflows, in which evolving queries are posed against an evolving body of knowledge over time, and already discovered documents in previous searches are no longer relevant [65,66]. A successful strategy in this case is to filter out results according to a cut-off date, thus reducing noise in the retrieval set. However, in retrospect, we noticed that another useful technique, which is very natural to an infodemic case, could be to decay the score of publications by their distance to the present time or explore their recency or freshness [67,68], as highlighted in Figure 7, rather than a hard cut-off (ie, December 2019 in our case) for all the rounds. We leave exploring such a strategy as future work.

To conclude, we believe our information retrieval pipeline can provide a potential solution to help researchers, decision makers, and medical doctors, among others, search and find the correct information in the unique situation caused by the COVID-19 pandemic. We detailed the different components of this pipeline, including the traditional index-based information retrieval methods and the modern NLP-based neural network models,

as well as insights and practical recipes to increase the quality of information retrieval of scientific publications targeted to the case of an infodemic. We grounded our results in the TREC-COVID challenge, where around 50 different teams participated in the 5 rounds of the competition. We showed very competitive results as judged by the official leaderboard of the challenge. Apart from the COVID-19 case, we believe our solutions can also be useful for other potential future infodemics.

Acknowledgments

The study received funding from Innosuisse project funding number 41013.1 IP-ICT. CINECA has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 825775.

Authors' Contributions

DT conceived the experiments. DT and SF conducted the experiments. DT, SF, EK, and PA analyzed the results. NB, EK, DVA, and PA prepared the data. SF, DT, JC, RG, and NN drafted the manuscript. All authors reviewed the manuscript.

Abstract

Background: Fatigue is the most commonly reported symptom in patients with persistent complaints following COVID-19 (ie, long COVID). Longitudinal studies examining the intensity of fatigue and differentiating between physical and mental fatigue are lacking.

Objective: The objectives of this study were to (1) assess the severity of fatigue over time in members of online long COVID peer support groups, and (2) assess whether members of these groups experienced mental fatigue, physical fatigue, or both.

Methods: A 2-wave web-based follow-up study was conducted in members of online long COVID peer support groups with a confirmed diagnosis approximately 3 and 6 months after the onset of infectious symptoms. Demographics, COVID-19 diagnosis, received health care (from medical professionals or allied health care professionals), fatigue (Checklist Individual Strength–subscale subjective fatigue [CIS-Fatigue]; 8-56 points), and physical and mental fatigue (self-constructed questions; 3-21 points) were assessed. Higher scores indicated more severe fatigue. A CIS-Fatigue score ≥36 points was used to qualify patients as having severe fatigue.

Results: A total of 239 patients with polymerase chain reaction/computed tomography–confirmed COVID-19 completed the survey 10 weeks (SD 2) and 23 weeks (SD 2) after onset of infectious symptoms, respectively (T1 and T2). Of these 239 patients, 198 (82.8%) were women; 142 (59.4%) had no self-reported pre-existing comorbidities; 208 (87%) self-reported being in good health before contracting COVID-19; and 62 (25.9%) were hospitalized during acute infection. The median age was 50 years (IQR 39-56). The vast majority of patients had severe fatigue at T1 and T2 (n=204, 85.4%, and n=188, 78.7%, respectively). No significant differences were found in the prevalence of normal, mild, and severe fatigue between T1 and T2 (*P*=.12). The median

CIS-Fatigue score was 48 points (IQR 42-53) at T1, and it decreased from T1 to T2 (median change: –2 points, IQR –7 to 3; *P*<.001). At T1, a median physical fatigue score of 19 points (IQR 16-20) and a median mental fatigue score of 15 points (IQR 10-17) were reported; these scores were lower at T2 for physical but not for mental fatigue (median change for physical fatigue –1 point, IQR –3 to 0, *P*<.001; median change for mental fatigue 0 points, IQR –3 to 3, *P*=.52). At the time of completing the follow-up survey, 194/239 (81.2%) and 164/239 (68.6%) of all patients had received care from at least one medical professional and one allied health care professional, respectively.

Conclusions: Fatigue in members of online long COVID support groups with a confirmed COVID-19 diagnosis decreases from 10 to 23 weeks after onset of symptoms. Despite this, severe fatigue remains highly prevalent. Both physical and mental fatigue are present. It remains unclear whether and to what extent fatigue will resolve spontaneously in the longer term.

KEYWORDS

COVID-19; SARS-CoV-2; long COVID; post-COVID-19 syndrome; post-acute sequelae of COVID-19; fatigue; post-viral fatigue; pandemic; online health; mental health; online support

Introduction

As the current COVID-19 pandemic continues to evolve, its impact becomes apparent. Clinical studies of hospitalized, laboratory-confirmed patients have shown that the acute phase of COVID-19 is characterized by a large array of respiratory and non-respiratory symptoms [1]. Over time, it has become clear that not all previously hospitalized patients fully recover from these symptoms in the months after the infection [2,3]. In addition, nonhospitalized patients can present persistent complaints months after the onset of infection-related symptoms [4]. These long-lasting symptoms after COVID-19 are referred to as *long COVID* [5], "a condition whereby affected individuals do not recover for several weeks or months following the onset of symptoms suggestive of COVID-19" [6], and they have a major impact on patients' quality of life (QoL) [7,8], care dependency [9], work participation [10,11], day-to-day activities, and physical functioning [12-14].

Fatigue, defined as "a subjective, unpleasant symptom which incorporates total body feelings ranging from tiredness to exhaustion creating an unrelenting overall condition which interferes with individuals' ability to function to their normal capacity" [15], is the most commonly reported symptom in patients with long COVID [2-4,16]. Similarly, other infections, such as severe acute respiratory syndrome (SARS) [17,18], Middle East respiratory syndrome (MERS) [19], and Q fever [20] have previously been linked to long-term fatigue, often referred to as postviral fatigue syndrome. Existing literature suggests that fatigue has several clinical presentations. A common distinction is made between physical fatigue (ie, difficulty performing physical activities) and mental fatigue (ie, difficulties concentrating and performing cognitive tasks) [21].

To date, longitudinal studies that examine fatigue intensity in patients with long COVID are lacking. Moreover, it is not known whether patients experience mostly mental or physical fatigue during and after the infection. Therefore, the objectives of this study were to (1) assess the severity of fatigue over time in members of online long COVID peer support groups; and (2) assess whether members of online long COVID peer support groups experience mental fatigue, physical fatigue, or both. We hypothesized that fatigue would be common and persistent and that both physical and mental fatigue would be present in patients with long COVID.

Methods

Study Design and Participants

This study is a prospective web-based survey of members of two Facebook peer support groups for patients with long COVID in the Netherlands (approximately 11,000 members; [22]) and Flanders (Belgium, approximately 1200 members; [23]), and a panel of approximately 1200 people who registered at a website of the Netherlands Lung Foundation (*coronaplein* [24]), an online platform providing additional information, advice, and peer support. Note that these totals represent the number of members of each group at the period of data collection. Between June 4 and June 11, 2020 (the time point of completing the first survey [T1]), members were invited to complete a web-based survey. Participants who completed the first survey [4,8,9] and who agreed to be contacted for a follow-up study received a second survey between August 31 and September 8, 2020 (ie, approximately three months after the first survey; the time point of completing the second survey [T2]). Ethical approval for this study was waived by the medical ethics committee of Maastricht University because the Medical Research Involving Human Subjects Act (WMO) does not apply to this study (METC2020-1978 and METC2020-2254). The medical ethics committee of Hasselt University formally judged and approved the study (MEC2020/041). Digital informed consent was obtained twice from all respondents (at the start of each survey). Exclusion criteria were intensive care unit (ICU) admission during the acute phase of infection, an onset of symptoms before January 1, 2020, being in the acute phase of COVID-19 when answering the first survey (ie, onset of infectious symptoms less than 3 weeks before filling out the first survey [25]), or an incomplete survey. Cross-sectional and follow-up data from this study on persistent symptoms, QoL, care dependency, construct-validity of the post–COVID-19 functional status scale, and information and care needs of members of online long COVID peer support groups have been published before [4,8,9,11,26,27]. This 2-wave web-based follow-up study was registered at the Netherlands Trial Registry (NTR8705). The

Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) checklist was used to guide reporting [28]. Of note: the current study focusses on patients with a confirmed COVID-19 diagnosis (ie, test-diagnosed cases). The results for the patients without a confirmed COVID-19 diagnosis are presented in Multimedia Appendix 1.

Assessment via Web-Based Surveys

The survey was developed in close collaboration with scientists, methodologists, health care professionals and COVID-19 patients from the long COVID peer support groups (the Netherlands and Flanders). It was digitalized by ASolutions [29] and was made available via their online platform. The survey consisted of general questions regarding demographics, clinical characteristics, and standardized questionnaires, including a fatigue questionnaire.

Demographic and Clinical Characteristics

Respondents received questions regarding demographical aspects such as gender, age, weight, height, educational level (low/medium/high; classification according to the International Standard Classification of Education 2011 [30]), and married/living with a partner (yes/no). In addition, the following clinical characteristics were assessed via self-report: pre-existing comorbidities (see Multimedia Appendix 2), health status (good/moderate/poor) during the infection and at the moment of completing the surveys, date of symptom onset, symptoms during acute phase of COVID-19 and at the moment of completing the surveys (see Multimedia Appendix 2), COVID-19–related hospitalization, and COVID-19 diagnosis (based on reverse transcription polymerase chain reaction (PCR) test or computed tomography (CT) scan of the thorax/symptom-based medical diagnosis by a physician/no formal test or diagnosis). Based upon the latter, patients were classified as either "test-diagnosed" COVID-19 (PCR or CT) or "presumed" COVID-19 (physician-diagnosed or no formal diagnosis/testing).

Received Health Care

Information regarding received health care (yes/no) by a medical professional (eg, medical specialist; general practitioner [GP]; nurse) or an allied health care professional (AHP; eg, physiotherapist [PT]; psychologist; occupational therapist [OT]; dietician; speech and language therapist) was recorded.

Standardized Fatigue Questionnaire

Fatigue, the primary outcome measure, was measured using a subscale of the Checklist Individual Strength (CIS). The Checklist Individual Strength–subscale subjective fatigue (CIS-Fatigue) is a standardized questionnaire [31,32] with high internal consistency and test-retest reliability; good discriminant, concurrent and criterion validity; and ability to detect change in subjective fatigue [33-37]. The questionnaire consists of 8 items scored on a 7-point Likert scale. Scores range from 8 to 56 points, and a higher score indicates more clinical symptoms of general fatigue (see Multimedia Appendix 3 for the CIS-Fatigue questionnaire) [31,32]. Based upon validated cutoff values, individuals can be classified as having normal (≤26 points), mild (27-35 points), and severe (≥36 points) fatigue [31-33].

Self-constructed Physical and Mental Fatigue Questions

A total of 3 self-constructed questions (all part of the CIS-Fatigue subscale) were used to evaluate physical fatigue ("*Physically* I feel exhausted," "*Physically* I feel I am in a bad condition," and "*Physically* I feel in a good shape"). In addition, to differentiate between physical and mental fatigue, 3 questions were constructed in which the word "physically" was replaced by the word "mentally" ("*Mentally* I feel exhausted," "*Mentally* I feel I am in a bad condition," and "*Mentally* I feel in a good shape," respectively) to estimate mental fatigue. The physical and mental fatigue questions were scored on a 7-point Likert scale, with scores ranging from 3 to 21 points. A higher score indicates worse physical and mental fatigue, respectively. These self-constructed physical and mental fatigue questions and explanations of the scoring are reported in Multimedia Appendix 4.

Statistical Analyses

Data are presented as means and standard deviations, medians, and interquartile ranges or as frequencies and proportions, where appropriate. Differences over time were analyzed by a paired *t*-test (or Wilcoxon signed-rank test) in continuous data and a McNemar test (or McNemar-Bowker test) in categorical data. If significant, a post hoc comparison of the McNemar-Bowker test was performed, and significant Bonferroni-adjusted *P* values were generated as corrections for multiple comparison. Statistical analyses were conducted using SPSS 25.0 (IBM Corporation). Figures were generated via GraphPad Prism 8.3.5 (GraphPad Software) and SankeyMATIC [38]. The level of significance was set at .01 for all statistical tests (two-tailed).

Results

Participants' Inclusion

In total, 2159 members of online long COVID peer support groups filled out the first survey, of which 220 were excluded for being in the acute phase of COVID-19 (n=14), ICU admission during the acute phase of COVID-19 (n=15), onset of symptoms before January 1, 2020 (n=8), and an incomplete first survey (n=183). From the 1939 patients who were included, 1556 consented to be approached for follow-up research, of which 1005 (64.6%) completed the second survey. Patients who did not respond to the second survey were younger and more often had a presumed COVID-19 diagnosis. Further details can be found in a previously published paper [11]. The 1005 patients completed the surveys on average 11.3 weeks (SD 2.2) and 23.5 weeks (SD 2.2) after onset of symptoms (T1 and T2, respectively). Overall, 239 test-diagnosed (hospitalized, n=62, and nonhospitalized, n=177) and 766 presumed (physician-diagnosed, n=454, and patients with no formal diagnosis/testing, n=312) patients with COVID-19 participated in this 2-wave web-based survey (see Multimedia Appendix 5 for the flowchart).

Demographical and Clinical Characteristics

Patients with confirmed COVID-19 were mostly middle-aged women (median age 50.0 years, IQR 39.0-56.0; 198/239 women, 82.8%) with a BMI indicating slight overweight (median BMI 26.0 kg/m^2, IQR 23.4-30.5), and they completed the first (T1)

and second (T2) survey on average 10.4 weeks (SD 2.4) and 22.6 weeks (SD 2.4) after onset of symptoms. Approximately 1 out of 4 patients (62/239, 25.9%) was hospitalized during the acute phase of COVID-19. The majority of respondents had no self-reported comorbidities (142/239, 59.4%) and good self-reported health status before the infection (208/239, 87%). Moreover, at T1 and T2, a minority of respondents self-reported good health (22/239, 9.2%, and 40/239, 16.7%, respectively [11]). Furthermore, patients retrospectively reported a median of 15 symptoms (IQR 11-18) during the acute phase of COVID-19, and 6 symptoms (IQR 4-9) and 6 symptoms (IQR 3-8) at T1 and T2, respectively. All details regarding patient characteristics can be found in Table 1.

Table 1. Characteristics of patients with confirmed COVID-19 (n=239).

Characteristic	Value
Women, n (%)	198 (82.8)
Age (years), median (IQR)	50.0 (39.0-56.0)
BMI (kg/m^2), median (IQR)	26.0 (23.4-30.5)

[b]T2: time of completing the second survey.

Received Health Care

During the first 10 weeks after the onset of symptoms, 2 out of 3 patients (157/239, 65.7%) received or sought care from at least one medical professional (GP: 139/239, 58.2%; medical specialist: 73/239, 30.5%; nurse: 18/239, 7.5%), whereas 1 out of 3 (90/239, 37.7%) received or sought care from at least one allied health care professional (PT: 76/239, 31.8%; psychologist: 27/239, 11.3%; OT: 7/239, 2.9%, dietician: 25/239, 10.5%; and speech and language therapist: 6/239, 2.5%). The cumulative proportion of patients who received care from a medical professional and allied health care professional at T2 respectively increased significantly to 81.2% (194/239; GP: 170/239, 71.1%; medical specialist: 131/239, 54.8%; nurse: 32/239, 13.4%; all P<.001) and 68.6% (164/239; PT: 157/239, 65.7%; psychologist: 55/239, 23%; OT: 27/239, 11.3%; dietician, 51/239, 21.3%; speech and language therapist, 21/239, 8.8%; all P<.001). Furthermore, the cumulative proportion of

patients who participated in an interdisciplinary rehabilitation program (in- or outpatient) increased significantly from T1 to T2 (10/239, 4.2%, to 32/239, 13.4%, respectively; *P*<.001). Details regarding received health care can be found in Table 2.

Table 2. Fatigue-related measures and received health care in patients with confirmed COVID-19 at on average 10 weeks (T1) and 23 weeks (T2) after onset of symptoms (n=239).

	Value		
	T1[a]	T2[b]	*P* value

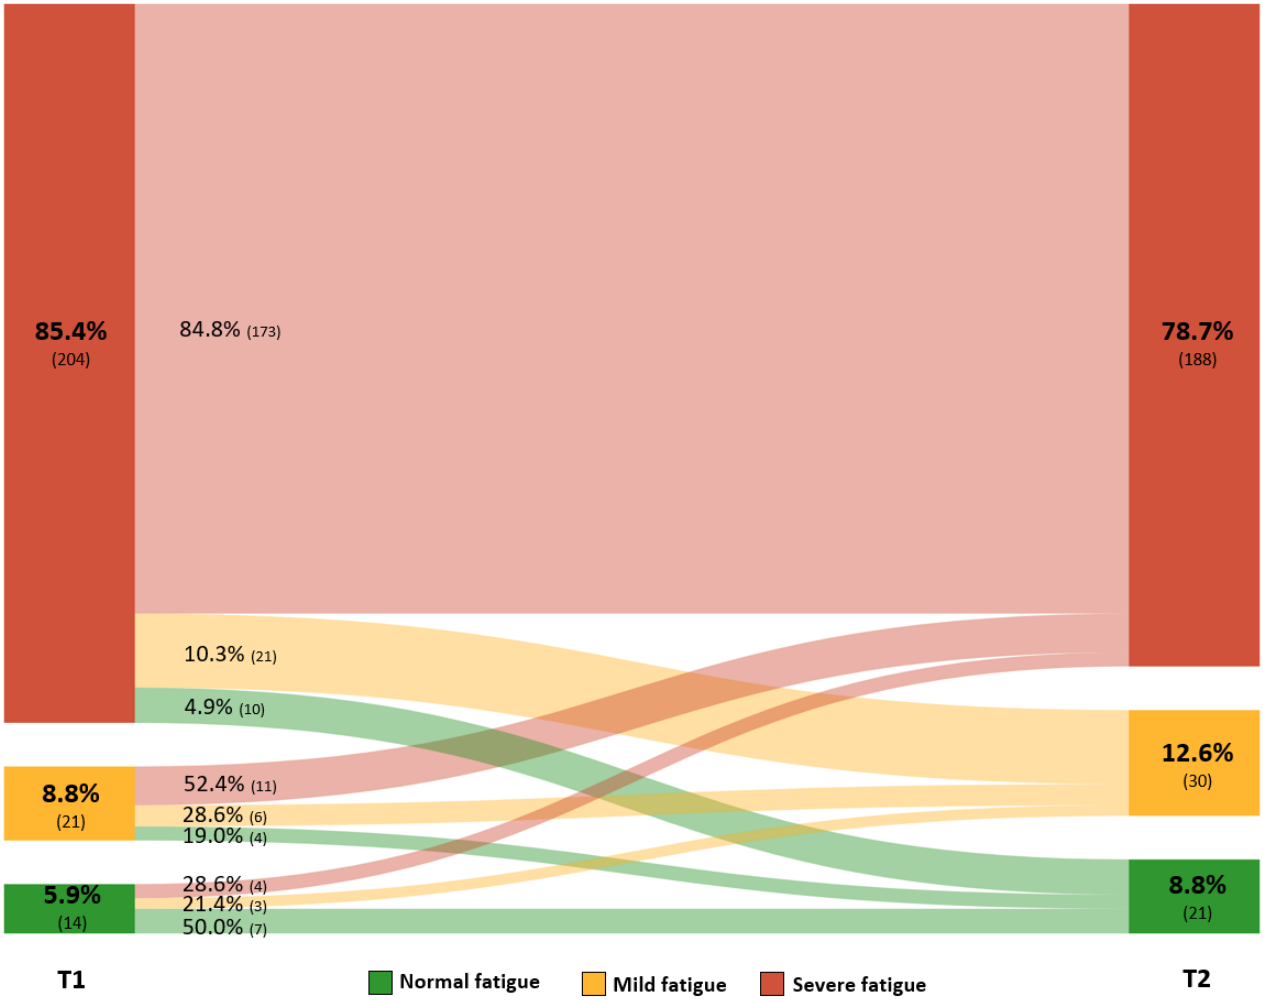
[c]CIS-Fatigue: Checklist Individual Strength–subscale subjective fatigue.

Standardized Fatigue Questionnaire

Patients with confirmed COVID-19 reported a median CIS-Fatigue score of 48 points (IQR 42-53) at T1. The majority (204/239, 85.4%) reported severe fatigue at approximately 3 months after the onset of COVID-19 symptoms. The median CIS-Fatigue score improved significantly between T1 and T2 (median change –2 points, IQR –7 to 3; *P*<.001) (Table 2), whereas no significant differences were found in the proportions of normal, mild, or severe fatigue (*P*=.12). An overview of the proportions of patients with normal, mild, and severe fatigue at T1 and T2, the proportional flow, and the direction of change can be found in Figure 1. In addition, Multimedia Appendix 6 shows the proportion, flow, and direction of the change of fatigue stratified for the type of diagnosis (ie, hospitalized and nonhospitalized test-diagnosed patients, physician-diagnosed patients, and patients without a formal diagnosis/test).

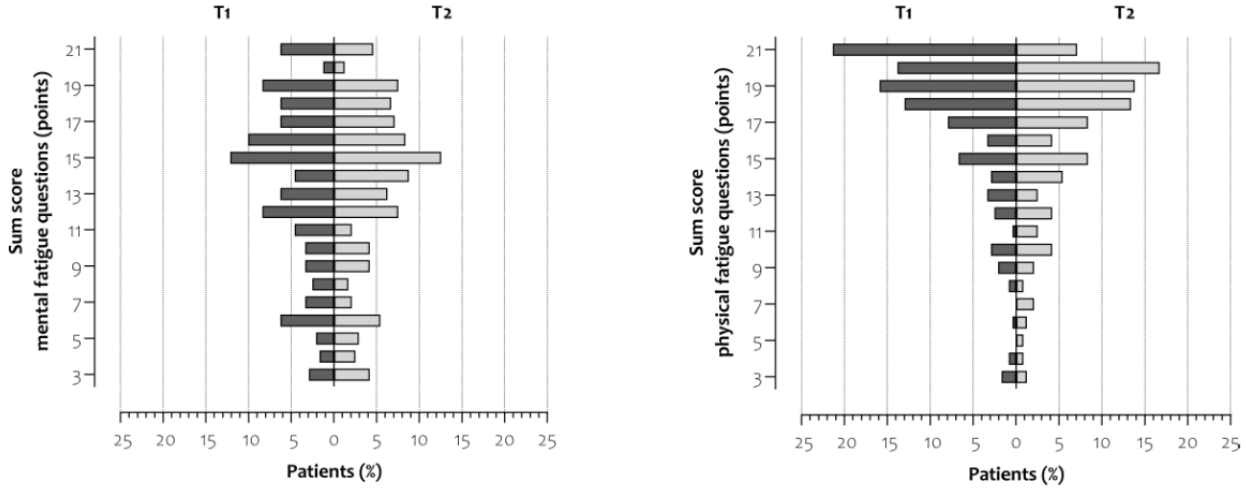
Figure 1. Prevalence and change in fatigue in patients with long COVID who have confirmed COVID-19, measured using the CIS-Fatigue scale at on average 10 (T1) and 23 (T2) weeks after onset of symptoms (n=239). The width of the lines is proportional to the flow rate. No significant change in the prevalence of normal (≤26 points), mild (27-35 points), or severe (≥36 points) fatigue was found between T1 and T2 (McNemar-Bowker test, *P*=.12). CIS-Fatigue: Checklist Individual Strength–subscale subjective fatigue; T1: time of completing the first survey; T2: time of completing the second survey.



Self-constructed Physical and Mental Fatigue Questions

Patients with confirmed COVID-19 reported median physical and mental fatigue scores of 19 points (IQR 16-20) and 15 points (IQR 10-17) at T1. Between T1 and T2, a significant decrease was found in physical fatigue score (median change –1 point, IQR –3 to 0; *P*<.001), but not in mental fatigue score (median change 0 points, IQR –3 to 3; *P*=.52) (Table 2). Figure 2 shows the distributions of patients across the spectrum of physical and mental fatigue at T1 and T2.

Figure 2. The distribution of patients with long COVID who have confirmed COVID-19 across the spectrum of self-constructed mental (left) and physical (right) fatigue at on average 10 (T1) and 23 (T2) weeks after onset of symptoms (n=239). Scores range from 3 to 21 points, and higher scores indicate higher levels of fatigue. T1: time of completing the first survey; T2: time of completing the second survey.



Discussion

Principal Findings

To the best of our knowledge, this is the first study to measure fatigue over time in members from online long COVID peer support groups with confirmed COVID-19 using a validated and standardized measurement with generic cutoff values to determine normal, mild, and severe fatigue. Our study indicates that severe fatigue is highly prevalent in patients with long COVID at approximately 3 and 6 months after the infection. Furthermore, our longitudinal follow-up data suggest that fatigue does not resolve over time in all patients, even if they receive health care. In addition, patients experience both physical and mental fatigue.

Fatigue is the most prominent symptom in patients with long COVID [2,4], irrespective of the severity of the initial infection [14]. Nevertheless, most studies are cross-sectional and use a binary question (eg, fatigued/not fatigued) to assess the prevalence of fatigue [2,16,39]. Therefore, little is known about the change in fatigue intensity over time [14,40]. Our study used a validated and standardized questionnaire to assess fatigue and was able to quantify fatigue intensity. Indeed, fatigue is highly prevalent in our sample. Moreover, fatigue was reported to be generally high. The median fatigue scores found in our sample are equal to or higher than those of other chronic diseases that are characterized by fatigue, such as chronic obstructive pulmonary disease [41], asthma [42], Q fever [20], multiple sclerosis [43], rheumatoid arthritis [44], or systemic sclerosis [45]. These findings are remarkable for such a young population with few self-reported comorbidities and good self-reported health status before the infection. Previously, other viral and nonviral infections have been linked to prolonged and debilitating fatigue [20,46-50]. For example, Lam and colleagues investigated long-term complaints in SARS survivors and found that approximately one-third of SARS survivors met the modified 1994 US Centers for Disease Control and Prevention criteria for chronic fatigue syndrome more than 3 years after having SARS [17]. Moreover, MERS survivors often experience chronic fatigue [19]. For patients with long COVID, it remains unclear whether fatigue will resolve spontaneously in the longer term. Our follow-up data show little to no improvement in the proportion of patients with severe fatigue between 3 and 6 months, despite receiving medical and allied health care. Consequently, almost two-thirds of the patients in our sample are progressing toward chronic fatigue (ie, severe fatigue that persists longer than six months [51]). The fact that some patients may experience debilitating chronic fatigue is worrisome and could have a major long-term impact upon these individuals as well as on the health care system and society as a whole [10,11,52]. Indeed, fatigue is strongly related to health-related QoL and aspects of day-to-day life [14,25,53,54], and it often involves sick leave, increased health care consumption, and more hidden costs, such as informal care by friends or family members [55-57].

Fatigue is a complex and challenging symptom, as multiple factors can play a role in the initiation and maintenance of fatigue, as seen in other chronic diseases [58]. It can present itself as mental fatigue, physical fatigue, or both [40]. Therefore, a patient-tailored treatment based upon a holistic and comprehensive assessment of systemic, physical, psychological, and behavioral factors is proposed to alleviate the fatigue symptom burden [59]. To date, it remains unknown which treatment strategies are effective to improve fatigue in patients with long COVID. Several treatment strategies for fatigue are proposed based upon knowledge from the fast-growing evidence regarding COVID-19 and other pathologies, such as multidisciplinary rehabilitation, energy conservation techniques, pacing, cognitive behavioral therapy, graded exercise therapy, or physical training [25,54,60-65]. Future research needs to provide evidence regarding underlying pathways, evaluate the effectiveness of existing treatment strategies, and identify susceptible candidates, as it is expected that not everyone will benefit from the same treatment strategy due to the multifactorial nature of fatigue. Moreover, anecdotal evidence shows that patients report having within-day and between-day variations in their daily symptoms, including fatigue [54,66,67]; these cannot be captured in detail by completing a questionnaire once or twice over a longer period of time. In this, the use of an

ecological momentary assessment may be valuable, as this approach involves repeated measurements of the participant's symptoms, behavior, and context in vivo and in real time [68]. More insights in diurnal variation in fatigue and its association with other symptoms may be useful in the development of more tailored treatment strategies for fatigue in patients with long COVID.

