Adults (aged ≥ 18 years) who resided in Sweden with Swedish verbal and written comprehension and ownership of a smartphone were eligible to be included in the study. Additional inclusion criteria were exposure to a potentially traumatic event in the past 2 years, according to the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) criteria, and mild to severe posttraumatic stress symptoms (PTSD Checklist for DSM-5 total score ≥ 10). Exclusion criteria included potentially life-threatening or harmful living conditions or symptoms (eg, recurring or ongoing traumatic event exposure, severe suicidal plans or ideation, current alcohol or drug abuse, lifetime manic or hypomanic episodes, or psychotic episodes). Additional exclusion criteria were current or pending psychotherapy, medical treatment changes, and medication with

counterindications such as benzodiazepines. Minor adjustments were made after the trial commenced. Participants who screened positive for alcohol or substance abuse in early remission (<12 months) with the current treatment were accepted in the study.

The required sample size of 160 participants was determined by an a priori power analysis in G*Power (version 3.1; Heinrich-Heine-Universität Düsseldorf) [22] based on the effect size of Cohen $d=0.5$ in the pilot study [12] and anticipated attrition of up to 25%.

Procedures

Enrollment began in May 2019 and ended in June 2020. We collected data nationwide in Sweden from Uppsala University. Study data and email invitations were managed using REDCap (Research Electronic Data Capture; [23]) hosted at Uppsala University.

Potential participants were recruited through social media advertisements linked to a web-based screening questionnaire. Eligible participants provided an email, received the consent form, and provided written informed consent. We informed participants how their data were managed and that participation was voluntary and confidential. Consenting participants booked an appointment for a phone interview with a member of the research team to confirm eligibility and assess psychiatric symptoms.

Subsequently, participants completed a baseline questionnaire before randomization. Participants randomized to access to the app were emailed written instructions for downloading PTSD Coach and instructed to use the app as they pleased. Participants who requested further guidance were encouraged to explore the app to identify helpful content. Participants on the waitlist received written notice through email that they would gain access to the app after the first follow-up assessment.

We called all participants and offered the opportunity to ask questions regarding the study or technical support, 7 days after randomization. All participants responded to daily assessments for 21 days in a separate investigation [24] and received a follow-up questionnaire with the primary and secondary outcomes 3 months later. Participants with access to the app responded to additional questions regarding helpfulness, satisfaction, and negative reactions. Participants were compensated with gift cards to the cinema after completing the follow-up questionnaire. Participants who left the study or were excluded before the follow-up assessment received a gift card.

Materials

The Intervention

The mobile app PTSD Coach was developed by the Veterans' Affairs National Center for PTSD and the Department of Defense's DHA Connected Health [5,25]. The resources in PTSD Coach are divided into four sections: *learn* (psychoeducation about posttraumatic stress, treatment, and coping in families), *track* (symptom self-evaluation with rating history and automatic feedback), *manage symptoms* (exercises for distress management inspired by cognitive behavioral therapy), and *get support* (contact information for crisis resources, professional assessment and treatment, and platforms

and advice promoting social support). Self-guided exercises in the app are prompted by voice, video, or text.

The Swedish version [12] was translated and adapted from the American original to a Swedish civilian context [5,6,13]. A team of 6 clinical psychologists, researchers, and psychology students conducted the first translation for the pilot trial of the app [12], and the authors revised the adaptation based on a version update of the original and input from Swedish users. During this trial, the Swedish version of PTSD Coach was not publicly available on app stores; therefore, access to the app could be restricted to participants with access to the app. However, the American version of PTSD Coach was available on app stores.

Posttraumatic Stress

The primary outcome, posttraumatic stress, was assessed at screening, baseline, and follow-up with the Posttraumatic Stress Disorder Checklist for the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (PCL-5) [26] in Swedish [27]. The PCL-5 is a 20-item self-report measure that maps directly onto the DSM-5 PTSD symptoms. The items are rated on a 5-point scale ranging from 0 (*not at all*) to 4 (*extremely*) [26], yielding a total sum of 0 to 80. The Swedish version was developed using a standard back-translation process [28] and corresponds well to the gold standard assessment of PTSD symptoms [27]. A total sum of ≥ 31 to 33 points may indicate probable PTSD in both the original and Swedish versions [27,29]. A ≥ 10 -point difference in the total sum score on previous versions of the PTSD Checklist has been estimated to equate with clinically significant change [6,13,14,30], and the range for clinically significant change is presumably similar for PCL-5 [29].

Depressive Symptoms

The secondary outcome depressive symptoms was assessed at baseline and follow-up with the Swedish version [31] of the Patient Health Questionnaire (PHQ)-9 [32]. The questionnaire is a widely used 9-item self-report measure of the DSM-5 criteria for depression with an additional item assessing functional impairment. The suggested cut-offs for probable depression range from 9 to 12 points [32,33]. The Swedish version has demonstrated satisfactory psychometric properties [31].

Somatic Symptoms

The secondary outcome, somatic symptoms, was assessed at baseline and follow-up with the Swedish version [34] of the PHQ-15 [35]. The self-rating scale consists of 15 items that measure the most common somatic symptoms reported in primary health care. The Swedish version of the PHQ-15 has favorable psychometric properties for the quantification of somatization in Swedish and similar populations, with suggested cut-off scores for symptom severity at 0 to 4 indicating minimal, 5 to 9 indicating low, 10 to 14 indicating moderate, and ≥ 15 indicating high symptom severity [34].

Helpfulness, Satisfaction, and Negative Effects

Perceived helpfulness and overall satisfaction with PTSD Coach were measured with a Swedish version [12] of the PTSD Coach

survey [5] at follow-up. The survey includes 14 questions that assess the perceived helpfulness of the app and 1 item asking about user satisfaction. [Multimedia Appendix 1](#) provides all items. Negative reactions were measured using the Negative Effects Questionnaire [36]. The original version was developed in Sweden and is available in several languages to assess the negative effects of psychological interventions. In this study, references to therapists and treatment in the items were changed to the app. Respondents rated whether they had experienced 20 potential negative reactions during the period they had access to PTSD Coach, how negative reactions affected them, and the probable cause of the reaction (ie, “other circumstances” or “used the app”). [Multimedia Appendix 2](#) shows all items.

Demographic and Clinical Characteristics

During the phone interview, the interviewer explored exposure to potentially traumatic events with open-ended questions (eg, “Please briefly tell me about the kind of severe event that you experienced at that time” and “What happened? You don’t need to tell me everything; I just need to understand what kind of event it was”) and categorized answers into categories from the Life Events Checklist for DSM-5 [37] in Swedish [27]. We assessed psychiatric comorbidity during the baseline phone interview with the Mini International Neuropsychiatric Interview [38] (Swedish version 7.0.0). We asked questions regarding demographic information, previous smartphone use, and previous treatment in the baseline questionnaire. Furthermore, participants provided information regarding treatment changes, the use of PTSD Coach, or other self-management apps in the follow-up questionnaire.

Randomization

An external statistician generated the allocation sequence in R software (R Foundation for Statistical Computing; [Multimedia Appendix 3](#)): a random number table with equal allocation to access PTSD Coach or waitlist (1:1) with an unstratified block design fixed at 20 allocations. The first author (IH) uploaded the random number table without reviewing it into the Uppsala University REDCap randomization tool before data collection. The block size, R-script, and allocation sequence were concealed to members of the research team who enrolled participants (the first author, a clinical psychologist, and 2 psychology students) or randomized participants (the first author, a PhD student, and a clinical psychologist). The condition was revealed in the REDCap graphical user interface, nonblinded but unalterable, after randomization.

Data Analysis

We analyzed data in R (versions 3.5.1 and 4.0.5) using linear mixed effects models (*nlme* package v3.1-141). We specified 3 separate multiple regression models a priori with the direct and interaction effects of condition and time on posttraumatic stress, depressive symptoms, and somatic symptoms. All randomized participants were included in the intention-to-treat

and per-protocol analyses. We replaced single missing item ratings in the outcomes with the individual’s mean item rating ($n=24$ had 1 missing item for the PHQ-15 at baseline, and $n=1$ had 1 missing value for the PHQ-15 post intervention). Missing data for the outcomes at follow-up were assumed to be missing at random conditional on the baseline PCL-5 scores, as dropout was related to the baseline PCL-5 scores but not to any other baseline variables. We addressed the missing data using multiple imputations in the primary analyses, and we conducted sensitivity analyses, as reported in [Multimedia Appendix 4](#). We included baseline posttraumatic stress as a predictor and imputed each outcome in 500 data sets (10 iterations) with predictive mean matching [39] (*mice* package v3.13.0 and *miceadds* package v3.11-6). We report pooled parameter estimates across all imputations. We calculated model-based, between-group standardized mean differences (Cohen d) with 95% CIs on the pooled within-group SD at baseline [40]. Negative reactions that were caused by circumstances other than using PTSD Coach were recorded as 0 (absent).

We conducted post hoc tests to assess whether the number of participants who reported clinically significant improvement or deterioration in posttraumatic stress (a 10-point difference on the PCL-5 from baseline to follow-up) or screened positive for PTSD (≥ 31 points on the PCL-5) at baseline and follow-up differed between conditions using chi-square tests. In addition, we explored whether remission from probable PTSD (≥ 31 to < 31 points) or development of probable PTSD (from < 31 to ≥ 31 points) differed between conditions using chi-square and Fisher exact tests.

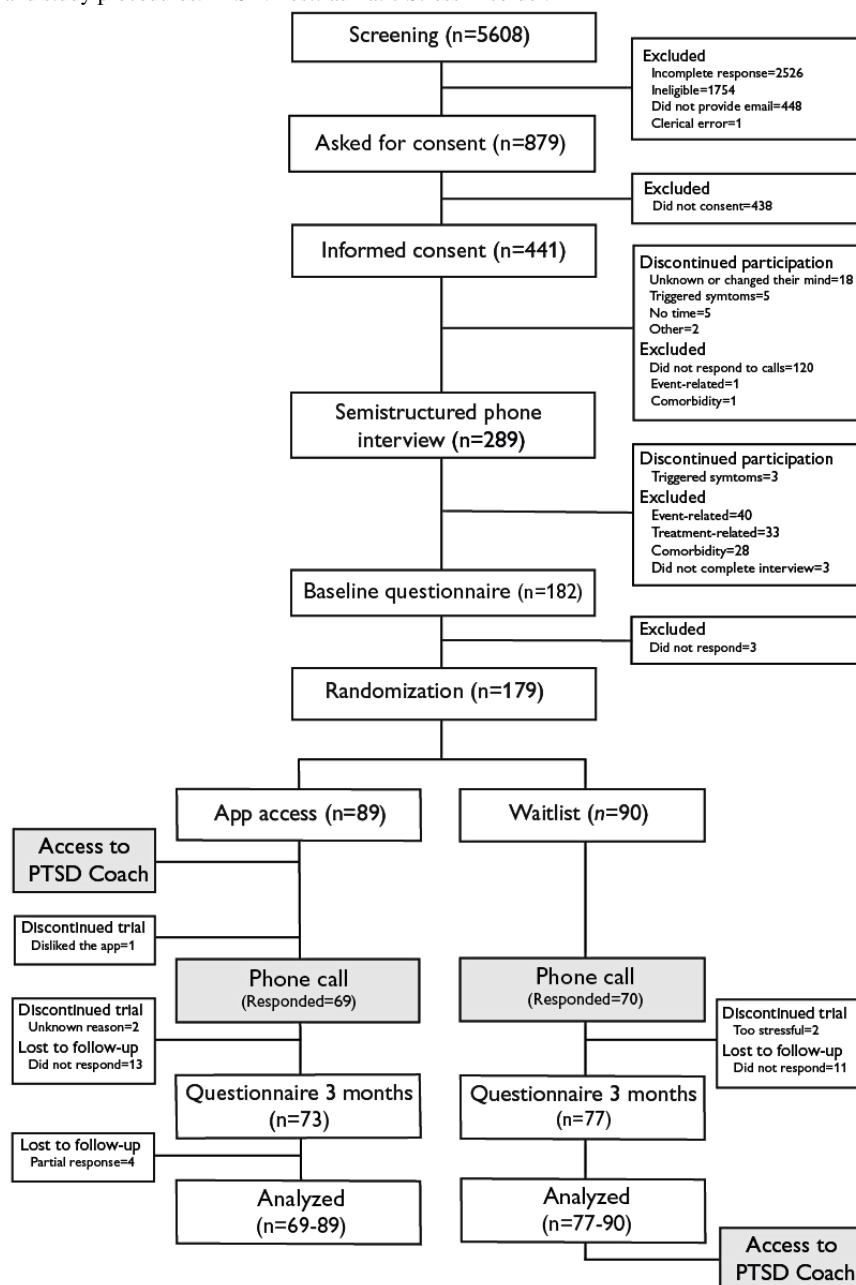

Ethics Approval

The regional ethical review board in Uppsala, Sweden, approved the study procedures before data collection (reference 2018/319).

Results

Overview

A total of 179 adults were included in the study, with 5 participants discontinuing participation after randomization ([Figure 1](#)). Using Welch t test, we detected no difference in posttraumatic stress between participants who discontinued participation ($n=5$; mean 50.60, SD 18.82) and those who completed the follow-up ($n=150$; mean 35.96, SD 15.90; $t_{4,2}=1.72$; $P=.16$). Participants who discontinued participation did not differ in baseline depressive symptoms ($t_{4,1}=0.63$; $P=.56$) or somatic symptoms ($t_{4,3}=0.35$; $P=.75$) compared with completers. However, baseline posttraumatic stress was higher among participants who were lost to follow-up ($n=24$; mean 42.96, SD 13.54) compared with completers ($t_{34}=2.29$; $P=.03$). Participants who were lost to follow-up did not differ in baseline depressive ($t_{32}=0.05$; $P=.96$) or somatic symptoms ($t_{30}=0.71$; $P=.48$) compared with completers.

Figure 1. Participant flow and study procedures. PTSD: Posttraumatic Stress Disorder.

Sample Characteristics

Most participants were women who used their smartphones daily (Table 1). The participants were on average 42.78 years (SD 10.90 years; app access mean 43.42, SD 10.60; waitlist mean 42.15, SD 11.21). We assessed the most severe potentially traumatic event in the past 2 years as perceived by the participants. Positive screening for disorders was assessed using the Mini International Neuropsychiatric Interview (Swedish version 7.0.0).

Most participants had experienced a potentially traumatic event firsthand in the past 2 years (Table 1), with 38 participants (app access: $n=21$; waitlist: $n=17$) reporting that their lifetime's worst potentially traumatic event occurred more than 2 years ago. Several participants (app access=38; waitlist=39) had received previous psychological treatment or counseling after exposure to a potentially traumatic event. The levels of posttraumatic stress, depressive, and somatic symptoms were moderate to high (Table 2), and probable psychiatric disorders were common (Table 1).

^dPHQ-15: Patient Health Questionnaire-15, somatic symptoms.

Confounding Factors

There was some contamination in both groups during the trial. At follow-up, 4 participants on the waitlist reported having used PTSD Coach (presumably the English version of the app), and 7 participants (app access=4; waitlist=3) reported using a self-management app other than PTSD Coach. We also detected potentially confounding factors—participants started psychological treatment (app access=10; waitlist=10), changed their medication (app access=8; waitlist=10), or started a new medication (app access=10; waitlist=8). Moreover, 26 people sought professional help, such as medical or psychological treatment, related to their trauma (app access=17; waitlist=9) during the intervention period. At follow-up, 17 participants with access to the app stated that they had not used PTSD Coach.

Primary Outcome: Posttraumatic Stress

Access to PTSD Coach led to a greater decrease in posttraumatic stress after 3 months compared with the waitlist ([Figure 2](#) and [Table 3](#)). The standardized mean difference was small (Cohen $d=-0.45$, 95% CI -0.70 to -0.20). The results from the sensitivity analyses per the protocol and excluding contamination ([Multimedia Appendix 4](#)) yielded highly similar results.

Furthermore, we explored the rates of improvement, response, and remission ([Table 4](#)). Participants with access to the app were more likely to show clinically significant improvement ($\chi^2_{1,150}=4.62$; $P=.03$) and less likely to fulfill the criteria for probable PTSD than participants on the waitlist after 3 months ($\chi^2_{1,150}=7.74$; $P=.005$). However, we detected no difference between conditions in remission from probable PTSD ([Table 4](#)).

Secondary Outcomes

Depressive and Somatic Symptoms

Access to PTSD Coach conferred a greater decrease in depressive symptoms after 3 months compared with the waitlist (Figure 3 and Table 3). The standardized mean difference was

small (Cohen $d=-0.35$, 95% CI -0.62 to -0.07). The sensitivity analyses per protocol and excluding contamination for depressive symptoms yielded highly similar results (Multimedia Appendix 4). We detected no difference in somatic symptoms based on access to PTSD Coach during 3 months (Figure 4 and Table 3). The standardized mean difference was trivial (Cohen $d=-0.13$, 95% CI -0.38 to 0.12).

Figure 3. Depressive symptoms from baseline to follow-up. The panels present pooled, model-based group means and 95% CIs and the distributions of unimputed observations (N=179). PHQ-9: Patient Health Questionnaire-9.

Figure 4. Somatic symptoms from baseline to follow-up. The panels present pooled, model-based group means and 95% CIs and the distributions of unimputed observations (N=179). PHQ-15: Patient Health Questionnaire-15.

Helpfulness and Satisfaction

Among participants with access to the app, 4 did not complete the PTSD Coach survey. Average ratings on helpfulness items ranged from 1.29 to 2.03 (Multimedia Appendix 1), which indicates that participants with access to PTSD Coach found the app slightly to moderately helpful. The helpful aspects of PTSD Coach are presented in Multimedia Appendix 5. The average sum score on helpfulness was 23.11 (SD 14.32; n=71). Most participants (50/69, 72%) were moderately or very satisfied with the app (n=69, mean 2.22, SD 1.07).

Negative Effects

Only 2 participants with access to the app did not respond to the Negative Effects Questionnaire, whereas 35 reported no negative reactions. In total, 36 people reported 1 to 8 negative reactions that, on average, affected them moderately (mean 2.07, SD 0.86), with an average total sum of 7.44 (SD 6.91; n=36). The most common negative reactions with moderate to extreme impact (Multimedia Appendix 6) were related to the design and evaluation of PTSD Coach, such as unfulfilled expectations on the app (14/71, 20%), its results (10/71, 14%), and perceiving the app as unmotivating (13/71, 18%) or confusing (8/71, 11%). Up to 13% (9/71) of participants experienced negative reactions in the form of psychological symptoms (Multimedia Appendix 2). Moderate to extreme symptom-related reactions included increased stress (7/71, 10%), arousal of distressing memories (6/71, 8%), anxiety (5/71, 7%), and symptom deterioration (5/71, 7%). In contrast, no one reported increased suicidality associated with the PTSD Coach or dependency on the app (Multimedia Appendix 2). Moreover,

we detected no difference in symptom deterioration between participants with access to the app and those on the waitlist (Table 4).

Discussion

Principal Findings

We conclude that access to PTSD Coach during 3 months decreased posttraumatic stress and depressive symptoms but not somatic symptoms, as compared with a waitlist control. Users perceived PTSD Coach as slightly to moderately helpful and moderately satisfactory. We found no evidence of symptom deterioration among users of PTSD Coach compared with the waitlist, and the most commonly reported negative reactions were related to the evaluation of the app and its design.

The participants' severity of posttraumatic stress was comparable [10,12] or lower [6,13,14] than the symptom burden in previous studies. Nonetheless, the treatment effect for posttraumatic stress was comparable with the response (range 5-11 points) observed in most previous studies [6,12-14]. Depressive symptoms decreased more than [10,14] or similarly [6,12] to the response in previous studies. Although participants exhibited moderate somatic symptoms, the app primarily targeted psychological distress, which could explain the lack of significant results. In addition, the origin of participants' mental health and somatic symptoms may be disparate.

The perceived helpfulness and satisfaction were generally lower than the American version of PTSD Coach [5] and greater than in the Swedish pilot study [12]. We speculate that the

participants' lower ratings of helpfulness compared with their satisfaction ratings may, in part, reflect modest expectations of the potential benefits of a smartphone app. Nonetheless, resolving technical issues and further cultural adaptation of the content may improve perceived helpfulness. Similar to participants in clinical trials of psychological treatments [36], approximately half of the intervention participants reported at least one negative reaction associated with using PTSD Coach. Using PTSD Coach may have triggered trauma-related symptoms (eg, stress, anxiety, and distressing memories), which would counteract the app's purpose. However, 87% (62/71) did not experience symptom-related negative reactions related to app use. Furthermore, we detected no differences in self-rated deterioration (clinically significant deterioration or development of probable PTSD) in posttraumatic stress between participants with and without access to PTSD Coach. Instead, access to the PTSD Coach was associated with self-rated response and recovery (ie, more instances of clinically significant improvement and fewer cases of probable PTSD) from posttraumatic stress compared with the waitlist.

Strengths and Limitations

Our rigorous evaluation of PTSD Coach, an app based on accumulated clinical expertise and research, illuminates the potential positive and negative effects of digital health interventions for posttraumatic stress. The strength of the procedure is that participants on the waitlist and with access to the app received equal attention from the research team. We opted for an inactive waitlist under genuine equipoise as to whether PTSD Coach would be superior, and the results would also, although imperfectly, represent the impact of access to PTSD Coach compared with situations in which professional care may be temporarily unavailable to increase ecological validity; for example, during waitlist for psychological treatment or in the aftermath of mass disaster situations. We did not specifically restrict participants from using sources of support, only other psychological treatments, which would reflect a situation in which access to expert treatment is scarce, but people use other sources of support. Nevertheless, the study design does not permit distinguishing whether PTSD Coach might function as a placebo, which has been discussed as a risk, particularly in smartphone apps [41], as it would entail using a sham or genuinely inactive app as a comparator. In addition, some intervention participants stated that they never used PTSD Coach, which may reflect that they did not receive the intervention. However, some of these participants reported that they had used the app when asked during the first week of the intervention period. To better understand symptom improvement in participants associated with app use, objective app data would be beneficial. We could have ascertained that the users had received the intervention and increased opportunities for gaining app access by sending instructions through multiple channels (eg, email, letter, and text).

We hope that the results of the intervention and negative effects can aid clinicians and users in making balanced and informed decisions about using self-management apps. We know that negative effects occurred, but not to what extent they persisted. Considering that the people lost to follow-up had elevated initial symptoms of posttraumatic stress and depression, negative

reactions might be underrepresented. Assessment of negative reactions in the waitlist condition would have enabled a controlled comparison. Nevertheless, the questionnaires would be dissimilar by necessity, as participants on the waitlist did not have access to PTSD Coach.

Another strength is that we used multiple methods of assessment at baseline and assessed both positive and negative outcomes with psychometrically sound instruments. However, the lack of specificity of the symptom measurement could have introduced bias to the promising results: self-ratings on the PCL-5 may not discriminate between posttraumatic stress and depressive symptoms [26]. The PCL-5 has greater sensitivity than specificity for detecting PTSD than the gold standard clinician assessment [26]. Furthermore, the assessment of outcomes is at risk of common method bias; for instance, the clinician screening for PTSD ($n=99$) differed from self-rated probable PTSD ($n=120$) at baseline. Multiple forms of assessment (clinician-assessed and self-rated) at follow-up would have improved the validity of the results.