Methodological Considerations and Limitations

The current study has several limitations. First, the survey was only made available to members of online long COVID peer support groups. This probably caused selection bias, as it is reasonable to assume that patients with high symptom burden are more likely to become members of online long COVID peer support groups. Second, all results were collected using a web-based survey. Therefore, besides the self-reported symptoms, the patients' height, body weight, and medical status before and during the infection were also based on self-report, which may have affected the internal validity of the current findings to some extent. Recently, the National Institute for Health and Care Excellence [69] proposed a case definition of long COVID whereby alternative diagnosis should be excluded when identifying patients with long COVID. Due to the nature and timing of this study (ie, early phase of the pandemic), this was not possible in the current study. Third, approximately 1 out of 3 participants who consented to be approached for follow-up research did not respond to the second wave of the survey. The authors have no information about the possible reasons for not responding to the second wave of the survey, although a between-group comparison was made to find possible differences [11]. Fourth, the majority of our sample were women, which limits our external validity. Nevertheless, evidence is growing that women are more prone to develop long COVID [70]. Fifth, self-constructed questions were used to quantify mental fatigue, although validated questionnaires (such as the Chalder fatigue index) to assess mental (and physical) fatigue are available [71]. Therefore, no definite conclusions on the burden of mental fatigue in online long COVID peer support groups can be drawn based on the current study. Nevertheless, the current results indicate that COVID-19 can impact both physical and mental fatigue in the long term. Furthermore, this study was conducted in adults, although evidence regarding long COVID in children and adolescents is starting to emerge [72,73].

Conclusions

Severe fatigue is highly prevalent in members of online long COVID peer support groups both at approximately 3 and 6 months after onset of symptoms. As not enough time has passed since the start of the COVID-19 pandemic, it is unclear whether this fatigue will resolve spontaneously in the longer term. Future research needs to focus on the prognosis, possible causes, and treatment strategies for physical and mental fatigue in patients with long COVID.

Acknowledgments

The research team acknowledges the valuable input from the patient representatives to develop the survey, and the technical support by ASolutions' Martijn Briejers and Oscar Wagemakers. The scientific work of YMJG is financially supported by Lung Foundation Netherlands grant 4.1.16.085, FVCM is financially supported by ZonMW (ERACoSysMed grant 90030355), and RM is financially supported by Lung Foundation Netherlands grant 5.1.18.232.

Conflicts of Interest

MAS reports grants from Netherlands Lung Foundation, AstraZeneca, Boehringer Ingelheim, and Stichting Astma Bestrijding, all outside the submitted work. FMEF reports grants and personal fees from AstraZeneca, personal fees from Boehringer Ingelheim, personal fees from Chiesi, personal fees from GlaxoSmithKline, grants and personal fees from Novartis, and personal fees from TEVA, outside the submitted work. RP reports personal fees from MEDtalk and Health Investment. DJAJ has received lecture fees from Chiesi and Boehringer Ingelheim in the last 3 years, which are unrelated to this paper. All other authors declare that they have no conflicts of interest. No financial support was received for the preparation of this manuscript.

Abstract

Background: Inpatient health care facilities restricted inpatient visitation due to the COVID-19 pandemic. There is no existing evidence of how they communicated these policies to the public nor the impact of their communication choices on public perception.

Objective: This study aims to describe patterns of inpatient visitation policies during the initial peak of the COVID-19 pandemic in the United States and the communication of these policies to the general public, as well as to identify communication strategies that maximize positive impressions of the facility despite visitation restrictions.

Methods: We conducted a sequential, exploratory, mixed methods study including a qualitative analysis of COVID-19 era visitation policies published on Pennsylvania-based facility websites, as captured between April 30 and May 20, 2020 (ie, during the first peak of the COVID-19 pandemic in the United States). We also conducted a factorial survey-based experiment to test how key elements of hospitals' visitation policy communication are associated with individuals' willingness to seek care in October 2020. For analysis of the policies, we included all inpatient facilities in Pennsylvania. For the factorial experiment, US adults were drawn from internet research panels. The factorial survey-based experiment presented composite policies that varied in their justification for restricted visitation, the degree to which the facility expressed ownership of the policy, and the inclusion of family-centered care support plans. Our primary outcome was participants' willingness to recommend the hypothetical facility using a 5-point Likert scale.

Results: We identified 104 unique policies on inpatient visitation from 363 facilities' websites. The mean Flesch-Kincaid Grade Level for the policies was 14.2. Most policies prohibited family presence (99/104, 95.2%). Facilities justified the restricted visitation policies on the basis of community protection (59/104, 56.7%), authorities' guidance or regulations (34/104, 32.7%), or scientific rationale (23/104, 22.1%). A minority (38/104, 36.5%) addressed how restrictive visitation may impair family-centered care. Most of the policies analyzed used passive voice to communicate restrictions. A total of 1321 participants completed the web-based survey. Visitation policy elements significantly associated with willingness to recommend the facility included justifications based on community protection (OR 1.44, 95% CI 1.24-1.68) or scientific rationale (OR 1.30, 95% CI 1.12-1.51), rather than those based on a governing authority. The facility expressed a high degree of ownership over the decision (OR 1.16, 95% CI 1.04-1.29), rather than a low degree of ownership; and inclusion of family-centered care support plans (OR 2.80, 95% CI 2.51-3.12), rather than no such support.

Conclusions: Health systems can immediately improve public receptiveness of restrictive visitation policies by emphasizing community protection, ownership over the facility's policy, and promoting family-centered care.

Introduction

During the global COVID-19 pandemic, health systems rapidly changed procedures and policies to minimize viral transmission and accommodate increased patient volumes and illness acuity [1]. One example of such a policy change is the restriction or elimination of family presence in inpatient settings [2-7]. The Centers for Disease Control and Prevention (CDC), the Center for Medicare and Medicaid Services, and national professional organizations recommended that health systems limit the presence of patients' family members to reduce viral spread [2,8,9]. This recommendation reverses decades of policy and cultural evolution emphasizing the integral role of family members during inpatient care, based on research demonstrating that family presence during hospitalization improves patients' and family members' outcomes [2,3,10,11]. The language health systems use to communicate such policy changes likely shapes public perceptions of inpatient health care facilities at a time when there is an increased need for urgent medical care [12,13].

In the last two decades, the internet has become a critical vehicle in communicating information during public health emergencies [14]. During past crises, the public reported relying on health websites and physicians as trustworthy information sources. Prior work reveals that when the public lacks trust in a health care system, individuals are less willing to cooperate with health recommendations and seek the health services offered [15]. Communication during crises shapes individuals' trust in health care systems through modifying their perceptions of the institutions' competency, responsibility, and ability to fulfill its obligations to the public [16]. Therefore, effective communication of novel, crisis-era policies by health systems is critical to promoting public health and trust.

Crisis communication during a public health emergency is most useful when leveraged to improve community health and outcomes, rather than aimed to promote the reputation or image of an organization [16-18]. For example, the Crisis and Emergency Risk Communication (CERC) framework [19], which was developed by the CDC, merges both risk communication (ie, stakeholder-tailored communication focused on promoting behavior change) and crisis communication (ie, communication to reduce the negative effects of a crisis on stakeholders). CERC emphasizes that communication is critical to reducing health and psychological stressors during a crisis, in part through reestablishing a sense of personal control and encouraging self-efficacy. In this way, the current understanding of crisis communication is that its ultimate goal is not to inform the public but rather to develop high-quality social relationships [14,16,20].

Inpatient visitation policies are an example of crisis communication provided by health systems during the COVID-19 pandemic, and these frequently appear on health systems' public websites. Despite widespread attention in the lay press [21-24], there is no published evidence systematically summarizing how health systems implemented national recommendations for restricted inpatient visitation, how they communicated these policies to the general public, and the impact of their communication choices on the public's willingness to engage with the health care system. Therefore, we sought to characterize external communication made by inpatient health care facilities regarding their visitation policies during the COVID-19 pandemic. We aimed to identify key strategies for communicating such policies to improve their public reception [10]. To do so, we aimed to (1) describe the visitation policies of inpatient health care facilities during the COVID-19 pandemic, (2) classify patterns of how facilities communicated these policies to the public, and (3) identify associations between these communication patterns and public perception of the facility.

Methods

Overview

We conducted a sequential exploratory mixed-methods study [25]: first, we conducted a qualitative content analysis of visitation policies published on the internet by inpatient health care facilities during the COVID-19 era, followed by a factorial survey-based experiment to identify associations between elements of visitation policy communication and individuals' perceptions of the facilities.

Qualitative Analysis of Visitation Policy Communication

We identified inpatient health care facilities using the Pennsylvania Department of Health directory. We collected text and screenshots of each facility's inpatient visitation policy from their websites between April 30 and May 20, 2020, during the first peak of COVID-19 cases in the United States and Pennsylvania (Multimedia Appendix 1) [26]. We eliminated duplicates of identical policies published by facilities within the same health system. We used Rural-Urban Commuting Area (RUCA) Codes to classify each facility as urban or rural (ie, RUCA >2) [27,28]. We assessed the readability of each policy using the Flesch-Kincaid Grade Level calculator [29]. This readability tool calculates an overall complexity of text using the mean sentence and word length, providing an overall score of educational school-grade levels 1 to 12 [30]. Scores >12 indicate a college-level education would be required to read the text.

Five investigators conducted qualitative analysis of the visitation policy statements. We first used qualitative content analysis, which sorts open-ended data using categories derived from close reading of texts; it is not associated with any particular theory or paradigm, but it is a generic means of categorizing the "informational content" of data [31]. We annotated the policy statements to identify the various functions they accomplished (eg, stating restrictions, justifying restrictions, expressing a facility's values; Table 1). Within each of these function categories, we derived more specific categories to describe their content (eg, what the specific restrictions were, what information a facility presented to justify them, what specific values a facility expressed). Second, we performed discourse analysis—a method that examines the contextual use of language [32,33], to allow us to generate hypotheses about the effects of the specific language used to convey policies on readers. Through annotation, we observed that policies varied in how they positioned facilities as agentive or nonagentive in enacting restrictions through use of voice (active vs passive), sentence structure, and modality. Annotation was done independently and then discussed as a team. Based on this discussion, a formal codebook was generated to capture patterns in function, content, and discourse. Each policy was then coded using NVivo 12 qualitative analysis software (QSR International) by at least 2 team members (AS, SP, DH, and MK), with discrepancies resolved and codebook refinements made by consensus and consultation with supervising investigators (JH and JC). Finally, we performed focused coding, prioritizing the codes that we believed were most important to how visitation policies were communicated, identifying relationships between these codes, and synthesizing related codes [34-38]. Focused coding was done through group discussion and captured via analytic memos.

Factorial Experiment of Visitation Policy Communication

We used the results of the qualitative analysis to develop a factorial survey-based experiment that tested the impact of variation in hospitals' public visitation policy communication. We selected three elements to vary based on our qualitative findings by generating a list of elements that varied and eliminating those well-established to influence public opinion and understanding (eg, reading level) or those that health systems may be unable or unwilling to change (eg, the visitation rules themselves). Our final selections included (1) how the inpatient facility justified restricting visitation (eg, community protection, regulations from a governing authority, or scientific rationale); (2) the degree to which the facility expressed ownership over the policy decisions (eg, use of active voice to indicate responsibility for decision-making); and (3) the inclusion or absence of family-centered care support plans (eg, virtual visits or team communication plans and expressions of concern for well-being). Although actual policies justifying the restricted visitation on the basis of governing authorities more frequently used passive voice, in our factorial experiment, these varied independently.

Our final 3×2×2 factorial experiment structure generated 12 hypothetical policies (Multimedia Appendix 1). For our visitation policy statements presented to participants in the survey, we used the most common visitation rules and language drawn from actual facility policies in a composite manner to represent our selected elements. We used a Flesch-Kincaid Grade Level range of 9.0 to 10.8 for all policies. This was lower than the average policy in our sample, but it remains above the recommended reading level for patient education materials, as we used facilities' actual word choices whenever possible for constructing the composite policies [39,40]. We reviewed our element selections and the survey with groups of clinical and nonclinical research staff and pilot tested the survey with nonclinical individuals prior to launch.

We recruited participants in October 2020, during the start of the second and largest peak of COVID-19 cases in the United States (Multimedia Appendix 1). We used Cloud Research's Prime Panels, an internet study recruitment platform that enables and ensures high-quality survey-based data collection from the over 50 million diverse enrolled participants who more closely represent the US population than other similar platforms, such as MTurk [41]. The platform also allows for recruitment based on targeted eligibility criteria. Potential participants were eligible to voluntarily choose to complete this study if they resided in the United States, were ≥18 years old, and were fluent in written English. We conducted stratified recruitment to ensure that a minimum of 44% of participants were women and 13% were Black or African American to reflect US demographics more closely [41]. We asked all participants to complete a survey that included reviewing the 12 hypothetical policies and responding after each using a 5-point Likert scale (ie, ranging from "1=not at all" to "5=very much"), indicating the participant's willingness to recommend the hospital on this basis alone. They then responded to survey items collecting their personal perspectives on COVID-19 risk and mitigation strategies, the 9-item Revised Healthcare System Distrust Scale (HSDS) [42], and a demographic questionnaire. We included three attention checks and participants who failed two of these checks were no longer eligible to be included in the analysis [41,43]. Participants received a nominal compensation for successful survey completion. All participants provided informed consent after reviewing written information prior to beginning the survey. All study procedures were approved by the University of Pennsylvania's Institutional Review Board.

Using the n.multiway function from the R package easypower, we calculated sample size estimates of our 3×2×2 factorial design based on the number of factors (ie, policy elements), the number of levels of each factor, and various effect sizes for a main effect of a factor or for the interaction between two factors on the willingness to recommend the hospital (Table S1 in Multimedia Appendix 1). We estimated that recruiting 1272 participants (ie, 106 for each of 12 hypothetical policies) would be sufficient to detect an odds ratio (OR) of 1.437 for the main effect or interaction with 90% power and an α=.05.

We examined the relationship among the three policy elements and willingness to recommend the hospital using mixed effects logistic regression. The participant was entered as a random effect to account for the clustering of responses by each participant [44]. The regression model was fit using maximum likelihood estimation and was implemented using the glmer function from the R package lme4 [45]. Prior to model building, we determined that continuous variables were appropriate to

enter as linear terms without transformation. The unadjusted associations between all predictor variables and the primary outcome were examined using *t* tests and chi-square tests for continuous and categorical variables, respectively. A priori, we decided to include all three tested elements in the baseline model. Other variables were selected for inclusion using backward variable selection in a stepwise manner from a model with all possible covariates. Those that were not significant (eg, age and gender of the participant) were not included in the final model given we had no prespecified hypotheses as to the direction of effect. The final model only included predictor variables with *P* values <.05 for the association between the variable and the primary outcome in the baseline model, including the three exposure variables [46]. We explored potential interactions among all three visitation policy elements by adding two-way interaction terms one at a time to the final model, but none were significant. Two-sided *P* values <.05 were considered statistically significant. All statistical analyses were conducted in R Studio.

Results

Qualitative Analysis of Visitation Policy Communication

We identified 513 inpatient health care facilities within Pennsylvania. Using RUCA classification, 80.3% (n=412) were urban and 20.7% (n=101) were rural. We identified inpatient visitation policies for 363 facilities, resulting in 104 unique policies after eliminating duplicates used for multiple facilities within a health system (Figure S1 in Multimedia Appendix 1). The mean Flesch-Kincaid Grade Level for the policies was 14.2 (ie, requiring college-level reading skills). In addition to English, the policy was available in Spanish for 2 of the 104 (1.9%) unique policies, representing 1.1% (4/363) of all facilities' policies.

Nearly all policies restricted inpatient visitation. A minority (29/104, 27.9%) prohibited all visitors, whereas most (70/104, 67.3%) identified exceptions permitting some visitation. Few (5/104, 4.8%) policies specified no restrictions. Of the 70 policies allowing exceptions, 37 (52.9%) offered standardized exceptions (eg, end-of-life care, childbirth, and pediatric patients), 16 (22.9%) offered case-by-case exceptions, 13 (18.6%) included both, and 4 (5.7%) included no information about exceptions. Other common rules were restrictions on visitors' movement through the facility and mandatory screening (eg, symptom checks) prior to entry.

There were 8 major functions of phrases within the published policies (Table 1), including communication of rules and exceptions, justification of the restrictive policy, indication that the policy was a deviation from normal procedures, statements of the facilities' values, and a recognition of the hardship that these policies cause for patients and their families. Most (85/104, 81.7%) policies included a justification, most commonly the protection of patients, staff, or community (59/104, 56.7%); guidance or regulations from governing or scientific authorities (34/104, 32.7%); or a scientific rationale (23/104, 22.1%). A minority (38/104, 36.5%) included a statement recognizing that these policies may distress families and patients or that the delivery of family-centered care may be impaired. Governmental agencies at the state or federal level (eg, the Centers for Disease Control and Prevention or the Pennsylvania Department of Health) were named as responsible for the restrictive policies. Policies rarely included an explanation of how restricting visitation relates to viral transmission.

Most policy statements delineating the visitation rules or indicating that the restrictions were a deviation from typical procedures used the passive voice (Table 2). Statements addressing resulting hardship, stating the facilities' values, or emphasizing the temporary nature of the policy used the active voice. Policies that justified restricted visitation on the basis of protection generally used the active voice, whereas those that justified restrictions due to authorities used passive voice.

Table 1. Function of statements within policies.

Function of statement	Example
Indicate that the policy is temporary	"[FACILITY] has put into place a temporary hospital and outpatient visitation policy"
Acknowledge that the policy differs from standard hospital policy	"This policy replaces our traditional open visitation policy"
State the rules themselves	"In end-of-life situations [FACILITY] will allow loved ones to visit with patients"
Justify implementation of the policy	"We are now increasing these restrictions due to federal and state recommendations related to COVID-19"
Recognize the hardship that the policy brings for patients and families	"We know that the no visitor policy may be upsetting for our patients, residents, and their families"
Emphasize the values driving the facility or health system	"The health and well-being of the children and adults we serve remains our top priority in every decision we make"
Identify where patients and potential visitors can obtain additional information	"Please call the [FACILITY] COVID-19 Information Line (XXX-XXX-XXXX) for clarification and additional details"

Table 2. Degree of ownership displayed within and across policy statements.

Statements demonstrating high or low ownership over policy decisions and implementation	Examples
High ownership	
Indicate that the policy is temporary	"We will regularly re-evaluate these visitor restrictions as we receive updates about COVID-19"
Recognize hardship that policy brings for patients and families	"We understand the importance of the support of friends and family to the healing process"
Emphasize values driving the facility or health system	"[FACILITY] is committed to the health, safety, and well-being of the communities we serve"
Offer alternatives to in-person family presence	"We strongly encourage the use of electronic methods to stay connected with loved ones including telemedicine, zoom, and extended phone time"
Justify policy implementation based on protection and safety	"Be assured that we are making these decisions in your best interest so that we can ensure the safety of you, your baby, and our staff"
Low ownership	
Acknowledge that the policy differs from standard hospital policy	"Beginning Tuesday, March 24, inpatient and outpatient visitation guidelines will shift from limited to restricted, outlined below"
State the policy itself	"All in-person visitation has been suspended (with limited critical exceptions)"
Justify the policy based on authority guidance and regulations	"This restriction has been implemented in compliance with updated corporate and state regulations to further reduce the risks associated with COVID-19"

Factorial Experiment of Visitation Policy Communication

In total, 6272 individuals in the Cloud Research Prime Panel system may have viewed the study description, and 1602 individuals may have opened the study link. Of these, 1356 participants completed the instrument for a conservatively estimated response rate of 25.5%. We excluded 34 responses due to failed attention checks. The 1321 participants in the final analysis had a median completion time of 9.2 minutes (IQR 6.4-14.2 minutes). Participants' characteristics are summarized in Table 3. A minority of individuals self-reported high personal risk of COVID-19 or having close contact with an individual at high risk of COVID-19. The majority were insured and demonstrated moderate to low levels of health care system distrust [42].

Results of the multivariable model are displayed in Figure 1 and Table S2 of Multimedia Appendix 1. Visitation policy elements significantly associated with a willingness to recommend the hospital included justifications for restricted visitation based on community protection (OR 1.44, 95% CI 1.24-1.68) or scientific rationale (OR 1.30, 95% CI 1.12-1.51), in contrast to regulations from a governing authority. The hospital displayed a high degree of expressed ownership over the policy (OR 1.16, 95% CI 1.04-1.29 vs low degree of ownership) and inclusion of family-centered care support plans (OR 2.80, 95% CI 2.51-3.12 vs absence of such support). Justification of visitation restrictions to support community protection was significantly more likely to result in willingness to recommend the hospital when compared with scientific rationale for restrictions in the pairwise comparisons from the final model (Figure 1). In the multivariable model, participants living in urban settings, reporting more trust in the health care system, and identifying as Democrats were significantly more willing to recommend the hypothetical hospitals after adjusting for visitation policy elements (Figure 1).

Table 3. Characteristics of survey participants.

Characteristic	Participants (N=1321)[a]
Age (years), median (IQR)	39 (30-55)
Gender, n (%)	
Women	710 (53.7)
Men	601 (45.5)
Transgender, nonbinary, other	10 (0.8)
Race, n (%)	
White, Caucasian American	967 (73.2)
Black, African American	248 (18.8)
Other[b]	106 (8)
Ethnicity, n (%)	
Not Hispanic, Latinx	1195 (90.5)
Hispanic, Latinx	115 (8.7)
Not reported	11 (0.8)
Educational attainment[c], n (%)	
Less than high school, GED[d]	269 (20.4)
Some college	383 (29)
Bachelor's degree	385 (29.1)
Graduate degree	284 (21.5)
Urban or rural residence, n (%)	
Urban	535 (40.5)
Suburban	514 (38.9)
Rural	261 (19.8)
Not reported	11 (0.8)
Political party, n (%)	
Democrat	566 (42.8)
Republican	396 (30)
Other[e]	359 (27.2)
Insurance status, n (%)	
Insured	1207 (91.4)
Uninsured	114 (8.6)
At high risk for COVID-19, n (%)	
No	775 (58.7)
Yes	325 (24.6)
Unsure, not reported	221 (16.7)
Close contact with someone at high risk for COVID-19, n (%)	
No	856 (64.8)
Yes	358 (27.1)
Unsure, not reported	107 (8.1)
Revised HSDS[f] score	
Mean (SD)	22.4 (7.2)
Median (IQR)	24 (17-28)

[a]Percentages may not add up to 100% due to rounding. For gender and HSDS (n=1320), 1 participant did not provide responses.

[b]For race, "Other" includes Asian, Asian American, Pacific Islander, Native American, Hispanic/Latino, Mestizo, Middle Eastern, Romanian, and multiracial.

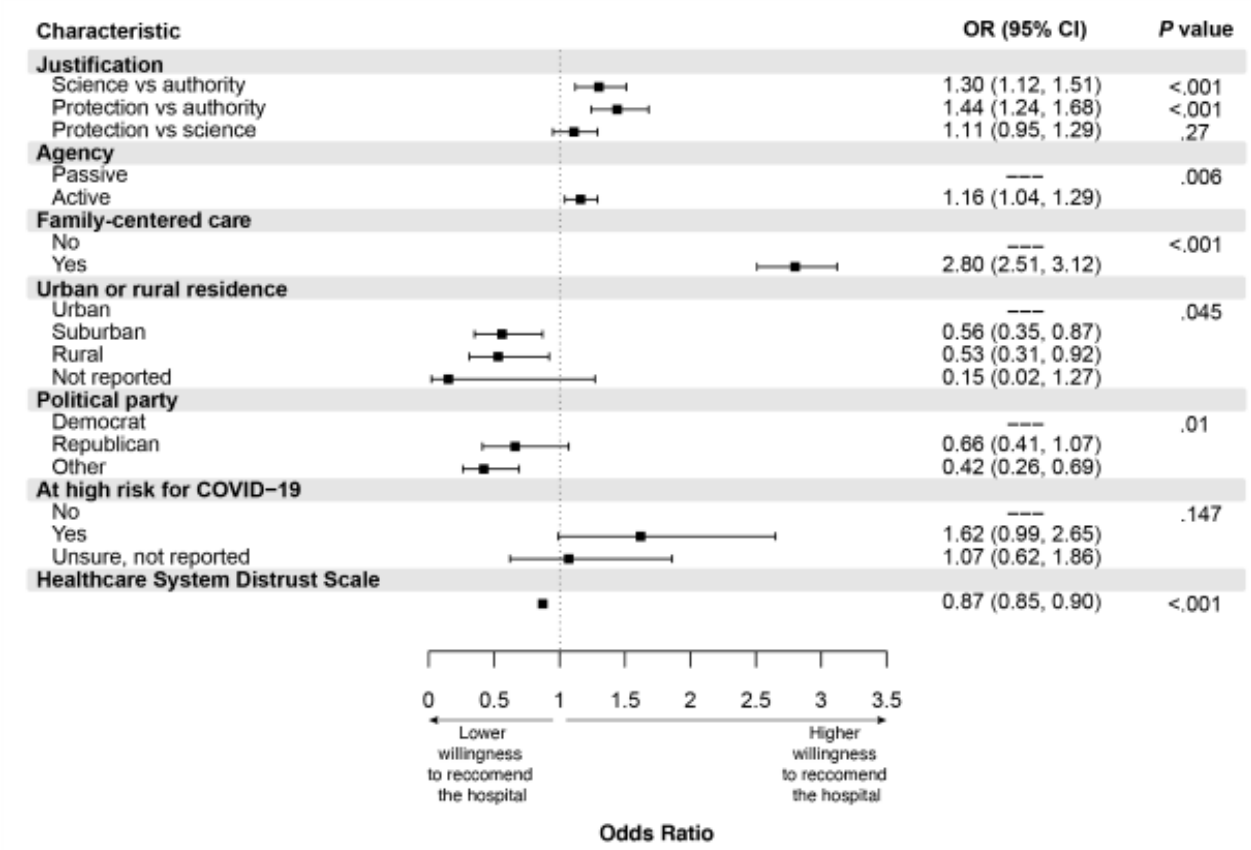
[c]For education attainment, "Some college" includes associate's or professional certificate; "Graduate degree" includes master's, doctoral, or professional degree.

[d]GED: general educational development.

[e]For political party, "Other" includes independent, democratic socialist, libertarian, and no political affiliation.

[f]HSDS: Healthcare System Distrust Scale. For the revised HSDS (9-item scale; range: 5-45), higher total scores indicate more distrust of the health care system.

Figure 1. Association of policy elements and respondent characteristics with willingness to recommend the hospital. OR: odds ratio.



Discussion

Principal Findings

Although health care systems across the globe have restricted inpatient family visitation during the COVID-19 pandemic [3-5], there is a lack of empirical research presenting what visitation rules health systems enacted, how health systems communicated these policies to the lay public, and the impact of those communication choices on public opinion. In this study, we present a mixed methods investigation including qualitative analysis of publicly available COVID-19 era inpatient visitation policies and a subsequent factorial experiment examining the impact of three key policy statement elements on lay individuals' willingness to recommend the hypothetical hospital to a family member. Most of the website-published policies prohibited family presence and justified these restricted visitations on the basis of community protection over authorities' guidance, regulations, or scientific rationale. A few policies addressed how restrictive visitation may impair family-centered care.

Our findings confirm the importance of communication choices during periods of crisis [12,13]. Importantly, we identify specific elements of visitation policy statements strongly associated with individuals' willingness to recommend the hospital. Because these are unrelated to the visitation rules themselves, health systems may rapidly implement these findings.

The goals of family-centered care are to respect family members as care partners, foster collaborations between family members and the health care team, and maintain family integrity [2,10]. There is broad recognition among clinicians and the general public that visitation policies restricting family presence for inpatients are undesirable and detrimental to family-centered care [2,3,5,21-24,47]. Our participants valued the inclusion of family-centered care support plans and recognition of resulting distress in hospitals' communication of visitation restrictions. Indeed, family-centered content was more strongly associated with individuals' willingness to recommend a hospital than any other element. However, few inpatient facilities' policy statements provided resources to promote family members' engagement with admitted patients or health care teams or

expressed empathy and compassion. Including empathy in crisis messages is known to result in a more positive public response and enhances the credibility of the messenger [12]. Health systems should prioritize communication and coping resources for family members distanced from inpatients during and after pandemic conditions and clearly communicate the existence of these resources to engender trust among community members [2].

Inpatient facilities' frequent use of the passive voice to communicate restrictive visitation rules suggests that they seek to distance themselves from unfavorable policies. For example, facilities frequently justified restrictive policies by referring to governing authorities while using the passive voice. When facilities used the active voice to express a high degree of ownership in the policies, they did so for favorable components of the policy statements. These patterns suggest that facilities may attempt to deflect responsibility for undesirable visitation restrictions. However, our findings indicate this is likely counterproductive. Individuals were more likely to recommend a facility that expressed ownership of restrictive policies, including providing a justification that did not rely on governing authorities and using the active voice when communicating restrictive rules. Community members may interpret facilities as being connected and invested in the communities they serve if systems express a high degree of ownership over decision-making, rely on community protection as a salient rationale for restrictions, and support family-centered care despite visitation restrictions.

Many of the inpatient facilities' policy statements did not reflect best practices in community and crisis communication [12]. Many failed to engage in two-way risk communication, in which the public is treated as full participants rather than passive information receivers or rule followers [16,48,49]. Such two-way risk communication strategies focus on building dialogue with public citizens who have rights and values. This can lead to improved public understanding of the risks and rationale for policies and recommendations. Furthermore, this approach to communication positions the rule-makers as transparent and worthy of trust. In contrast, facilities rarely explained the mechanisms through which restrictive family presence policies may reduce the transmission of COVID-19. Particularly early in the pandemic, when we collected the policies, community members likely did not have this scientific knowledge, limiting their ability to participate in the dialogue around visitation restrictions [50]. Additionally, policy statements intending to convey key messages to the general public should be written at a reading level accessible to those with low reading levels, given that the average American reads at an 8th grade reading level [39,40,51]. We elected not to test varied reading levels in our factorial design given the large body of work that exists supporting the need for accessible public health information [51], particularly during the COVID-19 crisis as the burden of impact has been disproportionately high in medically underserved communities [40,52-54]. Policy statements that require a college reading level are likely to contribute to misunderstandings and lack of trust [39,40,51,55]. Health systems should also offer their materials in non-English languages that are spoken by community members, yet this was rarely observed in our sample.

Although the communication of these crisis-era policies should be improved upon, an organization's pre-crisis credibility is critical to the public's trust in the organization during a crisis [12]. If a health system or facility has not already established itself as supportive of families, is not engaged with community health, and is not concerned about staff well-being, the organization's statements of these values may be meaningless. Therefore, the approach to communicating policies during COVID-19 and similar crises should also reflect a broader attention to the relationship between health systems and their surrounding communities both during and between acute public health crises.

Limitations

Our findings should be interpreted in the context of several limitations. First, we gathered policy statements from a single state. However, we did seek to capture all publicly available policies to eliminate selection or response bias introduced with other methods, such as surveys. Second, we captured policy statements immediately following the initial peak of COVID-19 cases in Pennsylvania, so our analysis does not reflect longitudinal changes to the policy statements or visitation rules [26]. We cannot comment on longitudinal trends in visitation policies enacted by inpatient facilities nor public perception of these policies in the context of national or local COVID-19 burden or governmental policies intended to control viral spread. Third, we were unable to find policies for all licensed inpatient facilities in Pennsylvania. However, we used widely available search engines, mitigating the risk that the public had access to an internet-published policy we did not locate. Fourth, the public may not read or compare policies available on websites. Nevertheless, the majority of inpatient facilities had internet-published policies, suggesting they believe there is an audience for this information. Fifth, our factorial experiment relied on participants from an internet research panel, which may not reflect the general US population [36]. We took steps to mitigate the risk of bias, including stratified recruitment on the basis of race and gender [49]. Sixth, we selected elements to vary in the policies for the factorial experiment. There may be alternative elements more important than the ones we selected. However, we selected elements based on our preceding content analysis, making our findings valuable even if other elements are considered important. Seventh, we tested composite policy statements without contextual factors that may lead a community member to recommend or discourage a particular hospital, and we did not require participants to choose between hospitals based on the policy statements, which may have limited variation in their responses. Despite this, we identified several significant findings.

Conclusions

Inpatient facilities frequently enacted restrictive inpatient visitation policies during the COVID-19 pandemic. Communication of these policies did not reflect best practices in crisis communication and may fail to represent health systems' commitment to their communities' health and their motives for establishing restrictive visitation policies. To

improve public perception, health systems and facilities should convey ownership over their policy decisions, justify unfavorable visitation rules based on community protection, and include resources supporting family-centered care. Policies should also use language accessible to those with lower reading levels and in languages other than English as locally relevant, provide clear explanations for novel policies, and more frequently incorporate statements of empathy and compassion when communicating crisis-era policies affecting the general public.

Abstract

Background: Social media enables the rapid consumption of news related to COVID-19 and serves as a platform for discussions. Its richness in text-based data in the form of posts and comments allows researchers to identify popular topics and assess public sentiment. Nonetheless, the vast majority of topic extraction and sentiment analysis based on social media is performed on the platform or country level and does not account for local culture and policies.

Objective: The aim of this study is to use location-based subreddits on Reddit to study city-level variations in sentiments toward vaccine-related topics.

Methods: Comments on posts providing regular updates on COVID-19 statistics in the Vancouver (r/vancouver, n=49,291), Toronto (r/toronto, n=20,764), and Calgary (r/calgary, n=21,277) subreddits between July 13, 2020, and June 14, 2021, were extracted. Latent Dirichlet allocation was used to identify frequently discussed topics. Sentiment (joy, sadness, fear, and anger) scores were assigned to comments through random forest regression.

Results: The number of comments on the 250 posts from the Vancouver subreddit positively correlated with the number of new daily COVID-19 cases in British Columbia (R=0.51, 95% CI for slope 0.18-0.29; P<.001). From the comments, 13 topics were identified. Two were related to vaccines, 1 regarding vaccine uptake and the other about vaccine supply. The levels of discussion for both topics were linked to the total number of vaccines administered (Granger test for causality, P<.001). Comments pertaining to either topic displayed higher scores for joy than for other topics (P<.001). Calgary and Toronto also discussed vaccine uptake. Sentiment scores for this topic differed across the 3 cities (P<.001).

Conclusions: Our work demonstrates that data from city-specific subreddits can be used to better understand concerns and sentiments around COVID-19 vaccines at the local level. This can potentially lead to more targeted and publicly acceptable policies based on content on social media.

KEYWORDS

COVID-19; public sentiment; social media; Reddit; Canada; communication; sentiment; opinion; emotion; concern; pandemic; vaccine; hesitancy

Introduction

Sixty-five percent of approximately 3.8 billion internet users are currently informed about top news stories from social media platforms such as Twitter, Facebook, and Reddit rather than traditional news outlets [1]. Surveys show that this trend has been especially apparent during the COVID-19 pandemic as more people seek timely updates on the crisis [2]. When used effectively, social media platforms can disseminate relevant health-related information to users such as patients, clinicians, and scientists [1]. However, the unfamiliarity of COVID-19 has led to the frequent transmission of false and conflicting information [3]. While awareness of "fake news" is high among Gen Z individuals and Millennials, less than a quarter of them report posts with false information, and only 8.7% opt to stop receiving updates from the account that produces misleading posts [4]. Propagated misinformation also negatively impacts compliance with public health policies such as social distancing [5].

In addition to what people express on social media, investigation of their underlying attitudes in conjunction with their comments can be key to determine political participation and predict "protester violence" [6,7]. In the context of the pandemic, posts on Twitter and Facebook have been used to examine attitudes toward contact tracing apps in the United Kingdom [8], and a dashboard was built to track emotions in Austria on the basis of the news platform derstandard.at, Twitter, and a chat platform for students [9].

Currently, one of the most critical steps to reducing the spread of COVID-19 is mass vaccination [10]. Unfortunately, social media also provides a platform for growing antivaccination movements and increasing vaccine hesitancy [11-13]. When examining the expression of these opinions that oppose scientific advice, studies capture sentiments across entire platforms or whole countries but fail to capture nuances at a more local level. Thus, we sought to use comments on Reddit to explore discussions surrounding COVID-19 in Toronto (Ontario), Calgary (Alberta), and Vancouver (British Columbia) as sentiment analysis can contribute to improving social management practices within each city.

Reddit is divided into subreddits, which contain posts and discussions relevant to a particular location or topic. As a platform that quickly aggregates content, it effectively disseminates the latest news regarding major events, including the COVID-19 pandemic. For example, daily posts on the Vancouver subreddit (r/vancouver), by the user cyclinginvancouver (u/cyclinginvancouver), provide updated statistics regarding the spread of COVID-19 in British Columbia. Similar posts can be found on the Calgary (r/calgary) and Toronto (r/toronto) subreddits. The posts themselves are unbiased, containing only information such as the number of new cases of COVID-19 infection as determined by a positive test, hospitalizations, vaccinations, and deaths. Thus, people are able to engage in free-form discussion in the comments. Comparatively, other platforms such as Twitter allows a global community to discuss the pandemic; hence, discussions are less specific to regional communities.

The aim of this study is to use location-based subreddits on Reddit to study city-level variations in sentiments toward COVID-19 vaccine–related topics. Here, we first present an analysis of comments from the Vancouver subreddit to understand the topics being discussed and people's attitudes toward local policies. We also specifically explore people's reactions and sentiments toward vaccines and how they align with vaccination rates. Then, we characterize differences in vaccine topics and sentiments among Vancouver, Toronto, and Calgary. Data from similar studies performed using Twitter [14] helped build some of our models, as our study is the first to examine comments from Reddit in this manner. Our novel approach of examining topics of local concern have the potential to inform how public policy can be tailored to specific geographical regions.

Methods

Data Collection

All analyses were performed using Python (version 3.7) and R (version 4.0.2). Our code can be found on GitHub at Mellaw/BDC_Reddit.

Reddit comments were acquired using the Python Reddit API Wrapper (PRAW; version 7.2.0) [15]. A read-only Reddit instance was created and used to obtain a subreddit instance for the Vancouver, Calgary, and Toronto subreddits (r/vancouver, r/calgary, and r/toronto, respectively). Relevant posts were acquired by searching the keywords *Covid-19 Update -*, *Alberta Totals:*, and *COVID-19 in Ontario* in the Vancouver, Calgary, and Toronto subreddits, respectively. Keywords were selected to be specific to posts providing daily updates on COVID-19 statistics. The title, time created, submission ID, and author were extracted and assembled into a data frame using pandas (version 1.2.4) [16]. The submission ID is a string unique to each post. It was used as an input to PRAW for interacting with each post's "CommentForest" or a list of comments and replies. The list method of CommentForest was used to extract the body text, author, and title of the post for all comments.

Twitter data were obtained from the paper "Global Reactions to COVID-19 on Twitter: A Labelled Dataset with Latent Topic, Sentiment and Emotion Attributes" [14] and were made available on OpenICPSR [17]. We used the version with 5000 tweets randomly sampled from the full data set of 132.1 million tweets. The tweets are in English and are from the United States, Singapore, India, and Brazil. Every tweet was scored on how intensely they demonstrated the emotions anger, fear, sadness, and joy on a scale from 0 to 1. Since the data set only provided the IDs of tweets, we used Tweepy (version 3.10.0) to hydrate the tweets [18].

We also used statistics for new cases of COVID-19 and total vaccinations in British Columbia, Alberta, and Ontario. These data, as well as numbers for fatalities, hospitalizations, tests, and recoveries, were provided through a web-based COVID-19 Tracker [19], where real-time data at both the national and provincial level were collected by volunteers. To ensure accuracy, statistics were updated primarily from live press

briefings, with some supplementation from news networks. Source URLs were also provided.

Data Processing

Preprocessing Raw Text

All Reddit comments and Tweets were converted to lowercase, and the Python software package [20] was used to remove nonalphabetical characters, URLs, and references to other users. Texts were then lemmatized using spaCy (version 3.0) [21] and stripped of stop words using Natural Language Toolkit (NLTK; version 3.6.2) [22]. The list of stop words was modified by removing "no" and "not."

Topic Extraction

Topic extraction was performed for Reddit comments by implementing Latent Dirichlet Allocation (LDA) through gensim (version 4.0.1) [23]. After tokenizing, comments were used to create a dictionary, which maps every word to a unique integer ID. This was then converted into a bag-of-words format, essentially counting how many times a word is used. To optimize the number of topics, LDA models were created for 1 to 14 topics. Other nondefault parameters include setting the chunk size to be the number of comments, the number of passes to 10, and α to "auto."

The optimal number of topics was deemed to be the one that minimizes mean Jaccard similarity while maximizing mean coherence across topics. Jaccard similarity is a metric for how many words 2 documents have in common [24]. If 2 topics were identical, their Jaccard similarity would be 1. Conversely, if 2 topics shared no words in common and were thus entirely distinct, their Jaccard similarity would be 0. Coherence for each topic was calculated with gensim using the "c_v" option. It measures the semantic similarity between high-scoring words, which is a function of how often the words co-occur across comments [25].

Each comment was quantitatively assessed to what extent they addressed each topic with a score from 0 to 1. For downstream analyses, a comment was considered to address a topic ("1") if the score was greater than 0.2 and not ("0") otherwise. Word clouds showing the top keywords for each topic were generated using wordcloud (version 1.8.1) and Matplotlib (version 3.4.2). Thus, we were able to identify vaccine-related comments.

Sentiment Analysis

Scores for emotional intensity were assigned to Reddit comments using a model built from the Twitter data set. Using scikit-learn (version 0.24), the Twitter data set was split into training (0.75) and testing (0.25) sets. Prior to modeling, the text of the tweets was processed into a data frame containing term frequency–inverse document frequencies (TF–IDF). The term frequency (TF) is the number of times a word appears in each tweet divided by the total number of words in that tweet. The inverse document frequency (IDF) is the logarithm of the total number of tweets divided by the number of tweets containing the word. TF–IDF is simply the TF multiplied by the IDF.

The TF–IDF data frame was used as the input to a random forest regression model. The model from scikit-learn was used with default parameters. The scores for anger, fear, sadness, and joy were the target variables. A total of 4 models were fitted, 1 for each emotion. To evaluate the models, the data in the TF–IDF data frame for the test data set were used as the predictors, and the root mean square error (RMSE) was used to compare model outputs with true values. The same processing workflow and models were applied to Reddit comments to predict emotional intensity.

Statistics

The correlation between the number of Reddit comments and new cases of COVID-19 was calculated using Pearson correlation in R. Time-series trends for the level of vaccine-related discussion and total vaccinations in British Columbia were compared using the Granger causality test from the lmtest package [26]. Comparisons across topics and cities were performed using the Mann–Whitney *U* test.

Results

Data Overview

From the r/vancouver subreddit, 49,291 comments across 250 daily update posts were obtained between July 13, 2020, and June 14, 2021. After preprocessing, 433 comments were found to be duplicated. To avoid including spam, duplicates from technical glitches, and placeholder text for deleted and removed comments, duplicates were excluded from further analysis, yielding 45,303 usable comments. These comments were contributed by 4261 users ("Redditors"). Summary statistics for r/calgary and r/toronto are also displayed in Table 1.

Table 1. Summary statistics for posts and comments extracted.

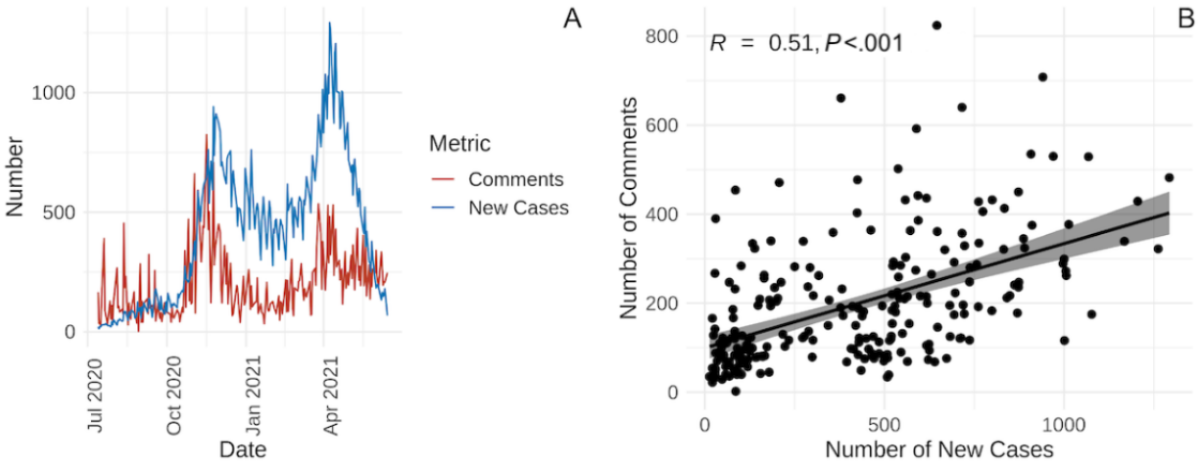
City	Total posts, n	Total comments, n	Usable comments, n
Vancouver	49,291	250	45,303
Toronto	20,764	234	19,105
Calgary	21,277	249	18,886

Vancouver-Specific Analyses

Engagement Level on Reddit Correlates With Daily New COVID-19 Cases

The number of new COVID-19 cases in British Columbia has 2 distinct peaks (Figure 1A). The first is in late November 2020, following a period of low, steady numbers in the summer, with exponential growth beginning in October 2020. The second is in early April 2021, after a local minimum in February 2021, and preceding a steep decline. The number of comments on daily update posts demonstrates a similar trend over time and was found to be significantly correlated with the number of new COVID-19 cases (R=0.51, 95% CI for slope 0.18-0.29; P<.001) (Figure 1B).

Figure 1. (A) Line plot depicting the number of new COVID-19 cases in British Columbia (blue) and the number of comments on each daily update post (red) from July 13, 2020, to June 14, 2021. (B) The number of new COVID-19 cases is significantly positively correlated with the number of comments on daily update posts (R=0.51; P<.001).



Thirteen Main Topics Related to COVID-19 Were Identified From Reddit Comments

By maximizing coherence and minimizing Jaccard similarity, the ideal number of topics was deemed to be 13 (Multimedia Appendix 1). Based on the word clouds (Multimedia Appendix 2) and examples of the first 25 words for the highest scoring comment for each topic (Table 2), the topics are as follows: (1) advocating for restrictions, (2) COVID-19 transmission, (3) impacts of COVID-19 on social spheres, (4) discussion about case numbers, (5) outbreaks in health care facilities, (6) debating how realistic public health orders are, (7) scientific concepts surrounding COVID-19, (8) monitoring travelers and people who have been exposed, (9) violating and enforcing restrictions, (10) vaccine uptake, (11) general speculations, (12) impact on hospitals, and (13) vaccine scarcity.

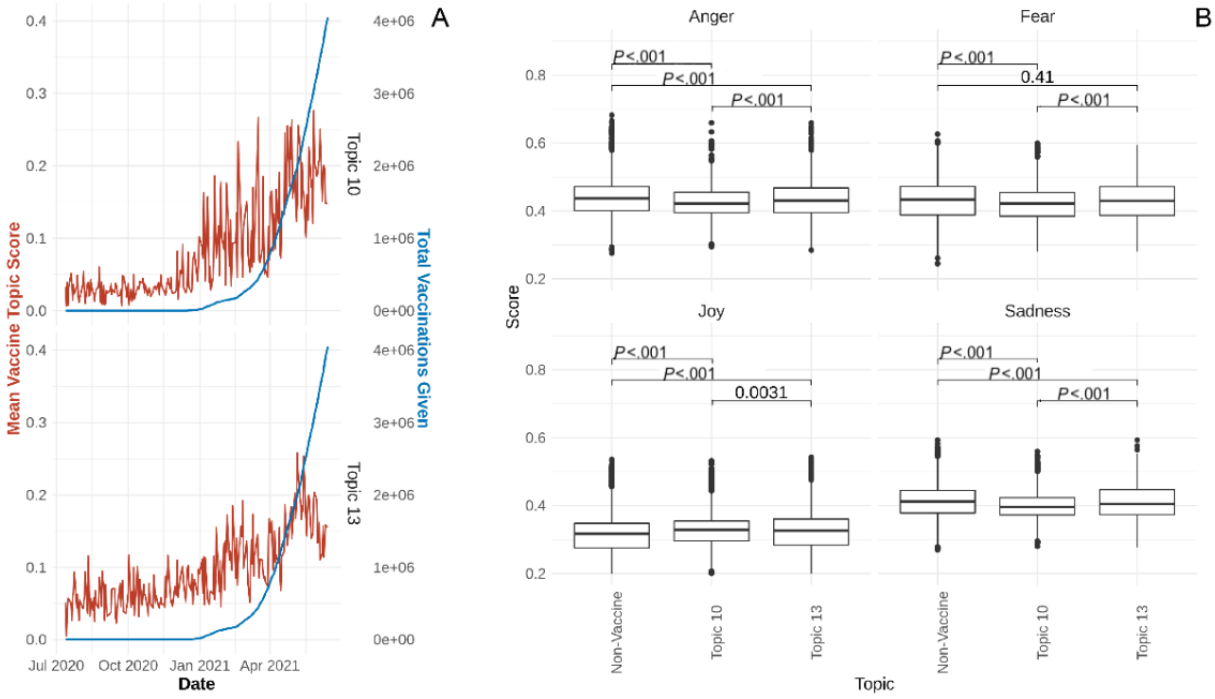
Table 2. Examples of processed comments with the highest score for each topic.

Topic	Processed comment
1	“well nt make zero case still strong restriction truck driver example implement policy nt truck unload instead local worker local worker also test daily one”
2	“not interpretation public health monitoring figure individual direct self isolate day know exposure identify contact tracing question yesterday student return class leave self isolation day”
3	“problem collective reason spread happen exponentially community strong social tie custom obligation ie wedding season lot young adult ca nt live together prior marriage taboo parent”
4	“monday multi day count new case consistent trend flat growth plateaue no acceleration no deceleration seven day trail average basically unchanged per day value near”
5	“six new healthcare facility outbreak braddan private hospital kin village madison care centre royal city manor william lake senior village creekside land outbreak chilliwack“
6	“isolation not fast literally never eliminate virus not canada certainly not globally country temporarily locally eliminate it which coincidentally island nation even island invariably virus introduce”
7	“vaccine currently use new mrna base one reprogram surface marker protein make machinary cell make virus spike protein immune system detect build resistance virus”
8	“people active public health monitoring result identify exposure know case active case recover case vancouver coastal health region case fraser health region case interior health region”
9	“nt see enforcement feasible transit security every bus take last night home bus driver keep tell people bus full pull ahead stop rather let people”
10	“reassurance calculation bc receive vaccine dose percentage first dose adult population date thursday usually shipment dose cumulative march dose march dose march dose april st dose”
11	“selectively ignore scientist scientist science deem trustworthy work right we medium company not part pov actually know people like answer question base see yes no”
12	“nine hospital bc vancouver coastal fraser health move emergency surgery least next two week mean combine elective surgery cancel low mainland fraser health abbotsford burnaby surrey memorial”
13	“parent age range little hesitant well reason azd vaccine cautious approach sure pfizer moderna slightly high effectiveness rating age group still month month half away”

Increase in Vaccine-Related Discussion Correlates With the Number of People Vaccinated

Specifically focusing on discussions surrounding vaccines, we see that the topic scores for topics 10 and 13 began to trend upward starting in January 2021, with topic 13 being slightly more highly discussed before then (Figure 2A). When overlaid with data on the total number of people vaccinated in British Columbia [19], we see that the rise in discussion precedes the rise in the number of vaccinations, although both trend similarly. The Granger test for causality was performed to evaluate the impact of vaccine discussion on total vaccinations. The results were significant for both topics (P<.001).

Figure 2. (A) Line plot displaying the daily average vaccine topic score (red) for topics 10 (top) and 13 (bottom) and the total number of vaccines administered up to that date (blue). (B) Box plots showing the distribution of emotional intensity scores. Comparisons between groups were made using the Mann–Whitney *U* test.



Vaccine-Related Comments Express Significantly Higher Positive Sentiments

Random forest regression models built using tweets labeled with emotional intensity scores were evaluated using RMSE values (Multimedia Appendix 3). Even when applied to Reddit comments, the model appears to retain validity. For each emotion, the processed comment with the highest score is displayed in Table 3. Additionally, the negative emotions (sadness, fear, and anger) are significantly, strongly positively correlated with each other and negatively correlated with joy (Multimedia Appendix 3).

Table 3. Examples of processed comments with the highest intensity scores for their respective emotions.

Emotion	Score	Processed comment
Joy	0.54	“depend happy plateau hit case day long time okay case day stay steady thing look cautiously optimistic definitely call”
Sadness	0.59	“not scientific datum notice friend indocanadian community really enthusiastic vaccine due really sad outlook india covid situation right lot family back india truly suffer take quite seriously”
Anger	0.68	“fucking sick people not give fuck people understand pass around hospital shit show soon”
Fear	0.63	“care home care home interior home town announce outbreak today mom nurse different care home town worried transmission partner lose grandparent already quarantine non covid today two fear come true sick scare sorry”

From July 2020 to April 2021, the emotional intensity scores were steady for all emotions (Multimedia Appendix 3). Negative emotions were expressed more than joy, with anger being the most prominent. From April 2021 onward, the mean scores for joy begin to trend upward while those for negative emotions all trend downward. Investigating the differences in emotional intensity scores between vaccine-related and non–vaccine-related comments, we found that comments for both vaccine topics had significantly higher scores for joy (P<.001) (Figure 2B). However, comments regarding vaccine availability had significantly lower scores for joy and higher scores for negative emotions (P<.001) compared to comments about vaccine uptake.

Comparison Across Cities

Stronger Positive-Sentiment is Exhibited in Vaccine-Related Comments Across Several Canadian Cities

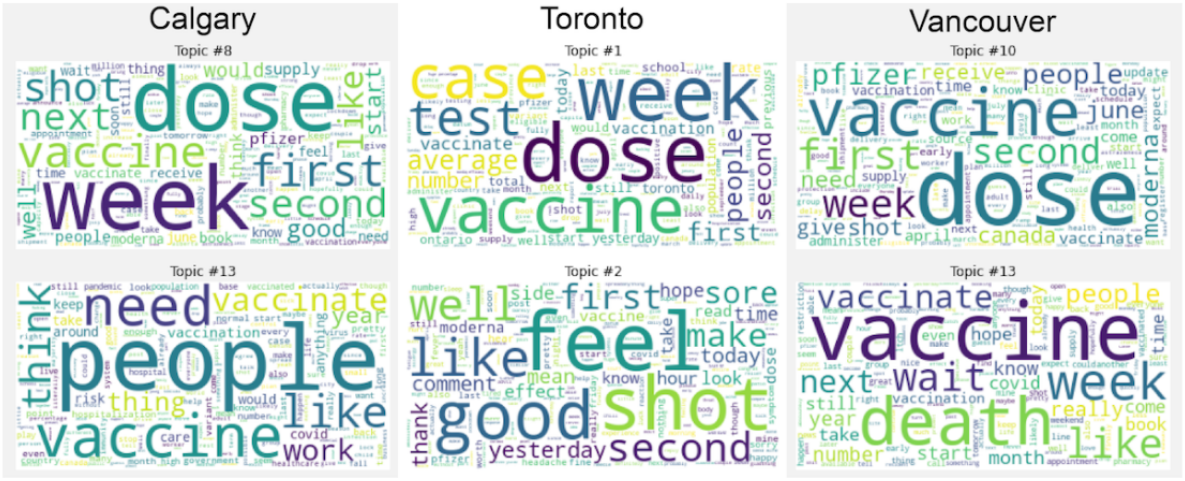
To elucidate the effect of public sentiment on vaccination rates, 2 additional major Canadian cities, Toronto and Calgary, were analyzed using the same approach taken for Vancouver. A total of 13 distinct discussion topics were identified in r/toronto and 14 topics in r/calgary. Both had 2 dominant vaccine-related topics (Figure 3). In Toronto, these discussed vaccine uptake and postvaccine feelings. In r/calgary the 2 vaccine-related topics identified were vaccine uptake and concerns around vaccination rates. Top-scoring comments for each

vaccine-related topic for Toronto and Calgary are shown in Multimedia Appendix 4.

Public sentiments for all emotions in Toronto and Calgary were significantly different between the 2 vaccine-related topics and between vaccine-related and non–vaccine-related comments (P<.001), except for the expression of fear in r/calgary comments (Multimedia Appendix 5). No significance was detected in the degree of fear between non–vaccine-related comments and those that discussed first and second dosages of COVID-19 vaccines.

In the Calgary Reddit community, comments discussing vaccination rates expressed lowest intensity for joy and the highest score for negative emotions (Multimedia Appendix 5). This coincides with Alberta having lower vaccination rates than British Columbia and Ontario (Multimedia Appendix 5). In Toronto, a higher degree of positive sentiment was observed in the vaccine-related comments (P<.001), with the highest median score occurring in comments that discussed vaccine side effects, followed by those pertaining to vaccine uptake (Multimedia Appendix 5).