Finally, retention was high, and we did not find evidence of bias associated with missing outcome data. We acknowledge that the predominantly female sample limits the generalizability of the results. Still, the sample was comparable with national estimates regarding marriage or cohabitation (59%) [42], university education (38%-50%) [43], and employment or studies (65%-70%) [44]. We conducted the study in an industrialized, Western society with high rates of smartphone ownership and tax-funded, low-cost mental health care. Similar interventions may need adaptations to promote symptom reduction among other genders or societal contexts.

Research Implications

In previous studies, the subjectively reported use of PTSD Coach was unrelated to changes in outcomes [6,13]. Therefore, access to PTSD Coach may affect symptoms by moderating processes other than usage frequency. The speculated mechanisms of change by using PTSD Coach include psychoeducation, coping skills, symptom awareness, and social support, which may assist treatment-seeking [6,7,10]. The content of PTSD Coach prompts seeking qualified care, which, if provided, would benefit symptom alleviation. We have limited information regarding adherence to the intervention or use of PTSD Coach during the trial, and future studies would benefit from recording objective use data or contextual information, such as when and where the use of a self-management app successfully mitigates short-term distress. Future research into the mechanisms of change and moderating processes would greatly advance the field and future design of effective mobile self-management interventions for populations in need. We also encourage others to explore the extent and persistence of negative effects concerning psychological or self-management interventions.

Clinical Implications

Given the observed efficacy, benefits, and harms of PTSD Coach, an unguided self-management app has limited potential to cure PTSD and is unlikely to replace evidence-based psychological treatments for posttraumatic stress when such treatment is warranted. Nevertheless, gaining access to PTSD

Coach seems superior to no intervention. Therefore, we believe the results support the feasibility of distributing PTSD Coach, along with other means of support, particularly after events that may temporarily restrict access to support or overwhelm treatment resources, such as pandemics, mass casualty situations, or other disasters. We speculate that access to similar content could boost the skills and knowledge acquired in previous counseling or treatment.

The impact of access to PTSD Coach during 3 months resulted in a slight reduction of posttraumatic stress. Although the average symptom reduction did not indicate a clinically significant change in posttraumatic stress, clinically significant improvement was more common among participants with access

to PTSD Coach. We believe that the benefits of disseminating a free, low-intensity intervention for potentially reducing trauma-related distress outweigh the risk of the negative effects we recorded. Nonetheless, we advise that users are informed about the possibility of negative effects to make an informed choice before using apps for mental health. Moreover, to adjust expectations, clinicians could inform users of the extent to which PTSD Coach may be beneficial or helpful. PTSD Coach is a low-risk, helpful, and effective intervention for reducing posttraumatic stress and depressive symptoms. Access to PTSD Coach may complement other psychological, medical, and social interventions for PTSD or provide an attainable first step for survivors of psychological trauma to learn, cope, and begin their road to recovery.

Acknowledgments

The authors thank the participants who offered their time and made an effort to participate in the study. The authors also thank Tove Ringmar for assisting with data collection and Hans Arinell for the independent statistical replication of the main findings. This study was funded by grants from the Swedish Board of Health and Welfare and the Swedish Crime Victim Authority (grant 03448/2017). Data are available upon request [45].

Abstract

Background: Cardiac rehabilitation is central in reducing mortality and morbidity after myocardial infarction. However, the fulfillment of guideline-recommended cardiac rehabilitation targets is unsatisfactory. eHealth offers new possibilities to improve clinical care.

Objective: This study aims to assess the effect of a web-based application designed to support adherence to lifestyle advice and self-control of risk factors (intervention) in addition to center-based cardiac rehabilitation, compared with cardiac rehabilitation only (usual care).

Methods: All 150 patients participated in cardiac rehabilitation. Patients randomized to the intervention group (n=101) received access to the application for 25 weeks where information about lifestyle (eg, diet and physical activity), risk factors (eg, weight and blood pressure [BP]), and symptoms could be registered. The software provided feedback and lifestyle advice. The primary outcome was a change in submaximal exercise capacity (Watts [W]) between follow-up visits. Secondary outcomes included changes in modifiable risk factors between baseline and follow-up visits and uptake and adherence to the application. Regression analysis was used, adjusting for relevant baseline variables.

Results: There was a nonsignificant trend toward a larger change in exercise capacity in the intervention group (n=66) compared with the usual care group (n=40; +14.4, SD 19.0 W, vs +10.3, SD 16.1 W; $P=.22$). Patients in the intervention group achieved significantly larger BP reduction compared with usual care patients at 2 weeks (systolic -27.7 vs -16.4 mm Hg; $P=.006$) and at 6 to 10 weeks (systolic -25.3 vs -16.4 mm Hg; $P=.02$, and diastolic -13.4 vs -9.1 mm Hg; $P=.05$). A healthy diet index score improved significantly more between baseline and the 2-week follow-up in the intervention group (+2.3 vs +1.4 points; $P=.05$), mostly owing to an increase in the consumption of fish and fruit. At 6 to 10 weeks, 64% (14/22) versus 46% (5/11) of smokers in the intervention versus usual care groups had quit smoking, and at 12 to 14 months, the respective percentages were 55%

(12/22) versus 36% (4/11). However, the number of smokers in the study was low (33/149, 21.9%), and the differences were nonsignificant. Attendance in cardiac rehabilitation was high, with 96% (96/100) of patients in the intervention group and 98% (48/49) of patients receiving usual care only attending 12- to 14-month follow-up. Uptake (logging data in the application at least once) was 86.1% (87/101). Adherence (logging data at least twice weekly) was 91% (79/87) in week 1 and 56% (49/87) in week 25.

Conclusions: Complementing cardiac rehabilitation with a web-based application improved BP and dietary habits during the first months after myocardial infarction. A nonsignificant tendency toward better exercise capacity and higher smoking cessation rates was observed. Although the study group was small, these positive trends support further development of eHealth in cardiac rehabilitation.

Introduction

Background

Mortality rates from coronary heart disease (CHD) have decreased in the last decades [1-3]. However, the falling mortality rates have led to an increased number of survivors who need support in the secondary prevention of recurrent coronary events [3,4]. Comprehensive cardiac rehabilitation programs, which are multidisciplinary medical and health behavioral interventions, effectively reduce CHD morbidity and mortality [3-7]. International guidelines strongly recommend participation in cardiac rehabilitation and have set therapeutic goals on risk factor and lifestyle management [7]. Cardiac rehabilitation goals include smoking cessation, medical management of low-density lipoprotein (LDL)-cholesterol and blood pressure (BP), maintaining a healthy diet, and participation in an exercise training program, also referred to as exercise-based cardiac rehabilitation [7]. Despite clear set goals, both attendance to cardiac rehabilitation and therapeutic goal attainment are suboptimal [8,9].

Cardiac rehabilitation programs in Sweden hold a high standard compared with European counterparts when it comes to providing guideline-recommended services [10]. Moreover, in 2019, the Swedish Web-System for Enhancement and Development of Evidence-Based Care in Heart Disease Evaluated According to Recommended Therapies (SWEDEHEART) registry reported that after participating in a 1-year long cardiac rehabilitation program, patients who had an myocardial infarction (MI) only reached target levels for LDL-cholesterol in about 60% of cases, only 55% of smokers were abstinent and 19% of patients had participated in exercise-based cardiac rehabilitation programs [9]. A lack of reaching therapeutic goals while offering guideline-recommended services indicates that alternative methods may be needed to improve patient outcomes.

Previous studies on eHealth cardiac rehabilitation have resulted in noninferiority or concluded that patients benefited with regard to lifestyle changes and risk factor management [11-20]. However, these studies have varied in sample size and follow-up time, and more studies are needed. eHealth is of interest to the

field of cardiac rehabilitation because it has the potential to overcome some known barriers to participation, such as geographical distance, communication barriers, and rigid follow-up structures, and to individualize cardiac rehabilitation programs [4,21].

Objectives

The aim of this study is to evaluate the efficacy of a web-based application as an addition to a comprehensive center-based cardiac rehabilitation program, in comparison with usual care center-based cardiac rehabilitation only. The web-based application was designed to support adherence to lifestyle advice and self-control of risk factors in patients who had an MI. In the planning phase of our study, we predicted that the web-based application would primarily affect patients' lifestyle and with that increased physical activity levels and exercise capacity [22]. The benefits of increased physical activity levels and participation in exercise-based cardiac rehabilitation are largely mediated through an increase in physical fitness. Submaximal exercise capacity is an objective measurement of physical fitness and was, therefore, chosen as the primary outcome [23].

Methods

Trial Design and Framework

The protocol, which followed the principles outlined in the Declaration of Helsinki, was approved by the Regional Ethical Review Board at Lund University (approval 2016/5). The protocol has been previously described in detail [22] and is summarized here.

We conducted an unblinded parallel multicenter randomized controlled trial (RCT) at 3 cardiac rehabilitation centers based at university hospitals in Sweden. At the time of the study, approximately 1200 patients aged <75 years were treated for acute MI at the 3 study centers each year.

Participants, Recruitment, and Randomization

The inclusion criteria were age 18-74 years, having had an MI within the last 2 weeks, owning a smartphone or having access to the internet via a computer or tablet, and being able to handle the software. The exclusion criteria were having an expected

survival of <1 year, dementia, severe psychiatric illness or drug abuse, severe physical disability limiting the patients' ability to participate in a center-based exercise-based cardiac rehabilitation, inability to speak or understand the Swedish language, and a 3-vessel or left main disease requiring coronary artery bypass grafting. The age criterion was set to match that applied by the SWEDEHEART registry.

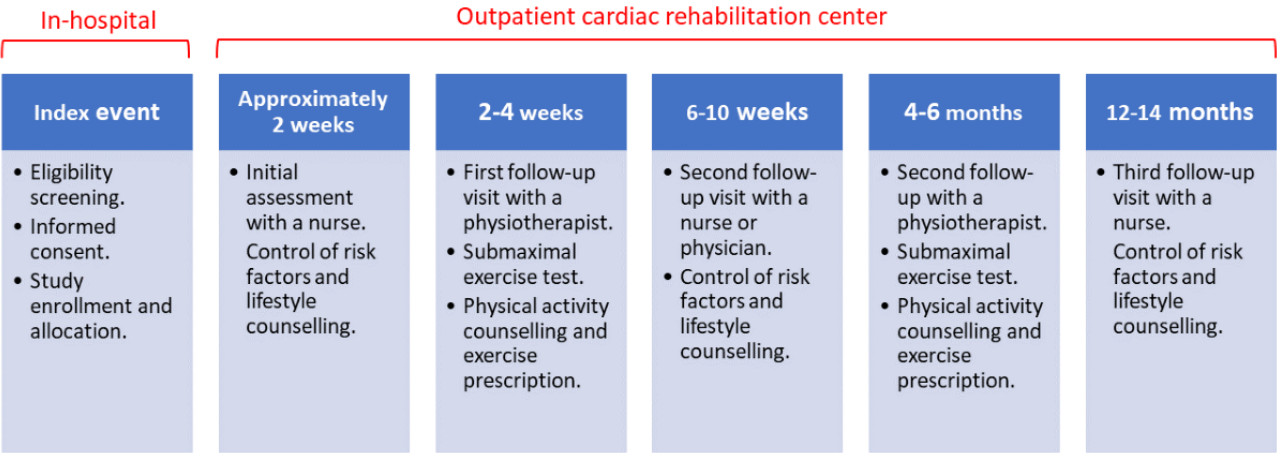

Eligibility screening and study inclusion were performed within 2 weeks of an index MI while participants were admitted to a coronary care unit at each participating hospital. Local study coordinators (physicians, nurses, or physiotherapists) provided eligible patients with information about the study, offered participation, and obtained written informed consent. Once included in the study, the participants were randomized to 1 of the 2 study arms using opaque sealed envelopes. The envelopes,

which included information on which study group the participant would be randomized to, were prepared by a member of the research team and shuffled by another member. The envelopes were thereafter sequentially numbered with unique numbers for each recruiting site. Upon recruitment, baseline questionnaires were administered.

Usual Care

Participants in both arms of the study were offered participation in a comprehensive cardiac rehabilitation program at each center. A description of the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) figure on the content of each follow-up visit is available in the protocol [22]. In short, the cardiac rehabilitation programs consisted of five outpatient follow-up visits: 3 visits with a nurse or physician and 2 visits with a physiotherapist (Figure 1).

Figure 1. The follow-up of the patients who have had a myocardial infarction, in the study.

The Intervention

Participants randomized to the intervention group of the study received access to the LifePod web-based mobile device app (Cross Technology Solutions AB) for the first 25 weeks of the cardiac rehabilitation program. The LifePod software contained two separate interfaces: one for the patient and one for the treating health care professionals (Figure 2). In the patient interface, the patient could log information about diet, physical activity and exercise, weight, heart rate, BP, and smoking, as

well as symptoms and intake of medication. The patient could compare his or her own data to guideline-recommended targets and received automated positive feedback on healthy lifestyle choices as well as general recommendations on exercise, daily physical activity, and healthy diet. In the medical interface assessed by the treating cardiac rehabilitation staff, the system ranked patients, giving high priority to, for example, patients reporting chest pain or out-of-range BP measurements. The medical interface was reviewed twice a week by a nurse.

Figure 2. Screenshots of the LifePod patient interface (top) and medical interface (bottom). The software could be accessed through a smartphone, tablet, or computer.

Data Collection

Patient outcomes were derived from the SWEDHEART registry. The SWEDHEART registry is a nationwide quality registry that records baseline characteristics, treatments, follow-up, and outcome data of patients who have had an MI [9]. Data collection started at the time of index MI and continued at all follow-up visits, as shown in Figure 1. The time points for data collection were prespecified in accordance with standardized SWEDHEART registry follow-up visits. Information was collected using standardized forms that can be downloaded from the SWEDHEART registry webpage [24].

At the physiotherapist visits at 2 to 4 weeks and 4 to 6 months, a submaximal exercise test on a bicycle ergometer was performed [25,26]. During the test, heart rate, systolic BP (SBP), perceived exertion, dyspnea, and chest pain were registered according to the Borg rating of perceived exertion and category ratio-10 scales [27]. The test was discontinued at Borg rating of perceived exertion 17, dyspnea 7 on the Borg category ratio-10 scale, or other routine discontinuation criteria for exercise stress testing, including, for example, chest pain and fall in SBP. At the first visit, the patients received individualized physical activity and exercise recommendations and were invited

to participate in exercise-based cardiac rehabilitation as a part of their comprehensive cardiac rehabilitation program.

The follow-up visits with a nurse or physician at approximately 2 weeks, 6 to 10 weeks, and 12 to 14 months focused on risk factors and lifestyle. Fasting plasma glucose (mmol/L), hemoglobin A_{1c} (mmol/mol), and plasma lipids (total cholesterol, LDL-cholesterol, high-density lipoprotein-cholesterol, and triglycerides; mmol/L) samples were drawn and analyzed using accredited methods at each hospital. BP was measured using a manual sphygmomanometer after a 5-minute rest with the patient in a sitting position. Weight (kg) was measured in light indoor clothing, and BMI (kg/m²) was calculated. Smoking status was self-reported. At baseline, 6 to 10 weeks, and 12 to 14 months, smoking abstinence was defined as being smoke-free for ≥1 month. At the 2-week visit, abstinence was defined as being abstinent at the time of the visit. Diet was evaluated using a 4-item questionnaire adapted from the national guidelines for the management of unhealthy lifestyle in the general population [28]. The questions aim to quantify the amount of vegetables, fruit, fish, and sweets consumed. Each question had 4 possible answers, giving 0 to 3 points. The scores for each question were subsequently added, forming the healthy diet index (0-12 points). Levels of physical

activity were self-reported using 2 sets of questionnaires. Haskell questions on physical activity and exercise evaluated both the number of days during the last week [1-7] with at least 30 minutes of physical activity and the number of days during the last week [1-7] with at least 20 minutes of exercise training [29]. The Frändin-Grimby physical activity questionnaire aims to evaluate the level of physical activity a person achieved in the last week on a scale of 1 to 6, with 1 being hardly any physical activity and 6 being regular strenuous physical activity [30].

The data that support this study's findings are available from the Uppsala Clinical Research Centre, Sweden. The primary responsibility for data monitoring, including data sharing, integrity, and security, was assigned to the principal investigator and local study coordinators. The trial was conducted according to Good Clinical Practice, and data were handled according to the Swedish Data Protection Authority and General Data Protection Regulations.

Statistical Methods and Outcomes

With a power of 90%, a 2-sided significance level of .05, and a mean difference of at least 10 (SD 20) W among the groups, the estimated sample size needed was 50 participants in each group [22]. However, the expected loss of adherence to the web-based application led to the formation of an unequal allocation ratio of 1:2 in the usual care group versus intervention group.

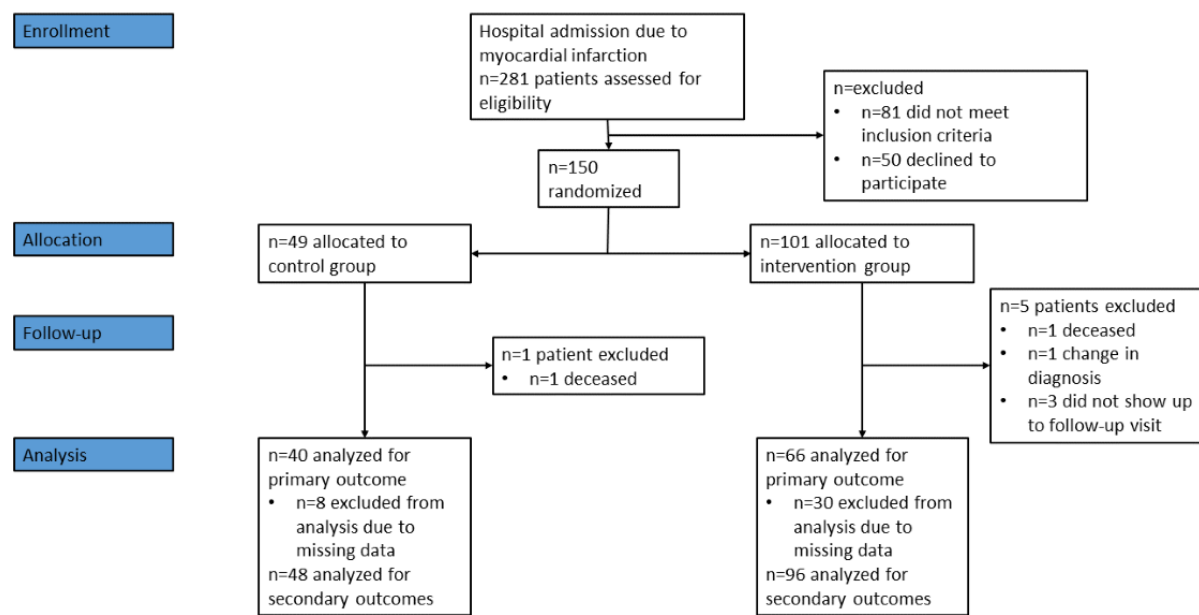

The primary outcome was the change (δ value) in submaximal exercise capacity, measured in Watts, between 2 submaximal exercise tests performed at 2 to 4 weeks and at 4 to 6 months. The secondary outcomes were changes (δ values) in dietary habits and physical activity, as well as SBP and diastolic BP (DBP), total cholesterol, LDL-cholesterol, high-density lipoprotein-cholesterol, triglycerides, fasting plasma glucose, hemoglobin A_{1c}, and BMI. The secondary outcomes also included smoking status and uptake and adherence to the web-based application. Uptake was defined as the proportion of patients who logged on to the patient interface at least once, and adherence was defined as the proportion of patients registering data at least twice per week on a weekly basis throughout the 25-week intervention period. An additional

analysis on the difference in mortality and number of hospital readmissions during the trial period was performed. Baseline characteristics are presented as means (SDs) for normally distributed continuous variables, medians (IQR) for nonnormally distributed continuous variables, and as numbers and percentages for categorical variables. Variable distribution was assessed by visual inspection of histograms and Q-Q plots and by calculating skewness and kurtosis; z values between -1.96 and 1.96 were used to define the normally distributed interval. To compare outcome measures of continuous variables among the groups, a 2-tailed Student t test or a Mann-Whitney U test was performed. A univariate analysis of variance, adjusting for age, gender, weight, previous CHD, and smoking status at index MI was also performed. In the analysis of variance, the dependent variables were the measured outcomes, and the independent variables were the intervention and chosen covariates. For categorical variables, a chi-square test and a logistic regression analysis adjusting for the previously mentioned covariates were used. For within-group comparisons, a paired t test was used for normally distributed variables and a Wilcoxon signed-rank test for skewed data. For all analyses, an α level of .05, and 2-tailed testing was used. Individuals with missing data on covariates or outcome variables were excluded from the analysis (listwise exclusion). All data were analyzed by using the SPSS (version 25.0; IBM Corp).

Results

Participant Recruitment and Flow

Of the 281 patients assessed for eligibility, 150 (53.4%) consented and indicated intent to attend cardiac rehabilitation and, if allocated to the intervention group, use the web-based application (Figure 3). In total, 32.7% (49/150) of the patients were allocated to the control group and 67.3% (101/150) to the intervention group. At the end of the study period, 1 participant in each group of the study had died. For 1 patient, the index event diagnosis changed during follow-up from MI to cardiac amyloidosis, and the patient was excluded from the analysis. Of the 150 patients, 3 (2%) did not attend their follow-up visits at 12 to 14 months after MI and were classified as lost to follow-up.

Figure 3. A flowchart displaying the recruitment process and flow of participants in the usual care and intervention groups.

Patient inclusion started in April 2016 and was finalized in April 2018. The follow-up period was completed in June 2019.

Baseline Characteristics

Baseline characteristics are presented in Table 1. The intervention group had a slightly higher prevalence of cardiac

comorbidities at baseline including a higher mean SBP and were more often taking cardioprotective medication compared with the usual care group. In addition, a proportionally higher number of patients in the intervention group had an ST elevation MI.

^kARB: angiotensin II receptor blocker.

^lDAPT: dual antiplatelet therapy.

^mSTEMI: ST elevation myocardial infarction.

ⁿNSTEMI: non-ST elevation myocardial infarction.

Primary Outcome

Because of missing data at the first or second follow-up with a physiotherapist, only 82% (40/49) of participants in the usual care group and 66% (66/100) in the intervention group qualified for analyses of the primary outcome.

Both groups increased their submaximal exercise capacity significantly between the first and second follow-up measurements (Figure 4). The intervention group increased their exercise capacity from 96.3 (SD 29.4) W to 110.8 W (SD 33.7 W; $P<.001$) and the corresponding values for the usual care group were 96.1 (SD 33.7) W to 106.5 W (SD 37.3 W; $P<.001$).

Figure 4. A boxplot of the change in submaximal exercise capacity in the intervention group and the usual care group. The difference in change in exercise capacity among the groups was nonsignificant.

There was no significant difference in the change in exercise capacity between the intervention group and the usual care group (+14.4, SD 19.0 W vs +10.3, SD 16.1 W; crude 95% CI -11.2 to 3.0, $P=.26$; adjusted 95% CI -12.0 to 2.8, $P=.22$) at follow-up. The variation in the observed difference fell within the expected limits of +20 W to -20 W.