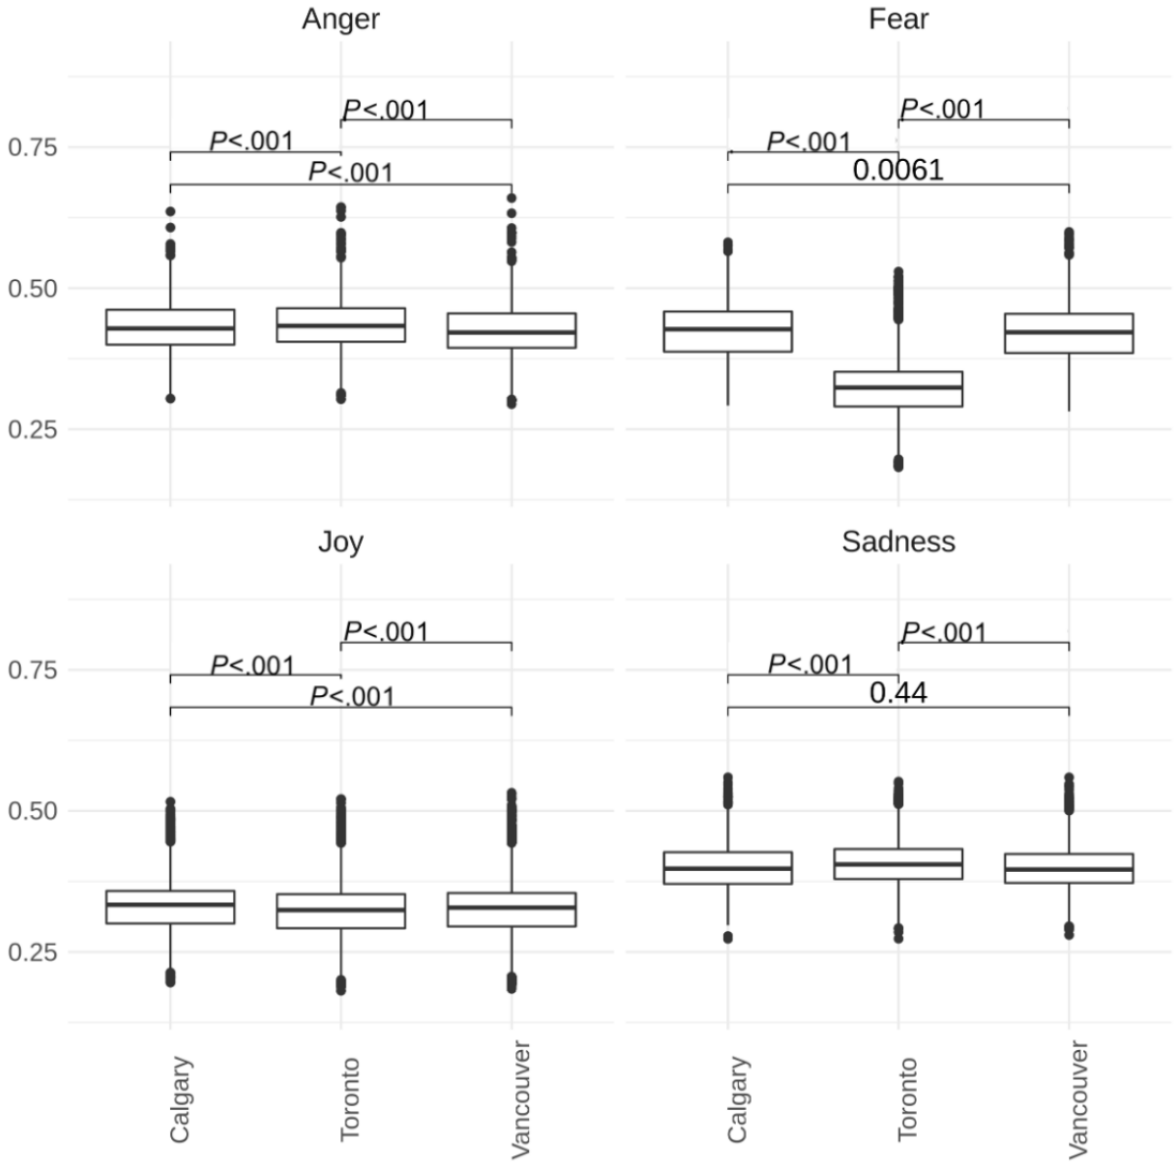
Figure 3. Word clouds for vaccine-related topics across the 3 cities.



Sentiments Toward Vaccine Uptake Significantly Differed Across Cities

Sentiments toward vaccine uptake, the only vaccine-related topic shared by all 3 cities, differed significantly among cities across all emotions (P<.001; Figure 4). Toronto had the highest scores for anger and sadness and the lowest scores for joy and fear. Vancouver and Calgary had statistically the same scores for sadness, but Calgary had significantly higher scores for the other emotions.

Figure 4. Box plots showing the distribution of emotional intensity scores for vaccine uptake. Comparisons between cities were made using the Mann–Whitney *U* test.



Discussion

Principal Findings

In this study, we analyzed comments on the posts in r/vancouver, r/calgary, and r/toronto, which provide daily updates on case numbers, hospitalizations, and other COVID-19–related statistics. We found that the number of comments made on the posts from the Vancouver subreddit positively correlated with the number of new daily COVID-19 cases in British Columbia. From the comments, 13 topics were identified. Two topics were related to vaccines, 1 regarding vaccine uptake and the other about vaccine supply. The levels of discussion for both topics were linked to the total number of vaccines administered. Calgary and Toronto also discussed vaccine uptake, and sentiment scores for this topic differed across the 3 cities (P<.001).

Since July 2020, British Columbia has experienced fluctuations in COVID-19 cases and accompanying restrictions. Cases exponentially increased from 280 cases per day (7-day averages) at the beginning of November 2020 to 833 cases per day at the end of November 2020 [27]. In response, British Columbia issued a 2-week policy on November 7, 2020, prohibiting social gatherings outside of households [28]. This policy was renewed on November 19, 2020, in addition to the implementation of a mask mandate for public spaces [28].

Additionally, in April 2021, cases in British Columbia ranged from 873 to 1130 per day (7-day averages), forming a third peak. The increase in cases caused British Columbia to introduce travel restrictions for nonessential travel between British Columbia health authority boundaries, and to extend the state of emergency twice within the month of April 2021 [29-31].

These peaks in case numbers align with the 2 peaks in engagement on Reddit, and they were found to be significantly positively correlated. This trend suggests that when case numbers increase, more discussion is generated. This finding

builds upon previous literature describing how people bond over the topic of COVID-19 on Twitter [32].

Furthermore, while the number of comments and the number of new cases of COVID-19 increase in tandem from October 2020, the number of comments peaks sooner and decreases at a faster rate than the number of new cases of COVID-19. This suggests that engagement on Reddit is a leading indicator of COVID-19 transmission, as is the case with Google searches, tweets, and Wikipedia page views [33].

However, for the second, higher peak in new cases of COVID-19 in April 2021, the number of Reddit comments increased, albeit at a lower rate, and did not exceed the peak in November 2020. Thus, rather than being a predictor of the number of cases, Reddit engagement patterns may instead be indicative of avoidance behaviors stemming from social media fatigue and the fear of COVID-19 arising from the stresses brought by the November wave [33].

To understand what people discuss on Reddit, we performed topic extraction and identified 13 topics through our model. Compared to studies analyzing themes circulating on Twitter at the beginning of the pandemic, in March 2020, we found that people have continued to compare case numbers, talk about restrictions, and share information on methods of preventing spread [34,35]. In addition, other topics that reflect British Columbia–specific policies and problems were discussed, such as the high transmission of COVID-19 within health care sectors such as long-term care homes during the second wave [36].

Two new, potentially more universal topics surrounding different facets of vaccines have also emerged. The first one addresses vaccine uptake, and the second one is about vaccine availability. Discussion for these topics began trending upward in November 2020, shortly after Pfizer and BioNTech announced the efficacy of their vaccine during phase 3 trials [37]. The level of discussion fluctuated as British Columbia prioritized vaccinating health care workers and residents of long-term care homes [38], but began to rise again in March 2021 as the public was administered vaccines [39].

At first, as the number of people vaccinated continued to grow, vaccine-related discussions increased as well. Comments on vaccine uptake have continued to increase, but have recently decreased for vaccine availability. Topic scores for vaccine availability were also generally higher than that of vaccine uptake until around March 2021. This is likely owing to reports of fluctuations and shortages in vaccine shipments [40,41]. Only recently has British Columbia been able to secure consistent and sufficient vaccine supplies enough to half the wait time between first and second doses [42,43]. Based on the significance of the Granger causality tests, it appears that discussion about either topic may have driven anticipation and demand for the vaccine.

Based on detailed discussions surrounding vaccines, we explored how people felt about them on Reddit by constructing a random forest regression model using tweets labeled with emotional intensity scores. The resulting RMSE values were considered acceptable, and the model was applied to predict emotional intensity scores for Reddit comments. Afterward, we extracted the cleaned comment with the highest score for each emotion. All 4 human authors agreed that the comments demonstrated the emotions they represented. To further validate the scores, a correlation matrix was created. As expected, the negative emotions (anger, fear, and sadness) were strongly positively correlated with each other but strongly negatively correlated with joy.

Observing the trends in emotional intensity of comments over time, we see that comments demonstrate more fear, anger, and sadness than joy [34]. However, comments expressing joy began increasing from April 2021, which coincides with the second peak in case numbers and rise in vaccinations. Since no similar changes were observed in November 2020, we concluded that vaccinations were related to the increase in comments expressing joy. To further confirm this, we compared emotional intensity scores between the 2 types of vaccine-related and non–vaccine-related comments and found that people expressed significantly more positive sentiments about vaccines.

Interestingly, the level of fear expressed about vaccine supply was not significantly different from that in non–vaccine-related comments, and both were significantly higher than vaccine uptake. Nonetheless, both vaccine topics had significantly lower anger and sadness scores than non–vaccine-related topics. This reflects concerns people have about not being able to get the vaccine [44].

Finally, we sought to compare vaccine sentiments across Canadian cities. In addition to discussing vaccine uptake as in Vancouver, Calgary, and Toronto, each had another regionally specific vaccine-related topics. For Toronto, these topics were about vaccine side effects. The word cloud had generally subjective and positive terms including “good” and “feel.” However, it’s emotional scores suggest that the topic may be polarized. Although it has the highest scores for joy, it also has the highest scores for fear. Nonetheless, both vaccine-related topics have significantly lower scores for anger and sadness than non–vaccine-related topics. This suggests that despite feeling generally positive about vaccines, there is still apprehension.

In Calgary, the second topic appears to be about vaccination rates. For this one, the sentiment is clear. The scores for negative emotions significantly exceed those for even non–vaccine-related topics. Since Calgary has the lowest vaccination rates and a lottery exclusively for vaccinated people as an incentive [45], it appears that Redditors are frustrated over the low uptake of vaccines.

When the common topic across all 3 cities—vaccine uptake—was compared, notable differences were observed. Calgary had the highest scores for fear, anger, and joy. Their highest-scoring comment for this topic embodies the first 2 emotions as it seems as though they had inadequate vaccine supply in the midst of high case numbers.

Interestingly, Toronto had the lowest scores for fear, despite also having the lowest scores for joy and the highest scores for sadness and anger. These sentiments could be attributed to frustration over booking vaccines [46] or having strict restrictions still in place despite high vaccination rates and

decreasing case rates [47]. The low scores for fear than those for Calgary and Vancouver, however, are challenging to explain, especially since vaccine-related topics display higher fear than non–vaccine-related topics within Toronto's own subreddit.

Based on our analyses, Reddit comments on posts in city-specific subreddits can be used to assess public sentiment toward COVID-19–related topics. Thus, it is a cost-effective and rapid way for officials to monitor citizens' response to policies. Implementation of sentiment analysis to understand public perceptions of policies in Italy enhanced the accountability and responsiveness of policymakers [48]. Additionally, since engagement on Reddit correlated with COVID-19 cases and vaccination rates, discussion on social media can serve as predictors for real-world statistics.

Finally, our analyses were able to capture variations in sentiment about the same vaccine-related topic across the 3 cities. Accordingly, it is possible for officials to design policies that specifically target populations. For example, reassuring messaging about vaccine side effects and safety may be most useful for Toronto. In contrast, Vancouver could focus more on increasing vaccine supply and Calgary on appealing to vaccine-hesitant groups.

Limitations

Despite the promise in our results, our analyses are not without limitations. First, the data were collected from subreddits, where anyone can comment. However, owing to the community-based nature of the subreddits, we assume that the comments are from commenters located in the cities we are studying. Therefore, the analysis is assumed to be specific to local and provincial policies.

Additionally, emotional intensity scores were assigned to Reddit comments based on tweets because no similarly labeled Reddit data set was available. Common libraries for sentiment analysis, including TextBlob and VADER, lacked specificity for COVID-19–related discussions. Since Twitter is similar to Reddit, in that people post and respond to short, publicly available messages under a username, we assumed that people would use similar language.

Conclusions

Using comments on daily posts containing updates on COVID-19 statistics from a location-specific subreddit, we were able to relate changes in web-based engagement, discussion, and emotional expression to case counts and vaccination rates. Topics relevant to local news and policies were identifiable, as were attitudes toward measures to curb disease spread, such as vaccines. Overall, our study shows that data from social media can be used to better understand concerns and sentiments surrounding the pandemic at the local level, which enables more targeted and publicly acceptable policies.

Abstract

Background: Given that governmental prevention measures restricted most face-to-face communications, online self-disclosure via smartphones emerged as an alternative coping strategy that aimed at reducing the impact of the COVID-19 pandemic on people's psychological health. Prepandemic research demonstrated that online self-disclosure benefits people's psychological health by establishing meaningful relationships, obtaining social support, and achieving self-acceptance, particularly in times of crisis. However, it is unclear whether these dynamics transition well to lockdown conditions where online self-disclosure must stand almost entirely on its own. Longitudinal investigations are needed to gain insights into the psychological functionalities of online self-disclosure during the COVID-19 pandemic.

Objective: This study aimed to determine the temporal associations between smartphone online self-disclosure (as a communicative behavior) and critical indicators of psychological health (including psychopathological, as well as hedonic and eudaimonic states) during the first COVID-19 lockdown in Austria.

Methods: We conducted a representative 2-wave panel survey between late March/April 2020 and May 2020. A total of 416 participants completed both waves (43.1% attrition rate, given n=731 participants who completed the first wave). A partially metric measurement invariant overtime structural equation model was used to determine the temporal associations among online self-disclosure, fear of COVID-19, happiness, and psychological well-being.

Results: The analysis revealed that fear of COVID-19 significantly predicted online self-disclosure over time (b=0.24, P=.003) and happiness over time (b=−0.14, P=.04), but not psychological well-being (b=0.03, P=.48), that is, stronger COVID-19 fears at T1 prompted more online self-disclosure and less happiness at T2. Online self-disclosure, on the other hand, significantly predicted happiness (b=0.09, P=.02), but neither fear of COVID-19 (b=−0.01, P=.57) nor psychological well-being (b=−0.01, P=.57) over time. Participants who engaged more strongly in online self-disclosure at T1 felt happier at T2, but they did not differ from less-disclosing participants concerning COVID-19 fears and psychological well-being at T2. Importantly, happiness and psychological well-being were significantly related over time (happiness T1 → psychological well-being T2: b=0.11, P<.001; psychological well-being T1 → happiness T2: b=0.42, P<.001).

Conclusions: Our findings suggest that online self-disclosure might play a pivotal role in coping with pandemic stressors. With restrictions on their options, individuals increasingly turn to their smartphones and social media to disclose their feelings, problems, and concerns during lockdown. While online self-disclosure might not alleviate fears or improve psychological well-being, our results demonstrate that it made people experience more happiness during this crisis. This psychological resource may help them withstand the severe psychological consequences of the COVID-19 crisis over longer timeframes.

Introduction

Background

Across the world, fears (ie, an intense emotion emerging from a perceived imminent threat [1]) related to the COVID-19 pandemic are having a pervasive influence on people's psychological health (understood in a "balanced" way as a continuum that includes both the *absence* of psychopathological and the *presence* of positive psychological states [2]) that extends beyond its immediate threat to physical health [3] and warrants extensive research efforts to face current and future challenges [4]. With respect to these COVID-19 fears, Schimmenti et al [5] used the apocalyptical label of the "four horsemen" to emphasize how significant various states of fear are in explaining people's behavior during the pandemic. According to them, COVID-19 fear involves the following four domains that are mutually connected: fear of/for the body (ie, the body as a potential source of danger and hypervigilance), fear of/for significant others (ie, interpersonal relationships as a potential threat and source for sorrow), fear of (not) knowing (ie, information as a potentially unsettling necessity), and fear of (in)action (ie, decisions that once made or avoided can be potentially harmful). Empirical evidence broadly supports their emphasis showing enhanced levels of fear and other harmful emotional states (such as depressive tendencies and stress) during the COVID-19 pandemic [6-9].

In addition to the fear of getting infected, most governments issued prevention orders that minimized public life and called for physical distance as the appropriate interpersonal norm for private and public gatherings. Consequently, unrestricted face-to-face social environments disappeared almost completely. To deal with this profound change and related adverse psychosocial states, individuals exercised various coping strategies [10,11].

This study focuses on one key coping strategy, *online self-disclosure.* Self-disclosure is defined as the communication of self-related private information to other people [1]. Self-disclosure has long been established as a critical coping behavior in institutionalized therapeutic contexts [12] and informal private settings [13]. In times of the pandemic and particularly during lockdowns, self-disclosure may instead be exercised frequently on social media, most notably via mobile devices such as smartphones. Affordances in such online contexts differ from most offline contexts when it comes to the frequency, breadth (ie, diversity), and depth (ie, intimacy) of self-disclosures [14,15]. Yet, prior research suggests that online self-disclosure can directly contribute to people's psychological health (as an efficient coping behavior) and indirectly by prompting offline self-disclosure as an additional coping resource [16].

Against this background, this study looks at the consequences of online self-disclosures during the first lockdown period of the COVID-19 pandemic in 2020.

This study contributes to our understanding of digital media's roles in times of a pandemic in several ways. First, we, for the first time, shed light on how self-disclosure via smartphones can help individuals cope with pandemic-related stressors, ultimately fostering psychological health. Second, and related to that, we focus on people's online self-disclosure as a communicative *behavior* rather than on *experiential* constructs such as perceived social support and feelings of loneliness. Third, from a methodological standpoint, this study contrasts itself from the great abundance of cross-sectional research by reporting results from a 2-wave longitudinal survey that took place during the first COVID-19 lockdown in Austria. Our sample followed representative quota data, allowing for greater generalizability of the results. Moreover, by employing measurement invariant overtime structural equation models, we can provide the first glimpse into temporal order and directional associations between key constructs. Overall, our study aims at providing the first empirical evidence about how online self-disclosure in times of COVID-19 serves as an effective coping behavior that is provoked by COVID-related fears and leads to improved psychological health.

Fear of COVID-19 as a Predictor of Online Self-Disclosure, Happiness, and Psychological Well-being

In comparison to previous years, overall media use has been on the rise during the COVID-19 pandemic [17,18]. Interestingly, a study by Ohme et al [19] revealed that people tend to prioritize mobile messengers over more public social media platforms when confronted with pandemic-related developments, indicating an immediate need for social support. Large-scale analyses of people's public social media activities exhibited more verbal expressions that would typically be considered as symptomatic of mental health hazards (eg, anxiety, depression, stress, and suicidal ideation), and outreaches for emotional and informational support [20]. Such private and public media activities align with the basic premise of the fever model of disclosure [21]. According to this theoretical approach, self-disclosure is understood as a self-regulative behavior that emerges as a function of experienced distress and aims for maintaining psychological health. Self-disclosing communications are assumed to become more likely under elevated levels of distress to elicit support from close others that may help people cope.

Undoubtedly, the COVID-19 pandemic has been a significant stressor for individuals, especially with respect to fear, as people are "worried, fearful, and uncertain about COVID-19 and the consequences it will have for themselves, their families, communities, and the nation" [6]. Following the fever model of disclosure [21], we theorize that online self-disclosure is one possible coping strategy that individuals use to deal with these fears during lockdown. Following this argumentation, we expected that COVID-19 fears lead to more frequent online self-disclosures. The first hypothesis (H1) was as follows: Fear

of COVID-19 positively predicts online self-disclosure on social media over time.

Except occasionally for playful media-induced feelings [22], fear is generally regarded as a negatively experienced emotion with high valence and arousal [23] that, if not reappraised or extinguished, can damage people's psychological health [24,25]. Protection measures (such as intensified online self-disclosure) may not always suffice to reappraise or eliminate the complex web of fears. In the case of the COVID-19 pandemic (in particular, during the first lockdown), people have been continuously afraid of and hypervigilant about any yet unknown or newly arising threats [5]. It is, therefore, not surprising that findings point toward a negative link between people's COVID-19 fears and their psychological health [26]. Since there were no major alleviating events during the timeframe of this study (ie, March/April to May 2020) that may have mitigated its impact, we hypothesized that people's COVID-19–related fear will have a negative influence on the following two key indicators of psychological health: happiness and psychological well-being. These indicators were selected because each reflects one of the following two dominant traditions in positive psychology: hedonism and eudaimonism [27,28]. More specifically, we follow a previous report [29] in their definition of *happiness* as the presence of pleasant and the absence of unpleasant emotions, and their definition of *psychological well-being* as an umbrella term that includes various eudaimonic experiences, such as meaning and purpose in life, satisfied psychological needs, and self-acceptance. While both indicators contribute individually to psychological health, it is their interaction that can lead people to flourish [30,31]. Due to this mutually reinforcing role in promoting the proverbial good life, we examined both their relationships with fear over time. The second hypothesis (H2) was as follows: Fear of COVID-19 negatively predicts (1) happiness and (2) psychological well-being over time.

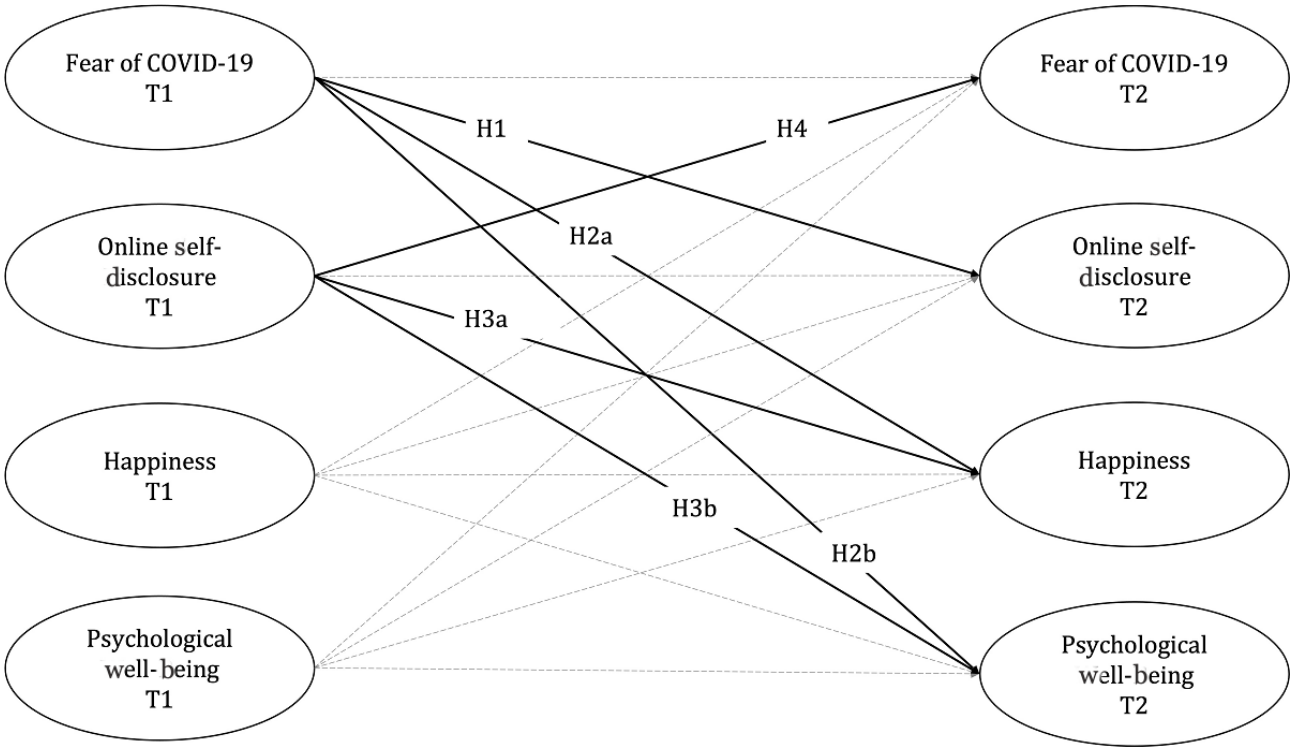
Online Self-Disclosure as a Predictor of Happiness, Psychological Well-being, and Fear of COVID-19

Everything considered, prepandemic research suggests that online self-disclosure can have positive consequences for psychological health. Luo and Hancock [32] detailed different mechanisms through which people may benefit. Most notably, disclosing personal feelings to others in social media constitutes the basis for meaningful online conversations that promote social capital [33] and interpersonal relatedness [34], and help against loneliness [35] and stressful life events [36]. As evidenced in the study by Trepte et al [16], online self-disclosure may also provide a fertile ground for long-term impacts, since it reinforces online self-disclosure in the course of time and carries over to offline (ie, face-to-face) self-disclosures.

This advantageousness might be reinforced during COVID-19 as people may have become more aware and intentional of their online self-disclosures [37]. Within formal therapeutic settings, research has highlighted how online treatments during the pandemic can facilitate self-disclosures and their benefits for psychological health [38,39]. More informally, the unique affordances of social media have been argued to facilitate self-disclosures during COVID-19 that, in turn, may help people to maintain a sense of control [40]. Nevertheless, Canale et al [41] did not find a significant direct correlation between emotional online self-disclosure and psychological health during COVID-19. Indirect effects, however, align with prepandemic links between online self-disclosure and social support. Here, cross-sectional studies have validated the positive effect of social support, very likely following online self-disclosure, on individuals' psychological health [41,42]. In other words, individuals who disclosed their COVID-19–related concerns online were more likely to receive immediate social support, such that they understood or got the impression that they are not alone. Based on these findings, we assumed that online self-disclosure should be positively related to happiness and psychological well-being during the pandemic. The third hypothesis (H3) was as follows: Online self-disclosure on social media positively predicts (1) happiness and (2) psychological well-being over time.

Online self-disclosure during the pandemic may help to not only improve positive psychological states at large but also cope with adverse feelings. The first cross-sectional evidence supports this position. As presented in the study by Canale et al [41], expressing emotions deliberately in online conversations was found to be beneficially associated with coping with COVID-19–related trauma. In this context, emotional online self-disclosures may be understood as a behavioral manifestation linked to adaptive emotion regulation strategies (such as acceptance and perspectivization) that help people cope with their COVID fears [43]. However, cross-sectional investigations cannot determine the directions in which these associations may work. Participants in the study by Canale et al [41] may have overcome COVID-19 trauma due to stronger self-disclosure activities; yet, considering that online conversations are often biased toward displaying positive information [44], it is equally possible that those participants who had scored lower on COVID-19 trauma were merely more motivated to disclose their feelings online. Still, following the report by Luo and Hancock [32], we assumed that people who engage in online self-disclosure during the pandemic might experience less fear about it at a later point in time. The fourth hypothesis (H4) was as follows: Online self-disclosure on social media negatively predicts fear of COVID-19 over time. The full theoretical model is shown in Figure 1.

Figure 1. Full theoretical model of this study. Solid lines indicate the paths that were included in the hypotheses, and dashed lines indicate the paths that were involved in statistical analysis.



Methods

Data Statement

The data of this paper (which is available at Open Science Framework Project Space [45]) is part of a more comprehensive project examining longitudinal relationships between smartphone use in times of COVID-19 and well-being. Importantly, the paper only reports variables that are relevant to the present research interest.

Sampling and Procedure

We conducted a 2-wave panel survey during the first COVID-19 lockdown in Austria. Data collection took place in late March/early April 2020 (T1) and May 2020 (T2) within a 1-month interval. This 1-month (ie, on average) interval was chosen because we were looking at medium-term processes unfolding over several weeks. There was a strong and unpredictable dynamic during the early stages of the COVID-19 pandemic. A larger time span (eg, 6 or 12 months) may have been problematic because several confounding events could have occurred during data collection, making the findings of a larger time-frame meaningless.

Before we started collecting data, we sought ethical clearance from the Institutional Review Board of the Department of Communication at the University of Vienna. Participants were recruited by the professional online polling institute Dynata. Complementarily, another sample was collected simultaneously at the University of Vienna using the same questionnaire, methodology, and quota plan. We used representative quotas for age, gender, and educational level in Austria. For participants to take part in the data collection, they were required to provide their consent, report whether they are using a smartphone, and be at least 16 years of age.

A total of 731 participants (mean age 40.49 years, SD 13.33 years; 394 [53.9%] women; 150 [20.5%] with lower secondary education or less, 340 [46.5%] with vocational school education or secondary education, and 241 [33.0%] with complete university education) completed the survey in the first wave. Among these participants, 416 also completed the second wave (mean age 41.97 years, SD 13.59 years; 226 [54.3%] women; 90 [21.6%] with lower secondary education or less, 187 [45.0%] with vocational school education or secondary education, and 139 [33.4%] with complete university education). The attrition rate between the two waves was 43.1%. There was no significant difference between participants who dropped out after the first wave (T1; n=315) and participants who also completed the second wave (T2; n=416) regarding gender (χ^2_2=1.37, P=.50, Cramér V=0.043), education (χ^2_5=5.33, P=.38, V=0.085), fear of COVID-19 (t_{729}=0.50, P=.62, Cohen d=0.037), online self-disclosure on social media (t_{729}=−1.45, P=.15, d=−0.108), happiness (t_{729}=0.40, P=.69, d=0.030), and psychological well-being ($t_{631.01}$=0.42, P=.68, d=0.032). Participants who dropped out at T2 had a lower age (mean 38.53 years, SD 12.80 years) than participants who participated in both surveys (mean 41.98 years, SD 13.55 years; t_{729}=3.49, P=.001, d=0.261).

Measures

All implemented measures were based on established scales. Given that this study was part of a more comprehensive survey, we opted for short scales that were constructed using high-loading items of these established scales to reduce dropout and prevent respondent fatigue while at the same time minimize reliability and validity losses.

Fear of COVID-19

Similar to Ahorsu et al [8], we employed 2 items measuring fear of COVID-19. We asked participants to indicate their agreement to the following 2 statements: "The coronavirus scares me" and "I am afraid that I could get infected with the coronavirus." Participants answered on a 5-point Likert scale ranging from "strongly disagree" to "strongly agree" (T1: Cronbach α=.76; mean 2.77, SD 1.07; T2: α=.80; mean 2.42, SD 1.07). Principal component analysis resulted in a 1-dimensional scale (eigenvalue=1.61; accounting for 80.03% of the variance).

Online Self-Disclosure on Social Media

We measured online self-disclosure on social media, with 4 items adapted from Schouten et al [35,46]. We asked participants how often they have used their smartphones during the last week to communicate the following content on social media platforms: "personal feelings about the corona crisis," "concerns about the novel coronavirus," "private problems regarding the corona crisis," and "fears of the novel coronavirus." Participants answered on a 7-point Likert scale ranging from "never" to "very often" (T1: α=.91; mean 2.30, SD 1.57; T2: α=.92; mean 1.87, SD 1.32). Principal component analysis indicated a 1-dimensional scale (eigenvalue=3.12; accounting for 78.00% of the variance).

Happiness

We assessed happiness with 3 items derived from Wirth et al [47,48] on a 7-point Likert scale ranging from "never" to "very often." Participants were asked how often they were "in a good mood," "happy," and "joyful" in the last week (T1: α=.92, mean 4.86, SD 1.40; T2: α=.94, mean 5.20, SD 1.36). Principal component analysis showed that happiness is a 1-dimensional scale (eigenvalue=2.59; accounting for 86.44% of the variance).

Psychological Well-being

For psychological well-being, we used 7 items derived from Diener et al [29]. We asked participants to indicate their agreement to the following 7 statements on a 5-point Likert scale ranging from "strongly disagree" to "strongly agree:" "I lead a purposeful and meaningful life," "I am optimistic about my future," "My social relationships are supportive and rewarding," "I am engaged and interested in my daily activities," "I actively contribute to the happiness and well-being of others," "I am competent and capable in the activities that are important to me," and "I am a good person and live a good life" (T1: α=.88, mean 3.97, SD 0.72; T2: α=.90, mean 3.95, SD 0.77). Principal component analysis resulted in a 1-dimensional scale (eigenvalue=4.05; accounting for 57.85% of variance).

Control Variables

As controls, we assessed participants' age, gender (1=male; 2=female), and education (compulsory school levels=low; secondary school levels=moderate; high school and university levels=high). Additionally, we controlled for the sampling method using a dummy variable (0=polling quota sample data; 1=university quota sample data).

Statistical Analysis

Using SPSS Amos [49], we conducted structural equation modeling with full information maximum likelihood estimation. Apart from our control variables, we controlled for autoregressive effects (eg, fear of COVID-19 at T1 as a predictor of fear of COVID-19 at T2). Furthermore, we estimated all reciprocal effects.

Before we conducted the data analysis, we additionally checked for longitudinal measurement invariance of all outcome variables by constraining all factor loadings of our latent variables at T1 and T2 [50]. Based on the comparative fit index (CFI), Tucker-Lewis Index (TLI), Bentler-Bonett Normed Fit Index (NFI), chi-square to degrees of freedom ratio (χ^2/df), and root mean square error of approximation (RMSEA), the goodness of fit of the model can be considered as good (CFI=0.95; TLI=0.93; NFI=0.91; χ^2/df=2.26, P<.001; RMSEA=0.04; 90% CI 0.04-0.05). We established a partial metric invariance model that does not fit the data worse compared to the unconstrained model (χ^2_9=16.54, P=.06). For this partial metric invariance model, 1 factor loading for happiness and 2 for well-being were not forced to be equal over time. Thus, partial metric invariance over time was established, indicating no substantial differences in meaning of all latent variables over time [50].

Results

Zero-order correlations and the main results of the structural model are shown in Table S1 and Table S2 in Multimedia Appendix 1. In line with H1, findings from the autoregressive latent variable model suggests that fear of COVID-19 positively predicts online self-disclosure on social media over time (b=0.24, SE=0.08, P=.003) (Figure 2). Neither happiness nor psychological well-being measured at T1 predicted online self-disclosure on social media at T2. However, we found that higher educated individuals were more likely to self-disclose online over time (b=0.30, SE=0.13, P=.03).

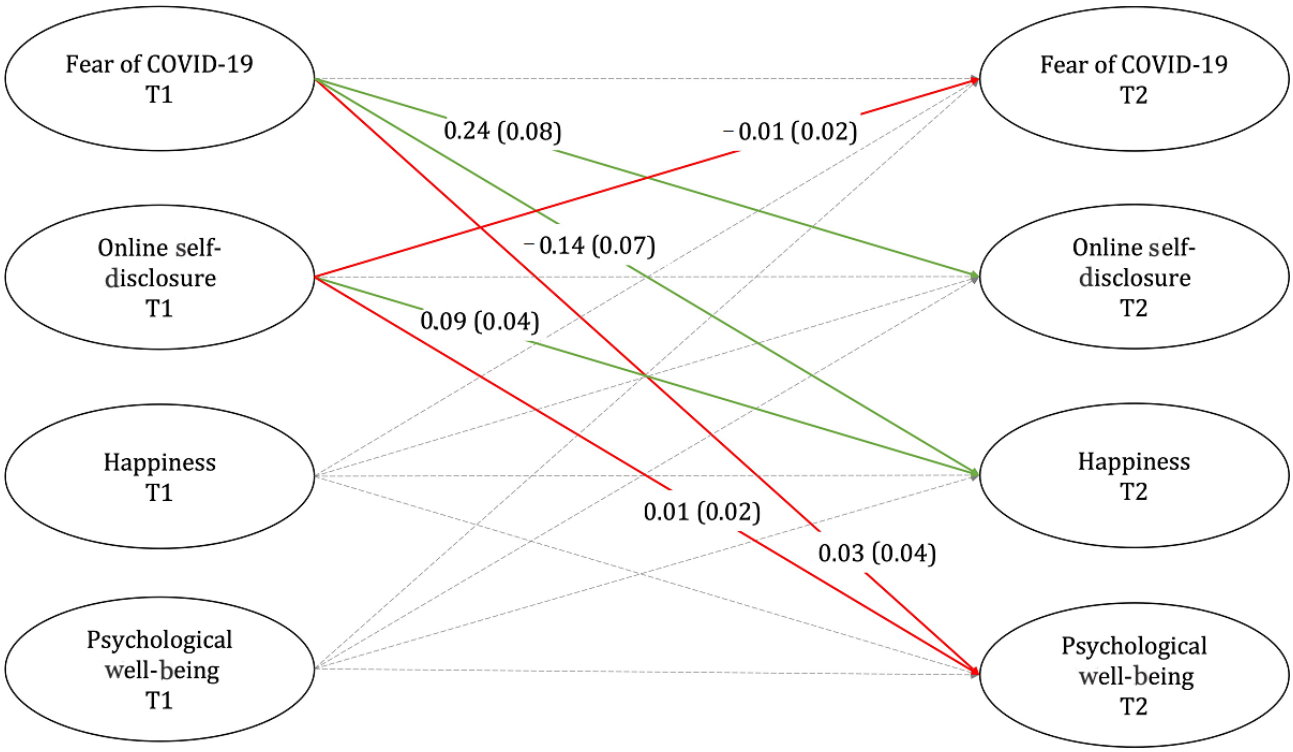
In H2, we assumed that fear of COVID-19 negatively predicts (1) happiness and (2) psychological well-being over time. While we found support for H2a (b=−0.14, SE=0.07, P=.04), there was no support for H2b (b=0.03, SE=0.04, P=.48). Furthermore, there were significant positive relationships between age and psychological well-being (b=0.01, SE=0.00, P=.004), as well as between female gender and psychological well-being (b=0.13, SE=0.06, P=.03).

In line with H3a, we found that online self-disclosure on social media positively predicted happiness (b=0.09, SE=0.04, P=.02). However, against the expectation formulated in H3b, online self-disclosure was found to be unrelated to psychological well-being over time (b=−0.01, SE=0.02, P=.57). Yet, it is important to note that psychological well-being and happiness were significantly related over time (happiness T1 → psychological well-being T2: b=0.11, SE=0.03, P<.001; psychological well-being T1 → happiness T2: b=0.42, SE=0.09, P<.001).

Finally, we found no support for H4, as online self-disclosure was not a significant negative predictor of fear of COVID-19

over time (b=−0.01, SE=0.02, P=.57). Combined with the findings for our first hypothesis, this suggests that fear can prompt self-disclosure, but the reciprocal relationship cannot be observed. Moreover, fear was not significantly predicted by any other variable in our data set, except for psychological well-being, indicating that individuals with high psychological well-being are less likely to experience fear of COVID-19 over time compared to individuals with lower scores (b=−0.15, SE=0.07, P=.04).

Figure 2. Summary of the principal results of the autoregressive structural equation model. Solid lines indicate the paths (presented with unstandardized path coefficients and standard errors in parentheses) that were included in the hypotheses, and dashed lines indicate the paths that were involved in statistical analysis (for detailed results including covariates, see Multimedia Appendix 1). Significant paths are displayed in green, and nonsignificant paths are displayed in red.



Discussion

Principal Findings

This study provides empirical support for the coping strategy of online self-disclosure. More specifically, our main findings reveal that more intense COVID-19 fears at the beginning of the first COVID-19 lockdown (T1) predicted greater online self-disclosure at the end of the lockdown 1 month later (T2), indicating that it has been considered a relevant means of coping in light of governmental restrictions. Further, the study shows that greater engagement in online self-disclosure at T1 coincides with increased feelings of happiness at T2, suggesting coping effectiveness with regard to hedonic emotional states. Notably, psychological well-being at T2 was not linked to COVID-19 fears and online-self disclosure at T1.

In the time of COVID-19, people all over the world have been confronted with significant psychological stressors, such as the likelihood of being infected or the social isolation resulting from lockdown measures. Social media provide a way to cope with these stressors, especially by disclosing self-related private information to other people. Such online self-disclosure has an important psychological function. By disclosing their concerns, fears, or personal problems during the lockdown, individuals connect with others and maintain the feeling of not being alone, which may save them from harmful health-related consequences.

In this study, using partially metric measurement invariant structural equation modeling, we found the first empirical evidence that fear of COVID-19 increased smartphone-based self-disclosure on social media, which, in turn, fostered individuals' happiness. Three aspects of our findings are particularly noteworthy. First, while fear of COVID-19 fostered online self-disclosure over time, we did not observe any evidence for the reverse effect. This means fear leads people to disclose their concerns using digital media, but this does not help to alleviate fear. Interestingly, happiness, which was positively predicted by online self-disclosure, did not reduce fear of COVID-19 over time either. In order to interpret these findings, we need to keep in mind that the study was conducted during the first lockdown in Austria in spring 2020, where the uncertainty regarding the pandemic, the epidemiologic characteristics of the coronavirus, and its consequences for human life were arguably at its peak in many countries. In other words, no matter the amount of online self-disclosure, fears of COVID-19 remained present, most likely due to the ongoing risks and uncertainties associated with it. In fact, the only construct that was found to reduce fear over time was psychological well-being. Individuals who report a high degree of psychological well-being may have more confidence in their ability to master or control the virus or exhibit stronger resilience against adverse psychological states [51]. Clearly, more empirical insight is needed to explain this finding.

Second, it is noteworthy that, compared to happiness, we did not observe a relationship between online self-disclosure and psychological well-being. Happiness can be understood as a relatively transient hedonic emotional state in which individuals experience pleasure and joy [29]. By contrast, psychological well-being includes more stable and long-term eudaimonic indicators such as life satisfaction and quality of life [52]. This refers to the notion that our current life and our life achievements are perceived as being close to our general ideals and goals in life [53]. The inconsistent effectiveness of online self-disclosure for coping may be explained by the contrast in both indicators' scopes. Disclosing to others how one personally feels about COVID-19, even if done repeatedly over the course of 4 weeks, may come as a habitualized temporal relief from pandemic-related stressors; however, it might not by itself be capable of changing the bleak circumstances that created these stressors in the first place (nor stressors unrelated to the pandemic) in such a brief period. Within 4 weeks, online self-disclosure may therefore "only" facilitate ephemeral affective states that got repeatedly threatened by COVID-19 but not more stable long-term self-evaluations that most likely go beyond the circumstances of the pandemic. However, as evident in our data, happiness and psychological well-being are positively and reciprocally related over time. This may suggest that online self-disclosure may impact psychological well-being indirectly, that is, by affecting happiness in the first place, which then influences individuals' psychological well-being. Unfortunately, with only 2 panel waves, we lack the data to test such mediated relationships.

Notwithstanding this limitation, one could argue that happiness serves as an important psychological resource in times of crisis. In states of happiness, individuals are likely to select and process emotionally congruent (ie, positive) information, which may facilitate self-confidence and prevent the emergence of depressive tendencies [54]. One could also assume that happy individuals differ from unhappy individuals in the ways in which they cope with the flow of negative media information surrounding the COVID-19 pandemic [55]. Of course, additional data are needed to firmly test these conjectures.

Third and finally, online self-disclosure was only predicted by fear and not by happiness and psychological well-being, pointing to the very nature of self-disclosure, that is, self-disclosure can be understood as a means to cope with *negative* stressors and not to communicate *positive* experiences. Accordingly, online self-disclosure is not reduced (nor enhanced) in positive life situations. The combination of these findings supports the notion that online self-disclosure comes as a suitable coping strategy in the face of physical distance and government restrictions impeding face-to-face–based coping that appears to withstand the general positivity bias in social media environments.

Limitations

Some limitations need to be acknowledged. Lockdowns and other government measures to fight COVID-19 differ between countries, which may have a significant impact on self-disclosure behaviors. Thus, findings from Austria may not be generalizable to other countries, necessitating additional empirical evidence. Related to this, data collection in this study started at the beginning of the lockdown in March/April 2020, lasting until the end of the lockdown in May 2020 in Austria. The findings may thus not be generalizable to the entire period of the COVID-19 pandemic, such as subsequent COVID-19 lockdowns, that is, individuals may behave in different ways during a second lockdown than they did during the first lockdown. Therefore, familiarity with a lockdown situation and compliance with government measures should be taken into account in future research. Moreover, future studies should use more measurements, ideally spanning over lockdown and nonlockdown periods.

With regard to methodology, we relied on participants' self-reports to measure online self-disclosure. Clearly, self-report data have limitations as they are prone to social desirability and other measurement errors. Participants in this study may have underestimated or overestimated their levels of online self-disclosure. Related to this, our measures and data allow no assumptions about the content of online self-disclosure. Individuals may have enclosed several emotional states, such as fears, practical problems, economic issues, and health-related aspects. In order to shed light on the content of self-disclosure during the pandemic, qualitative methodologies are particularly warranted. Moreover, although we could observe effects over the course of 1 month, our research design did not allow any conclusions about longitudinal mediation mechanisms. Future research should continue this work with more panel waves. Such data would also account for mediation paths among fear of COVID-19, online self-disclosure, and psychological outcomes.

Finally, the relationship between online self-disclosure and psychological well-being may depend on individual predispositions. For instance, chronically distressed individuals may not benefit from online self-disclosure [32]. The reason can be found in their distress-related tendency to share more negative or inauthentic information, which is usually accompanied by more negative received feedback. Future research should investigate these individual-level contingent conditions.

Conclusions

Taken together, our findings suggest that self-disclosure in online digital media can play a major role in restoring people's happiness during COVID-19 and the lockdowns it has brought upon us. With the worldwide spread of COVID-19, fear was a prevalent emotional reaction among many people. To deal with this fear, individuals used digital media, especially social media via their smartphones, to disclose their feelings, problems, and concerns. We showed that such online self-disclosure opportunities contributed to the psychological health of individuals. Although online self-disclosure did not affect psychological well-being, it made people happier over time, which is an important psychological resource in times of uncertainty, crisis, and stress.

Acknowledgments

We would like to thank the group of master's students at the University of Vienna, namely Nadja Daurer, Katharina Feistritzer, Paula Gerhardus, Vera Odorizzi, Aminta Mahmoudi, Raphael Schörkhuber, Stefan Stangassinger, Patrick Stelzl, and Kerstin Widler, for their assistance with the recruitment of participants.

Authors' Contributions

JM and KK drafted the initial manuscript and reviewed and revised the manuscript. JM conceptualized the study and conducted the statistical analysis. AN and AS administered and conceptualized the study, wrote sections of the manuscript, and reviewed and revised the manuscript. All authors approved the final manuscript as submitted and agreed to be accountable for all aspects of the work.

Conflicts of Interest

None declared.

Abstract

Background: COVID-19 is caused by the SARS-CoV-2 virus and has strikingly heterogeneous clinical manifestations, with most individuals contracting mild disease but a substantial minority experiencing fulminant cardiopulmonary symptoms or death. The clinical covariates and the laboratory tests performed on a patient provide robust statistics to guide clinical treatment. Deep learning approaches on a data set of this nature enable patient stratification and provide methods to guide clinical treatment.

Objective: Here, we report on the development and prospective validation of a state-of-the-art machine learning model to provide mortality prediction shortly after confirmation of SARS-CoV-2 infection in the Mayo Clinic patient population.

Methods: We retrospectively constructed one of the largest reported and most geographically diverse laboratory information system and electronic health record of COVID-19 data sets in the published literature, which included 11,807 patients residing in 41 states of the United States of America and treated at medical sites across 5 states in 3 time zones. Traditional machine learning models were evaluated independently as well as in a stacked learner approach by using AutoGluon, and various recurrent neural network architectures were considered. The traditional machine learning models were implemented using the AutoGluon-Tabular framework, whereas the recurrent neural networks utilized the TensorFlow Keras framework. We trained these models to operate solely using routine laboratory measurements and clinical covariates available within 72 hours of a patient's first positive COVID-19 nucleic acid test result.

Results: The GRU-D recurrent neural network achieved peak cross-validation performance with 0.938 (SE 0.004) as the area under the receiver operating characteristic (AUROC) curve. This model retained strong performance by reducing the follow-up time to 12 hours (0.916 [SE 0.005] AUROC), and the leave-one-out feature importance analysis indicated that the most independently valuable features were age, Charlson comorbidity index, minimum oxygen saturation, fibrinogen level, and serum iron level. In the prospective testing cohort, this model provided an AUROC of 0.901 and a statistically significant difference in survival (P<.001, hazard ratio for those predicted to survive, 95% CI 0.043-0.106).

Conclusions: Our deep learning approach using GRU-D provides an alert system to flag mortality for COVID-19–positive patients by using clinical covariates and laboratory values within a 72-hour window after the first positive nucleic acid test result.

Introduction

COVID-19 is caused by the SARS-CoV-2 virus and is suspected to be of zoonotic origin, with spillover from bats or pangolins into humans in Wuhan, China [1,2]. COVID-19 has become one of the largest public health emergencies of the past century with over 203 million confirmed cases and 4.3 million deaths as of August 2021 according to the World Health Organization [3]. The COVID-19 pandemic has overwhelmed global medical supply chains, hospitals, and economies, which has led governments to respond with varying policies, including mask mandates and travel restrictions [4,5]. At times, hospitals and health care workers have become so overburdened with patients with COVID-19 that they have been forced to ration care, raising logistical and ethical concerns [6].

The clinical course of COVID-19 is diverse with most individuals experiencing mild or asymptomatic disease, but many patients develop life-threatening diseases, including features such as cytokine storms, thrombotic complications, or severe acute respiratory syndrome requiring mechanical ventilation or extracorporeal membrane oxygenation [7]. A major medical challenge is therefore to reliably triage patients according to their risk for severe disease. Age is consistently observed to be a predominant risk factor for severe disease [7], but deaths are not limited to older adults and the majority of older patients survive COVID-19 [7]. Other comorbidities and laboratory test values are expected to be capable of further individualizing and enhancing mortality prediction. Recent studies investigating statistical and machine learning (ML) models for mortality prediction have confirmed that detailed evaluation of medical records can facilitate further stratification of patients [8-12].

A systematic review of 147 published or preprint prediction models found consistent problems with inherent biases in the data sets investigated or created in all such studies, ultimately concluding that “we do not recommend any of these reported prediction models for use in current practice” [12]. Clinical practices differ in the nature of their observational electronic health record (EHR) data set, patient population, clinical practices, and electronic record or laboratory ordering practices. Correspondingly, the literature review conducted at the outset of this study indicated that the existing prediction models were likely unsuited to our clinical setting without essentially starting afresh by retraining, validating, and testing predictions.

We describe Mayo Clinic’s experience assembling, what is to our knowledge, the largest reported COVID-19 database for mortality prediction and using this database to create a system for COVID-19 mortality prediction, tailored to a unique patient population. Despite the biases inherent to it, because this large and growing database represents a health care system spanning 5 states and 3 time zones over a study window greater than 11 months, our model is expected to be the least confounded and the most generalized COVID-19 mortality predictor published to date. We report the successful development and validation of a state-of-the-art ML model to provide mortality prediction shortly after confirmation of SARS-CoV-2 infection in this Mayo Clinic patient population and discuss in detail the various logistical and scientific challenges involved in the early deployment of such a system in a rapidly changing pandemic environment.

Methods

Study Design

This work required the development of a data set and the subsequent modeling of the resultant cohort. After data collection and cleaning, 2 broad classes of algorithms were considered to model this data. The first approach ignores the time series nature of the underlying data and applies traditional ML classifiers. The second approach explicitly models the time series data while dealing with the missing-not-at-random (MNAR) values by using specialized recurrent neural networks (RNNs). Both types of modeling methods were run independently and compared using cross-validation, and a single winning model was selected for prospective performance validation.

EHR and Laboratory Information System Observational Cohort Data Collection

This study adheres to a research protocol approved by the Mayo Clinic Institutional Review Board. Data were retrospectively collected after March 1, 2020 on COVID-19–positive individuals presenting to a Mayo Clinic site or health system, while excluding patients without research consent or from European Union countries covered by the general data protection regulation law. We restricted our focus to 11,807 patients with a positive COVID-19 nucleic acid test result on or before January 27, 2021 and at least one non-COVID test result. Although the data collection system is deployed and ongoing, the January cutoff was selected for this study to provide sufficient cohort size while allowing a minimum of 3 weeks of follow-up to accurately establish survival status. Mayo Clinic’s EHR and laboratory information system (LIS) contain data from each of its 3 campuses (Rochester, Minnesota; Jacksonville, Florida; Scottsdale, Arizona) as well as the surrounding health system sites spanning 5 states (MN, IA, WI, FL, and AZ). Although the EHR contains clinically reportable laboratory results, many of these can only be reported within defined ranges, which can result in qualitative text values rather than the raw numeric measurements. Because many ML algorithms typically work better with quantitative rather than qualitative results, we used the LIS to gather such laboratory testing measurements and the EHR to gather the remaining variables. The EHR data were queried from an underlying Db2 database (IBM Corp), and the LIS data were queried from an SQL database (Microsoft).

Multivariate Time-Series Data With Missingness

The clinical covariates collected were age, sex, height, weight, Charlson comorbidity score, temperature, blood pressure, respiratory rate, oxygen saturation (SpO_2) levels, and diagnoses of chronic kidney disease or diabetes mellitus. Furthermore, we included laboratory test values from a basic metabolic panel, complete blood counts, and some less routine test results of relevance to COVID-19, as determined by scientific literature and physician collaborators. Table 1 details the features collated into our database. In Multimedia Appendix 1, we provide a detailed breakdown of these clinical covariates and laboratory values in our cohort (Table S1 of Multimedia Appendix 1) as well as the cohort's geographic distribution (Figure S1 of Multimedia Appendix 1). Differentiating between missing data and absence of a condition is not possible from EHR diagnostic codes, particularly for patients treated in an outpatient setting. Therefore, we focused mainly on the Charlson comorbidity index [13], which is populated in our EHR when there is a recorded medical history during a "patient encounter" in the EHR. Thus, this variable is available and can be assigned a value corresponding to no comorbidities, which is distinct from missingness in the case of no recorded medical history in the EHR. However, owing to their emphasis within the literature, we also included chronic kidney disease [9] and diabetes mellitus [14] as independent comorbidity variables using their ICD-10 (International Classification of Diseases) codes while acknowledging that these variables conflate missingness with lack of a condition.

Clinical covariates such as pre-existing conditions, height, and weight were sampled infrequently, whereas heart rate and SpO_2 were recorded every 15 minutes for inpatients in our EHR, and other laboratory tests were intermediate in terms of frequency. Therefore, to deal with these multiscale time series measurements, we used the laboratory measurements as the starting point to define our sampling time points. For the variables of sex, age, weight, height, diabetes mellitus, chronic kidney disease, and Charlson comorbidity index, we encoded these variables to exist at the first time point only; in our top performing RNN models, we observed no difference in performance using this strategy when compared to repeating the observations at each time point. For the frequently observed variables of blood pressure systole, blood pressure diastole, temperature, pulse, respiratory rate, and SpO_2, we computed the minimum and maximum measurements for each calendar day and appended these to each laboratory time point during those dates; if no laboratory time point existed on a given day, we created a new one at noon using these minimum and maximum values. We considered time points within ±72 hours of each patient's first positive polymerase chain reaction (PCR) result and performed a sensitivity analysis on the length of the patient follow-up after this positive test result.

Table 1. Feature measurements collected.

Abbreviation	Description (units or levels)
sex	Sex (male or female)
age	Age at time of polymerase chain reaction–positive test result (years)
weight	Weight (kg)
height	Height (cm)
PCR	SARS-CoV-2 nucleic acid test (+ or –)
SERO	SARS-CoV-2 serology antibody test (+ or –)
BASAA	Basophil count test (10^9/L)
EOSAA	Eosinophil count test (10^9/L)
HCT	Hematocrit test (%)
HGB	Hemoglobin test (g/dL)
LYMAA	Lymphocyte count test (10^9/L)
MCV	Mean corpuscular volume test (fL)
MONAA	Monocyte count test (10^9/L)
NEUAA	Neutrophil count test (10^9/L)
PLTC	Platelet count test (10^9/L)
RBC	Red blood cell count test (10^{12}/L)
RDW	Red cell distribution width test (%)
WBC	White blood cell count test (10^9/L)
CRP	C-reactive protein test (mg/L)
D-DIMER	D-dimer test (ng/mL)
FERR	Ferritin test (mg/L)
IL6	Interleukin-6 test (pg/mL)
TRPS	Troponin T test (ng/L)
FIBTP	Fibrinogen test (mg/dL)
LD	Lactate dehydrogenase test (U/L)
IRON	Serum iron test (mg/dL)
TIBC	Total iron binding capacity test (mg/dL)
SAT	Percent iron saturation test (%)
TRSFC	Transferrin test (mg/dL)
BUN	Blood urea nitrogen test (mg/dL)
CHL	Chloride test (mmol/L)
GLU	Glucose test (mg/dL)
CALC	Calcium test (mg/dL)
CREA	Creatinine test (mg/dL)
POTA	Potassium test (mmol/L)
ALB	Albumin test (g/dL)
BICA	Bicarbonate test (mmol/L)
SODI	Sodium test (mmol/L)
BILI	Bilirubin test (mg/dL)
BPsystole	Blood pressure systole (mm Hg)

Abbreviation	Description (units or levels)
BPdiastole	Blood pressure diastole (mm Hg)
Temp	Temperature (°C)
Pulse	Heart rate (1/min)
Resp	Respiratory rate (1/min)
SpO_2	Oxygen saturation (%)
Charlson	Charlson comorbidity index (10-year survival probability)
CKD	Chronic kidney disease (+ or –)
DM	Diabetes mellitus (+ or –)

Time-Flattened ML Models

Time series data were flattened/encoded to a fixed length list of features by carry forward imputation (ie, selection of the most recently observed covariate values), ensuring compatibility with traditional ML models. Specifically, after the data are flattened in this fashion, it forms a tabular prediction task suitable for any canonical supervised classification algorithm. The recently published [15] Python-based automated ML tool AutoGluon-Tabular (v0.2.0) was utilized to enable standardized and reproducible ensemble stacking of many model classes (eg, deep neural networks, LightGBM boosted trees, CatBoost boosted trees, Random Forests, Extremely Randomized Trees, XGBoost, and k-Nearest Neighbors).