Secondary Outcomes

The secondary outcomes are shown in Tables 2-4. Crude analyses showed that at the 2-week follow-up, there was a

significantly larger decrease in SBP in the intervention group than that in the usual care group. SBP remained lower in the intervention group than in the usual care group for the remainder of the follow-ups; however, the difference among the groups was nonsignificant. In the adjusted analysis, the decrease in SBP was significantly larger in the intervention group between baseline and 2 weeks and for both SBP and DBP between baseline and 6 to 10 weeks (Figure 5).

^aNumbers are presented as mean (SD), median (q1, q3), and *P* values. Crude and adjusted *P* values are shown for the differences in mean or median change (δ) between baseline and 2-week follow-up, comparing the intervention and usual care groups.

^bAdjusted for gender, age, weight, previous heart disease, and smoking status at the time of the index event.

^cSBP: systolic blood pressure.

^dDBP: diastolic blood pressure.

^eNot adjusted for weight.

The healthy diet index scores improved to a significantly larger extent between baseline and the 2-week follow-up in the intervention group than in the usual care group, mostly because of an increase in the consumption of fish and fruit (Table 2). However, this improvement was not sustained for the rest of the follow-up period (Tables 3 and 4).

There were no significant differences in self-reported physical activity among the groups. Results from the Haskell questions on physical activity and exercise [29] showed a mean change in number of days of performing at least 30 minutes of physical activity between baseline and the first follow-up with a physiotherapist at 2 to 4 weeks, which was 3.1 days (SD 2.2 days) for the intervention group and 2.5 days (SD 2.3 days) for the usual care group (adjusted *P*=.13). The corresponding numbers between baseline and the second follow-up with a physiotherapist at 4 to 6 months were 2.6 days (SD 2.6 days) and 1.8 days (SD 2.2 days) for the intervention and control groups, respectively (adjusted *P*=.08). The mean change in the number of days performing at least 20 minutes of exercise training between baseline and the first follow-up with a physiotherapist was 0.2 days (SD 2.0 days) for the intervention group and 0.1 days (SD 1.7 days) for the control group (adjusted

P=.76), and the corresponding numbers between baseline and the second follow-up were 1.2 days (SD 2.2 days) and 1.3 days (SD 2.4 days) for the intervention and control groups, respectively (adjusted *P*=.79).

According to the Frändin-Grimby physical activity questionnaire [30], the mean change in the level of physical activity a person achieved in the last week between baseline and the first follow-up with a physiotherapist at 2 to 4 weeks was 0.1 (SD 1.0) point in the intervention group and 0.3 (SD 1.0) point for the usual care group (adjusted *P*=.21). The mean change between baseline and the second follow-up visit with a physiotherapist at 4- to 6-month visit was 0.6 (SD 1.2) in the intervention group and 0.8 (SD 1.1) in the usual care group (adjusted *P*=.46).

A total of 33 smokers were included in the trial, 22 in the intervention group and 11 in the usual care group. At the 2-week follow-up, 64% (14/22) of smokers in the intervention group and 55% (6/11) of smokers in the usual care group reported being abstinent from smoking (adjusted *P*=.76). At 6 to 10 weeks, the numbers were 64% (14/22) vs 46% (5/11; adjusted *P*=.24), and at 12 to 14 months, they were 55% (12/22) vs 36% (4/11; adjusted *P*=.74), for the intervention and control groups, respectively.

Table 3. Secondary outcome measures at the 6- to 10-week follow-up.^a

^aNumbers are presented as mean differences (SD), median differences (q1, q3), and *P* values. Crude and adjusted *P* values are shown for the differences in mean or median change (δ) between baseline and 12- to 14-month follow-up, comparing the intervention and usual care groups.

^bAdjusted for gender, age, weight, previous heart disease, and smoking status at the time of the index event.

^cSBP: systolic blood pressure.

^dDBP: diastolic blood pressure.

^eNot adjusted for weight.

^fLDL: low-density lipoprotein.

^gHDL: high-density lipoprotein.

^hHbA_{1c}: glycated hemoglobin A_{1c}.

Figure 5. Decrease in systolic and diastolic blood pressure between baseline and follow-up visits (absolute values). *P* values are adjusted for gender, age, weight, previous coronary heart disease, and smoking status at the time of the index event.

Uptake and Adherence

Attendance to the cardiac rehabilitation program was generally high. A total of 93% (93/100) of patients in the intervention group attended the first follow-up visit with a physiotherapist, and 71% (71/100) attended the second. The corresponding percentages for the usual care group were 98% (48/49) and 86% (42/49). However, only 66% (66/100) of patients in the intervention group and 82% (40/49) of patients in the usual care group performed a submaximal exercise test at both visits.

A total of 92% (92/100) of patients in the intervention group attended the 6- to 10-week follow-up and 96% (96/100) attended the 12- to 14-month follow-up, and the corresponding numbers for the usual care group were 98% (48/49) for both follow-up visits.

Uptake to the web application was 86.1% (87/101). Adherence (the proportion of the 87 patients who continued to log data at least twice per week) declined during the trial period, from its highest of 91% (79/87) at week 1 to 56% (49/87) at week 25 (Figure 6).

Figure 6. Percentage of patients logging data to the web-based application at least twice weekly.

The most frequent parameters to be logged to the web-based application by patients in the intervention group were intake of medication and consumption of vegetables, followed by physical activity ([Multimedia Appendix 1](#)).

Additional Analysis

There was no difference in the frequency of deaths due to any cause ($n=1$ in each group, $P=.62$). The frequencies of rehospitalizations during the 12- to 14-month follow-up period were also similar among the groups. In total, 22% (22/100) of the patients in the intervention group and 27% (13/49) of the patients in the usual care group were rehospitalized due to any cause ($P=.58$), and 8% (8/100) versus 4% (2/49) of the patients were hospitalized due to ischemic heart disease ($P=.35$).

Discussion

Principal Findings

In our study, evaluating the effects of a web-based application as an addition to usual care cardiac rehabilitation as compared with usual care alone, we found that there was a trend toward better exercise capacity in the intervention group; however, this was not statistically significant. On the other hand, the patients receiving access to the web-based application had a significantly reduced SBP at the first 2 follow-up visits, a reduced DBP at the second follow-up visit, and an initial increase in intake of fish and fruit. Although cardiac rehabilitation attendance was high in both groups, adherence to the web-based application declined over time.

After the baseline exercise test, all patients in our study received individualized physical activity recommendations and an individualized exercise prescription and were invited to participate in exercise-based cardiac rehabilitation based at the cardiac rehabilitation center. Those in the intervention group were, in addition, advised to rate their perceived exertion and time spent in exercise and log the information on the web-based application, after which they would receive automated positive feedback. Although attendance to physiotherapy follow-up visits was high, not all patients completed the submaximal exercise tests. The reasons for noncompletion were not officially documented, but according to clinical experience, reasons often include common cold, leg or joint pain, and perceived inability to exercise. During follow-up, both groups had a significant improvement in submaximal exercise capacity and, although not significant, there was a 4.1 W difference among the groups in favor of the intervention group. Increased physical activity levels using telehealth in cardiac rehabilitation have been demonstrated in previous studies. A recent meta-analysis showed that this applied especially to studies where telehealth was used as an adjunct to comprehensive cardiac rehabilitation [16]. The web-based application in our study did not specifically provide feedback on adherence to the exercise-based cardiac rehabilitation program but rather to increase physical activity levels in general, which may perhaps partly explain the lack of significant differences in exercise capacity among the groups.

The benefit of the combination of involvement of health care professionals with eHealth has been shown to be beneficial in studies addressing cardiovascular risk factors [31-33]. For example, a recent RCT found that participants using an

exercise-focused smartphone app had better fitness levels (measured by maximal oxygen consumption or VO_{2peak}) compared with usual care after a follow-up at the 1-year postcardiac rehabilitation [32]. The information that participants logged into the smartphone app was monitored by a physiotherapist who provided personal feedback. Adherence to the smartphone app was high, and participants felt that they reported to an individual involved in their care rather than a database or a robot. This knowledge can be used in the design of future studies aiming to increase the exercise-based cardiac rehabilitation adherence with the overall aim of increasing patients' physical fitness.

Most patients who had an MI were already on a regime of cardioprotective medication when discharged from the hospitals (Table 1). Despite this, a significant difference in BP control was observed among the groups, in favor of the intervention group. In our crude analysis, patients in the intervention group had a significantly larger SBP decrease between baseline and the 2-week follow-up. A numerical but nonsignificant difference among the groups then remained throughout the trial period. After adjusting for relevant covariates, the observed differences in BP control increased, in favor of the intervention group, and included a significant difference in SBP and DBP decrease between baseline and the 6- to 10-week follow-up. Patients in the intervention group achieved an 11.3 mm Hg larger decrease in SBP between baseline and the 2-week follow-up compared with patients in the usual care group, the difference being 8.8 mm Hg at the 6 to 10-week follow-up and 7.0 mm Hg at the 12- to 14-month follow-up. The choice of covariates was based on observed differences in baseline characteristics, which indicated a higher comorbidity in the intervention group. As such, not adjusting for baseline differences could have masked a difference among the groups. Hypertension is a predominant risk factor for CHD morbidity and mortality [7]. Previous meta-analyses have shown that a 10 mm Hg reduction in SBP reduces the risk of future CHD events by 22%, irrespective of the method of BP reduction [34]. Given the magnitude of the observed decrease in BP in our study, the difference is likely to have some clinical benefit. An improvement in reaching BP goals when having access to a web-based application as an aid in cardiac rehabilitation is in line with previous studies [11-13,20,35]. For example, Widmer et al [35] also demonstrated a substantial BP difference, with patients who after a percutaneous coronary intervention received digital health intervention (web-based or smartphone-based) as a complement to traditional cardiac rehabilitation having significant improvements in SBP (-10.8 mm Hg, $P<.001$ vs -6.1 mm Hg, $P=.36$) at a 3-month follow-up. Because intake of medication was the most frequently logged parameter in the web-based application, one possible reason for improved BP values in the intervention group might be an increased compliance to antihypertensive medication. Increased adherence to medication has been demonstrated in a previous study on a web-based application in cardiac rehabilitation [36]. In addition, increased patient engagement with self-monitoring has been shown to improve BP control [37,38]. The difference in BP among the groups declined throughout the trial period. One reason might be that adherence to behavioral recommendations has been seen

to decline over time in cardiac rehabilitation, or it could have something to do with decreasing adherence to the web-based application which is a known methodological challenge within eHealth [11,39]. As there was no measurement done at the end of the 25-week intervention period, we do not know exactly when the differences attenuated.

We also observed a significant beneficial effect on healthy dietary choices. During the first 2 weeks of follow-up, patients in the intervention group had a significantly higher score on the health diet index and higher intake of fish and fruit. Following a healthy diet rich in healthy oils and plant-based food has been shown to reduce cardiovascular events [40]. Previous studies on eHealth in cardiac rehabilitation have shown both improvement and no effect on dietary habits [15,16,41]. Here, the data were self-reported, which has considerable limitations, and the results should be interpreted with caution [42].

Smoking is a leading cause of preventable death globally and is a strong risk factor for CHD [7]. There was a numerical difference in the number of smokers who reported being abstinent at the follow-up visits, but owing to the low number of smokers in our study population, the differences were not statistically significant. In addition, whether the numerical difference was due to the intervention or chance finding cannot be stated. However, telehealth interventions in cardiac rehabilitation have been shown to reduce the likelihood of smoking by 23%, giving promise to using eHealth as a tool to tackle this important risk factor [16].

Adherence to eHealth

eHealth has the potential to improve participation and adherence to cardiac rehabilitation programs by including patients more actively in their own care and increasing flexibility and accessibility [21]. In our study, although uptake to the web-based application was high, adherence declined over time, with just over half of the users logging data at least twice weekly at the end of the 25-week intervention period. The main reason for limiting the intervention time to 25 weeks was to harmonize the intervention length with usual care, as most usual care cardiac rehabilitation interventions take place during the first 6 months after MI (nurse and physiotherapist visits, exercise training sessions, and patient education). In addition, patients usually have the highest level of motivation for lifestyle changes during the first months after MI [39]. The last reason was that adherence to eHealth interventions in cardiac rehabilitation has been shown to attenuate over time (weeks to months) [11,43]. In our study, reported reasons for stopping the use of the web-based application were mostly related to stress, some experienced a lack of feedback and some experienced too much feedback. User attrition in studies on eHealth is a well-known methodological challenge, with attrition rates reaching up to 60% to 80% [43]. High attrition rates can make it difficult to measure an intervention's effect and subsequently threaten both internal and external study validity [44,45]. Van der Mispel et al [44] studied user and website characteristics related to attrition. They demonstrated that attrition was higher for men and younger adults, as well as for less interactive components of the studied application. Buys et al [46] reported a general interest in technology-enabled home-based cardiac rehabilitation

among patients with cardiovascular disease. Their study demonstrated that patients with different characteristics were interested in different types of technology-based cardiac rehabilitation; for example, older patients were more interested in web-based options, and younger patients were more interested in app-based cardiac rehabilitation. They also looked at which parts of cardiac rehabilitation patients wanted to have technology-based options, including ideas on exercise, healthy meals, and stress management. This indicates that even if technology-based cardiac rehabilitation aims to make traditional programs more flexible and individualized, even the technology platforms need to be adjusted to individual needs for optimum effect.

Strengths and Limitations

In our study, we used data collected through standardized protocols from the SWEDEHEART registry [9,47]. The registry is well established in Swedish cardiac rehabilitation centers and is used daily by personnel. At the time of the study, SWEDEHEART nationwide coverage was >75%, registering eligible cases from 97% of Swedish hospitals. Data quality is regularly monitored, showing >95% agreement with data from hospital records [48]. Using SWEDEHEART prespecified time points for follow-up and procedures provided a standardization, which otherwise can be a challenge in multicenter trials. Cardiac

rehabilitation program attendance was high, and few participants were lost on follow-up.

The study was unblinded. Although blinding is preferred in RCTs, it is difficult to blind patients and health care providers in eHealth interventions. The follow-up data do not include information on the use of commercial web-based applications by the patients in the usual care group. The age limit considered in this study may restrict generalizability to all age groups. There might have been some selection bias, where more motivated patients would be more likely to agree to participate in a study using digital technology, requiring active participation. When interpreting the results, one should keep in mind the potential sources of inaccuracy in point BP measurements, which is a known source of bias in the clinical setting [49].

Conclusions

Digital technologies provide new opportunities in health care. Our results add to existing evidence and suggest that complementing comprehensive cardiac rehabilitation programs with a web-based application may positively affect risk factor outcomes and lifestyle, including BP and dietary choices. In addition, web-based technologies can be used to make cardiac rehabilitation programs more flexible and individualized, but further efforts should be invested to find ways to improve patient adherence to the platforms.

Acknowledgments

The study was funded by the Faculty of Medicine at Lund University, The Department of Coronary Care at Skåne University Hospital *Centre of Excellence in Skåne* Funds, and Avtal om Läkarutbildning och Forskning Grants County Council of Västerbotten. This study was partially sponsored by Cross Technology Solutions AB. The funding party had no role in design of the study, analysis of data, or writing of the manuscript.

Abstract

Background: Immune-mediated inflammatory diseases (IMIDs) are systemic conditions associated with a high social and health impact. New treatments have changed the prognosis of IMIDs and have increased patient autonomy in disease management. Mobile apps have enormous potential to improve health outcomes in patients with IMIDs. Although a large number of IMID apps are available, the app market is not regulated, and functionality and reliability remain uncertain.

Objective: Our aims are to review available apps for patients with IMIDs or caregivers and to describe the main characteristics and functionalities of these apps.

Methods: We performed an observational, cross-sectional, descriptive study of all apps for patients with IMIDs. Between April 5 and 14, 2021, we conducted a search of the App Store (iOS) and Play Store (Android) platforms. We used the names of the different IMIDs as search terms. The inclusion criteria were as follows: content related to IMIDs, English or Spanish language, and user population consisting of patients and health care consumers, including family and caregivers. The variables analyzed were as follows: app name, type of IMID, platform (Android or iOS), country of origin, language, category of the app, cost, date of the last update, size, downloads, author affiliation, and functionalities.

Results: We identified 713 apps in the initial search, and 243 apps met the criteria and were analyzed. Of these, 37% (n=90) were on Android, 27.2% (n=66) on iOS, and 35.8% (n=87) on both platforms. The most frequent categories were health and well-being/fitness apps (n=188, 48.5%) and medicine (n=82, 37.9%). A total of 211 (82.3%) apps were free. The mean time between the date of the analysis and the date of the most recent update was 18.5 (SD 19.3) months. Health care professionals were involved in the development of 100 (41.1%) apps. We found differences between Android and iOS in the mean time since the last update (16.2, SD 14.7 months vs 30.3, SD 25.7 months) and free apps (85.6% vs 75.8%; respectively). The functionalities were as follows: general information about lifestyles, nutrition, or exercises (n=135, 55.6%); specific information about the disease or treatment (n=102, 42%); recording of symptoms or adverse events (n=51, 21%); agenda/calendar (n=44, 18.1%); reminder medication (n=41, 16.9%); and recording of patient-reported outcomes (n=41, 16.9%). A total of 147 (60.5%) apps had more than one functionality.

Conclusions: IMID-related apps are heterogeneous in terms of functionality and reliability. Apps may be a useful complement to IMID care, especially inpatient education (their most frequent functionality). However, more than half of the IMID apps had not been developed by health care professionals or updated in the last year.

KEYWORDS

immune-mediated inflammatory disease; mobile app; mHealth; mobile health; chronic disease; disease management; outcomes; functionality; quality; patient education; health outcomes; reliability

Introduction

Immune-mediated inflammatory diseases (IMIDs) are systemic conditions characterized by altered immune regulation causing chronic inflammation in specific organs or systems [1]. IMIDs include rheumatologic diseases (eg, rheumatoid arthritis, ankylosing spondylitis, and psoriatic arthritis), digestive diseases (eg, Crohn disease and ulcerative colitis), and dermatologic diseases (eg, psoriasis). It is estimated that 5% to 7% of the world's population has an IMID [1]. Besides, IMIDs are associated with a high social and health impact in terms of morbidity and mortality, quality of life, and psychological and occupational aspects.

Management and treatment of IMIDs have changed substantially in the last decade, mainly due to the emergence of biological therapies [2]. However, since these new treatments are associated with problems related to administration, toxicity, and adherence, patients should receive adequate training and information. Besides, patients are becoming increasingly active and require more information. A survey conducted in the 27 countries of the European Union revealed that, in the previous 3 months to the survey, 53% of citizens sought online health information related to injury, disease, nutrition, improving health, and similar data [3].

Mobile health (mHealth) technologies incorporating strategies for remote self-management may offer an effective alternative to classic outpatient-based approaches [4]. In particular, broad accessibility to mobile apps enables them to complement health care 24 hours a day, 7 days a week at low cost [5-7]. Apps help to better understand and manage chronic diseases such as IMIDs [8]. Besides, patients with IMIDs are younger than patients with other chronic diseases, and they are more familiar with these technologies [1]. Thus, apps represent an opportunity to improve self-management of care and improve their quality of life.

Health care professionals could play an essential role not only in the review or verification of the contents of these apps but also in their prescription to the best candidates and the recommendation of the most reliable options. However, the lack of studies providing detailed IMID-related app characteristics limits health care professionals' knowledge in this field. Available IMID apps vary substantially in terms of features, functionality, and reliability [4,9-14]. Up-to-date information about the current situation of apps for patients with IMIDs can be a substantial help to health care professionals in guiding patients and identifying possible risks derived from their use, as well as identifying the needs and directions for future development of these tools. Thus, our objectives were to provide a review of the apps available in the marketplace for patients with IMIDs or caregivers and to identify and describe the main characteristics and functionalities of these apps.

Methods

We performed an observational, cross-sectional, descriptive study of all the smartphone apps designed for patients with IMIDs available on the iOS and Android platforms.

The methodology used for the selection of the apps followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) system. We searched the iOS Apple Store and Android Google Play Store from April 5 to 14, 2021 using the following terms: "ankylosing spondylitis," "Crohn's disease," "IBD," "inflammatory bowel disease," "immune-mediated inflammatory diseases," "immune-mediated inflammatory disorders," "psoriasis," "psoriatic arthritis," "rheumatoid arthritis," and "ulcerative colitis." As the resultant app list was potentially endless (similar to a Google search), we used the approach followed in previous reviews and performed the screening process until 20 consecutive apps yielded no new potentially relevant apps [15,16].

Two researchers with experience in the analysis of apps, design, and development, and in the management of patients with IMIDs (authors RRJ and VEV) performed identical searches independently. The inclusion criteria were as follows: content related to IMIDs, English or Spanish language, and user population consisting of patients and health consumers, including family or caregivers. Those apps that did not target patients (ie, apps targeting health professionals) were excluded.

The variables analyzed were the name of the app, type of IMID (ankylosing spondylitis, Crohn disease, psoriasis, psoriatic arthritis, rheumatoid arthritis, or ulcerative colitis), platform (Android or iOS), country of origin, language, category of the app, cost, date of the last update, size, downloads, author affiliation, and functionalities. The author's affiliation was classified as follows: university, health administration or government, hospital/clinic, foundation, patient association, pharmaceutical company, and technology company. Concerning technology companies, we identified two categories depending on whether they were health related or not. Functionalities were further classified into the following categories: information (disease or treatment and lifestyle, nutrition, and exercises), self-diagnosis, disease activity monitoring, symptom or patient-reported outcome (PRO) recording, medication reminders, adherence monitoring, agenda/calendar (a diary or calendar with or without function to record an appointment), contact with health care professionals, and social network. The app search method was developed by the authors and has not been validated. This methodology to analyze app characteristics has been used in other similar studies [4,16,17].

The data were collected from the description and the screenshots available at the app store websites. In cases where one of the variables was not available or there was any doubt, the app was downloaded onto an iPhone 11 (version 14.4.2) or a Xiaomi Redmi Note 7 (version 9.0). For the categorization of author

affiliation, we conducted Google searches using the name or the website provided by the app store.

The researchers (RRJ and VEV) evaluated each app independently. Data were analyzed using SPSS Statistics for Windows, Version 21.0 (IBM Corp; descriptive statistics). The homogeneity of the groups was analyzed using a univariate analysis by applying the chi-square test to compare qualitative variables and the *t* test or Mann-Whitney test to compare quantitative variables. A *P* value <.05 was considered statistically significant. Cohen kappa (κ) test was performed to determine the reliability of the data analyzed by these two independent researchers (RRJ and VEV).

The two researchers jointly analyzed those apps again in which the information collected varied between them. Discrepancies were discussed and an agreement was reached.

Results

General Characteristics

We identified 713 apps in the initial search in the two app stores; of these, 470 were excluded (Figure 1). We finally analyzed

243 apps: 37% (n=90) on Android, 27.2% (n=66) on iOS, and 35.8% (n=87) on both platforms. Concerning app characteristics, the agreement between the two researchers was excellent ($\kappa=0.868$).

Most of the apps belonged to the health and well-being/fitness and medicine categories. The mean time since the last update was 18.5 (SD 19.3) months, and the mean app size was 28.6 (SD 46.9) Mb. A total of 43 (17.7%) apps required payment for use, with a mean price of US \$10.30 (SD US \$12.00). Concerning the language, 86.8% (n=211) of the apps analyzed were in only one language, and 15 (6.2%) were in three or more languages. A total of 234 (96%) apps were in English, and 11.4% (29/243) were in Spanish. Table 1 shows the remaining general app characteristics.

We found statistically significant differences ($P<.001$) between the Android and iOS apps, as follows: time since the last update, 16.2 (SD 14.7) months vs 30.3 (SD 25.7) months; apps with cost, 14.4% vs. 24.2%; and size, 11.2 (SD 13.9) Mb vs 50.2 (SD 77.9) Mb.

App Author Affiliation

The most frequent type of author affiliation was a nonhealth technology company (n=77, 31.7%; [Table 2](#)). The author

affiliation was not available in 27.2% (n=66) of apps. Concerning the country of origin, 38.3% (n=93) of apps were from the United States, 8.2% (n=20) were from India, and 7.8% (n=19) were from the United Kingdom.

Table 2. App author affiliation.

Characteristics	Apps (N=243), n (%)
Type of author/developer	
Nonhealth technology company	77 (31.7)
Health-related technology company	57 (23.5)
Pharmaceutical company	12 (4.9)
Hospital/clinic	6 (2.5)
Foundation	18 (7.4)
Patient association	4 (1.6)
Health administration/government	2 (0.8)
University	1 (0.4)
Not available	66 (27.2)
Continent of origin

Europe	55 (22.6)
Asia	32 (13.2)
Oceania	5 (2.1)
South America	1 (0.4)
Not available	44 (18.1)

Type of IMIDs Targeted by the Apps

A total of 135 (55.5%) apps were specifically aimed at one IMID, and 21 (8.6%) were aimed at all IMIDs (Table 3).

Concerning author affiliation, we found statistically significant differences between specific ankylosing spondylitis-related apps and specific psoriasis-related apps. These differences were

found in the number of apps developed by a health-related technology company (50% in psoriasis apps and 6.7% in ankylosing spondylitis), nonhealth technology company (20% in psoriasis apps and 40% in ankylosing spondylitis), and in those apps where this information was not available (30% in psoriasis apps and 53% in ankylosing spondylitis; $P<.001$). No statistically significant differences were found between the rest of the recorded app characteristics and the type of IMIDs.

Table 3. Type of immune-mediated inflammatory diseases targeted by the apps.

Characteristics	Apps (N=243), n (%)
Ankylosing spondylitis	56 (23.0)
Crohn disease	93 (38.3)
Psoriatic arthritis	39 (16.0)
Psoriasis	50 (20.6)
Rheumatoid arthritis	111 (45.7)
Ulcerative colitis	89 (36.6)

App Functionalities

Analysis of the functionalities of the 243 apps revealed that 60.5% (n=147) had more than one functionality. A total of 135 apps offered information about lifestyle, nutrition, and physical exercise, and 102 apps offered information about the disease or its treatment (Table 4). We found that only 6 apps offered information specifically about biological therapies. Table 5

shows the main app functionalities related to the different IMIDs.

The mean number of functionalities per app was 2.1 (range 1-7). No statistically significant differences were found between the number of functionalities and the remaining variables, except for author affiliation. Apps developed by health-related technology companies presented a higher average number of functionalities.

Table 4. Functionalities of the apps.

Functionality	App (N=243), n (%)
General information about lifestyle, nutrition, exercise	135 (55.6)
Specific information about the disease or its treatment	102 (42.0)
Recording of symptoms or adverse events	51 (21.0)
Agenda/calendar	44 (18.1)
Medication reminder ^a	41 (16.9)
Recording of patient-reported outcomes	41 (16.9)
Monitoring the activity/severity of the disease	34 (14.7)
Contact with health care professionals	24 (9.9)
Social network	16 (6.6)
Other	36 (14.8)

^a27 of 41 made it possible to monitor adherence.

Table 5. Main app functionalities concerning the different immune-mediated inflammatory diseases.

	Information, n (%)	Recording of symptoms or adverse events, n (%)	Agenda/calendar, n (%)	Reminder medication, n (%)	Recording of PROs ^a , n (%)	Monitoring the activity/severity of the disease, n (%)	Contact with health professionals, n (%)	Social network, n (%)
AS ^b (n=56)	46 (82.1)	8 (14.3)	8 (14.3)	7 (12.5)	7 (12.5)	4 (7.1)	3 (5.4)	1 (1.8)
CD ^c (n=93)	68 (73.1)	21 (22.6)	24 (25.8)	19 (20.4)	19 (20.4)	15 (16.1)	9 (9.7)	5 (5.4)

Discussion

Principal Findings

We provide a comprehensive and unique review of IMID-related apps available for patients in the Play Store and Apple Store. The marketplace offers hundreds of solutions, thus making it difficult for the user to filter [17]. Health care professionals are unaware of the real situation of these apps and how they can help patients manage their disease. To the best of our knowledge, this is the only review published so far on the features and functionalities of apps for all IMIDs. The main findings show that functionalities and reliability were heterogeneous. Although most apps offer information, information on biological therapies is scarce. Few apps allow patient interaction, such as recording adverse events, setting alarms for medication, or recording PROs.

We analyzed 243 apps for the most important IMIDs and identified features that may contribute to our understanding of the current landscape and the development of future solutions. Most of the apps targeted rheumatoid arthritis and inflammatory bowel diseases (IBDs). This distribution is proportional to the prevalence of the IMIDs in real life [1]. Among the characteristics of the apps, we highlight the involvement of health care professionals in the development of 41.2% (n=100) of apps. However, 54.3% (n=132) of apps had not been updated in the last year, and the most frequent functionality was that of providing information.

The use of IMID-related apps is still in its infancy [11,18]. The medical fields with the most experience in apps are diabetes, mental health, and cardiovascular disease [7,17,19]. McKay et al [20] carried out a systematic review of apps related to one or more health conditions and found no IMID-related apps. In 2018, there were only 56 IBD-related apps available [21]. In a

cohort of 193 German patients with rheumatologic diseases, 91.2% regularly used a smartphone, and 68.4% believed that using medical apps could be beneficial for their health. However, only 4.1% of these patients used health-related apps, of which none were rheumatology-specific [8]. In a similar study performed on 575 French patients diagnosed with rheumatoid arthritis, only 4.7% used a health app [22].

In addition to the limited number of IMID apps, some of the negative characteristics such as a lack of robust scientific evidence prevent clinicians from using health-related apps or recommending them to patients [11,13,23]. It is estimated that only 38% of international consensus statements are completely covered by IBD-related apps focusing on patient education [4]. In a systematic review of self-management apps for persons with arthritic pain, Bhattarai et al [16] observed that a small number of arthritic pain apps offer a comprehensive self-management approach incorporating evidence-based strategies through the Stanford Arthritis Self-Management Program [16].

Currently, there is no specific legislation on the use of the apps and standards or official guidelines on app development. Similarly, there are no official repositories, mainly due to the fast-moving pace of mHealth [5,24]. The Food and Drug Administration launched the Digital Health Precertification Program (Pre-Cert Program) to evaluate mobile-based interventions in real-world conditions [7,25]. Despite the availability of validated tools for assessing the quality of apps, such as the Mobile App Rating Scale [26], there is minimal agreement on methods and the most appropriate criteria for this task [19]. Besides, few IMID-related apps have been developed or validated using these methodologies [14,27,28]. Author affiliation is an important characteristic when searching for a trustworthy app and has been a quality criterion in numerous studies [19]. However, most of the apps did not describe the credentials of the author or professionals who participated in the development. The fact that neither store requires qualifications or affiliations to be listed is one of the main reliability problems of health apps [10,17,29,30]. Thus, external sources, such as the developer's website if available, are needed. Even so, in 27.2% (n=66) of the apps we reviewed, we could not find any information about the author. We observed that more than half of the author affiliations were related to technology companies, although only 41% (n=100) were identified as involving some type of health professional. Only 7 of the 20 rheumatoid arthritis apps assessed by Luo et al [10] involved a health professional in content development. In another review of apps for medication management, 72.9% of apps were developed by technology companies, 2.1% by academic institutions, and 5.2% by other bodies (governments and nonprofit organizations), and there was insufficient information available about author affiliation in 17.1% [17]. Only 14.6% of apps were developed with the involvement of a health care professional. In a review of apps for rheumatic diseases, authors found that health care professionals were involved in the development of 40% of the apps [12]. Con and Cruz [4] reviewed 26 IBD-related apps and found that health professionals were involved in the development of 19.2% [4].

The level of the update is also a potential cause for concern. Given the rapid advance in IMID care, information must be constantly updated. In our study, we found that more than half of the apps had not been updated in the previous year, while in 25.1% (n=61), the last update had been over 2 years previously. In a review of 20 rheumatoid arthritis apps, only 12 had been updated in the previous year [10]. Concerning other diseases, Collado-Borrell et al [31] observed that 52.4% of cancer-related apps had updated their software within the previous year. We observed that the apps available in the Play Store were more recently updated than those in the App Store. These results contrast with those of studies that have shown the average quality of health apps to be better on iOS than on Android [32].

On the other hand, one of the advantages of these tools is that most health-related apps are free [4,17,31,33], thus favoring their accessibility. Consistent with other studies, we observed that 82.3% (n=200) of IMID-related apps were free [10,17,31,33]. However, in IMID apps requiring payment, the cost is slightly higher (US \$10.30) than the average observed in other reviews (US \$1.01-4.74) [4,9,10,17,31,33]. Concerning the country of development, the most frequent was the United States, followed by India. Other app review studies have shown a similar distribution [33], likely due to the potential of information and communication technology companies in these countries.

Many of the health-related apps emerged as tools for consulting information, and this is still the most frequent functionality, although 60.5% (n=147) of the apps analyzed had more than one functionality. Our results are consistent with those of other studies and highlight that most apps offer passive functionalities such as information about the disease, treatments, lifestyle, nutrition, and physical exercise. Medication information was the feature most desired by a cohort of 193 patients with rheumatic disease [8]. Mollard et al [11] observed that 25% of apps available for rheumatoid arthritis were exclusively for patient education. Con and Cruz [4] observed that 50% of IBD apps had exclusively diary functionalities that made it possible to track several activities or records, although there was considerable heterogeneity regarding the detail with which symptoms were able to be recorded. In that study, 34.6% of apps only provided information, 11.5% recorded PROs, and 7.7% had two reminder systems. Only 1 app allowed communication between patients and professionals. Similar results were obtained in a review of rheumatoid arthritis apps, in which 50% only allowed symptom tracking and 25% had only provided information [10]. Tabi et al [17] analyzed 328 apps for medication management and observed that 41.2% could share data and reports, although no app allowed bidirectional communication with health professionals.

Several studies have shown the usefulness of apps for improving adherence [17,34]. This feature is even more important in drugs that are not administered daily, such as biological therapies, as delays in administration may be more frequent. For instance, 20% to 40% of patients with IBD are nonadherent. Alerts or reminders to take medication are the most frequent feature of apps and improve adherence. In general, apps are the preferred method for reminding patients to take their medication regularly [8]. However, in our review, only 16.9% (n=41) of apps have

this functionality, and only 11.1% (n=27) enable medication adherence to be monitored.

Encouraging enthusiastic patients to engage with apps regularly is another barrier [11]. For example, many patients download an app for the sole purpose of obtaining health information. However, after initial use of the app, there is unlikely to be continual engagement once the desired information is obtained [11]. Long-term engagement can be problematic, with app interventions progressively becoming less effective over time [7]. Some functionalities involving patient participation, such as sending messages and gamification, can also improve long-term engagement [19]. Gamification is a specific characteristic of mHealth interventions that could favor behavioral change and increase user engagement. However, we only found 1 app with the functionality of gamification in our review.

Limitations and Strengths

A possible limitation is that we did not assess the privacy and confidentiality of apps since this information is not available in most cases. The relationship between the use of health apps and privacy risk is understudied [10]. Most reviews and studies that assess app quality do not analyze this aspect [19,20]. In fact, the number of health apps that define privacy policies is

low [35]. Nevertheless, to our knowledge, this is the first review to cover most IMIDs and analyze their characteristics in detail. We believe that our review can provide health professionals with a real-world picture of the apps available for patients with IMIDs and help them to identify strengths and weaknesses. We have observed that there are a large number of free apps in English available for patients diagnosed with IMIDs, especially for consulting information. However, when recommending apps or instructing patients to search for them, health care professionals should be aware of some critical factors. Professionals and patients should check the author's affiliation and the update date, as there are many IMID apps with nonproven developers and without updates. Future legislation for apps should focus specifically on bridging these gaps.

Conclusions

This review provides health professionals with an overview of available IMID-related apps and their characteristics. IMID-related apps continue to be heterogeneous in terms of their functionalities and reliability. Apps may act as a useful complement to IMID care, especially in patient education, as this is their most frequent functionality. However, more than half of the IMID apps had not been developed by health care professionals or updated in the previous year.

Abstract

Background: Interventions in early childhood education and care (ECEC) services have the potential to improve children's diet at the population level.

Objective: This study aims to test the efficacy of a mobile health intervention in ECEC services to reduce parent packing of foods high in saturated fat, sugar, and sodium (discretionary foods) in children's (aged 3-6 years) lunch boxes.

Methods: A cluster randomized controlled trial was undertaken with 355 parent and child dyads recruited by phone and in person from 17 ECEC services (8 [47%] intervention and 9 [53%] control services). Parents in the intervention group received a 10-week fully automated program targeting barriers to packing healthy lunch boxes delivered via an existing service communication app. The program included weekly push notifications, within-app messages, and links to further resources, including websites and videos. The control group did not receive any intervention. The primary outcomes were kilojoules from discretionary foods and associated nutrients (saturated fat, free sugars, and sodium) packed in children's lunch boxes. Secondary outcomes included consumption of kilojoules from discretionary foods and related nutrients and the packing and consumption of serves of discretionary foods and core food groups. Photography and weights of foods in children's lunch boxes were recorded by trained researchers before and after the trial to assess primary and secondary outcomes. Outcome assessors were blinded to service allocation. Feasibility, appropriateness, and acceptability were assessed via an ECEC service manager survey and a parent web-based survey. Use of the app was assessed via app analytics.

Results: Data on packed lunch box contents were collected for 88.8% (355/400) of consenting children at baseline and 84.3% (337/400) of children after the intervention. There was no significant difference between groups in kilojoule from discretionary foods packed (77.84 kJ, 95% CI -163.49 to 319.18; $P=.53$) or the other primary or secondary outcomes. The per-protocol analysis, including only data from children of parents who downloaded the app, also did not find any statistically significant change in primary (-1.98 kJ, 95% CI -343.87 to 339.90; $P=.86$) or secondary outcomes. Approximately 61.8% (102/165) of parents in the intervention group downloaded the app, and the mean service viewing rate of weekly within-app messages was 26% (SD 14.9). Parents who responded to the survey and participating services agreed that it was appropriate to receive lunch box information via the app (40/50, 80% and 6/8, 75%, respectively).

Conclusions: The intervention was unable to demonstrate an impact on kilojoules or associated nutrients from discretionary foods packed in children's lunch boxes. Low app downloads and program message views indicate a need to explore how to improve factors related to implementation before further testing similar mobile health interventions in this setting.

Introduction

Background

Poor diet characterized by excessive intake of foods high in sugar, salt, and sodium and low intake of core foods such as fruits and vegetables is associated with a higher risk of chronic disease [1]. The consumption of foods high in saturated fat, sugar, or salt exceeds optimal levels worldwide [2], and in countries such as the United States, the United Kingdom, and Australia, excessive consumption of such nutrients has been reported across all age groups [3-5]. In Australia, foods high in saturated fat, sugar, or sodium, and low in nutrients such as fiber (from here on referred to as *discretionary foods*) [6], contribute up to 38% of the total daily energy intake of a child aged 4 to 8 years [5]. Given this, international and national dietary guidelines recommend limiting the consumption of discretionary foods [7-10].

Early childhood education and care (ECEC) services constitute an ideal setting for reaching and engaging families to influence lifelong eating habits [11,12]. In the United States, the United Kingdom, and Australia, up to 80% of children attend some kind of formal ECEC service in the year before school [13-15], with an average attendance of 2 to 3 days per week [15]. A significant number of ECEC services in these countries require children to bring food from home in a lunch box (approximately 30%-50%) [13,14,16]. Australian studies report that between 50% and 60% of lunch boxes include discretionary foods [17,18], with one reporting an average of 2 serves included per lunch box [18]. As such, there is potential to improve children's diet by targeting the packing of discretionary foods in lunch boxes.

A systematic review of interventions to improve the contents of lunch boxes identified just 3 randomized controlled trials that examined interventions to improve the packing of discretionary foods within the ECEC setting [17,19,20]. Of the 3 trials, 2 reported significant results for reducing the packing of discretionary foods [17,19]. Both were intensive multicomponent interventions, including teacher education, child curriculum, and face-to-face education sessions with parents [17,19]. Despite the success of these interventions, evidence suggests that the sustainability and scalability of such intensive designs may be limited [21,22]. In particular, face-to-face parent-related components have been identified as difficult for parents to attend because of time and travel burden [23] and challenging for ECEC services to implement [21].

The use of digital health-delivered interventions has been proposed as a way of overcoming barriers to engaging parents in nutrition interventions, as well as enhancing scalability [24-26]. Digital health interventions (DHIs), in particular the

use of mobile phone apps or mobile health (mHealth) interventions, have been identified as an effective way of providing health-related information to parents [27] and influencing child health outcomes [25,28-30]. In addition, mobile apps designed to facilitate parent ECEC service communications are increasingly available for use by ECEC services in Australia, offering an alternative to face-to-face delivery of nutrition interventions by drawing on existing digital platforms [26]. Using existing apps to deliver nutrition interventions has also been recommended to capitalize on technologies developed by experts in user-centered design and with established commercial appeal [26]. Therefore, integrating a lunch box intervention into an existing ECEC parent communication app shows promise as a novel way of delivering digital content and engaging with parents.

Objective

To the authors' knowledge, no trials have been conducted to assess whether mHealth interventions can support the packing of healthy lunch boxes for children attending ECEC services. To address this gap in research evidence, the aim of this study is to determine the efficacy of using an mHealth intervention versus no intervention in ECEC services to reduce the packing of discretionary foods in children's lunch boxes. We hypothesize that as a result of the intervention, lunch boxes of children with parents in the intervention group would achieve a mean reduction of 123 kJ from packed discretionary foods relative to the control. Additional outcomes include the intervention's impact on children's consumption of food, parental use of the app, intervention fidelity, and other process evaluation measures.

Methods

Ethics Approval

Ethical approval was obtained from the Hunter New England (HNE) human research ethics committee (06/07/26/4.04) and ratified by the University of Newcastle ethics committee (H-2008-0343). The trial is reported in line with the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and online Telehealth) reporting guidelines ([Multimedia Appendix 1](#)) [31], and a protocol has been previously published [32].

Study Design and Setting

The study used a cluster randomized controlled trial design and targeted the parents of children attending center-based ECEC services (ie, long day care and preschools). The ECEC services were located in the HNE Local Health District of New South Wales (NSW), Australia. ECEC services were randomized to a 10-week intervention group or no intervention control group. Within NSW, long daycare services can provide center-based

education and care for children aged from 6 weeks to 6 years for ≥ 8 hours per day. Preschools typically enroll children aged between 3 and 6 years and provide care for 6 to 8 hours per day [33]. In 2016, approximately 920,370 people were reported to live in the HNE area, with 51,900 of these being children aged 0 to 4 years [34]. The area includes major metropolitan centers and inner regional communities, with a small proportion (14%) of people in remote communities [35].

Sample

The sampling frame comprised ECEC services from the region that required parents to provide food for consumption at the service (ie, lunch box services). The list of ECEC services that required parents to provide food was obtained from a government database and represented approximately 53% of all ECEC services in the region [16]. Of these services, existing users of the app required for the intervention and those not using any app (ie, services able to commence using the intervention app) were identified using previous, unpublished data on app use by services in the region.

Recruitment and Eligibility

Recruitment for the trial occurred in 2 phases. Initially, ECEC services were eligible to participate in the trial if they enrolled children aged 3 to 6 years and were existing users of the designated parent communication app. As this eligibility criterion did not result in adequate ECEC services being recruited, phase 2 recruitment extended the eligibility criteria to include ECEC services not yet using the app but willing to commence using the app for the trial. For both phases, recruitment involved research assistants posting and emailing information statements and consent forms to ECEC services outlining the study, data collection procedures, and requesting participation. Written consent was obtained from service managers. Parents or carers (hereafter referred to as *parents*) of children aged 3 to 6 years were eligible to participate if their child attended during the designated days of data collection and if they used or indicated a willingness to download the intervention app on the consent form. To obtain parental consent for participation in the study, ECEC service staff distributed hard copies of parent information statements and consent forms. Parents could also consent on the day of the data collection.

Random Allocation and Blinding

Before baseline data collection, ECEC services were randomly allocated to the intervention group or no intervention control group in a 1:1 ratio by a statistician independent of the trial using a computerized random number generator. Before randomization, ECEC services were stratified by rural location and socioeconomic status (SES) of the service, as evidence indicates that these factors are associated with family dietary intake [36,37]. To ensure equity of access to the intervention, ECEC services were also stratified by those with high numbers of Aboriginal child enrollments (defined as those with $>10\%$ Aboriginal children enrolled). Stratification by this number of factors was deemed appropriate for the sample size [38]. Owing to the nature of the intervention, ECEC services and parents were not blinded to the intervention; however, outcome assessors were blinded to the service allocation.

Intervention Development

Details of the intervention and its development, including the application of theory, cultural, and other stakeholder consultation processes, have been published elsewhere [32]. Briefly, the intervention was based on an mHealth lunch box intervention originally designed for primary (elementary) schools by the research team, which reported promising pilot data on the packing of discretionary items in school [39,40]. Similar to the original intervention, the behavior change wheel (BCW) and COM-B (Capability, Opportunity, Motivation, and Behavior) model were used to inform the current intervention [41]. The BCW framework is based on 19 theories of health behavior change and facilitates the systematic development of behavior change interventions. The COM-B model is the behavior system behind the BCW framework, which supports the identification of essential conditions for changes, including capability, opportunity, and motivation [41]. The resulting mHealth intervention, *SWAP IT for Childcare*, comprised 7 behavior change techniques targeting 8 barriers to packing healthy lunch boxes. (Multimedia Appendix 2). Barriers were identified from the literature and formative interviews with a convenience sample of parents from 3 local ECEC services. The adaptation process was then guided by the Framework for Reporting Adaptations and Modifications–Enhanced (Multimedia Appendix 3) [42].

Intervention App

The app used for the intervention (Skoolbag) was an existing app designed to be available for use by schools or ECEC services to communicate with parents. Commonly, ECEC services use the app to share parent newsletters, reminders, and other service information. The app had not been previously used to deliver nutrition interventions in the ECEC setting.

Intervention Strategies

The *SWAP IT for Childcare* intervention comprised 3 components.

Provision of Weekly Push Notifications and Within-App Messages

A total of 11 push notifications messages were delivered over 10 weeks (1 per week, with an additional introductory message delivered in week 1). The push notifications were sent by the app provider. Each push notification alerted users to a within-app message, which aimed to target parent barriers to packing healthy lunch boxes. The message was accessible via the push notification or could be accessed as part of the static content within the app. A summary of each push notification, within-app message, and the behavior change techniques is available in the published protocol [32].

Provision of SWAP IT Options and Supporting Resources Via the App

Several of the within-app messages provided a weblink to *SWAP IT Options*—a comprehensive list of foods suitable for packing in the lunch box. The web-based list was developed by dietitians on the research team with expertise working within the setting. The lists were divided into sections (sweet snacks, savory snacks, and lunch foods) with drop-down tabs to explore foods

recommended as *swap from* and *swap to*. Links to other supporting information relevant to each message were also provided, including fact sheets, short videos, and website links.