AutoGluon-Tabular models were fit to our tabular data frames using the "AutoGluon.TabularPrediction.fit" function using all the default parameters except eval_metric='roc_auc'. After running the fit function, access to each individual model created by AutoGluon was achieved by the "get_model_names" method on the resulting prediction object. This then allowed us to pass the specified model to the "predict_proba" method's optional "model" argument for each of the following model types: KNeighborsUnif, KNeighborsDist, NeuralNetFastAI, LightGBMLarge, NeuralNetMXNet, RandomForestGini, ExtraTreesGini, RandomForestEntr, ExtraTreesEntr, LightGBM, XGBoost, LightGBMXT, CatBoost, WeightedEnsemble_L2. Hereon, we refer to WeightedEnsemble_L2 as the "AutoGluon" model since this was the output of the "predict_proba" method when no single model type was specified.

For relatively static features such as height, weight, or Charlson comorbidity index, we would expect the time-flattened models to be at no disadvantage, whereas the more frequently measured data such as laboratory values or blood pressure will lose information, particularly about trends in the covariates. For instance, 2 individuals with a fever of 39°C recorded in the most recent observation would be treated the same even if one had a sustained high fever and the other had a brief downward trending spike. Of course, there are many potential degrees of freedom to capture more information in the flattened data; one could define a fixed number of the most recent observations or fit a line through the observations over time and pass the slope and intercept as features to the classifier. However, ultimately, the choice to flatten the time series is a choice of convenience and one that attempts to leverage the extensive research efforts devoted to tabular prediction, and therefore, we study here only the last observation carried forward modeling, since proper modeling efforts should account for the time series structure in the EHR data. We next look at models of this form.

RNN Time Series Models

As the second approach, we implemented the modified gated recurrent unit (GRU) binary classification models proposed by Che et al [16] that are capable of accounting for the MNAR patterns within EHR data, and we adopt their notation. For a given patient, we have $D = 54$ variables and a given time series of T time points can be represented as a $T \times D$ matrix X whose rows $x_t \in$  D, $t = 1, \ldots, T$ represent the t-th observation with D variables  , $d = 1, \ldots, D$. Accompanying each observation x_t is a time stamp $s_t \in$  , which starts at time 0, $s_1 = 0$ and a binary masking vector $m_t \in \{0, 1\}^D$ with  taking value 1 when  is observed and 0 otherwise. From these values, we can compute the time intervals.

With these definitions, we can look at various modifications to the standard GRU architecture whose j-th hidden unit has a reset gate  and update gate  with hidden state  at time t and update the equations.

With matrices W_z, W_r, W, U_z, U_r,U and vectors b_z, b_r, b composed of model parameters, $\odot$ is the Hadamard product, and $\sigma(\cdot)$ is the elementwise sigmoid function. Before modifying the architecture, there are 3 methods to use the GRU above to handle missing data: in "GRU-Mean," missing values are imputed by their means in the training data; in "GRU-Forward," missing values are imputed by their last observed value; and in "GRU-Simple," we simply concatenate the x_t, m_t, and δ_t variables into a single observation vector x 't and pass this through the GRU equations above. The GRU-D method uses trainable decay weights.

With W_γ and b_γ being trainable model parameters. The observations are then replaced by the update.

where  is the last observed value of the *d*-th variable and  is the empirical mean of the *d*-th variable in the training data. The modified GRU update equations for GRU-D become the following.

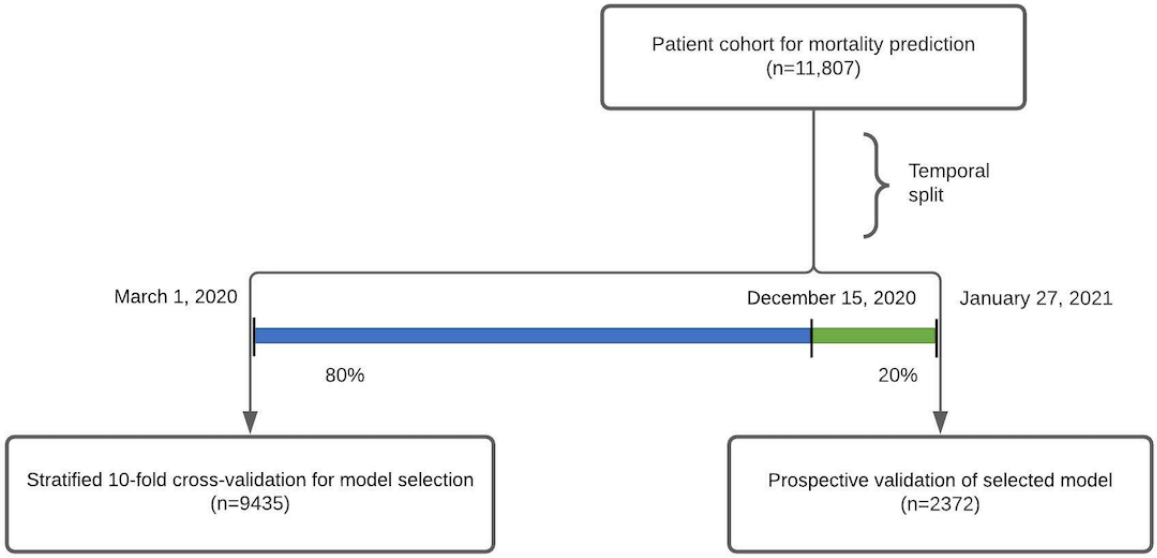
where V_z, V_r, V are new model parameters to directly handle the masking vector m_t in the model.

Our implementation of the above equations in Python is a slightly modified version of the code available on the GRU-D paper's [16] GitHub repository. For the core RNN algorithms, we only edited the original GRU-D code, where required, to be compatible with the more recent versions of tensorflow.keras (version 2.1.0) and numpy (version 1.19.2) used in our high-performance computing cluster environment. We selected the specific RNN algorithm by setting the "--model" argument to be "GRUforward," "GRU0," "GRUsimple," and "GRUD" for GRU-forward, GRU-mean, GRU-simple, and GRU-D, respectively. We utilized the default hyperparameters of the algorithm; however, in our testing, we found that increasing the batch size from 32 to 256 facilitated faster training of the algorithms. Therefore, a batch size of 256 is the only nondefault hyperparameter selection made in our implementation of the RNN algorithms.

Temporal Cohort Split

As depicted in the CONSORT (Consolidated Standards of Reporting Trials) diagram of Figure 1, patients who first tested positive for COVID-19 from March 1, 2020 through December 15, 2020 (9435/11,807, 79.9%) were assigned to a model selection cohort, whereas patients who first tested positive for COVID-19 from December 16, 2020 through January 27, 2021 (2372/11,807, 20.1%) were used as a prospective testing cohort for the final algorithm. All experiments in the model selection cohort were performed using an identical 10-fold stratified cross-validation using binary classification with the positive class defined as death within 21 days of the first positive PCR test result. Only the single best performing model was evaluated on the prospective cohort after being fit against the entire model selection cohort.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram demonstrating the temporal split of our cohort for model selection and prospective validation.



Results

Model Selection

In Figure 2 and Table 2, we compared the results of our various models by using cross-validation area under the receiver operator characteristic (AUROC) curve in the training cohort. Although not in a statistically significant way, we recapitulated the findings of Che et al [16], discovering that the GRU-D model has the highest average cross-validation AUROC curve among all other standard variants of GRU modeling in time series with missing values. In addition, GRU-Simple has higher average cross-validation AUROC curve than the GRU-Forward and GRU-Mean, and the most notable difference underlying these categories is the inclusion of missingness indicators as features to GRU-Simple, which could indicate the value of MNAR patterns in the classification task. GRU-D's biologically inspired architecture attempts to make even more efficient use of this information and exceeds the performance of all the tested RNN methods. AutoGluon, which only had access to the last measurement of each variable, showed strong performance despite this limitation. In Table 2, each individual AutoGluon model was also benchmarked (those with suffix "-AutoGluon"), along with the final ensemble estimate (labeled simply as "AutoGluon"). Although GRU-D ultimately outranked AutoGluon, each method's performance fell within the other's

standard error intervals. AutoGluon's automated hyperparameter tuning and model stacking may indicate that GRU-D could benefit from the addition of hyperparameter search. However, this process may risk overfitting this cross-validation data set, and thus, we selected GRU-D with the default settings rather than attempting to further improve the cross-validation AUROC curve via hyperparameter optimization.

Figure 2. Receiver operating characteristic curves for the 18 models evaluated. AUROC: area under the receiver operating characteristic.

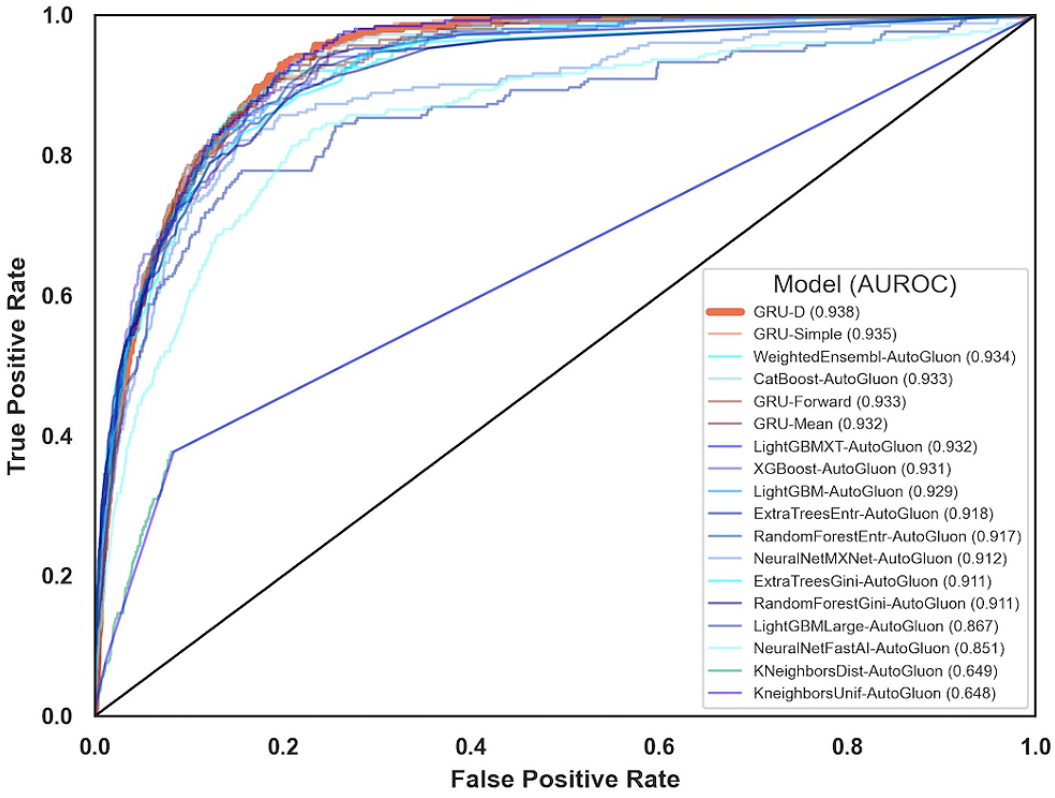


Table 2. Modeling results sorted by performance.

Model	Area under the receiver operator characteristic curve (SE)
KNeighborsUnif-AutoGluon	0.648 (0.011)
KNeighborsDist-AutoGluon	0.649 (0.011)
NeuralNetFastAI-AutoGluon	0.858 (0.013)
LightGBMLarge-AutoGluon	0.867 (0.014)
NeuralNetMXNet-AutoGluon	0.907 (0.008)
RandomForestGini-AutoGluon	0.911 (0.007)
ExtraTreesGini-AutoGluon	0.911 (0.009)
RandomForestEntr-AutoGluon	0.917 (0.008)
ExtraTreesEntr-AutoGluon	0.918 (0.007)
LightGBM-AutoGluon	0.929 (0.007)
XGBoost-AutoGluon	0.931 (0.006)
LightGBMXT-AutoGluon	0.931 (0.005)
GRU-Mean	0.932 (0.005)
GRU-Forward	0.933 (0.006)
CatBoost-AutoGluon	0.933 (0.005)
AutoGluon	0.934 (0.005)
GRU-Simple	0.935 (0.004)
GRU-D	0.938 (0.004)

Length of Time Series

Clearly, we would expect availability of more time series data to result in improved model performance. To determine if predictions could be made utilizing data prior to 72 hours of a patient's first positive PCR test result, we assessed the performance of GRU-D when we restricted the time series to 12, 24, 48, and 72 hours of follow-up after the first positive PCR test result. The results in Table 3 demonstrate that although we lose performance when predicting earlier in the patient's disease, we are still able to provide accurate predictions even using data within the same day (12 hours of follow-up) that a patient tests positive for COVID.

Table 3. GRU-D performance versus length of time series.

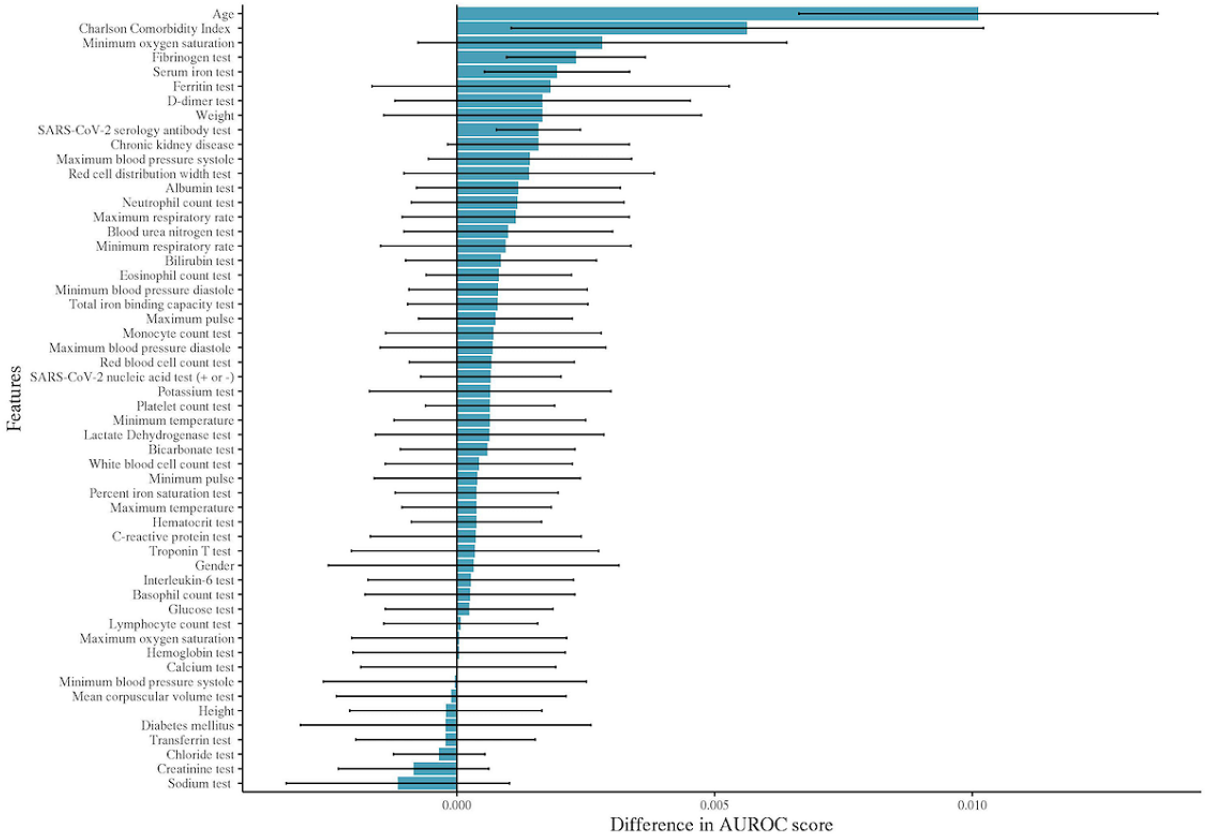
Follow-up after positive finding for polymerase chain reaction	Area under the receiver operator characteristic curve (SE)
12 h	0.916 (0.005)
24 h	0.919 (0.006)
48 h	0.925 (0.005)
72 h	0.938 (0.004)

MNAR as an Asset and Feature Importance

To demonstrate the fact that MNAR data can improve model predictions by GRU-D, we generated a synthetic data set with laboratory test values replaced by Bernoulli coin flips. Therefore, the only valuable information contained within this data set's laboratory values is the missing data patterns that can be viewed as encoding clinical suspicion or concern. For instance, the D-dimer laboratory value is ordered less frequently than other tests, and therefore, its presence alone can be informative of clinical concern for thrombotic events. Our results found that randomizing the laboratory values resulted in an AUROC curve of 0.904 (0.006), which indicates that the laboratory values in aggregate contributed 0.034 to the AUROC score (since this is the drop in performance compared to the model with actual laboratory values). We ran a further experiment omitting the laboratory values entirely, which produced a lower AUROC of 0.890 (0.006). Therefore, the missing patterns alone contributed 0.014 to the AUROC. To contextualize this finding, we dropped each feature individually from the model, assessed the decrease in the AUROC score, and summarized the top 10 features in the decreasing order of the difference in the AUROC score (Figure 3). We note here that the drop due to missing patterns exceeds the drop due to removing any single variable from the analysis, making the MNAR pattern one of the most valuable pieces of information available to GRU-D. In Multimedia Appendix 1, we show a detailed error analysis of our model using these top 10 features. The fact that age and Charlson comorbidity index are the most significant contributors to mortality prediction is consistent with

the well-known risk factors for COVID mortality. The findings of the fibrinogen test, serum iron test, and ferritin test were the 3 most important laboratory values in our models. The presence of chronic kidney disease, weight, serology test, and SpO_2 were the clinical covariates that also ranked in the top 10 variables by importance. Interestingly, height had low importance, indicating that BMI may not be as effective as weight itself in mortality prediction. However, a limitation of this drop-one-feature variable importance is that a low-ranking feature such as height cannot be said to be irrelevant, just that any information it carries is redundant within other features.

Figure 3. Feature importance in the GRU-D recurrent neural network model as defined by the average drop in the area under the receiver operator characteristic curve (with 95% CI) when each feature is individually removed from the analysis. The top 5 features are seen to be age, Charlson comorbidity index, minimum oxygen saturation, fibrinogen levels, and serum iron levels. AUROC: area under the receiver operator characteristic.

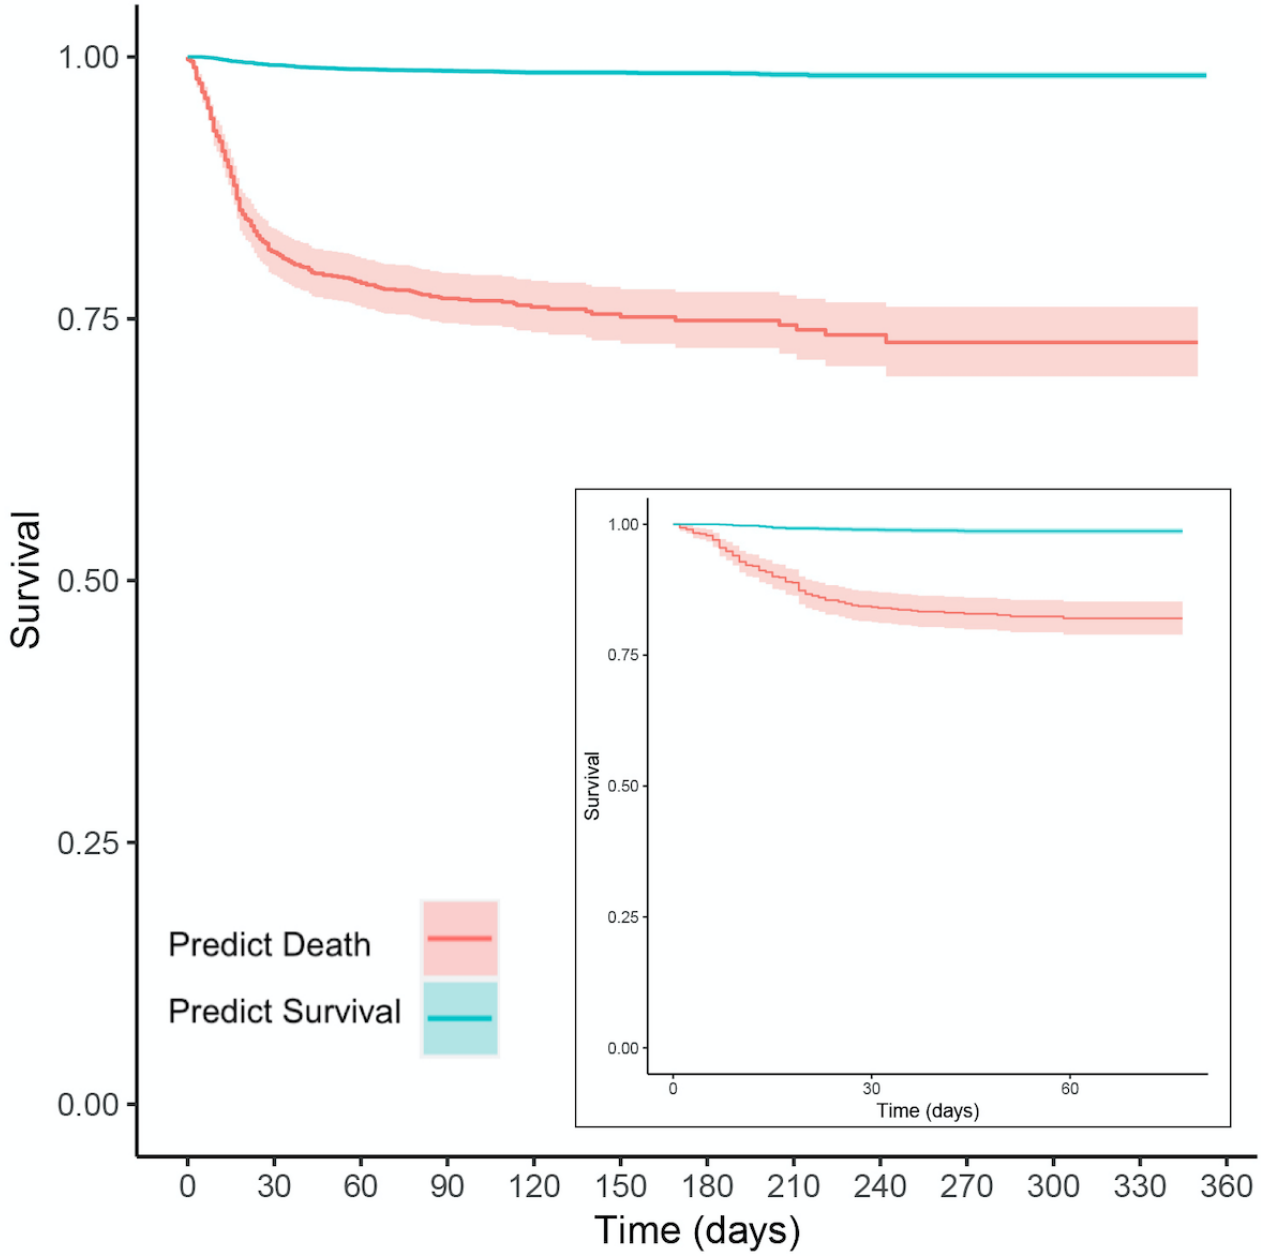


Prospective Validation and Survival Analysis

To demonstrate the efficacy of our proposed mortality prediction, we performed a Kaplan-Meier analysis using the survival R library [17]. Specifically, we chose a decision boundary on the GRU-D model's ROC curve, which provided a specific delineation of high-risk and low-risk groups of patients. In our cross-validation cohort, binary classification provides accuracy of 89% (95% CI 88%-90%), recall of 80% (95% CI 74%-85%), precision of 17% (95% CI 15%-19%), and a negative predictive value of 99% (95% CI 99%-100%). Furthermore, although the precision is somewhat low with numerous false positives, we see among the survivors over twice the rate of mechanical ventilation or extracorporeal membrane oxygenation when they are predicted to die by GRU-D (Fisher exact test $P<.001$, odds ratio 2.1, 95% CI 1.8-2.5). We validated this performance in our prospective testing cohort, finding an AUROC of 0.901, accuracy of 78% (95% CI 76%-79%), recall of 85% (95% CI 77%-91%), precision of 14% (95% CI 12%-17%), and a negative predictive value of 99% (95% CI 99%-100%).

Our Kaplan-Meier analysis results in Figure 4 demonstrate the statistically significant stratification provided by our ML model in both the cross-validation and prospective testing experiments. Building a Cox Proportional Hazards model for our prediction in the cross-validation cohort provides a statistically significant difference in survival between the 2 groups ($P<.001$ for the likelihood ratio, logrank, and Wald tests), with a prediction of survival having a substantially improved hazard ratio of 0.053 (95% CI 0.043-0.066). We validated this finding in the prospective testing cohort with a statistically significant difference in survival between the 2 groups ($P<.001$ for the likelihood ratio, logrank, and Wald tests), with a prediction of survival having a substantially improved hazard ratio of 0.067 (95% CI 0.043-0.106).

Figure 4. Kaplan-Meier survival curves for the GRU-D stratified populations in the cross-validation cohort (main figure) and the prospective test cohort (inset), where teal is the prediction of low risk of death and red is the prediction of high risk. Both figures have 95% CIs visualized for the teal and red curves, although the teal confidence bands are tight due to our large sample sizes.



Discussion

Study Overview

In this study, we collected and processed over 50 laboratory and clinical covariates in a population of nearly 12,000 Mayo Clinic patients who tested positive for SARS-CoV-2 by PCR. In this large and geographically diverse data set, we found that the GRU-D RNN could provide state-of-the-art mortality prediction. This performance remained strong even in a held-out test set that mimics how a deployed system would be trained retrospectively and then prospectively utilized in a clinically evolving pandemic setting.

Principal Results

Our cross-validation experiments summarized in Table 2 indicated that the top performing model to predict mortality in our cohort was the GRU-D RNN. We thus selected the GRU-D method to predict the mortality of patients with COVID-19 and prospectively found an AUROC of 0.901, accuracy of 78% (95% CI 76%-79%), recall of 85% (95% CI 77%-91%), precision of 14% (95% CI 12%-17%), negative predictive value of 99% (95% CI 99%-100%), and a statistically significant difference in survival (P<.001, hazard ratio for those predicted to survive, 95% CI 0.043-0.106). As can be expected in prospective validation, we observed a modest drop in AUROC although most of the performance characteristics were close to their original cross-validation estimates, that is, the negative predictive value was largely unchanged, while precision and

accuracy showed minor decreases with the recall showing modest improvements.

We chose a prospective/retrospective split in time since this is the most realistic way to assess the potential performance of a system if launched clinically, because it would be trained on data up until its go-live date and then run prospectively in a potentially evolving pandemic environment. Notably, the cutoff date for the 80/20 split creating the prospective test set was December 15, 2020, which is the day after the first COVID vaccine received the United States Food and Drug Administration approval, meaning that our prospective cohort represented a distinctly different clinical environment compared to the period in which the model was trained. The relatively minor loss of performance in prospective validation shows the robustness of the modeling herein, but the observed loss of performance also demonstrates the need for continued retraining/validation of such a model during a constantly evolving pandemic.

Limitations

The application and deployment of ML methods in clinical practice require concerted care and diligence. One may be inclined to interpret the high negative predictive value of our prediction algorithm as an indication that the best use of the algorithm in practice is as a screening mechanism to discharge patients who are not at risk in order to conserve resources for higher-risk individuals. However, such a conclusion illustrates a pitfall of using a correlative prediction algorithm to make causal conclusions. The algorithm is highly confident that under the current standards of care at Mayo Clinic, these individuals are not likely to succumb to their illness; this is quite distinct from asserting that it is safe to reduce the care for these patients. Arriving at this latter conclusion would likely require a randomized controlled trial, and given the much lower survival rate published in the New York City data set [11] where medical systems were overcapacity, it seems unlikely that reducing care from those who survived in our cohort would have been a safe measure. Because the Mayo Clinic health systems have not been overcapacity, our mortality predictions should be viewed as representing patient stratification when full clinical support is available.