ECEC Service Endorsement of Program

To encourage initial and ongoing engagement with the app content, intervention ECEC service managers were asked to endorse the *SWAP IT* program and demonstrate support to parents. To do this, the research team provided 2 templates to service managers to communicate with parents during the course of the trial, which service managers could deliver via the app or by email. ECEC services were asked to deliver the communications the week before the intervention and midintervention (weeks 5-6).

Service Implementation Strategies to Increase App Uptake and Engagement

Although not an implementation trial, to maximize uptake and engagement with the intervention, some implementation strategies were undertaken [43].

Use Financial Strategies and Train Stakeholders

Before the intervention, ECEC services that had not used the app before the trial (intervention: 6/17, 35%; control: 5/17, 29%) had their access paid for by the research team during the trial period. Remote training was provided to new ECEC services on how to use the app by the app provider.

Engage Consumers

On recruitment, parents were supported to gain access to the app if not already doing so. Multiple strategies were used to maximize the number of parents on the app before and during the intervention. This included the research team providing emails to service managers to send to parents, as well as researchers sending emails sent directly to consenting parents asking them to download the app. Emails included step-by-step instructions on how to download the app and were distributed via printed flyers to ECEC services.

Control

The ECEC services allocated to the control group received no intervention. ECEC services had access to the app to use for their own communications but did not receive any of the intervention strategies or content.

Sample Size and Power Calculations

This study aimed to recruit 390 children from 18 ECEC services. Allowing a 15% attrition rate, this would enable the detection of a mean difference of 123 (SD 200) kJ in the primary outcome (kilojoules from discretionary foods), with an α of .01 (adjusting for multiple outcomes using Bonferroni adjustments) and an estimated intraclass correlation coefficient of 0.1 with 80% power. Such an energy reduction would represent approximately a quarter of a serve reduction in packed discretionary foods and could be expected to result in the detection of approximately 2.2 g less sugar, 0.6 g less saturated fat, and 44 mg less sodium [32].

Measures and Data Collection Procedures

Overview

Service baseline data were collected between May 2018 and July 2018. The 10-week intervention was delivered between July and September 2018. Postintervention data were collected for child lunch box outcomes during October and November 2018, and parent data were collected from October to December 2018.

The primary outcome measures were mean energy (kJ) provided by discretionary foods and mean energy (kJ), saturated fat (g), free sugars (mg), and sodium (mg) provided by all foods packed in the lunch box. Secondary outcomes were mean energy from discretionary foods (kJ) and mean energy (kJ), saturated fat (g), free sugars (mg), and sodium (mg) from all foods consumed by children from their lunch box. Other secondary outcomes were the number of serves of core food groups (bread and cereals, fruits, vegetables, dairy, meat, and meat alternatives) and number of discretionary food serves packed and consumed by children.

Packing and Consumption of Foods from Lunch Boxes

To assess the effectiveness of the intervention, data on food contents packed and consumed from lunch boxes were collected by trained research assistants, on one day, via weighed food records before the child's first meal and at the end of the child's last meal. ECEC services were asked not to inform parents of the day of data collection to reduce performance bias on lunch box packing behaviors. Weighed food records were used as evidence indicates this is the most accurate way of capturing portion sizes and quantities eaten [44,45]. On the day of data collection, the children were instructed to leave all uneaten food in the lunch box. Lunch box contents were also recorded on written standardized forms and digitally photographed to verify weighed records and identify inedible waste. Food record data were extracted by trained dietitians and entered into a nutrition analysis database (FoodWorks) [46]. Consumption data were derived by subtracting the weight of the food left at the completion of the last meal from the weight of food packed before meals. FoodWorks was used to produce nutrient data and the core food group serves data for both packed and consumed amounts of food. The software uses core food group classifications and serve sizes consistent with the Australian Guide to Healthy Eating [6]. For foods that were homemade, an appropriate standard recipe was sourced from within the FoodWorks database. As FoodWorks does not have the function to calculate discretionary food serves, this was undertaken manually by trained dietitians, using definitions based on the Australian Guide to Healthy Eating [6]. If further guidance was required, discretionary food classifications were sourced from the National Nutrition Survey food classification databases [47] or consensus from the research team. Further details of the FoodWorks data extraction processes and analysis are reported elsewhere [48].

Parent and Service Characteristics

Parent-child dyad characteristics were collected via consent forms and as part of a wider web-based survey sent via parent email before the intervention. Service operational characteristics

were collected via service manager pen and paper surveys completed at baseline. During a site visit, the service nutrition context was measured by trained observers using a modified version of the Environment and Policy Assessment Observation (EPAO) tool. The tool was adapted to include only nutrition items from the original EPAO tool relevant to ECEC services where foods are brought from home (ie, items related to services that provide food were omitted). Additional items were added related to staff monitoring of lunch boxes for discretionary foods, staff actions taken as a result of discretionary foods in lunch boxes, and the presence of specific lunch box guidelines at the service [49].

Process Evaluation

Intervention fidelity was captured via app analytics and through a service manager, self-completed written record. App analytics were used to access data on app downloads and the *SWAP IT* program use. Parent and service measures of acceptability and feasibility of the *SWAP IT* program were undertaken using a web-based survey and service manager pen and paper survey. Acceptability and feasibility questions were modified versions of items taken from the Acceptability of Intervention Measure and the Feasibility of Intervention Measure [50]. Questions to determine if any cointerventions occurred during the trial and capture any adverse events as a result of the intervention were included in the service manager pen and paper survey. Further details of the process data collection methods and items used within the surveys are provided in [Multimedia Appendix 4](#) [50].

Statistical Analysis

A statistician independent of the study performed all analyses using SAS (version 9.4) statistical software. Descriptive statistics were generated for service, parent, and child characteristics. The Australian Statistical Geography Standard Remoteness Structure [51] was used to classify parent residences as a major city, inner regional city, or outer city location. This classification was included as health disparities, including nutrition-related risk factors, exist between major city and inner regional cities (characterized by shorter distances by road to access services) and outer city locations (characterized by longer distances by road to services) [52].

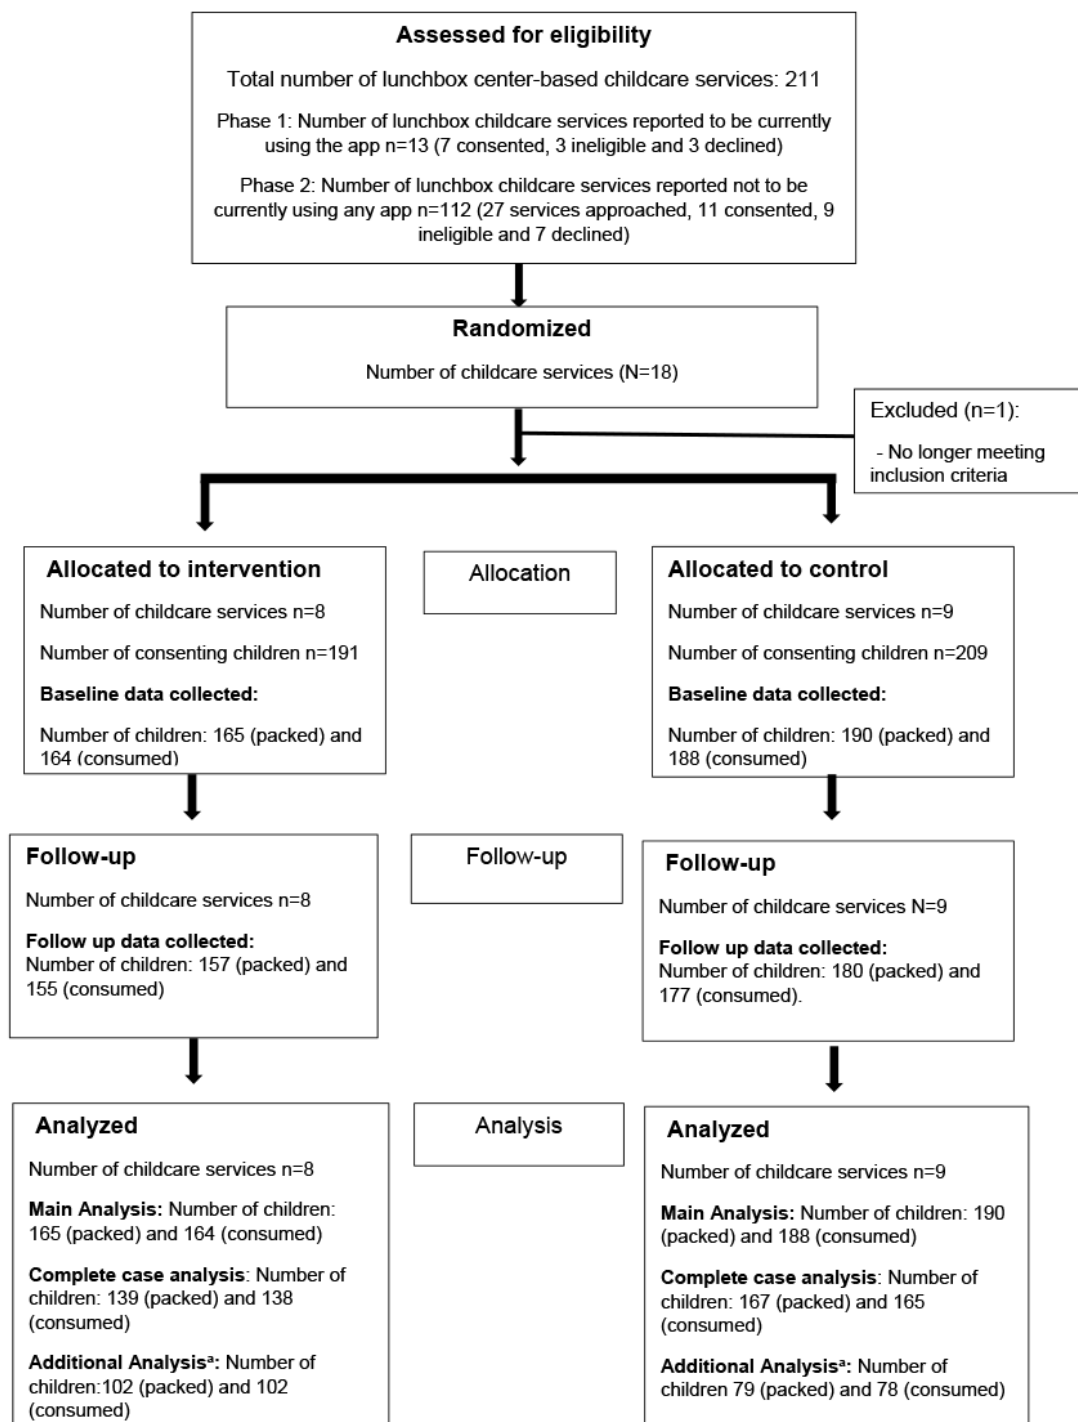

A measure of between-group differences in primary and secondary outcomes was assessed for paired data using 2-level

hierarchical linear regression models. Models were adjusted for potential ECEC service level clustering through a service random effect and controlled for baseline service EPAO score and if ECEC services were existing app users before the trial. An intention-to-treat analysis was undertaken [53], with multiple imputations undertaken for primary and secondary outcomes using the SAS MI and MIANALYZE procedure. Complete case analysis and prespecified subgroup analyses by child gender and SES were undertaken by adding a group by subgroup interaction fixed effect. SES was determined by parent postcodes and classified as being in the top or bottom 50% of NSW according to the Socioeconomic Indexes for Areas [54]. A sensitivity outcome analysis, modeled similarly to the complete case analysis, was undertaken whereby the effects of the intervention were assessed in parents known to have only downloaded the app (181/400, 51%). In addition to the analysis prespecified as part of the trial protocol [32], an exploratory analysis was performed to explore any association between how often the service routinely used the app (mean hours per week) and the parent viewing rate of within-app messages using Spearman rank order correlation.

Results

Sample

The combined consent rate of ECEC services was 45% (18/40; 40 services approached to reach the required 18 services). A service in the intervention arm ceased using the required app and withdrew from the study (before baseline data but after random allocation). Within the 17 consenting ECEC services, 400 parent-child dyads consented to participate in the baseline data collection. The mean parent consent rate was 51%. Data on packed lunch box contents were collected for 88.8% (355/400) of the children at baseline and for 84.3% (337/400) after the intervention. Consumption data were collected for 88% (352/400) of children at baseline and for 84.3% (337/400) after the intervention ([Figure 1](#)). The number of parents from the intervention group completing the web-based survey after the intervention was 21.6% (41/190). Parents who completed the survey were less likely to have a Technical and Further Education certificate or diploma ($P=.04$) or be from an inner regional city. ($P=.04$). Postintervention service pen and paper surveys were completed by all intervention ECEC services.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram. ECEC: early childhood education and care.

^aAnalysis including only parents known to have downloaded the app required to receive the intervention

Parent and Service Characteristics

Baseline characteristics of ECEC services, parents, and children with lunch box data at baseline are reported in Table 1. Characteristics were similar across groups; however, the intervention group had a higher proportion of parents located in the outer regional areas than the control group. As the

intervention was delivered at the cluster level rather than at the individual level, geographical remoteness was accounted for by stratifying services by this factor during randomization and not controlled for as part of the analysis. Before the intervention, 12% (2/17) of ECEC services in the intervention group were existing users of the app, and 35% (6/17) of ECEC services had not been using any app.

Packing and Consumption of Foods From Lunch Boxes

The results for the primary outcomes after multiple imputation and for complete case analysis are presented in [Table 2](#). There was no significant difference between groups for the primary outcomes (kilojoules from discretionary foods and kilojoules from saturated fat, free sugars, and grams of sodium from all foods) packed or consumed. In addition, there was no difference in secondary outcomes, including packed or consumed serves

of any core food groups or discretionary food serves between groups ([Table 3](#)). Data regarding the nutrients and food groups consumed are presented in [Multimedia Appendix 5](#). The sensitivity analysis, which included only those parents known to have downloaded the app (181/355, 51%), also did not detect any statistically significant differences ([Multimedia Appendix 6](#)). The subgroup analysis by gender and SES demonstrated no significant differences between groups ([Multimedia Appendix 7](#)).

^hDairy and alternatives: examples of 1 serve=1 cup milk, 2 slices of hard cheese (40 g), and three-fourth cup yogurt [6].

Process Evaluation

Intervention Fidelity

All (11/11, 100%) of the push notifications messages were delivered via the app to intervention ECEC services as planned. A message video link failed at week 9 and was resent as part of an unplanned additional message in week 11. All service managers reported sending the preintervention and midway planned support messages to parents (7/7, 100%; missing data 1/7, 14%).

App Downloads and SWAP IT Program Use

All ECEC services had access to the app, and it was available for all parents to download. The percentage of intervention families with data at baseline (as included in the multiple imputation analysis) and known to have the intervention app was 61.8% (102/165; missing data on app ownership 15/165, 9.1%).

Data on the number of unique within-app message views are presented in [Multimedia Appendix 4](#) [50]. As app analytics only provided deidentified data, data specific to parents in the trial could not be separated from data on all users of the app at the intervention ECEC services. The number of unique within-app message views decreased over time, with a mean of 139 (SD 42.7) views per message and a mean viewing rate of 26% (SD 14.9%).

SWAP IT Program Acceptability

Data on the acceptability of the SWAP IT program by service managers and parents are reported in [Multimedia Appendix 4](#) [50]. Parents who completed the survey reported that they liked the SWAP IT program (34/41, 83%) and found the program useful (33/41, 80%) and easy to use (36/41, 87%). Only 57% (4/7) of ECEC services rated the overall program as useful; however, most agreed that the resources within the program were helpful for families (6/7, 86%). Both ECEC services (8/8, 100%) and families that completed the survey (41/41, 100%) agreed or had no feelings either way regarding the timing and frequency of the push notification measures.

Feasibility of Ongoing Use of the App

Most ECEC services and parents who completed the survey agreed that it was appropriate to deliver lunch box information via the app (6/8, 75% and 40/50, 80%, respectively). During the intervention, most intervention ECEC services reported using the app for functions other than the delivery of the program (6/7, 86%; eg, for distribution of parent newsletters). Self-reported use of the app ranged from 0 to 2 hours per week. Only 57% (4/7) of ECEC services indicated that they planned to continue to use the app, with 29% (2/7) of ECEC services indicating they were unsure and 14% (1/7) of services reporting that they did not plan to continue with the app after the end of the SWAP IT program.

Cointervention and Adverse Events

The service reported changes in the frequency of parent complaints or concerns regarding healthy lunch box policy did not differ between the groups. No contamination was reported; that is, the app was not used to send any other health or nutrition

information. No ECEC services in the intervention or control groups reported exposure to additional nutrition interventions throughout the duration of the trial.

Outcomes From the Study Protocol Not Reported

Owing to the null findings, neither a cost-effectiveness analysis, as specified in the study protocol, nor the planned analysis of data collected on the usual daily dietary intake of children (to be able to detect any compensatory dietary behaviors) was conducted.

Association Between ECEC Service Hours of Routine Use of the App and Parent Viewing Rate

The exploratory analysis found an association between the number of routine hours of use of the app by ECEC services and the parent viewing rate of within-app messages; however, this association was not significant ($P=.21$; data not provided).

Discussion

Principal Findings

To our knowledge, the SWAP IT *Childcare* trial is the first trial to evaluate the efficacy of an mHealth intervention to improve lunch box contents in ECEC settings internationally. However, contrary to our hypothesis, the intervention had no impact on the primary outcome of the number of kilojoule from discretionary foods packed in children's lunch boxes. In addition, process evaluation found low parent app downloads and message viewing rates.

When looking to compare the findings of the trial with other published studies, we were unable to identify any other healthy eating-focused mHealth interventions or DHIs targeting parents and children through ECEC settings. Therefore, we have primarily compared the findings with those of the original SWAP IT trial publications conducted in the primary school setting [39].

Although the results of our parent survey data indicated that delivery of a lunch box program via the app was considered appropriate, the mean viewing rate of the within-app message was only 26% (SD 14.9). Furthermore, only 61.8% (102/165) of parents in the intervention group were known to have downloaded the app, leaving 38.2% (63/165) of parents unexposed to program content. Such process data are in contrast to findings reported in a SWAP IT pilot study undertaken in a primary (elementary) school setting [39]. The intervention in the SWAP IT pilot study was similar to this study, including push notifications and within-app message content; however, it also included the distribution of resources to parents, policy, and classroom resources [39]. The pilot study reported higher parent app downloads (89%) and message views (between 35% and 120% over the 10-week intervention) and was able to demonstrate a reduction in the packing of kilojoules from discretionary foods (-221 kJ; $P=.08$, nonsignificant) [39].

Contextual differences between the ECEC and school settings in the study region may potentially explain the differences in the findings between these trials. In the school trial, all schools were existing users of the app used to deliver the SWAP IT program compared with just 2 ECEC services in the intervention

arm of this trial. In addition, most parents were existing users of the app (355/400, 88.8%) [39]. Greater integration and preprogram use of the app may have meant that parents in the school trial were more likely to be routinely accessing the app to receive information and, in doing so, were more likely to access the *SWAP IT* program content. This premise is supported by our exploratory analysis, which found a positive nonsignificant association between how much time the ECEC services used the app for general communication with parents and the *SWAP IT* parent message viewing rate. In addition, it is possible that the inclusion of supportive ECEC service-based strategies targeting nutrition curriculum and policy, similar to that undertaken to the trial in schools, may have been useful in increasing the impact of the intervention.

Our ability to detect an effect on discretionary food packing may have also been limited by the lower than anticipated baseline packing of discretionary foods in the participating ECEC services [48]. The trial baseline data found ECEC child lunch boxes contained only a mean of 1.33 (SD 1.16) serves of discretionary foods [48]. This was considerably lower than the mean of 2.5 serves per lunch box reported in schools in the same region [55]. Although the serves of discretionary foods packed in the ECEC services exceeded recommended serves per day for our age group (ie, 0-0.5 serves) [6], the lower number of serves packed at baseline possibly limited scope for further improvement without a more intensive intervention approach. In contrast, a large scope for improving vegetable packing and consumption in children attending ECEC services was evident from the trial baseline data (only 0.3 mean vegetable serves packed and 0.1 serves consumed) [48]. As such, future iterations of the intervention would benefit from the inclusion of specific strategies to improve vegetable packing and intake, along with continued efforts to minimize discretionary foods.

The intervention's lack of impact on parent packing of discretionary foods may have also been because of the decline in the rate of program message opening over the course of the trial. The pattern of the continued drop-off in use observed in our study is similar to those reported in many mHealth and DHI interventions [39,56-59]. The drop-off in engagement occurred in the trial despite the inclusion of several features explicitly designed to enhance engagement (user consultation, use of behavior change techniques, reminders, and information being provided from a credible source) [60,61] and the addition of a specific intervention strategy to prompt ongoing use (service manager delivered support messages). Additional factors found to be associated with sustained DHI use in the literature include

perceived ongoing relevance, novelty value, tailoring, and self-monitoring [60,62]. Further qualitative exploration of parents' reasons for low engagement and consideration of additional evidence-based features that could be added to the program to enhance engagement would be beneficial.

Strengths and Limitations

The strengths of this study include explicit mapping of behavior change theory to design the intervention, use of objective gold standard measures to assess lunch box contents, high follow-up rate, comprehensive process measures, and randomized trial design. A key limitation of the trial is that the app analytics could only capture use data at the service level, meaning that the true proportion of parents who accessed the messages is unknown (as message views may have been from parents from the service but not participating in the evaluation component of the trial). This limited our ability to conclusively determine whether the null findings were generally more likely to be a result of poor access, the program content itself, or a combination. This limitation extends to our additional analysis of only those parents who were known to have downloaded the app. Finally, given the low survey response rate (41/190, 21.6%) and differences in characteristics in survey completers compared with the overall parent sample, our acceptability survey data may have been influenced by response bias. The generalizability of the findings to ECEC services outside of the study region may be limited.

Conclusions

The intervention failed to decrease energy from discretionary foods in children's lunch boxes. However, the use of apps was rated as an appropriate modality for delivering information related to the packing of healthier foods in lunch boxes. Process data suggest that the lack of impact may have been because of factors associated with the implementation of the intervention, such as the low parent uptake and use of the app, as well as the lower than expected levels of packing of discretionary foods at baseline. Given these limitations, the current feasibility of using mHealth interventions to target parent packing of healthier foods in lunch boxes is still uncertain. Future trials should invest time in collecting formative data on how ECEC services and parents currently use and engage with different digital platforms to best identify the ideal technology to deliver parent-focused nutrition interventions in this setting. In addition, given drop-offs in use over time, exploration of parent reasons behind poor ongoing use will also assist in enhancing program design and content to improve engagement.

Acknowledgments

The authors would like to acknowledge the staff involved in collecting the data and data entry, including Jayde Kerr, Monique Santarelli, and consulting statistician Christophe Lecathelinais. The authors would also like to extend their appreciation to the app provider Skoolbag and participating early childhood education and care services.

Abstract

Background: Suboptimal understanding of depression and mental health disorders by the general population is an important contributor to the wide treatment gap in depression. Mental health literacy encompasses knowledge and beliefs about mental disorders and supports their recognition, management, and prevention. Besides knowledge improvement, psychoeducational interventions reduce symptoms of depression, enhance help-seeking behavior, and decrease stigma. Mental health apps often offer educational content, but the trustworthiness of the included information is unclear.

Objective: The aim of this study is to systematically evaluate adherence to clinical guidelines on depression of the information offered by mental health apps available in major commercial app stores.

Methods: A systematic assessment of the educational content regarding depression in the apps available in the Apple App Store and Google Play was conducted in July 2020. A systematic search for apps published or updated since January 2019 was performed using 42matters. Apps meeting the inclusion criteria were downloaded and assessed using two smartphones: an iPhone 7 (iOS version 14.0.1) and a Sony XPERIA XZs (Android version 8.0.0). The 156-question assessment checklist comprised general characteristics of apps, appraisal of 38 educational topics and their adherence to evidence-based clinical guidelines, as well as technical aspects and quality assurance. The results were tabulated and reported as a narrative review, using descriptive statistics.

Results: The app search retrieved 2218 apps, of which 58 were included in the analysis (Android apps: n=29, 50%; iOS apps: n=29, 50%). Of the 58 included apps, 37 (64%) apps offered educational content within a more comprehensive depression or mental health management app. Moreover, 21% (12/58) of apps provided non-evidence-based information. Furthermore, 88% (51/58) of apps included up to 20 of the educational topics, the common ones being listing the symptoms of depression (52/58, 90%) and available treatments (48/58, 83%), particularly psychotherapy. Depression-associated stigma was mentioned by 38% (22/58) of the apps, whereas suicide risk was mentioned by 71% (41/58), generally as an item in a list of symptoms. Of the 58 included apps, 44 (76%) highlighted the importance of help seeking, 29 (50%) emphasized the importance of involving the user's support network. In addition, 52% (30/58) of apps referenced their content, and 17% (10/58) included advertisements.

Conclusions: Information in mental health and depression apps is often brief and incomplete, with 1 in 5 apps providing non-evidence-based information. Given the unmet needs and stigma associated with the disease, it is imperative that apps seize

the opportunity to offer quality, evidence-based education or point the users to relevant resources. A multistakeholder consensus on a more stringent development and publication process for mental health apps is essential.

KEYWORDS

health literacy; mental health literacy; depression; mobile apps; apps; telemedicine; mHealth; self-management; mobile phone

Introduction

Background

Depression affects >264 million people worldwide and was the third major contributor of years lost to disability in 2017 [1]. Yet, approximately 50% of the people living in high-income countries and at least 75% of the people living in low- and middle-income countries [2,3] have neither been diagnosed nor receive treatment. Untreated depression is associated with increased morbidity and mortality, including death by suicide, poverty and unemployment at an individual level, and significant increase in health expenditure at health system level because of increased health care use and decreased workforce productivity of the affected individuals [3,4]. Although the reasons for this wide treatment gap are multifarious, suboptimal understanding of depression and mental health disorders in the general population is considered an important contributor to low use of mental health services. Studies assessing the general population's mental health literacy through the use of standardized clinical vignettes have shown poor recognition of common mental health disorders [5-7].

Mental Health Literacy

Mental health literacy is defined as “the knowledge and beliefs about mental disorders, which aid their recognition, management or prevention” [8]. It encompasses the acquisition of factual knowledge of mental health disorders as well as development of competencies and beliefs enabling prevention, early recognition of symptoms, help seeking, self-help, and provision of first aid to others [5]. Evidence-based clinical guidelines for management of depression indicate that psychoeducation is pivotal in terms of disease management [9-12] and necessary to expand the shared-decision model of care in mental health services [13].

Educational Topics

Educational topics focused on depression may include information related to its natural history, symptoms and signs, treatment options such as pharmacotherapy and a range of nonpharmacological treatments and possible side effects, as well as information related to prognosis and effective self-management interventions [9]. Psychoeducational interventions have been shown to increase mental health literacy and, most importantly, to yield small but significant reductions in symptoms of depression and mental distress [14,15], hence offering simple, inexpensive, and readily available tools for symptom management [14].

There are other notable benefits of psychoeducation, particularly stigma reduction [16-18] and increased help-seeking behavior [6,19-21]. Mental health stigma remains a significant barrier to

the use of mental health services because it affects the access and quality of health care provision for people living with mental health disorders and depression [22,23]. Social stigma or public stigma are linked to discrimination, avoidance, and inadequate treatment [24], whereas self-stigma or internalized stigma may erode self-esteem and self-efficacy or lead to anger or indifference [24], which may in turn hamper help seeking [25]. Although multilevel coordinated and sustained efforts are needed to mitigate the prevailing mental health stigma, simple interventions such as the use of personal narratives have shown promise in fostering depression awareness [26,27] and more positive attitudes among the public [26,28,29].

Mental Health Apps

Since the early 2000s, the search for health information has shifted increasingly to the web [30], and this trend has further intensified with the advent of smartphones [31] and mobile apps. A recent systematic review on the provision of medical education using smartphones reported that approximately two-thirds of the reviewed interventions were effective in improving patients' knowledge and clinical outcomes [32]. The Apple App Store and Google Play, which are the major sources of apps worldwide [33], currently include >10,000 mental health apps [34] that offer a wide range of functionalities comprising education, screening, and self-management programs for a wide range of disorders [35,36]. However, most of the published apps have not been assessed in clinical trials and are not evidence based [34,37].

Given the increasing popularity of health apps, a number of studies evaluating direct-to-consumer apps have been published in recent years, including the general characteristics of the apps [38], key features and functionalities of highly downloaded [39] or highly rated apps [40], techniques commonly used in face-to-face psychotherapy [41], or adherence of self-guided app interventions to evidence-based clinical guidelines [42]. These studies include a variety of assessment methodologies, from researcher-developed checklists [38,41,42] used in specific projects to the use of standardized assessment tools such as the Mobile App Rating Scale [36,43] or the Organization for the Review of Care and Health Applications–24 Question Assessment [44], focusing on the usability and technical aspects of the apps. In contrast, the health-related content of apps is seldom included in assessment checklists.

Existing mental health apps often include educational components, either as its sole functionality or within a depression or mental health management app. The trustworthiness, adherence to evidence, and depth of information offered by these apps is unclear because, to date, no reviews offering an in-depth assessment of the content of education on

depression modules provided by mental health apps has been published.

Therefore, this study aims to systematically evaluate the adherence to evidence-based clinical guidelines of the information on depression provided by mental health and depression apps available in the Apple App Store and Google Play.

Methods

We followed a rigorous assessment process, developed at our center and used in previous app assessment projects [45-48], by adapting systematic review methodology for the app search, selection, assessment, and data analysis.

Development of the Assessment Criteria

The research team designed the assessment criteria to evaluate the clinical and technical features of apps. The criteria included the following three domains:

1. *General attributes*, as described in the app store description, including developer, category, ratings, education-delivery format, target group, country of origin, and cost.
2. *Appraisal of depression education modules*, comprising the scope of information provided by the app and its adherence to evidence-based clinical guidelines from the Royal Australian and New Zealand College of Psychiatrists [11], Singapore's Ministry of Health [49], the United Kingdom's National Institute for Health and Care Excellence [50], and the American Psychiatric Association [9], as well as concordance with expert opinions on content of mental health awareness public campaigns [51,52]. The criteria included 46 questions encompassing 38 educational topics on symptoms and diagnostic criteria of depression, natural

history, importance of help seeking, treatment (including pharmacological and nonpharmacological treatments, side effects of medication, and importance of treatment adherence), stigma, recovery, and suicide prevention information and resources. [Multimedia Appendix 1](#) [9,11,49,50,53] presents the educational content appraisal questionnaire.

3. *Technical aspects and quality assurance of the app*, including usability, app credibility, in-app advertisements, privacy and security safeguards, and gamification.

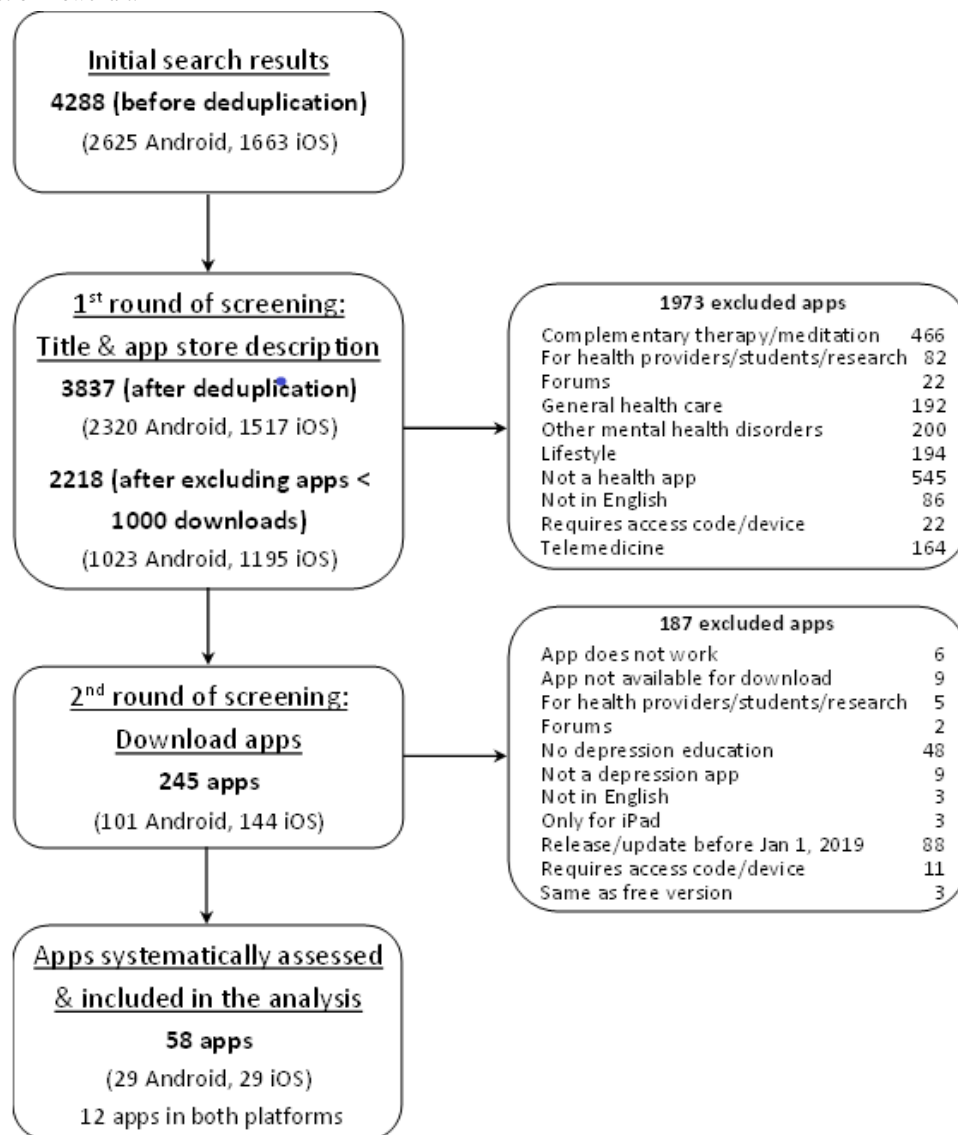

Selection of Apps

The Apple App Store and Google Play were systematically searched using 42matters, a proprietary app database [54], on July 8, 2020, using the terms *depression*, *depressive*, *depressed*, *mood disorder*, *sadness*, and *melancholia*. The search was limited to four app store categories: education, health and fitness, lifestyle, and medical. Eligible apps were required to conform to the criteria presented in [Textbox 1](#).

The app selection process is presented as a flowchart ([Figure 1](#)) [55]. Before screening for eligibility, we excluded all Android apps with <1000 downloads as reported in the 42matters search output. As iOS does not report the number of app downloads, the iOS versions of the excluded Android apps were also excluded on the assumption that the app would have a similar number of downloads in both app stores. The remaining apps underwent a 2-step selection process that consisted of (1) screening the app name and app store description from the 42 matters search output and (2) downloading and screening for eligibility all apps included in step 1. Working in parallel, 2 pairs of investigators (LM and Goh Jun Wei; LM and Matthew Teo Siu Yan) independently completed the app selection process. Disagreements were resolved through discussion.

Textbox 1. Inclusion and exclusion criteria for smartphone app selection.

<p>Inclusion criteria</p> <ul style="list-style-type: none"> • Provides information about depression, including clinical presentation, diagnosis, and management (both pharmacological and nonpharmacological) • Targets depression or includes depression information within a general mental health app • Uploaded or updated from January 1, 2019, onward • Downloaded at least 1000 times • Available for free or requires payment to download, use, or expand functionalities (in-app purchases) and is available for download in the Apple App Store or Google Play • Available in English <p>Exclusion criteria</p> <ul style="list-style-type: none"> • Presents an overview of common physical and mental disorders, using a glossary format • Targets health care providers (eg, physicians, psychologists, and counselors) or the support network of a person with depression or consists exclusively of peer-support forums • Offers teleconsultation services with physicians, psychologists, counselors, or other health care providers • Consists of a stand-alone depression screening questionnaire, without education modules • Offers complementary medicine, meditation, or lifestyle improvement • Does not provide any depression-related information or includes non-health-related content (ie, music playlists, wallpapers, and so on) • Requires an access code to log in, or could not be used after 2 log in attempts because of technical problems, or was withdrawn from the app store at the time of access

Figure 1. App selection flowchart.

App Assessment and Data Analysis

Apps were assessed by 2 assessors working in parallel using an iPhone 7 (iOS version 14.0.1) and a Sony XPERIA XZs (Android version 8.0.0) smartphone. If apps were available on both platforms, as per the 42matters search output, we assessed both versions and counted each version as an individual app. We used descriptive statistics to analyze the data. We compiled and tabulated the results and reported them as a narrative synthesis.

Subgroup Analysis of Android Apps

We performed a subgroup analysis of Android apps to assess whether the number of app downloads was associated with the educational content or the quality or number of features offered by the apps. Apps were categorized into two groups: apps downloaded 1000-10,000 times and apps downloaded >10,000 times. The assessment included selected items from all 3 sections of the assessment. The data were tabulated and compared using a significance test for categorical variables: the chi-square test was used if each category contained >10 variables and a 2-tailed Fisher exact test was used if any of the categories

in the contingency table contained <10 variables. Statistical significance was set at $P < .05$. Statistical analyses were performed in RStudio (R version 4.0.3). iOS apps were not included in this analysis because the Apple App Store does not include this information.

Results

The app search retrieved 2218 results after removing duplicates and excluding apps with <1000 downloads, of which 245 were downloaded and 58 were included in the analysis. [Figure 1](#) describes the app selection process.

General Characteristics of Apps

[Table 1](#) presents a summary of the characteristics of the included apps. Of the 58 apps included in this analysis, 29 (50%) were Android apps and 29 (50%) were iOS apps; 21% (12/58) of the apps were available on both platforms, and 60% (35/58) of the apps belonged to the health and fitness app store category. Of the 29 Android apps, 3 (10%) had been downloaded >1 million times [56-58]. Of the 58 included apps, 15 (26%) offered only education and information modules, whereas 37 (64%) offered

education modules along with other mental health or depression management features. A simple interface that did not allow for user feedback or customization was offered by 41% (12/29) of

the Android apps and 31% (9/29) of the iOS apps. More than 10% of the apps offered education modules targeted to specific user groups.

Table 1. General characteristics of apps (N=58).

Feature	Android (n=29), n (%)	iOS (n=29), n (%)	Total (N=58), n (%)

Depression Education Modules

Overview

[Multimedia Appendix 2](#) presents a detailed description of the educational content in included apps. The apps offered a variety of information or educational topics, as summarized in [Table 2](#). Most of the apps (51/58, 88%) included up to 20 educational

topics. One in five apps provided non-evidence-based information, mostly in the form of personal opinions of the developers or columnists. Most of the apps informed users about the symptoms of depression and listed available treatments. Personal narratives on depression [51] were included only in approximately 20% of the apps.

Table 2. Depression education topics included in the apps (N=58).

Education topics included in the app	Android (n=29), n (%)	iOS (n=29), n (%)	Total (N=58), n (%)
General information on depression			
Personal narratives of depression	6 (21)	6 (21)	12 (21)
Depression is different from sadness	20 (69)	19 (66)	39 (67)
Demographic and epidemiological facts	15 (52)	18 (62)	33 (57)
Natural history of the disease	6 (21)	12 (41)	18 (31)
Lists symptoms of depression	26 (90)	26 (90)	52 (90)
Explains what recurrence and relapse are	9 (31)	5 (17)	14 (24)
Addresses stigma linked to depression	11 (38)	11 (38)	22 (38)
Mentions suicide risk linked to depression	23 (79)	20 (69)	43 (74)
Screening for depression			
Describes diagnostic criteria of depression	7 (24)	6 (21)	13 (22)
Provides reference to DSM-5 ^a or ICD-10 ^b	3 (10)	3 (10)	6 (10)
Administers a screening questionnaire

Symptoms and Natural History of Depression

Of the 58 included apps, 52 (90%) listed the symptoms of depression, whereas 39 (67%) stated the difference between depression and occasional low moods or sadness. Brief information on the epidemiology of depression was included in half of the assessed apps. Stigma associated with depression was mentioned by 38% (22/58) of the apps, whereas only 10% (6/58) included information on recovery.

Suicide risk associated with depression was mentioned by 74% (43/58) of the apps, generally as an item in a list of symptoms. Suicide prevention resources were offered by 60% (35/58) of the apps, including 55% (16/29) of the Android apps and 66% (19/29) of the iOS apps. The most common resource offered by the apps was information on crisis helplines (telephone numbers or website addresses).

Screening for Depression

Of the 58 included apps, 13 (22%) offered information on the diagnostic criteria for depression, 6 (10%) referenced psychiatric diagnostic manuals, and 10 (17%) explained the need to confirm diagnosis of depression after a positive screening test. Of the 58 apps, 27 (47%) apps administered a screening questionnaire for depression, commonly the Patient Health Questionnaire-9 [59]. Only 48% (13/27) of the apps responded to positive screening test scores by either offering self-management exercises for the user to engage with or suggesting consulting with a health care provider, commonly a physician, whereas the rest of the apps did not provide any feedback.

Treatment of Depression

Of the 58 included apps, 44 (76%) highlighted the importance of seeking help when affected by depression and consulting specialized providers if the symptoms were severe or persistent. Half of the Android apps and one-third of the iOS apps also emphasized the importance of involving members of the user's support network. Few apps included providers' contact information, and when such information was present, it was limited to contact information of the app development team; none of the apps included geolocated lists of health care providers by; for example, facilitating a search through navigation providers such as Google Maps.

More than 90% of the apps listed existing treatments for depression, without providing a description of what each category entailed. Psychotherapy was the most commonly mentioned treatment category (44/58, 76%), followed by medications (37/58, 64%), whereas 12% (7/58) of the apps included brain stimulation treatments as well. Nevertheless, few apps offered more comprehensive information on the different

treatment modalities, including explanations of what each treatment involves and relevant examples (eg, types of psychotherapy and antidepressant groups). Information on psychotherapy modalities was offered by 34% (10/29) of the Android apps and 52% (15/29) of the iOS apps, whereas few Android or iOS apps offered information on medication types (8/58, 14%), side effects (13/58, 22%), nonaddictive nature of frequently used antidepressants (5/58, 9%), or gradual initiation and discontinuation of therapy (10/58, 17%).

Benefits of lifestyle modifications, including regular exercise, was mentioned by 67% (39/58) of the assessed apps, whereas complementary medicine, including St John's wort, light therapy, and acupuncture, was mentioned by 7% (4/58) of the apps.

Technical Aspects and Quality Assurance of the App

All assessed apps worked as intended and were generally easy to use. Data entry from users was not requested by 31% (9/29) of the iOS apps and 41% (12/29) of the Android apps (Table 3).

Of the 58 included apps, 13 (22%) available on both platforms did not include a privacy policy (6/29, 21%, Android apps and 7/29, 24%, iOS apps). These apps offered passive information that did not require data entry by users, except for 3% (1/29) of the Android apps and 7% (2/29) of the iOS apps, which requested the user's email address to set up a password.

Of the 58 apps, 30 (52%) included references or the author's signature or shared links to reputable websites for the information provided. Half of the Android apps and a quarter of the iOS apps did not declare developers' affiliations, and 41% (24/58) of the apps included a disclaimer that the information provided did not replace a health care provider's advice.

Of the 58 apps, 10 (17%) contained advertisements. These apps were free to download and use, except for an Android app that offered in-app purchases. The advertisements included in 75% (6/8) of the Android apps filled the screen and disrupted the use of the app, whereas 25% (2/8) of the apps included banner advertisements that allowed users to continue using the app. All advertisements were generally unrelated to the app content, promoting other Google Play apps, video games, beauty products, education support centers, and health care services such as dental services. Of these 8 Android apps, 1 (13%) promoted psychological services. In contrast, 100% (2/2) of the iOS apps offered banner advertisements that allowed for continued use of the app. The advertisements were not related to the app content.

Table 3. Technical features and quality assurance of included apps (N=58).

Characteristics	Android (n=29), n (%)	iOS (n=29), n (%)	Total (N=58), n (%)

Subgroup Analysis of Android Apps

Our subgroup analysis assessing the association between the Android apps' popularity (as indexed by the number of app downloads) and the breadth and depth of the educational topics covered showed no statistically significant difference between apps downloaded <10,000 times and apps downloaded >10,000 times. Nonetheless, apps downloaded 1000-10,000 times

provided non-evidence-based information more often than apps downloaded >10,000 times (7/15, 47% vs 3/14, 21%, respectively); however, this difference was not statistically significant. Of the 7 apps providing non-evidence-based information and downloaded <10,000 times, 2 (29%) belonged to the medical category in the app store. Of these 2 apps, 1 (50%) claimed that adhering to the *Law of Attraction* improve depression outcomes. [Table 4](#) summarizes the analysis.

Table 4. Android apps subgroup analysis according to number of downloads (N=29).

Discussion

Principal Findings

To our knowledge, this is the first systematic assessment of the information on depression in existing mental health and depression apps. Our findings suggest that the information included in these apps is often limited and not aligned with evidence. Most of the assessed apps offered brief, factual information on symptoms and treatment options, with only a few apps addressing all aspects of disease presentation and management or including information on recovery or providing personal narratives of people living with depression. The inclusion of personal accounts of people living with, and recovering from, a mental health disorder has been associated with increased understanding of the mental health disorder and recovery process, validation of the personal experience, and reduction of stigma [28,60].

Patient education is one of the pillars of effective depression management resulting in better treatment compliance and improved outcomes [9,11], particularly if they are complemented

with personal narratives and positive messages emphasizing recovery [51]. Adequate health literacy is associated with tolerance and acceptance of people living with a mental disorder [16], increased help-seeking behavior [16], and adherence to treatment [61,62], and it is a prerequisite to engage in shared-decision models of care [63]. Yet, 25% of the potentially eligible apps, including some of the most popular mental health apps with >1 million downloads each, were excluded in the second round of screening because they did not provide any information on depression.

Access to mental health care is often inadequate, particularly in low- and middle-income countries [3] and among people of lower socioeconomic status as well as those living in remote areas in high-income countries [64,65].