Therefore, we conclude that the algorithm is better deployed as an alert system that flags only those patients it deems as high risk to provide the treating physician with an additional data point that aims to summarize the many covariates and the laboratory values routinely available. In this context, the algorithm has had abundant experience in the provider's system, effectively "seeing" all patients with COVID-19 that have attended Mayo Clinic and conveying these lessons to physicians who could not have gained such experience personally.

A web interface to this model may allow for widespread usage but given the complexity and error-prone nature of users providing the high dimensional time-series measurements with correct units, the system is better suited for integration within the EHR/LIS infrastructure. We are now exploring the details of deployment of such a GRU-D alert system, which involves discussions with physicians to assess numerous implementation details, for example, deciding whether the alerts would be passive EHR/chart-based flags or a direct page to the frontline clinical provider. Passive chart alerts are less intrusive to existing workflows (ie, a direct page interrupts a physician while tending to other patients) but also provide less-immediate feedback. Additionally, active alerts could also be sent to a triage group to consider if evaluation is needed (for example, from the registered respiratory therapist) rather than interrupting bedside clinicians. Furthermore, for either type of alert, there is the question of prescribing a bedside assessment or leaving it to provider discretion, which is again a matter of balancing disruption of the workflow with the likelihood of missing a critical event. There will not be a universally appropriate implementation for all hospital systems owing to staffing and procedural differences. However, since our algorithm predicts overall COVID-19 mortality and is not tailored to flag imminent events such as cardiopulmonary arrest, it may be appropriate to consider less intrusive chart alerts without prescribed bedside follow-ups.

We have also seen nuances in the challenges and opportunities presented by MNAR data. In the context of traditional statistical inference and imputation, MNAR data is a worst-case scenario so challenging that many practical applications effectively ignore the reality and proceed with algorithms designed for the missing completely at random or missing at random settings. A diligent statistician making this decision may perform a sensitivity analysis under a very limited set of assumed MNAR mechanisms to provide some assurances regarding the robustness of the chosen imputation or analytical strategy [18]. However, here we have demonstrated that classification problems can be quite distinct in this regard. Specifically, if the missing data mechanism is tightly coupled to the ultimate prediction task, it is entirely possible for MNAR data to be an asset rather than an impediment. One can construct a context where the class label is so tightly linked to the missing data mechanism that the patterns of missingness provide more discriminative power than the underlying values themselves (see Multimedia Appendix 2) [19]. In LIS systems, the number of potential laboratory tests that could be ordered at any time is astronomical, and it is unlikely that a practicing physician will ever order a "complete observation" of every test available on a single patient at every point in time. Instead, tests are ordered based on reasonable clinical suspicion that a test might return an abnormal result. From a prognostication point of view, this clinical suspicion is an enormously valuable piece of information that will almost never be captured in a structured data field in the EHR. If an algorithm cannot build off of this clinical suspicion as a starting point, it is also likely that its conclusions may appear to be a "step behind" the ordering clinician. Instead, an algorithm should learn what it can from the MNAR data patterns (here partly encoding clinical suspicion) in addition to the final value returned by the laboratory test.

We also note some of the real-world challenges that are faced when attempting to deploy such an alert system into clinical practice. First, in the retrospective experimental design followed here and by other papers in the literature, the time series data are constructed using the time of sample collection since this is the most biologically accurate way to represent the data and build predictive models. However, in practice, if there can be

delays in the turnaround for certain tests, this will either result in delayed predictions (so that the deployed testing data match its retrospective training counterpart) or result in biased predictions when delayed laboratory test results are treated as missing. Therefore, although 72 hours is early in the course of illness, it is crucial that we have demonstrated reasonable performance even when only considering data collected on the same day as the first positive PCR result, because a real-world delay of 48 hours on certain laboratory test values may occur during a global pandemic, and thus, it is critical that the system can still provide accurate and timely predictions even when laboratory test results are delayed. Additionally, with vaccines now being delivered, the models presented herein should be considered as mortality predictions for an unvaccinated individual, and in practice, a vaccinated individual will be expected to be at low risk for mortality based on the clinical trials data.

Another challenge in dealing with LIS data comes from nonstandardization of test coding prior to reporting to the EHR. In a multisite system, the same laboratory test may have multiple test codes to account for the different ordering facilities or variability in local billing regulations. This creates the potential for discrepancies in the values stored within the underlying database such as differing units of measure. Substantial effort is therefore devoted to linking the LIS results to the EHR to ensure consistency across test codes and complete coverage of results in the EHR. The COVID-19 pandemic has created added complexity due to the rapidly evolving and continuously updating availability of COVID-19 nucleic acid and antibody tests. Therefore, effective data collection and deployment of ML methodologies necessitates extensive team-based laboratory and medical expertise to ensure that data aggregation and modeling efforts can be rapidly modified to suit the changing nature of the underlying data set. Scalability also presents practical challenges. This is illustrated by a scenario in which internal workflows began to fail due to limitations in the number of query results being returned by Tableau, necessitating that SQL queries take place on a high-performance computing cluster using a Python/Pandas toolchain. Although these logistical challenges may be of limited academic interest, they are important to document, as such barriers have been a greater impediment to rapid real world deployment than more traditional topics in the ML literature such as the identification of appropriate classification algorithms.

Comparison With Prior Work

For context, in Table 4, we summarize some of the largest published COVID-19 mortality studies and specifically, the cohorts analyzed and the most relevant features identified. When smaller cohorts see insufficient numbers of deaths for direct mortality prediction, studies tend to focus on the prediction of severe outcomes. For instance, in a cohort of 123 patients with COVID-19 in Vulcan Hill Hospital, China, in the study of Pan et al [20], the mortality classifier based on XGBoost yielded an AUC of 0.86-0.92. Likewise, in a cohort of 372 Chinese cases (99.7% cohort survival rate), Gong et al [9] found that the following variables provided an AUROC of 0.85. Similarly, in a study of 375 patients with COVID-19 conducted by Ko et al [21], the mortality prediction model based on XGBoost had 92% accuracy. In a study of 398 COVID-19–positive patients by Abdulaal et al [22], 86% accuracy was achieved (95% CI 75%-93%). In a large study of 2160 cases over 54 days from 3 hospitals in Wuhan, China with sufficient cases to assess mortality (88% cohort survival rate), Gao et al [8] reported 0.92-0.98 as the AUROC using an ensemble classifier. Furthermore, Vaid et al [11] used 4098 inpatient cases over 68 days in New York City (83% cohort survival rate) to achieve an AUROC of 0.84-0.88 in mortality prediction. Kim et al [23] studied 4787 patients and their XGBoost-based classifier demonstrated an AUC of 0.88-0.89 (95% CI 0.85-0.91) in predicting the need for intensive care, which is distinct from mortality prediction. Bolourani et al [24] studied 11,525 patients to achieve an AUROC of 0.77 in predicting respiratory failure within 48 hours of admission, which is also distinct from mortality prediction, based on data from the emergency department by using an XGBoost model.

The dramatically different cohort mortality rates and the associated predictive accuracies may be in part due to the differing straining of the local health care systems at the time of study (both Wuhan and New York City experienced waves of patients that at different times overwhelmed the health care infrastructure), and the relatively geographically narrow nature of each of these data sets underscores why it is unlikely that these mortality predictions would extend directly to our patient population in a health care system spanning 3 time zones and multiple locales unrepresented in the literature.

Table 4. Summary of the related studies.

Study	Patients (n)	Model/algorithm	Cohort survival	Prediction	Area under the receiver operating characteristic curve	Feature importance
Pan et al [20]	123	XGBoost	52.8%	Mortality	0.86-0.92	Lymphocyte percentage, prothrombin time, lactate dehydrogenase, total bilirubin, eosinophil percentage, creatinine, neutrophil percentage, and albumin level
Gong et al [9]	372	Nomogram	99.7%	Severity	0.85 (95% CI 0.790-0.916)	Higher lactate dehydrogenase, C-reactive protein, red blood cell distribution width, direct bilirubin, blood urea nitrogen, and lower albumin
Ko et al [21]	375	XGBoost	98.1%	Mortality	—,[a] accuracy of 92%	Not assessed
Abdulaal et al [22]	398	Artificial neural network	—	Mortality	—, accuracy of 86% (95% CI 75%-93%)	Altered mentation, dyspnea, age, collapse, gender, and cough
Shi et al [10]	487	Custom risk score calculation	100%	Severity	—	Advanced age, presence of hypertension, and being male
Gao et al [8]	2160	Ensemble model based on logistic regression, gradient-boosted decision tree, neural network, and support vector machine	88%	Mortality	0.92-0.98	Consciousness, chronic kidney disease, lymphocyte counts, sex, sputum, blood urea nitrogen, respiratory rate, oxygen saturation, D-dimer, number of comorbidities, albumin, age, fever, and platelet count
Vaid et al [11]	4098	XGBoost	83%	Mortality	0.84-0.88	Age, anion gap, C-reactive protein, lactate dehydrogenase, oxygen saturation, blood urea nitrogen, ferritin, red cell distribution width, and diastolic blood pressure.
Kim et al [23]	4787	XGBoost	—	Need for intensive care	0.88-0.89	Activities of daily living, age, dyspnea, body temperature, sex, and underlying comorbidities
Bolourani et al [24]	11,525	XGBoost	—	Predicting respiratory failure	0.77	Invasive mode of oxygen delivery being a nonrebreather mask, emergency severity index values of 1 and 3, maximum respiratory rate, maximum, oxygen saturation, Black race, age on admission, eosinophil percentage, serum sodium level, and serum lactate level.
This study	11,807	GRU-D	95.4%	Mortality	0.938 cross-validation; 0.901 prospectively	Figure 2, top 5: age, Charlson comorbidity index, minimum oxygen saturation, fibrinogen level, and serum iron level

[a]Not available.

As indicated in Table 4, this study represents the largest cohort collected for mortality prediction in COVID-19, and the GRU-D algorithm shows state-of-the-art performance. Notably, many papers selected models based on XGBoost, which also showed strong cross-validation performance in our data. However, Table 2 demonstrates that XGBoost was not even in the top 5 algorithms that we assessed. Additionally, in agreement with Gao et al [8], we find that ensemble algorithms such as AutoGluon can provide stronger performance, although as noted previously, the GRU-D algorithm ended up ranked most highly in our cross-validation experiments.

Conclusions

We have aggregated and analyzed one of the largest multistate COVID-19 EHR databases for mortality prediction. Using this database, we have trained and prospectively validated a highly effective ML algorithm using the GRU-D neural network architecture to predict the mortality of patients with COVID-19 shortly after their first positive PCR test result.

Acknowledgments

We thank the Advanced Diagnostics Laboratory, Department of Laboratory Medicine and Pathology, and the Center for Individualized Medicine at Mayo Clinic for funding this research. We thank Dr Nicholas Chia for his insightful discussions and feedback on this manuscript. We are grateful to the thorough and constructive comments of the anonymous reviewers whose feedback greatly improved our paper.

Conflicts of Interest

JCO has equity in Doximity, Inc, and has received small grants from Nference, Inc, and personal fees from Bates College. None of these are related to the current paper.

Abstract

Background: COVID-19 has threatened the health of tens of millions of people all over the world. Massive research efforts have been made in response to the COVID-19 pandemic. Utilization of clinical data can accelerate these research efforts to combat the pandemic since important characteristics of the patients are often found by examining the clinical data. Publicly accessible clinical data on COVID-19, however, remain limited despite the immediate need.

Objective: To provide shareable clinical data to catalyze COVID-19 research, we present Columbia Open Health Data for COVID-19 Research (COHD-COVID), a publicly accessible database providing clinical concept prevalence, clinical concept co-occurrence, and clinical symptom prevalence for hospitalized patients with COVID-19. COHD-COVID also provides data on hospitalized patients with influenza and general hospitalized patients as comparator cohorts.

Methods: The data used in COHD-COVID were obtained from NewYork-Presbyterian/Columbia University Irving Medical Center's electronic health records database. Condition, drug, and procedure concepts were obtained from the visits of identified patients from the cohorts. Rare concepts were excluded, and the true concept counts were perturbed using Poisson randomization to protect patient privacy. Concept prevalence, concept prevalence ratio, concept co-occurrence, and symptom prevalence were calculated using the obtained concepts.

Results: Concept prevalence and concept prevalence ratio analyses showed the clinical characteristics of the COVID-19 cohorts, confirming the well-known characteristics of COVID-19 (eg, acute lower respiratory tract infection and cough). The concepts related to the well-known characteristics of COVID-19 recorded high prevalence and high prevalence ratio in the COVID-19 cohort compared to the hospitalized influenza cohort and general hospitalized cohort. Concept co-occurrence analyses showed potential associations between specific concepts. In case of acute lower respiratory tract infection in the COVID-19 cohort, a high co-occurrence ratio was obtained with COVID-19–related concepts and commonly used drugs (eg, disease due to coronavirus and acetaminophen). Symptom prevalence analysis indicated symptom-level characteristics of the cohorts and confirmed that well-known symptoms of COVID-19 (eg, fever, cough, and dyspnea) showed higher prevalence than the hospitalized influenza cohort and the general hospitalized cohort.

Conclusions: We present COHD-COVID, a publicly accessible database providing useful clinical data for hospitalized patients with COVID-19, hospitalized patients with influenza, and general hospitalized patients. We expect COHD-COVID to provide researchers and clinicians quantitative measures of COVID-19–related clinical features to better understand and combat the pandemic.

Introduction

COVID-19 has threatened the health of tens of millions of people all over the world. The global pandemic caused by COVID-19 has sparked massive research efforts in the fight against the novel disease, including characterizing the disease and clinical progression, identifying risk factors for hospitalization, and finding drugs that can be repurposed to lessen disease severity [1-3]. Utilization of clinical data from different institutions, hospitals, and nations can accelerate these research efforts since important characteristics of the patients are often found by examining the shared clinical data. Although many studies sharing epidemiological data [4,5], public health [6], and social measures [7] for COVID-19 research have been conducted, publicly accessible clinical data on COVID-19 remain limited despite the immediate need [8], mainly owing to the potential risk to patient privacy that can still exist even after deidentification of the data [9].

Recognizing the need for publicly accessible electronic health record (EHR)–derived data in a broad range of clinical and translational research, we previously developed Columbia Open Health Data (COHD). COHD provides open and easy access to prevalence and co-occurrence statistics on conditions, drugs, procedures, and demographics derived from structured EHR data from NewYork-Presbyterian/Columbia University Irving Medical Center (NYP/CUIMC) [10], which serves the large and diverse population of NYC and its surrounding areas. Since its deployment, COHD has accelerated biomedical research by providing 2 informative resources, prevalence and co-occurrence statistics, and their derived association metrics [10-12].

NYC was one of the first epicenters of COVID-19 in the United States with the first confirmed case on February 29, 2020 [13]. As one of the largest academic medical centers in NYC, NYP/CUIMC has admitted more than 4000 patients as of September 1, 2020. We aim to provide shareable clinical data to catalyze future COVID-19 research by presenting Columbia Open Health Data for COVID-19 Research (COHD-COVID), a publicly accessible database providing clinical concept prevalence, the clinical concept prevalence ratio between cohorts, clinical concept co-occurrence, and clinical symptom prevalence for a cohort of hospitalized patients with COVID-19 and comparator cohorts (a cohort of hospitalized patients with influenza and a general hospitalized patient cohort) derived from NYP/CUIMC's electronic health records. In addition to providing publicly accessible data files via the Figshare data repository, we also developed the COHD-COVID web application programming interface (API) for easy access and better usability.

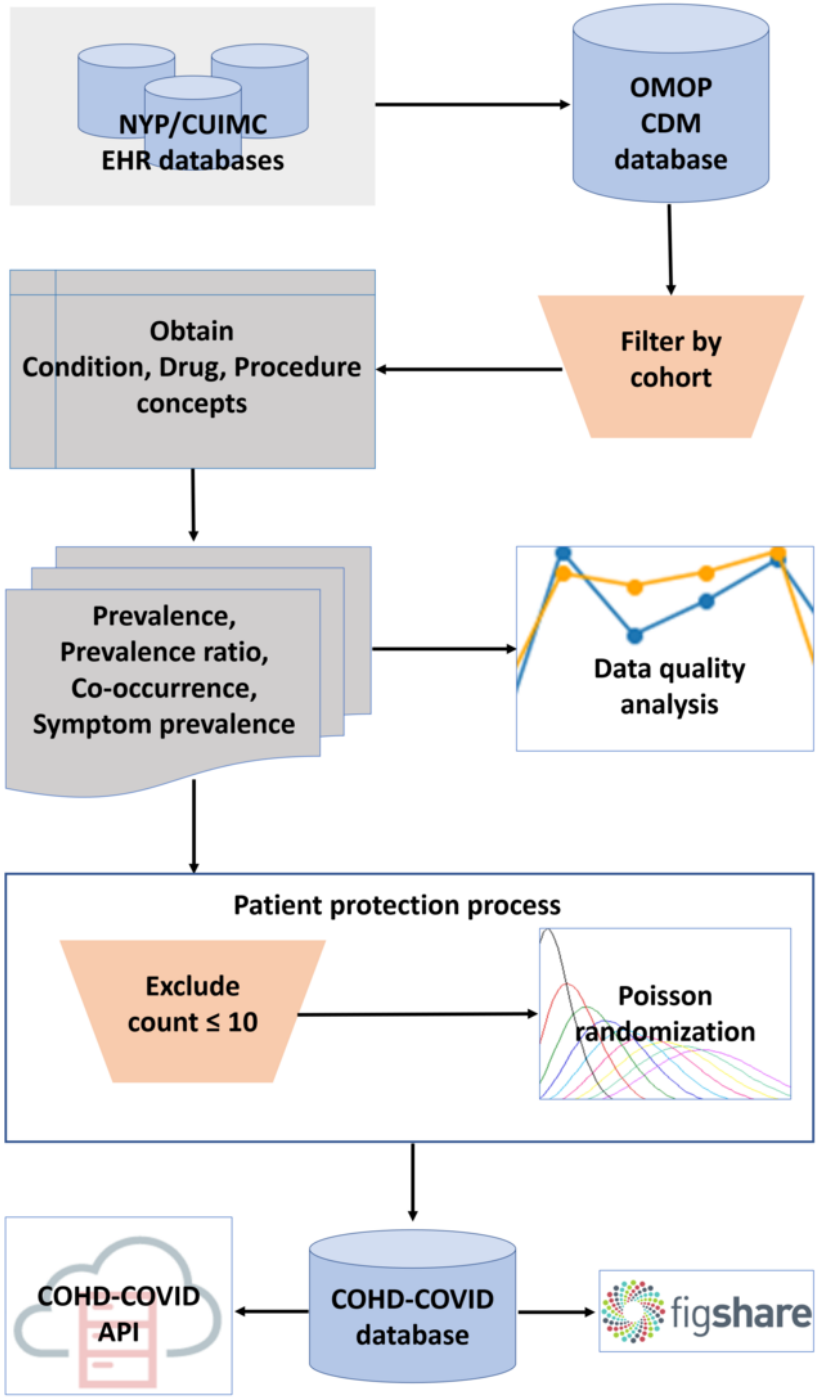
Methods

Methods Overview

We used the term "concept" to refer to clinical entities and events such as conditions (ie, diagnosis), drugs, and procedures. The concepts and their names are defined by the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM). When concepts are referenced in this paper, the name of the concept is styled in italics (eg, *Disorder of respiratory system*) to distinguish the formalized concepts from regular text. We also styled entities in the OMOP CDM (eg, *person_id* column in *condition_occurrence* table) in italics.

Figure 1 depicts the overall workflow to create COHD-COVID. Columbia's clinical data warehouse was converted to the OMOP CDM. We first filtered the EHR data in accordance with the cohort definitions, and then EHR for each patient's inpatient visits were identified. Condition, drug, and procedure concepts were obtained from the identified visits. Concept prevalence, concept prevalence ratio, concept co-occurrence, and symptom prevalence analyses followed using the obtained concepts. To protect patient privacy, we excluded rare concepts observed in 10 or fewer visits and perturbed the true counts using Poisson randomization. Perturbation of the true counts and exclusion of rare concepts reduce the uniqueness of individual in the data, which can minimize the risk of reidentification [9]. Perturbed counts generated by the Poisson randomization process do not show a significant difference from the true counts [10]. The resulting data were stored in a MySQL database and made publicly available via the COHD-COVID web API [14]. All analyses were conducted using Python 3.5.2. This study received institutional review board approval with a waiver for informed consent.

Figure 1. Overall workflow of Columbia Open Health Data for COVID-19 Research (COHD-COVID). API: application programming interface; NYP/CUIMC: NewYork-Presbyterian/Columbia University Irving Medical Center; OMOP CDM: Observational Medical Outcomes Partnership Common Data Model.



Data Source

We utilized EHR data from the NYP/CUIMC's clinical data warehouse, where inpatient and outpatient data dating back to 1985 are stored. EHR data were collected during routine clinical care. Patients were notified of potential uses of their data for research at the point of care and data collection. NYP/CUIMC has converted its clinical data warehouse to OMOP CDM on a regular basis. Since NYP/CUIMC covers NYC and the surrounding area, which has a diverse population of 8.2 million people and was an early COVID-19 epicenter, the EHR data from NYP/CUIMC can provide a diverse and large sample of patients with COVID-19.

Three different patient cohorts were used in this study. The COVID-19 cohort was defined as hospitalized patients aged

≥18 years with a COVID-19–related condition diagnosis or a confirmed positive COVID-19 test result during their hospitalization period or within the prior 21 days. Patients identified with the COVID-19 cohort definition from March 1, 2020, to September 1, 2020, were included in the COVID-19 cohort. The influenza cohort was similarly defined as patients aged ≥18 years who had at least 1 occurrence of influenza conditions or precoordinated positive measurements or positive influenza test results during their hospitalization period or within the prior 21 days. The general cohort was defined as all hospitalized patients aged ≥18 years. Patient visits from calendar years 2014 to 2019 were included for the influenza and general cohorts. All cohorts were divided into subcohorts stratified by sex (male vs female) and age (adults aged 18-64 years vs seniors aged >65 years) for further investigation. The COVID-19 and influenza cohort definitions were adapted from the cohort definitions created by the Observational Health Data Science and Informatics' (OHDSI's) international network study for COVID-19 [3]. Summary statistics of the cohorts are provided in Table 1.

Patients belonging to the cohorts based on the 3 cohort definitions above were identified using the unique *person_id* from the *person* table in the OMOP CDM. Condition, drug, and procedure concepts observed in these patients during inpatient visits were extracted from the *condition_occurrence*, *drug_exposure*, and *procedure_occurrence* tables in the OMOP CDM, respectively. Inpatient visits of patients and the concepts in these visits were identified using *person_id* along with *visit_occurrence_id* from the *visit_occurrence* table. We used visit-based counts instead of patient-based counts in the following analyses for robust comparison between cohorts that had different observation windows. For example, if we use patient-based counts, the patients included in cohorts with longer observation windows are likely to be observed with more concepts than the patients in cohorts with shorter observation windows, which could inject bias into the metrics used in the analyses. Thus, we used visit-based counts to mitigate the effect of different observation window lengths to reduce the bias.

Table 1. Basic statistics of 3 cohorts in the Columbia Open Health Data for COVID-19 Research database. The statistics summarized here are based on the data from NewYork-Presbyterian/Columbia University Irving Medical Center as of September 1, 2020.

	COVID-19 cohort	Influenza cohort	General cohort
Time range	March 1, 2020, to August 31, 2020	January 1, 2014, to December 12, 2019	January 1, 2014, to December 12, 2019
Patients, n	4127	3261	175,930
Total inpatient visits, n	4846	3860	314,680
Male patients; inpatient visits, n (%)	2103 (51.0); 2518 (52.0)	1454 (44.6); 1732 (44.9)	67,662 (38.5); 128,908 (41.0)
Female patients; inpatient visits, n (%)	2024 (49.0); 2328 (48.0)	1807 (55.4); 2128 (55.1)	108,268 (61.5); 185,772 (59.0)
Adult patients (aged 18-64 years); inpatient visits, n (%)	2147 (52.0); 2511 (51.8)	1315 (40.3); 1553 (40.2)	104,020 (59.1); 173,843 (55.2)
Senior patients (>65 years); inpatient visits, n (%)	1980 (48.0); 2335 (48.2)	1946 (59.7); 2307 (59.8)	71,910 (40.9); 140,837 (44.8)

Concept Prevalence and Concept Prevalence Ratio Analysis

We calculated the concept prevalence in each cohort as detected from the EHR. The concept prevalence is defined as in equation **(1)**.

where  is the prevalence of concept *C* in cohort *H*,  is the set of unique inpatient visits of patients in cohort *H* observed with concept *C*, and T_H is the set of unique inpatient visits of patients in cohort *H*. We also calculated hierarchical concept prevalence by defining  as the set of unique visits of patients observed with concept *C* or any of concept *C*'s descendant concepts as defined in the *concept_ancestor* table in the OMOP CDM. For example, the hierarchical count for *Ibuprofen* (OMOP concept ID 1177480) not only includes entries where the specific concept *Ibuprofen* was used, but also includes entries using other descendant concepts, such as *Ibuprofen 600 MG Oral Tablet* (OMOP concept ID 19019073). Taking hierarchical relationships into account mitigates some of the issues with coding variations across time and practices as different concepts with minor semantic differences can be aggregated into higher-level concepts.

The concept prevalence ratio indicates how frequently concept *C* occurs in cohort *A* relative to cohort *B*. The natural logarithm of the concept prevalence ratio is defined as in equation **(2)**.

where $LR(C_{A,B})$ is the log ratio of the prevalence of concept *C* for cohort *A* to cohort *B*,  is prevalence of concept *C* in cohort *A*, and  is prevalence of concept *C* in cohort *B*. Hierarchical concept prevalence ratio can be calculated by using hierarchical concept prevalence  and  .

Concept Co-occurrence Analysis

Concept co-occurrence represents how frequently a specific concept pair appears in a cohort. We defined concept co-occurrence prevalence as in equation **(3)**.

where  is the co-occurrence prevalence of concepts C_1 and C_2 in cohort H,  is the set of unique visits of patients observed with concept C_1 and C_2 in cohort H, and T_H is the set of unique visits of patients in the cohort H. We also calculated hierarchical concept co-occurrence using the hierarchy of concepts as described above.

COVID-19 Symptom Prevalence Analysis

Since clinical symptoms often include multiple granular clinical concepts, a set of related concepts for a symptom is required to calculate the prevalence of the symptom. For example, dyspnea, which is one of the major symptoms of COVID-19, can be detected as standard concept *Dyspnea* or *Acute respiratory distress* in different patients. The 2 concepts do not have any hierarchical relationship and thus will not be aggregated by the hierarchical prevalence analyses. Thus, a concept set containing both *Dyspnea* and *Acute respiratory distress* is needed for accurate calculation of the prevalence of dyspnea. We defined symptom prevalence as in equation **(4)**.

where  is prevalence of symptom S in cohort H,  is the set of unique visits of patients observed with concept C_i, T_H is the set of unique visits of patients observed in the cohort H, s is the number of the unique concepts in the concept set for symptom S, and $\cup$ is the union operator. Hierarchy between concepts is not considered in the symptom prevalence analysis since a concept set of a symptom already reflects hierarchy for that symptom.

We used concept sets for 11 major symptoms of COVID-19 (*Cough*, *Chills*, *Abdominal pain*, *Diarrhea*, *Dyspnea*, *Fatigue*, *Fever*, *Myalgia*, *Nausea and vomiting*, *Tachypnea*, and *Throat pain*), which have been defined by OHDSI to calculate symptom prevalence. The concepts included in each symptom are available in Figshare [15].

Data Quality Analysis

Assessing the quality of EHR data is critical for its effects on secondary analysis for research in the health care and medical domains [16]. We calculated the sum of nonrandomized counts of all concepts on a monthly basis for the COVID-19 cohort and on a yearly basis for the general and influenza cohorts. For each of the condition, drug, and procedure domains, we examined the total counts of concepts with the number of visits to detect any issues regarding data quality and temporal plausibility of the EHR data we used in the study [17]. We also calculated the annual mean (SD) values of concept prevalence and concept co-occurrence for the general and influenza cohorts to assess the temporal variance of each concept and concept co-occurrence pair.