Mental health apps may play an important role in improving access to mental health care, supported by an increasing expansion of mobile network coverage to remote areas worldwide [31]. However, our assessment shows that apps currently available in public app marketplaces do not offer a holistic, evidence-based self-management program to meet these

health needs. For example, less than half of the assessed apps include a screening test for depression and only a subset of these apps offer follow-up recommendations to users potentially living with depression. Of the 58 assessed apps, 12 (21%) offered non-evidence-based information, including developers' or columnists' personal views on depression, and suggested scientifically unproved treatments. Of these 12 apps, 2 (17%) were classified as *medical* in the app store. Lack of evidence-based information in health apps is a recurrent theme in most systematic assessments performed by our group [45,46,48] and others [42,66,67], revealing that current app development and publication processes overseen by app stores might not be suitable for health apps. We previously highlighted the lack of governance and quality assurance of the health app industry [48], which we believe constrains the further development of health apps as genuine tools to support access to mental health care. Therefore, it is imperative to develop a multifaceted approach involving the research community, commercial app developers, app store managers, and official regulatory bodies to define development and publication regulatory frameworks for health apps.

Our subgroup assessment of Android apps suggests an association between the number of downloads and the overall quality of the apps. In the analysis, apps downloaded >10,000 times were more trustworthy, included more evidence-based content, presented better compliance with data privacy and security, presented references to endorse claims, and incorporated health care providers into the app development team more often than apps downloaded <10,000 times. Excluding app credibility, the differences were not statistically significant, probably because of the small size of the sample.

In this study, we used an established systematic assessment approach, which is based on the rigorous systematic review and

which we have applied to various health domains [46-48] over the years. This methodology included the use of a commercial database to search for eligible apps, which provides a wider geographical scope for the search, and the development of exhaustive assessment criteria using renowned evidence-based clinical guidelines and our center's criteria for technical and quality assurance of apps.

There are limitations to our research as well. The search strategy included depression-related terms and omitted education-based terminology; thus, we may have omitted some relevant apps. However, the inclusion of such terms would have greatly increased the overall number of retrieved apps and would have also led to retrieval of many irrelevant apps because the database used for app retrieval does not allow the use of search strings; instead, it retrieves individual results for each search term. We restricted our search to apps for mental health, excluding apps offering medical or general health advice that may have presented summaries on depression presentation or management. Our assessment was limited to apps downloaded at least 1000 times, which may have omitted newly launched apps that have yet to reach the minimum required number of downloads. We also restricted our search to apps in English, potentially excluding relevant apps in languages other than English.

Conclusions

Information in mental health and depression apps is often brief and incomplete, with 1 in 5 apps providing non-evidence-based information. Given the unmet needs and stigma associated with depression, it is imperative that apps seize the opportunity to offer quality, evidence-based education and point users to relevant resources. A multistakeholder consensus on a more stringent development and publication process for mental health apps is essential.

Acknowledgments

The authors wish to thank Mr Matthew Teo Siu Yan and Mr Goh Jun Wei for their assistance in screening and assessing the apps. LM gratefully acknowledges Nanyang Technological University Research Scholarship (LKCmedicine) support for her PhD studentship which enabled this work. JL is supported by the Ministry of Health National Medical Research Council Clinician Scientist Award (MOH-000013). JC's post at Imperial College London is supported by the National Institute for Health Research Northwest London Applied Research Collaboration. JC is supported by the National Research Foundation, Prime Minister's Office, Singapore, under its Campus for Research Excellence and Technological Enterprise program.

Authors' Contributions

LM had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. LM, KG, and JC provided the concept and design of the study. LM acquired, analyzed, and interpreted the data; performed statistical analysis; and provided administrative, technical and material support. The manuscript was drafted by LM and ACS. All authors contributed for critical revision of the manuscript for important intellectual content. JC obtained the funding. KG and JC were responsible for supervision.

Conflicts of Interest

JL has received honoraria from Otsuka and Janssen. There are no other conflicts of interests.

Abstract

Background: Sleep disturbance symptoms are common in major depressive disorder (MDD) and have been found to hamper the treatment effect of conventional face-to-face psychological treatments such as cognitive behavioral therapy. To increase the dissemination of evidence-based treatment, blended cognitive behavioral therapy (bCBT) consisting of web-based and face-to-face treatment is on the rise for patients with MDD. To date, no study has examined whether sleep disturbance symptoms have an impact on bCBT treatment outcomes and whether it affects bCBT and treatment-as-usual (TAU) equally.

Objective: The objectives of this study are to investigate whether baseline sleep disturbance symptoms have an impact on treatment outcomes independent of treatment modality and whether sleep disturbance symptoms impact bCBT and TAU in routine care equally.

Methods: The study was based on data from the E-COMPARED (European Comparative Effectiveness Research on Blended Depression Treatment Versus Treatment-as-Usual) study, a 2-arm, multisite, parallel randomized controlled, noninferiority trial. A total of 943 outpatients with MDD were randomized to either bCBT (476/943, 50.5%) or TAU consisting of routine clinical MDD treatment (467/943, 49.5%). The primary outcome of this study was the change in depression symptom severity at the 12-month follow-up. The secondary outcomes were the change in depression symptom severity at the 3- and 6-month follow-up and MDD diagnoses at the 12-month follow-up, assessed using the Patient Health Questionnaire-9 and Mini-International Neuropsychiatric Interview, respectively. Mixed effects models were used to examine the association of sleep disturbance symptoms with treatment outcome and treatment modality over time.

Results: Of the 943 patients recruited for the study, 558 (59.2%) completed the 12-month follow-up assessment. In the total sample, baseline sleep disturbance symptoms did not significantly affect change in depressive symptom severity at the 12-month follow-up ($\beta=.16$, 95% CI -0.04 to 0.36). However, baseline sleep disturbance symptoms were negatively associated with treatment outcome for bCBT ($\beta=.49$, 95% CI 0.22 - 0.76) but not for TAU ($\beta=-.23$, 95% CI -0.50 to 0.05) at the 12-month follow-up, even when adjusting for baseline depression symptom severity. The same result was seen for the effect of sleep disturbance symptoms on the presence of depression measured with Mini-International Neuropsychiatric Interview at the 12-month follow-up. However, for both treatment formats, baseline sleep disturbance symptoms were not associated with depression symptom severity at either the 3- ($\beta=.06$, 95% CI -0.11 to 0.23) or 6-month ($\beta=.09$, 95% CI -0.10 to 0.28) follow-up.

Conclusions: Baseline sleep disturbance symptoms may have a negative impact on long-term treatment outcomes in bCBT for MDD. This effect was not observed for TAU. These findings suggest that special attention to sleep disturbance symptoms might be warranted when MDD is treated with bCBT. Future studies should investigate the effect of implementing modules specifically targeting sleep disturbance symptoms in bCBT for MDD to improve long-term prognosis.

Introduction

Major Depressive Disorder

Major depressive disorder (MDD) is among the most prevalent and debilitating psychiatric disorders [1-3], and it has been estimated to be the third leading cause of disability worldwide [3]. The MDD burden is particularly prominent in Western societies and poses an immense burden on society [1,3,4]. Although MDD, in many cases, can be successfully treated with evidence-based psychological and pharmacological therapies [5], some patients do not respond to treatment or do not receive adequate treatment [6]. To alleviate the burden of the disorder, we need to understand the mechanisms that may impact the lack of treatment response and develop strategies for broader dissemination of evidence-based psychological treatments [5,7].

Depression and Sleep Disturbance

MDD is a heterogeneous condition with a variety of presentations and a broad constellation of associated symptoms. Sleep disturbances are core symptoms of MDD, covering mostly insomnia (difficulties in falling asleep, wakefulness after sleep onset, and/or waking up early and not being able to get back to sleep) and, to a lesser extent, hypersomnia (excessive daytime

sleepiness and/or excessive total sleep time) [8]. Although insomnia and hypersomnia are common symptoms of MDD, they may also be diagnosed as independent psychiatric disorders [9]. Insomnia and mood disorders seem to have a bidirectional relationship, with insomnia increasing the risk for MDD, although MDD also increases the risk for insomnia symptoms [8]. This complex relationship seems to be founded on both common predisposing biological factors and cognitive and behavioral elements perpetuating both disorders, such as attentional biases and conditioning of arousal and negative affect in the bedroom [10]. Several studies have examined the impact of insomnia on the effect of MDD treatment and have consistently shown that insomnia affects the response to evidence-based treatment for depression, such as cognitive behavioral therapy (CBT) [11-14]. A total of 2 studies [12,14] reported that insomnia symptoms may double the risk for nonremission following depression treatment. In another study, patients exhibiting a limited response to treatment were more likely to present with recurring insomnia and depressive episodes, whereas optimal responders were consistently lower on insomnia measures [11]. In addition, a randomized controlled trial on older patients with MDD found that patients who presented with persistent insomnia symptoms, that is, reporting

symptoms at baseline and the 3-month follow-up, were less likely to reach remission at the 6- and 12-month time points [13]. Furthermore, insomnia symptoms are among the most frequent residual symptoms following depression treatment [15-17]. Hypersomnia has not received the same attention as comorbid insomnia in MDD, perhaps because it is less common [18]. However, studies have found that persons with MDD who experience both hypersomnia and insomnia are more severely depressed compared with individuals with depression with only insomnia or no sleep disturbance symptoms [18,19].

Digital Interventions

Digital interventions are often recommended as a tool to increase the dissemination of evidence-based psychological treatments [5,7]. Meta-analyses have shown that internet-based, guided self-help CBT (iCBT) is effective for treating depressive symptoms [20,21], and it may allow patients to circumvent some of the financial and structural barriers to psychological treatment [22]. However, iCBT is also affected by sleep disturbance symptoms. A cohort study on iCBT for depression in routine care showed that more sleep problems predicted higher depression by the end of treatment [23]. Furthermore, a randomized controlled trial on iCBT for chronic stress showed that the treatment effect was mediated by the reduction in insomnia symptoms [24]. Interestingly, some studies have shown that iCBT for insomnia also has significant effects on depressive symptoms [25,26], and in some cases, studies have also included insomnia management in the iCBT treatment manual for depression [27]. However, the added effect of doing so is yet to be documented.

As the self-help format in iCBT has a more rigid treatment structure, it might be more challenging to adapt the treatment to the individual's symptom presentation. Standard CBT protocols often do not target sleep disturbance symptoms during treatment. However, within the face-to-face consultation, the therapist may have more flexibility to address other issues experienced by the patient. Perhaps even more so in routine care treatments, where therapists are not required to adhere strictly to a protocol as in a research project. The therapist could also favor another treatment approach that emphasizes sleep disturbance symptoms more than CBT. Digital interventions might lack this flexibility, when some or all of the treatment is delivered in a standardized format with predetermined exercises. One study also showed that although some patients feel empowered and safe in the iCBT format, others experience isolation and feel burdened by the limited therapist support [28].

Blended CBT

Blended CBT (bCBT) might help bridge this gap between web-based and face-to-face treatment. In bCBT, patients receive a combination of web-based and face-to-face therapy. This may help therapists and patients adhere to treatment protocols while allowing for a different kind of flexibility during the physical consultations compared with the structured, guided self-help programs [29]. Face-to-face consultations in bCBT can alleviate the feelings of isolation that patients may experience in guided self-help, and it can help make the structured treatment content of CBT relatable and adaptable to the patient's symptom profile [30]. However, no study has yet investigated the impact of sleep

disturbance symptoms on digital interventions for MDD, including bCBT, compared with face-to-face treatments. As digital interventions are increasingly being offered to patients with MDD to augment the reach of evidence-based treatment, it is relevant to examine the association between the severity of sleep disturbance symptoms and treatment response to bCBT.

Objectives

The objectives of this study are to investigate (1) whether baseline sleep disturbance symptoms have a negative impact on treatment outcomes for depression independent of treatment modality and (2) whether sleep disturbance symptoms impact bCBT and treatment-as-usual (TAU) in routine care equally.

On the basis of previous research, we hypothesized a priori that sleep disturbance symptoms would be negatively associated with treatment outcome independent of treatment modality.

Methods

Overview

This study was a substudy of the E-COMPARED (European Comparative Effectiveness Research on Blended Depression Treatment Versus Treatment-as-Usual; described in more detail in a study by Kleiboer et al [31]).

The trial was registered in clinical trial databases (ClinicalTrials.gov NCT02542891 [France], NCT02389660 [Poland], NCT02361684 [Spain], NCT02449447 [Sweden], and NCT02410616 [Switzerland]; other clinical databases: German Clinical Trials Register DRKS00006866 [Germany]; Netherlands Trials Register NTR4962 [the Netherlands], International Standard Randomised Controlled Trial Number registry ISRCTN12388725 [United Kingdom], and ClinicalTrials.gov NCT02796573 [Denmark]) and was conducted based on CONSORT (Consolidated Standards of Reporting Trials) [32].

Study Design and Setting

The E-COMPARED trial was conducted as a 2-arm, parallel randomized controlled, noninferiority trial in nine European countries: France, Germany, the Netherlands, Poland, Spain, Sweden, Switzerland, the United Kingdom, and Denmark.

The trial was conducted in routine primary care facilities (sites: Germany, Poland, Spain, Sweden, and the United Kingdom) or specialized mental health care facilities (sites: France, the Netherlands, Switzerland, and Denmark).

Eligibility Criteria

To be included in the study, patients had to (1) be aged ≥ 18 years, (2) fulfill Diagnostic and Statistical Manual of Mental Disorders-IV (DSM-IV) diagnostic criteria for MDD, and (3) exhibit minimal to severe symptoms of depression based on a score of ≥ 5 on a screening with the Patient Health Questionnaire-9 (PHQ-9; described in more detail in the *Assessment Instruments* section).

The exclusion criteria were as follows: (1) currently being at high risk for suicide (2) having fulfilled the DSM-IV diagnostic criteria for substance dependence, psychotic illness, bipolar

affective disorder, or obsessive-compulsive disorder; (3) receiving psychological treatment at the time of enrollment for depression in primary or specialized mental health care facilities; (4) being unable to comprehend the spoken and written language of the country where the study was conducted (eg, English in the United Kingdom); (5) not having access to a computer with a fast internet connection; and (6) not having or not willing to carry a smartphone that is compatible with the mobile component of the intervention being offered.

Randomization and Blinding

Eligible participants were randomized by a team of independent researchers (the randomization team) affiliated with the principal investigator organization (Vrije Universiteit Amsterdam) into two arms: TAU or bCBT. Randomization was performed at the individual level, stratified by country. The randomization team created the allocation scheme with a computerized random number generator (Random Allocation Software developed by Mahmood Saghaei) at an allocation ratio of 1:1. Block randomization with variable block sizes that varied between 8 and 14 allocations per block was applied.

None of the investigators or clinicians were aware of the randomization scheme, but blinding for treatment allocation was not possible owing to the nature of the treatment. Nonetheless, the outcome assessors were blinded.

Treatment Arms

TAU was defined as the routine care that patients received when diagnosed with depression in the specific country and treatment setting where they were recruited. Thus, TAU varied between

countries, between treatment settings, and among patients and included pharmacological treatment, psychotherapy, a combination of both, or none of the above (see Table 1).

The bCBT combined individual face-to-face CBT with CBT delivered through an internet-based treatment platform with mobile phone components (integrated either in the treatment platform or as a separate system). The core components of the bCBT treatment were the following: (1) psychoeducation, (2) cognitive restructuring, (3) behavioral activation, and (4) relapse prevention. These were delivered over 10 to 20 sessions. The ratio between the number of face-to-face sessions and the number of web-based modules varied according to practice in the participating countries. However, a minimum of 33% of the sessions were face-to-face, and a minimum of 33% of the sessions were provided through the web. In addition to the core CBT components, other components such as mindfulness, coping skills training, or problem solving could also be included (insomnia management was not included in this trial). However, they were not allowed to take up more than a quarter of the total treatment (no more than approximately 25% of the face-to-face and web-based sessions combined). This was done to prevent excessive heterogeneity in the treatment programs.

bCBT was provided by CBT therapists who received training on how to deliver the treatment. CBT therapists were (1) licensed CBT therapists, (2) CBT therapists in training working under the supervision of an experienced licensed CBT therapist in specialized mental health care facility, (3) licensed psychologists, or (4) psychologists in training working under the supervision of a licensed psychologist with a CBT orientation in primary care.

Table 1. Overview of blended cognitive behavioral therapy (bCBT) and treatment-as-usual (TAU) applied in each country.

Country	Platform for bCBT	Duration (weeks)	Web-based modules	FTF ^a sessions	Sequencing	TAU
Germany	Moodbuster	10-13	10	5	Alternate	TAU from GP ^b
Sweden	Iterapi	10	6	4	Alternate	TAU from GP ^c
Netherlands	Moodbuster	20	10	9	Alternate	FTF TAU ^d
United Kingdom	Moodbuster	11	5	6	Alternate	FTF CBT
Spain	Smiling is fun ^e	10	8	3	1-4-1-4-1 ^f	TAU from GP
France	Moodbuster	16	8	8	Alternate	FTF CBT
Switzerland	Deprexig ^g	18	9	9	Alternate	FTF CBT
Poland	Moodbuster	6-10	6	7	Alternate	FTF CBT
Denmark	NoDep ^h	12	6-8	6	Alternate	FTF CBT

^aFTF: face-to-face.

^bGP: general practitioner.

^cSweden also included psychotherapy clinics and student mental health care facilities. However, these are at the same level of care as GP.

^dPsychotherapy (cognitive behavioral therapy, interpersonal psychotherapy, or supportive therapy), antidepressant medication, running therapy, or a combination of these.

^eAdditional module on coping skills.

^fThe sequence was as follows: 1 FTF session, 4 web-based modules, 1 FTF session, 4 web-based modules, and 1 FTF session.

^gAdditional modules on mindfulness, interpersonal skills, positive psychology, emotion-focused therapy, and childhood experiences.

^hTwo additional modules on restructuring of beliefs and management of rumination that clinicians could add to the web-based sessions if deemed necessary.

As can be seen in Table 1, none of the bCBT protocols included sleep disturbance symptoms interventions. However, we do not know to what extent sleep disturbance symptoms were included in the TAU protocol.

Measures

Sociodemographic factors, MDD diagnoses, severity of depressive symptoms, and psychiatric comorbidities were measured at baseline. The clinical outcome measures used in this study were severity of depressive symptoms assessed at baseline and at the 3-, 6-, and 12-month follow-up and MDD diagnosis assessed at baseline and at the 12-month follow-up.

Assessment Instruments

MDD Severity

The PHQ-9 was used to assess the severity of depression. It includes symptom domains of MDD based on DSM-IV (ie, sleep disturbance, sad mood, appetite and weight, concentration, self-criticism, suicidal ideation, interest, energy and fatigue, and psychomotor agitation and retardation). It consists of 9 items, each scored on a 0 to 3 scale, with the total score ranging from 0 to 27 and higher scores indicating more severe depression [33]. The PHQ-9 is frequently used in clinical trials to assess treatment outcomes and can be used in different patient populations such as those who receive primary care and specialized mental health care [34]. The PHQ-9 was used to screen for the presence of at least a minimum level of MDD severity (cutoff ≥ 5). Furthermore, the PHQ-9 total score was applied as the primary outcome. For this study, the 12-month follow-up was used as the primary end point. The 3- and 6-month follow-ups were the secondary end points.

MDD Diagnosis

The Mini-International Neuropsychiatric Interview (MINI) for DSM-IV is a structured interview probing the 17 most common psychiatric diagnoses using dichotomous questions requiring a yes or no response [35]. The MINI was used to establish MDD diagnoses as well as to screen patients for eligibility and detect comorbid psychiatric diagnoses. The MINI was also used to evaluate whether the patients still fulfilled the diagnostic criteria for an MDD diagnoses at the 12-month follow-up and was applied as a secondary outcome and secondary end point.

Assessment of Sleep Disturbance Symptoms

A total of four sleep disturbance items from the Quick Inventory of Depressive Symptomatology (QIDS)–Self-Report were used to measure sleep disturbance symptoms [36]: (1) difficulty falling asleep, (2) awake during the night, (3) waking up too early, and (4) sleeping too much. Each item was scored from 0 to 3, with higher scores indicating greater symptom severity. This approach to measure sleep disturbance symptoms has been validated previously for the 3 insomnia items [37]. However, the middle-answer categories (scores of 1 and 2) did not perform as well for items 2 and 3 [37]. Therefore, on the basis of previous research, a score ≥ 2 on an item was chosen to indicate the presence of that specific type of sleep disturbance [38]. A combination of any (or none) of the 4 types of sleep disturbance symptoms was possible.

Analysis Plan

Characteristics of the sample at baseline were described using descriptive statistics and compared across groups using 2-tailed *t* tests for continuous variables and chi-square tests for categorical variables. If the continuous variables violated the assumption of normality, equivalent nonparametric tests were used (Wilcoxon signed rank test).

The primary analysis was performed using a linear mixed effects model with random intercept [39,40] with sites added as a random variable. The outcome variable was the difference in score on the PHQ-9 between baseline and at 12-month follow-up. The baseline sum score of the first 4 items on the QIDS–Self-Report pertaining to sleep disturbance symptoms was used as a predictor variable and was controlled for the baseline level of depression severity on the PHQ-9. To test for an effect of treatment modality (bCBT vs TAU), an interaction term between the sleep disturbance symptoms and treatment modality was added. A sensitivity analysis excluding item 3 in the PHQ-9 (pertaining to sleep disturbance) was also performed as this item could potentially confound the analyses.

Secondary analyses were also conducted with linear mixed effects models applying the same predictor and outcome variables as well as an interaction term, but at 3- and 6-month follow-up. In addition, an analysis using the same predictor variable and the presence versus absence of MDD diagnoses at 12-month follow-up as the outcome was conducted. This analysis was performed using a logistic mixed effects model.

All models were adjusted for the baseline level of depression on the PHQ-9 and sociodemographic variables (gender, marital status, highest education, and age).

All analyses followed the intention-to-treat principles according to CONSORT guidelines [41]. Missing values were handled by using all available data in mixed effects models. A double-sided significance level of .05 was applied. All calculations were performed using R version 3.6.3 [42]. Linear mixed effects models were fitted using the lme4 package [40].

Ethical Considerations

Ethical approval for the trials was obtained locally in each country (Denmark: De Videnskabssetiske Komitéer for Region Syddanmark; S-20150150; France: Comité de protection des personnes, Ile de France V; 15033-n° 2015-A00565-44; Germany: Ethik Kommission DGPsychologie, Universität Trier; MB 102014; The Netherlands: METC VUMC; 2015.078; Poland: Komisja ds. Etyki Badan Naukowych; 10/2014; Spain: Comision Deontologica/Comite Etico de Investigacion en Humanos; H1414775276823; Sweden: Regionala etikprovningssamnden; 2014/428-31; Switzerland: Kantonale Ethikkommission Bern; 001/2015; United Kingdom: NRES Committee London-Camden and King's Cross; 15/LO/0511). All participants provided written informed consent beforehand.

Results

Characteristics of the Sample

The sample consisted of 943 adult patients with MDD recruited from routine care across the 9 participating European countries.

The mean age was 39 (SD 13) years, with mainly women included (644/943, 68.3%). The majority were either married or living together (517/943, 54.8%) and were well educated. At baseline, the sample, on average, presented with a moderate to severe degree of depression (mean PHQ-9 score 15.35, SD

4.77). There were no differences between the groups on any sociodemographic measures or on depressive or sleep symptomatology at baseline. The characteristics of the participants are summarized in Table 2.