Results

Results Overview

In this section, we show a sample of the results of analyses using the data from COHD-COVID. Since COHD-COVID contains massive amounts of data covering several thousand concepts, it is worth noting that only a small sample of the results is shown in this section. Users can obtain the results of interest in addition to the results shown in this section by using the COHD-COVID API [14] or by downloading the flat data files from Figshare [15]. The results of all analyses, concept definitions, and concepts included in each symptom are available as tab-delimited flat files in Figshare, except the concept prevalence ratio analyses, since they can be directly computed from concept prevalence data. COHD-COVID API [14] provides all results.

Concept Prevalence Analysis

Figure 2 shows the prevalence of 10 condition (Figure 2A) and drug concepts (Figure 2B) in the COVID-19 cohort, influenza cohort, and general cohort. We chose the 10 most prevalent condition and drug concepts in the COVID-19 cohort for this use case. For drug concepts, we chose the most prevalent drug ingredient concepts using hierarchical analysis to count multiple drugs that have different brand names, dosages, and formulations but are based on the same ingredients together. The condition concepts were chosen without hierarchical analysis to identify the top 10 specific conditions. *Fever* showed the highest prevalence (0.2619) among all condition concepts for the COVID-19 cohort, followed by *Cough* (0.2491) and *Dyspnea* (0.2594). *Acetaminophen* was the most prevalent (0.7912) drug ingredient used for patients with COVID-19, followed by *Enoxaparin* (0.5803) and *Glucose* (0.4424). Figures 3 and 4 show the prevalence of 10 condition and drug concepts, respectively, in the COVID-19 cohort stratified by age (Figures 3A and 4A) and gender (Figure 4A and 4B). The 10 condition and drug concepts were the top 10 most prevalent concepts in the full COVID-19 cohort without stratification.

Figure 2. (A) Condition and (B) drug concept prevalence in the COVID-19 cohort, influenza cohort, and general cohort.

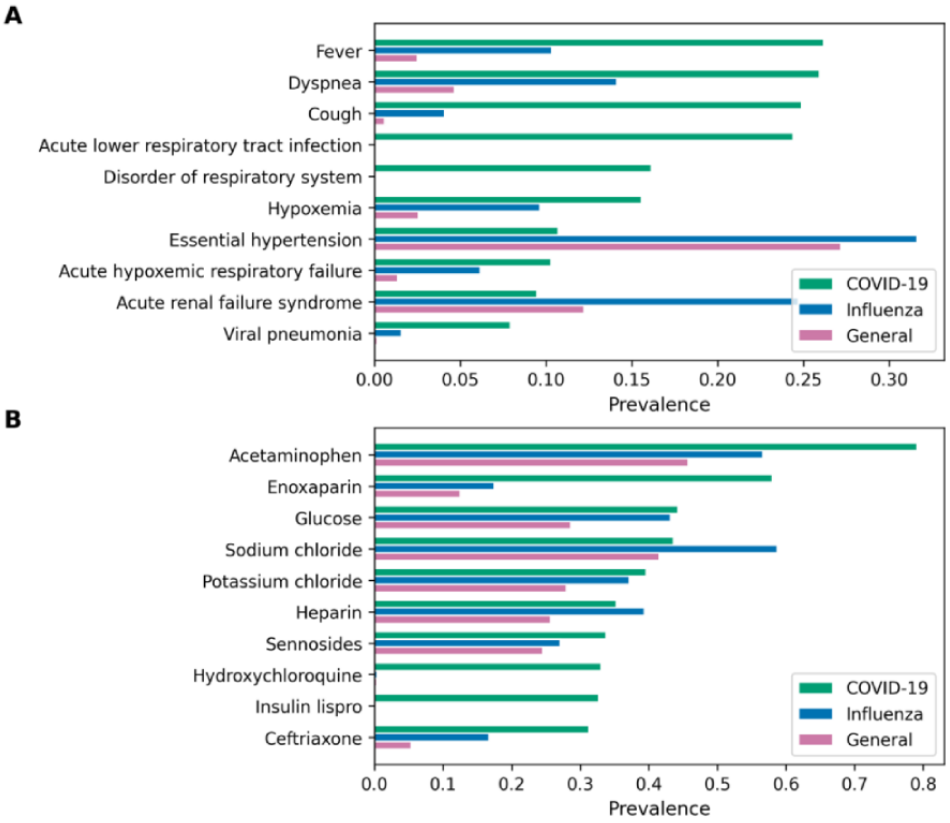


Figure 3. Condition concept prevalence in (A) age and (B) sex sub-cohorts of the COVID-19 cohort. The full COVID-19 cohort indicates original COVID-19 cohort without stratification.

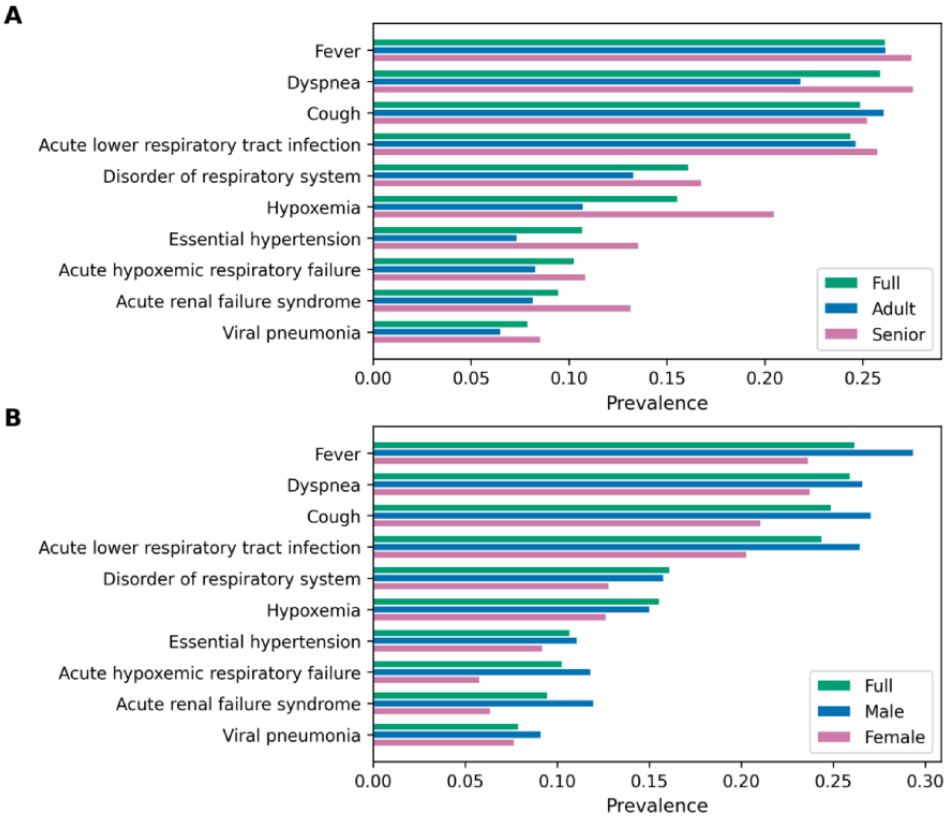

Figure 4. Drug concept prevalence in (A) age and (B) sex subcohorts of the COVID-19 cohort. The full COVID-19 cohort indicates original COVID-19 cohort without stratification.

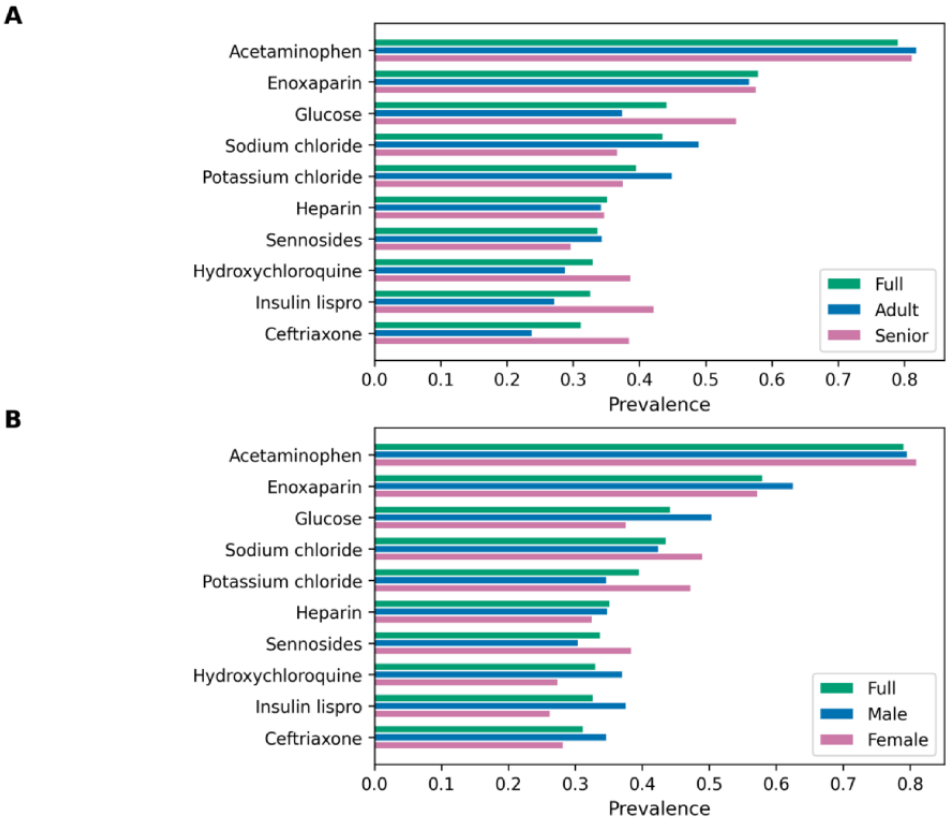


Concept Prevalence Ratio Analysis

Table 2 shows the top 10 condition concepts that showed the highest concept prevalence ratio for the COVID-19 cohort relative to the comparator cohorts (general cohort and influenza cohort). *Disease due to Coronavirus* and *Acute lower respiratory tract infection* showed the highest concept prevalence ratio for the COVID-19 cohort relative to the influenza cohort and the general cohort, respectively.

Table 2. Top 10 condition concepts that show the highest concept prevalence ratio for the COVID-19 cohort relative to the general and influenza cohorts.

Influenza cohort (prevalence ratio)	General cohort (prevalence ratio)
Disease due to Coronavirus (3.28)	Acute lower respiratory tract infection (7.30)
Disorientated (2.44)	Disorder of respiratory system (5.56)
Blood chemistry abnormal (2.25)	General finding of observation of patient (5.17)
Acute respiratory distress syndrome (2.16)	Outcome of delivery – finding (5.13)
Cerebral infarction (1.84)	Chest pain on breathing (5.09)
Cough (1.81)	Disease due to Coronavirus (4.95)
Viral pneumonia (1.61)	Patient status finding (4.60)
Acute respiratory distress (1.52)	Unplanned pregnancy (4.23)
Heart disease (1.32)	Acute respiratory distress syndrome (4.17)
Delivery normal (1.28)	Deliveries by cesarean (3.98)

Concept Co-occurrence Analysis

Table 3 shows the top 10 most frequently co-occurring concepts with *Acute lower respiratory tract infection* in the COVID-19 cohort. *Acute lower respiratory tract infection* was chosen among the 10 most prevalent condition concepts in the COVID-19 cohort. We used nonhierarchical concept co-occurrence to obtain the result.

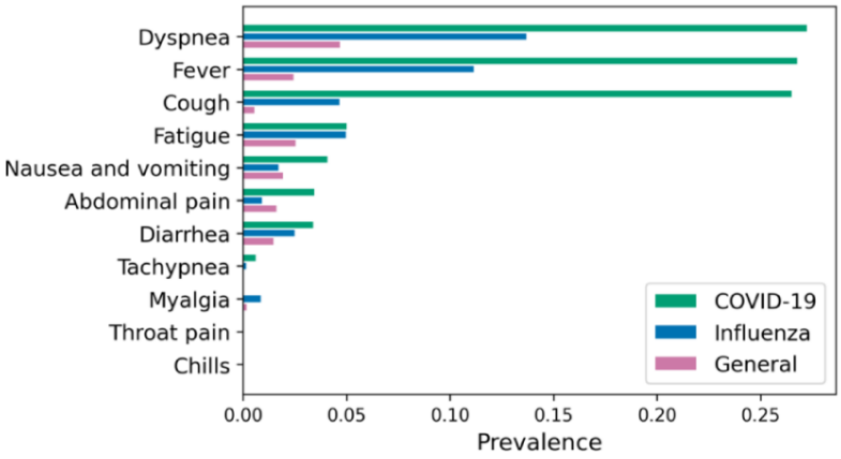
Table 3. The 10 concepts that most frequently co-occurred with Acute lower respiratory tract infection in the full COVID-19 cohort.

Concept name	Co-occurrence prevalence
Disease due to Coronavirus	0.2329
Radiologic examination, chest; single view	0.2214
Infectious agent detection by nucleic acid (DNA or RNA); severe acute respiratory syndrome coronavirus 2	0.2205
Acetaminophen 325 MG Oral Tablet	0.2037
0.4 ML Enoxaparin sodium 100 MG/ML Prefilled Syringe	0.1504
Hydroxychloroquine Sulfate 200 MG Oral Tablet	0.1246
50 ML Glucose 500 MG/ML Prefilled Syringe	0.1085
Ceftriaxone 1000 MG Injection	0.1073
Blood typing, serologic; ABO	0.1044
Glucose 0.4 MG/MG Oral Gel	0.0970

COVID-19 Symptom Prevalence Analysis

Figure 5 shows the prevalence of the 11 major COVID-19 symptoms for all 3 cohorts. In the COVID-19 cohort, *Dyspnea* showed the highest prevalence among the 11 symptoms followed by *Fever* and *Cough*.

Figure 5. Symptom prevalence of 11 major symptoms in patients with COVID-19 for all 3 cohorts.



Data Quality Analysis

Figure 6 shows the total counts across all concepts in the condition domain (Figure 6A), drug domain (Figure 6B), procedure domain (Figure 6C), and the total visits per month between March 2020 and August 2020 (Figure 6D) for the COVID-19 cohort. The total counts of conditions, drugs, procedures, and total visits all show steep increases in March and April 2020, when the number of COVID-19 cases surged in NYC (Figure 6E) [18]. The total counts of all domains and the total visits decreased starting May 2020 as the number of patients with COVID-19 in NYC decreased.

Figure 7 shows the total counts per year across all concepts in the condition domain (Figure 7A), drug domain (Figure 7B), procedure domain (Figure 7C), and the total visits per year between 2014 and 2019 (Figure 7D) for the general cohort and influenza cohort. The total counts of conditions, drugs, procedures, and total visits per year for the 2 cohorts show consistent trends.

The annual mean (SD) value of concept prevalence and concept co-occurrence for the general and influenza cohorts are available in Figshare [15] to assess the temporal variance of each concept and concept co-occurrence pair. The mean and standard deviation of annual concept prevalence and co-occurrence should only be compared to each other to assess the stability of the concept over the given time period of the data set.

A change in the EHR system can affect the quality and characteristics of EHR data collected for secondary research. NYP/CUIMC changed its EHR system as of February 1, 2020, from Allscripts to Epic, which might affect the COVID-19 cohort data and its characteristics as opposed to the influenza and general cohorts, which were collected prior to the EHR change. To detect the impact of the change, we performed a *t* test for all concepts reported in the COVID-19 cohort between the counts from a pre-Epic period (January 1, 2020, to January 31, 2020) and from a post-Epic period (February 1, 2020, to February 29, 2020). The post-Epic period was chosen to minimize the inclusion of dates when COVID-19 would have impacted clinical practices in NYC. The counts of concepts were recorded on a daily basis. We considered that there would be no difference between the 2 periods if the counts for the concept from the 2 periods are the same (ie, all 0 counts for the

2 periods). Of all 1066 unique concepts reported in the COVID-19 cohort, 119 (11.2%) concepts showed a significant difference ($P \leq .01$) between the pre- and post-Epic periods. The *P* values of the *t* tests for all individual concepts are available in Figshare [15] to allow users to factor in these data quality considerations for each concept.

Figure 6. Total counts across all concepts in the (A) condition domain, (B) drug domain, (C) procedure domain, and (D) the total visits per month between March 2020 and August 2020 for the COVID-19 cohort. (E) Total COVID-19–positive cases per day in New York City from March 2020 to August 2020.

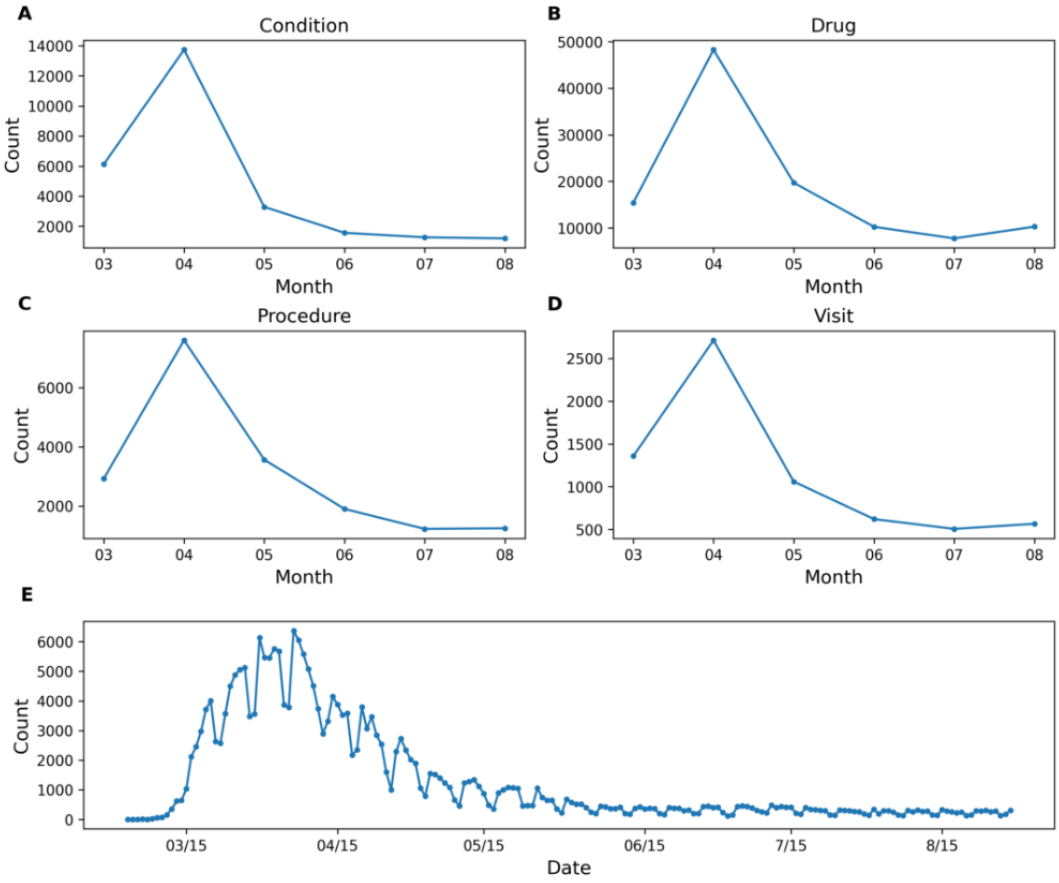


Figure 7. Total counts across all concepts in the (A) condition domain, (B) drug domain, (C) procedure domain, and (D) the total visits per year between 2014 and 2019 for the general and influenza cohort.

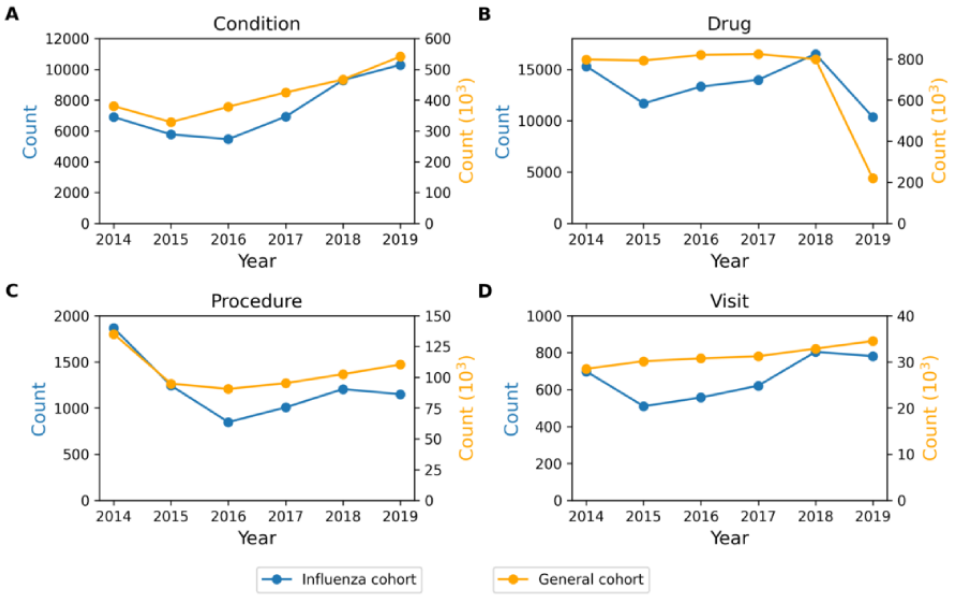

Discussion

Principal Findings

In this study, we present a publicly accessible database providing clinical concept prevalence, clinical concept co-occurrence, and clinical symptom prevalence for hospitalized patients with COVID-19, hospitalized patients with influenza, and general hospitalized patients. We showed the utility of the data for future data-driven studies by exploring the results of the concept prevalence analysis, concept prevalence ratio analysis, concept co-occurrence analysis, and symptom prevalence analysis. Results from the analyses aligned with published findings and can be used to find novel hypotheses as described in the following discussion. The results of all analyses were provided as flat files in Figshare [15] and also easily accessible through web API [14].

Concept prevalence analysis on the 3 cohorts can be used to determine the clinical characteristics of the COVID-19 cohort. A comparison of the prevalence of these concepts between the COVID-19 cohort and the influenza or general cohorts provides contextual evidence regarding whether the concept is associated with COVID-19 or if it is common among hospitalized patients. Figure 2A shows that *Fever*, *Cough*, *Dyspnea*, and *Acute lower respiratory syndrome* were more highly prevalent in the COVID-19 cohort than in the 2 comparator cohorts. The concepts highly prevalent in the COVID-19 cohort were well-known symptoms of COVID-19, concurrent with existing studies. As shown in Figure 2B, *Hydroxychloriquine*, which was one of the drugs widely administered to patients with COVID-19 [19] during the early months of the pandemic, showed high prevalence in the COVID-19 cohort.

Concept prevalence analysis on the COVID-19 cohort and its subcohorts can be used to determine the clinical characteristics of the subcohorts and determine if these characters differ between the sexes or between adult and older patients. Figure 3A shows that the senior cohort had higher prevalences in all 10 condition concepts than the full and adult cohorts and also shows that *Essential hypertension* and *Hypoxemia* were particularly more prevalent in senior patients with COVID-19, which indicates that senior patients are more likely to have these apparent symptoms of COVID-19 than adult patients. Figure 4A shows that drug ingredients related to type 2 diabetes (eg, *Glucose* and *Insulin Lispro*) showed higher prevalence in senior patients than in adult patients, which indicates that type 2 diabetes is a more common comorbidity among senior patients with COVID-19.

Concept prevalence ratio analysis can be used to unveil how often specific concepts appeared in the COVID-19 cohort compared to the comparator cohorts. Table 2 shows that common and general symptoms of COVID-19 (eg, *Chest pain on breathing*, *Cough*, and *Disease due to coronavirus*) showed a high prevalence ratio in the COVID-19 cohort relative to the general cohort. In contrast, more severe symptoms of COVID-19 (eg, *Disoriented*, *Acute respiratory distress syndrome*, *Viral pneumonia*, and *Blood chemistry abnormal*) showed a higher prevalence ratio in the COVID-19 cohort than in the influenza cohort. Since both cohorts include hospitalized patients, these results may indicate that the aforementioned conditions are more strongly associated with the SARS-CoV-2 infection than with influenza. We also observed high prevalence ratios in concepts related to delivery in the COVID-19 cohort relative to the general cohort. Regrading *Outcome of delivery – finding*; for example, we observed a visit prevalence rate of 1.18% in the COVID-19 cohort, but only 0.0070% in the general cohort, yielding a prevalence ratio of 5.13. During normal times, deliveries only account for a small fraction of all inpatient visits. However, during the pandemic, there was a dramatic decrease in elective surgeries and hospitalizations besides those related to COVID-19 since hospital capacity was diverted their focus toward patients with COVID-19. In contrast, patients going into labor cannot be rescheduled and were regularly tested for SARS-CoV-2, which increased their representation within the COVID-19 cohort.

Potential associations between specific concepts of interest can be found through co-occurrence analysis. For instance, Table 3 confirms that the concepts associated with SARS-CoV-2 tests (ie, *Disease due to Coronavirus*, *Radiologic examination, chest; single view*, and *Infectious agent detection by nucleic acid [DNA or RNA]; severe acute respiratory syndrome coronavirus 2*) showed high co-occurrence prevalence with *Acute lower respiratory tract infection*, which shows natural strong associations between testing concepts for COVID-19 and one of the most prevalent concepts in the COVID-19 cohort.

Symptom prevalence analysis can be used to examine symptom-level characteristics of the cohorts. The COVID-19 cohort showed higher prevalence in dyspnea, fever, and cough symptoms than the other 2 comparator cohorts, which is concurrent with the known characteristics and symptoms of COVID-19 [20]. In contrast, a few of the known COVID-19 symptoms (eg, myalgia, throat pain, and chills) did now show high prevalence in the COVID-19 cohort, which might indicate that those symptoms are not clinically distinctively prevalent in patients with COVID-19.

Most of the results from the analyses align with those of existing studies, thus empirically validating the utility of COHD-COVID. COHD-COVID also can be used to find novel hypotheses related COVID-19. COHD-COVID can be used as cross-institutional data to validate or support other COVID-19 studies. For instance, the high prevalence ratio of *Cerebral infarction* in the COVID-19 cohort compared to that in the influenza cohort (Table 2) corroborates with reports from a few studies that SARS-CoV-2 might be more likely to cause thrombotic vascular events, including stroke, than other coronavirus and seasonal infectious diseases [21,22].

While we admit that the aggregated concept-level analyses may not be suitable to answer some clinical research questions, COHD-COVID will be useful for hypothesis generation and for validating emerging newly published findings on COVID-19 using real-world data. COHD, the precedent study of COHD-COVID, has been integrated into the National Center for Advancing Translational Sciences Biomedical Data Translator program, where the EHR-based data associations from COHD are linked to other sources of knowledge via knowledge graphs, allowing automated algorithms to perform

reasoning on these knowledge graphs to answer biomedical questions and suggest novel hypotheses [23,24].

Limitations

There are several limitations to this study, which should be noted. One of the limitations is that analyses performed in this study can be affected by the factors included in the data acquisition process (eg, change in the EHR system, human biases, and errors during entry). For example, coding trends and patterns (ie, the trend and pattern of frequently used concepts) can be changed through a shift in system. Another limitation is that multiple visits from the same patient can be used to calculate the metrics in the analyses since we used visit-based counts instead of patient-based counts for the analyses. This could affect the results of the specific concepts appearing in patients who are hospitalized more frequently. We also admit that some of results from the analyses cannot be validated by existing or up-to-date findings, considering rapidly growing and changing knowledge related to COVID-19. Thus, it is desirable to conduct a literature search before utilizing the data and results. We will update the data and results on a regular basis to further alleviate this limitation.

The EHR data used in this study were obtained from a single site: NYP/CUIMC. Even though NYP/CUIMC is a large academic medical center whose services cover the city and its surrounding areas, we admit that performing the analyses on the basis of the EHR data across multiple institutions and nations will be beneficial since multiple sites can diversify the population, improve accuracy, increase power and sensitivity to rare conditions, validate results by comparing across sites, and reduce variance that might exist in specific locations. Since the OMOP CDM provides the fundamentals to perform the same analyses on clinical data across different sites, we hope to collaborate with future studies sharing clinical characteristics of patients with COVID-19 and to generate a larger, richer, and more robust database that can be leveraged in translational research on COVID-19.

Conclusions

In this study, we present COHD-COVID, a publicly accessible database providing useful clinical data for hospitalized patients with COVID-19, hospitalized patients with influenza, and general hospitalized patients. The analyses using the data from COHD-COVID confirmed the well-known clinical characteristics of patients with COVID-19 and can also be used to find novel hypotheses related to COVID-19. We expect COHD-COVID will provide researchers and clinicians quantitative measures of COVID-19–related clinical features to better understand and combat the pandemic.