Table 2. Comparison of characteristics across treatment modalities (N=943).

Characteristic	Total sample (N=943)	TAU ^a (n=467)	bCBT ^b (n=476)	P value ^c

Insomnia items , n (%)				
Difficulty falling asleep	453 (48)	225 (48.2)	228 (47.9)	.99
Awake during the night	512 (54.3)	251 (53.7)	261 (54.8)	.76
Waking up too early	321 (34)	149 (31.9)	172 (36.1)	.18
Hypersomnia item , n (%)				
Sleeping too much	135 (14.3)	65 (13.9)	70 (14.7)	.77

^aTAU: treatment-as-usual.

^bbCBT: blended cognitive behavioral therapy.

^cA 2-tailed *t* test was performed for continuous variables (age, PHQ-9, QIDS). Chi-square test was performed for categorical variables (gender, marital status, education, trial site and, insomnia and hypersomnia prevalence).

^dPHQ-9: Patient Health Questionnaire-9.

^eQIDS: Quick Inventory of Depressive Symptomatology.

Observed Results

In this study's sample of 943 patients, 764 (81%) reported at least one symptom of sleep disturbance symptoms at baseline. The most common symptom of sleep disturbance upon entering the study was midnocturnal insomnia (512/943, 54.3%), which was reported by more than half of the participants. Sleep onset insomnia (453/943, 48%) followed in close succession.

Hypersomnia was markedly less prevalent than the rest (135/943, 14.3%).

As measured by the sum of the first 4 items in the QIDS pertaining to sleep, the level of sleep disturbance reduced over time, as seen in Table 3. In Figure 1, the levels of severity of depressive and sleep disorder symptoms are presented for the total sample and for each treatment condition.

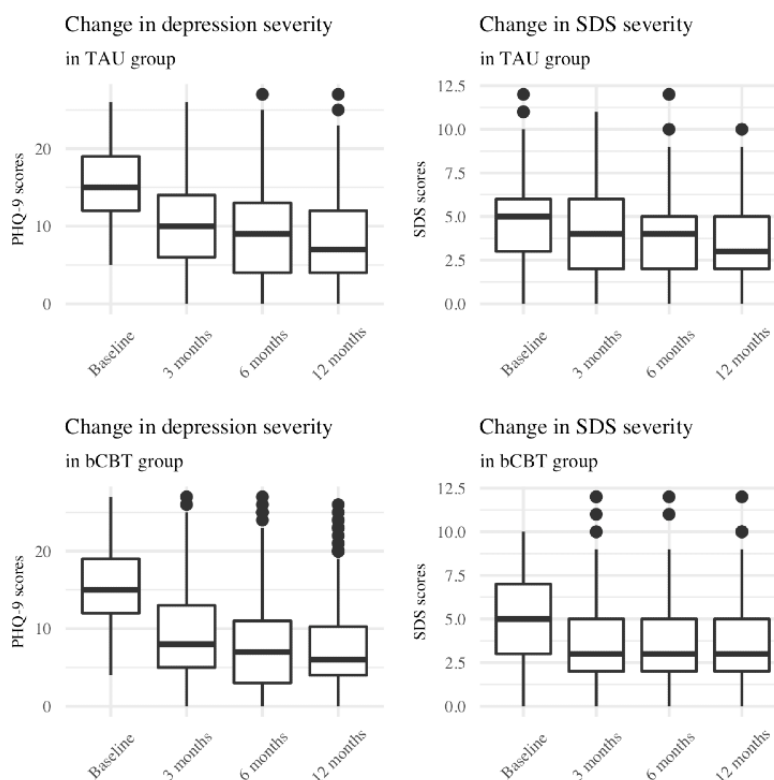

Table 3. Observed means of sleep disturbance symptom severity.

Time point	Total sample, mean (SD)	TAU ^a , mean (SD)	bCBT ^b , mean (SD)
Baseline	4.79 (2.42)	4.87 (2.52)	4.77 (2.31)
3 months	3.89 (2.43)	3.83 (2.49)	3.94 (2.37)

Figure 1. Changes in symptoms severity of depression and sleep disturbance symptoms from baseline to 12-month follow-up. bCBT: blended cognitive behavioral therapy; PHQ-9: Patient Health Questionnaire-9; TAU: treatment-as-usual.

Primary Analysis

In the total sample, the level of sleep disturbance symptoms did not significantly predict the change in depression symptom severity from baseline to the 12-month follow-up ($\beta=.16$, 95% CI -0.04 to 0.36). However, there was a difference between the groups, with the effect of baseline sleep disturbance symptoms being nonsignificant in the TAU group ($\beta=-.23$, 95% CI -0.50 to 0.05), but being significant for the bCBT group ($\beta=.49$, 95% CI 0.22 - 0.76). When including an interaction term with group,

the interaction was significant ($\beta=.59$, 95% CI 0.23 - 0.94), indicating a significant difference in how the change at 12 months was affected by baseline sleep disturbance symptoms between the groups. In a sensitivity analysis, we removed item 3 in the PHQ-9 (pertaining to sleep disturbances), which led to similar results. Therefore, we decided to continue using the full PHQ-9, given that it is the validated version and for the purpose of comparability. The results of the models are presented in Table 4.

Table 4. Associations between change in depression score and sleep score.

Outcome	All participants (N=943)			TAU ^a (n=467)			bCBT ^b (n=476)		
	Regression coefficient			Regression coefficient			Regression coefficient		
	n (%)	β^c	Adjusted β^d (95% CI)	n (%)	β^c	Adjusted β^d (95% CI)	n (%)	β^c	Adjusted β^d (95% CI)
Primary outcome									
Change in depression score at 12-months follow-up: sleep score at baseline, per 1 unit increase	558 (59.2)	.21	.16 (-.04 to .36)	274 (58.7)	.01	-.23 (-.50 to .05)	284 (59.7)	.35	.49 (.22 to .76)

Secondary Analyses

In line with the primary finding, baseline sleep disturbance symptoms severity did not significantly predict the presence of MDD diagnoses for the total sample as assessed by the MINI MDD module at 12-month follow-up (odds ratio [OR] 1.05, 95% CI 0.96-1.16). However, again, the effect was significant for the bCBT group (OR 1.18, 95% CI 1.02-1.38) and not for the TAU group (OR 0.94, 95% CI 0.82-1.08).

Owing to the diversity in interventions offered in the comparison group (TAU), we performed the same analyses for a subset of sites where the patients received face-to-face CBT as the comparator (United Kingdom, France, Switzerland, Poland, and Denmark). As was the case for all sites, the results of the subgroup were not significant for the total sample ($\beta=.27$, 95% CI -0.09 to 0.63), and only the bCBT group showed a significant effect of sleep disturbance symptoms ($\beta=.69$, 95% CI 0.19 - 1.19). However, the interaction term with group was nonsignificant ($\beta=.56$, 95% CI -0.07 to 1.22). This could be owing to the subgroup including fewer participants, thus widening the CI. Analyses of the presence of depression according to the MINI did not result in any significant results, which again may be caused by the smaller sample size.

The effect of sleep disturbance symptoms on the change in the severity of depressive symptoms was nonsignificant from baseline to the 3- and 6-month follow-up for both treatment

formats, suggesting that sleep disturbance symptoms may not have an effect on short-term treatment gains.

Of the 4 items on sleep disturbance symptoms in the QIDS, 3 pertained to insomnia and 1 pertained to hypersomnia (see Table 2). Exploratory analyses were performed to examine whether there was a difference between the effect of hypersomnia and insomnia. When performing the same analysis as the primary analysis but excluding the hypersomnia item, it did not change the results. Furthermore, hypersomnia alone did not predict the treatment effect.

Discussion

Principal Findings

The objectives of this study were to investigate (1) whether baseline sleep disturbance symptoms have a negative impact on treatment outcomes independent of treatment modality and (2) whether sleep disturbance symptoms impact bCBT and TAU in routine care equally.

Overall, sleep disturbance symptoms did not have an impact on the treatment response. However, when comparing the treatment arms, a difference was observed in the effect of sleep disturbance symptoms on treatment outcome between bCBT and TAU. Higher baseline sleep disturbance symptoms indicated a decreased treatment response in the bCBT group, whereas TAU was unaffected. Interestingly, the effect of baseline sleep disturbance symptoms was only present at the 12-month

follow-up. This finding points to a long-term effect of sleep disturbance symptoms on the course of depression following bCBT, even though treatment initially seems unaffected. Despite the effect being small, it was supported by the fact that sleep disturbance symptoms also significantly affected the risk of being diagnosed with MDD at the 12-month follow-up in the bCBT group.

However, in a secondary analysis of a subgroup of sites, we compared bCBT only with face-to-face CBT. This analysis showed that although sleep disturbance symptoms still significantly impacted bCBT, there was no significant difference between treatment arms in this subgroup. Not surprisingly, this could indicate that the face-to-face and blended CBT conditions were more similar in content and outcome compared with the remaining TAU formats. Perhaps the less structured TAU conditions were slightly more attentive to the presence of sleep disturbance symptoms, indicating a shortcoming in common CBT protocols for MDD.

This study found results that support previous research and results that contradict previous findings. In line with previous research and our hypothesis, bCBT was affected by sleep disturbance symptoms. However, contrary to this, TAU and the face-to-face CBT subgroup were unaffected by sleep disturbance symptoms.

The finding that sleep disturbance symptoms have a negative impact on bCBT represents an important addition to the existing literature on sleep disturbance symptoms and MDD treatment. It is in accordance with previous research showing an increased risk for MDD nonremission following face-to-face treatment [11,12,14], as well as studies showing that insomnia symptoms decrease treatment response in iCBT [23,24]. Hence, the results of this study extend the findings from previous research by confirming the association between sleep disturbance symptoms and treatment response for MDD in a new treatment format, bCBT.

Furthermore, the analyses showed that a higher endorsement of sleep disturbance items at baseline was associated with a lower treatment response at 12-month follow-up. This corroborates the findings of Pigeon et al [13] and Troxel et al [14]. However, although these authors only used a dichotomous measure of MDD (remission vs nonremission), the analyses of this study expanded this by showing an association between the severity of sleep disturbance symptoms and the degree of symptom alleviation at 12-month follow-up.

Although the long-term effect of baseline sleep disturbance symptoms on bCBT for MDD is in line with previous research [13], the finding of this study that treatment response at the 3- and 6-month follow-up was unaffected by sleep disturbance symptoms is not consistent with previous findings. Different explanations may apply. First, none of the previous studies investigated bCBT. This finding may be uniquely associated with bCBT. However, there are no clear indications as to why this should be the case. Second, neither MDD nor sleep disturbance symptoms has been measured uniformly in previous research. Notably, this study used sleep disturbance items from a depression scale (QIDS) to measure sleep disturbance symptoms. Although this method has been validated [37,43],

it is not the most reliable measure of sleep disturbance symptoms. In the study by Troxel et al [14], subjectively measured sleep disturbance symptoms did not predict treatment outcome alone, but it did when coupled with an objective indicator. Another notable difference is the outcome measures used across these studies. As mentioned, previous research has generally focused on dichotomous outcomes [12-14], whereas this study used the PHQ-9 to measure the size of the treatment effect. If the MINI had been applied at the 3- and 6-month follow-up as well in this study, it would have been interesting to compare the dichotomous findings regarding nonremission at these time points. These differences might affect the comparability with the studies and therefore the findings of this study should not discount previous research.

The missing effect of sleep disturbance symptoms on TAU is also noteworthy. It might indicate that TAU practitioners were more attentive to sleep disturbance symptoms and implemented an intervention for sleep disturbance symptoms when necessary. However, this is still contrary to the study by Pigeon et al [13], who found a significant effect of insomnia on MDD treatment in routine care. Therefore, it may be worth noting that the study by Pigeon et al [13] is relatively old. It could be hypothesized that owing to the increased attention to sleep disturbance symptoms in the past years [8,10], routine care practitioners may treat patients reporting sleep disturbance symptoms differently today. This may help explain why TAU was unaffected by sleep disturbance symptoms in this study. However, it is highly speculative.

Strengths and Limitations

Some strengths of this study are worth noting. Primarily, this study used a randomized and longitudinal design with multiple measurement points. Using this design, we can determine the extent to which bCBT compares with established effective treatments. Furthermore, we can determine the extent to which treatment effects are sustained following treatment.

Second, this study used a large, heterogeneous sample spanning 9 different European countries, lending the study great ecological validity. Furthermore, the comparison between TAU and bCBT provides clinically useful results, as TAU reflects the everyday treatments delivered by clinicians rather than the standardized treatments of a research trial. This part of the design could also be framed as a weakness because an efficacy study using only standardized protocols can be easier to interpret. However, this would have been at the cost of the finding's generalizability [44], which was highly important in the E-COMPARED study [31].

Some limitations of the analyses of this study should also be considered. Primarily, the E-COMPARED study was not geared to investigate a research question regarding sleep disturbance symptoms, which is highlighted by the lack of a dedicated insomnia measure. However, as indicated by Manber et al [37], the items from the QIDS perform satisfactorily in discriminating the presence of sleep disturbance symptoms. Furthermore, we decided to pool hypersomnia and insomnia items to establish an aggregated score for sleep disturbance symptoms. Given the higher prevalence of insomnia, as was also evident in the sample of this study, this approach might be considered questionable.

Focusing solely on insomnia symptoms would provide a clearer picture of what sleep disturbance symptoms entail. However, given that hypersomnia and insomnia symptoms may co-occur and have been associated with more severe depression in adolescents [18,19], capturing the full phenomenon seemed prudent.

This study provides important findings regarding the use of bCBT to treat MDD with marked sleep disturbance symptoms. When the treatment format moves from face-to-face to internet-based, the potential for broader dissemination generally comes at the cost of treatment flexibility. The analyses of this study indicated that sleep disturbance symptoms might affect the less flexible treatment format, bCBT, more than it affects TAU. However, given that this was a secondary analysis of a study that was not designed to test this hypothesis, the results should be interpreted cautiously. It will be important for future research to test whether these findings are supported when using dedicated sleep disturbance measures. Nonetheless, it would also be of interest to see if treatment outcomes in bCBT can be improved by using web-based add-on sessions for sleep disturbance symptoms. Previous research has shown that iCBT

can effectively treat sleep disturbance symptoms [25,45-48], and there is a call for research on sequential or concomitant treatment of MDD and sleep disturbance symptoms [49]. Finally, it is of interest to investigate whether these findings extend to other forms of diagnostic complexity. Future studies should compare bCBT with face-to-face therapy for patients with MDD with other common comorbidities such as alcohol use or anxiety disorders.

Conclusions

Baseline sleep disturbance symptoms may have a negative impact on long-term treatment outcomes in bCBT for MDD. TAU seems to be unaffected by the severity of the baseline sleep disturbance symptoms. This suggests that extra attention to comorbidity such as sleep disturbance symptoms, which was investigated here, might be important when treating depression with bCBT in routine care.

Future research should investigate whether there is an improved treatment outcome in bCBT for MDD with comorbid sleep disturbance symptoms when using add-on modules targeting sleep disturbance symptoms.

Acknowledgments

The authors thank the E-COMPARED (European Comparative Effectiveness Research on Blended Depression Treatment Versus Treatment-as-Usual) consortium for giving us the opportunity to conduct this secondary analysis on their trial data. In addition, the authors thank Innovation Fund Denmark for funding the Danish trial in the ENTER project, which delivered data to the E-COMPARED project.

Abstract

Background: Therapist-supported, internet-delivered cognitive behavioral therapy (iCBT) is efficacious for generalized anxiety disorder (GAD), but few studies are yet to report its effectiveness in routine care.

Objective: In this study, we aim to examine whether a new 12-session iCBT program for GAD is effective in nationwide routine care.

Methods: We administered a specialized, clinic-delivered, therapist-supported iCBT for GAD in 1099 physician-referred patients. The program was free of charge for patients, and the completion time was not predetermined. We measured symptoms with web-based questionnaires. The primary measure of anxiety was the GAD 7-item scale (GAD-7); secondary measures were, for pathological worry, the Penn State Worry Questionnaire and, for anxiety and impairment, the Overall Anxiety Severity and Impairment Scale.

Results: Patients completed a mean 7.8 (SD 4.2; 65.1%) of 12 sessions, and 44.1% (485/1099) of patients completed all sessions. The effect size in the whole sample for GAD-7 was large (Cohen $d=0.97$, 95% CI 0.88-1.06). For completers, effect sizes were very large (Cohen $d=1.34$, 95% CI 1.25-1.53 for GAD-7; Cohen $d=1.14$, 95% CI 1.00-1.27 for Penn State Worry Questionnaire; and Cohen $d=1.23$, 95% CI 1.09-1.37 for Overall Anxiety Severity and Impairment Scale). Noncompleters also benefited from the treatment. Greater symptomatic GAD-7-measured relief was associated with more completed sessions, older age, and being referred from private or occupational care. Of the 894 patients with a baseline GAD-7 score ≥ 10 , approximately 421 (47.1%) achieved reliable recovery.

Conclusions: This nationwide, free-of-charge, therapist-supported HUS Helsinki University Hospital-iCBT for GAD was effective in routine care, but further research must establish effectiveness against other treatments and optimize the design of iCBT for GAD for different patient groups and individual patients.

Introduction

Background

Generalized anxiety disorder (GAD) [1] is a common but underdiagnosed and undertreated condition [2,3]. The global annual prevalence of GAD in high-income countries may be 2.3%, and this disorder is associated with increased functional impairment [4].

Pharmacotherapy and psychotherapy are considered first-line GAD treatments [5,6]. Among psychotherapies, cognitive behavioral therapy (CBT) is the most studied, with large effect sizes (Hedges $g=0.90$ [7]). However, traditional face-to-face CBT is relatively resource-consuming and limited in access.

The need to resolve the accessibility and affordability challenges of face-to-face CBT led to the development of internet-delivered CBT (iCBT), with notable work occurring in Sweden, the Netherlands, Denmark, Australia, and Canada, for example [8]. A typical iCBT intervention is location-independent and includes a program with therapeutic content and homework. It is accessible 24/7 through a web-based platform or mobile app, with or without therapist support. In therapist-supported iCBT, remote therapist support is most often asynchronous. While the intensity of therapist support in iCBT can vary, it requires far less therapist time compared with face-to-face or real-time remote psychotherapy and thus may be more cost-effective [9,10].

As demonstrated in recent meta-analyses of randomized controlled trials (RCTs) [9,11-16], therapist-supported iCBTs are efficacious in several psychiatric disorders and may be as efficacious as short-term face-to-face CBT. Therapist-supported iCBTs for depression and anxiety have higher efficacy and adherence than unguided programs do [12,17-19], which is likely due to the high level of client-therapist alliance, comparable with that in face-to-face therapies [20]. In general, iCBTs reduce symptomatic deterioration more than waiting lists (3.1% or 5.8% vs 17.4% [13,21]). For therapist-supported iCBT for GAD, efficacy has also been established for both diagnosis-specific and transdiagnostic programs [9,16].

However, RCT efficacy studies, being the gold standard for clinical evidence, have their own shortcomings. Participants are more likely to be highly motivated, have had thorough screening, and have received more intensive treatment than in routine care. Therefore, RCT-validated treatments may or may not yield similar results or level of adherence in routine care depending on whether the criteria are lax [22-24]. Addressing these limitations, routine care studies are now accepted as valid scientific evidence for their clinical effectiveness and safety [25]. Although there is strong real-world evidence for the effectiveness of therapist-supported iCBT in general [8,9,13], studies focusing on GAD are limited.

We identified 5 publications comprising 7 therapist-supported iCBT interventions focusing on GAD in routine care using 3 different programs at 2 clinics. ThisWayUp clinic in Australia performed 6 interventions comprising 2 programs [23,26-28], and Online Therapy Unit in Canada performed 1 intervention [29]. These studies mainly reported large intention-to-treat (ITT)

effect sizes (0.91-1.30), although 1 outlier study reported effects as large as 2.06 and 2.10 [28]. ThisWayUp trials reported full completion rates of 36% to 55%. Although these 3 programs demonstrated the overall feasibility of iCBT for GAD, the recruitment schemes, program length, and therapist support intensity in these trials varied widely (see the Design Comparison section in the Discussion section), and the Online Therapy Unit's trial was relatively small. More routine care studies are needed to confirm their conclusions and elucidate the optimal program design.

The HUS Helsinki University Hospital has developed and is providing nationwide, original Finnish language therapist-supported iCBT programs for several psychiatric conditions (further referred to as HUS-iCBTs), including one for GAD. Intake for the 12-session program requires a physician's referral, it is free of charge, and therapist support is provided centrally by a specialized clinic. As the combination of setting and design of the HUS-iCBT for GAD differs from those studied earlier, the effectiveness of these programs may differ.

Objective

The aim of this study is to examine the effectiveness of HUS-iCBT for GAD in routine care. We hypothesized that the intervention would have a large overall effect size and the patients' completion rate would be comparable (36%-55%) with the reported routine care studies.

Methods

Setting and Design

The HUS-iCBTs were delivered centrally by the iCBT clinic at HUS Psychiatry. The interventions were free of charge, diagnosis-specific, and therapist-supported programs. All physicians in Finland can refer their patients to therapy. The referring physicians received support from the instructions on the web. A specially trained mental health professional screened all referrals centrally. We deliberately implemented these inclusion procedures to enable virtually unlimited nationwide access for the clinical population despite the limited number of therapists.

The study was an observational, nationwide, open-label, real-world trial.

Participants

Participants were recruited from those entering HUS-iCBT for GAD between February 2016 and December 2018. To be accepted for the treatment, patients had to (1) be diagnosed with GAD (ICD-10 [1]), (2) have an email address, and (3) have an internet-based bank account or mobile ID (the means of official e-identification in Finland). Comorbidity (other than the exclusion criteria) and concomitant pharmacological and psychological treatments were allowed, as the intervention was part of routine care. Exclusion criteria were acute psychosis or mania, severe personality disorders, severe suicidality, or neurological or neuropsychiatric disorder with cognitive decline. These were screened centrally from the physician's referral before the referral was accepted. The only additional inclusion

criterion for the study was a baseline score of ≥ 8 on the GAD 7-item scale (GAD-7 [30]).

Ethical Considerations

The patients provided informed consent after the first log-in. The study protocol was approved by the ethics committee of the HUS and pertinent institutional authorities.

Intervention and Procedure

The new iCBT program for GAD was designed by an expert group to be diagnosis-specific because the existing evidence base was clearly the strongest at the time, in 2013. This new program consisted of 12 consecutive sessions and a follow-up session 3 months after treatment completion. The program was theoretically based on several models of GAD and anxiety, including aspects of the cognitive avoidance model [31], model of intolerance of uncertainty [32], metacognitive therapy [33], and Acceptance and Commitment Therapy [34], as well as social

aspects, such as assertiveness training. The sessions included text and videos, as well as educational illustrations, example stories, therapeutic exercises, and homework (Textbox 1).

After approval, the patients received an email and a letter prompting them to sign in and begin treatment. A schedule of 1 session per week was recommended, and a minimum 24-hour waiting period was enforced between sessions to encourage daily life practice. The program sent email prompts for arriving messages and, after 2 weeks of inactivity, log-in reminders. Nevertheless, no maximum completion time was required if the patient remained active in therapy.

Although HUS-iCBT for GAD was therapist-supported, several persuasive elements used in unguided iCBT programs [35] were originally included and are listed in Textbox 2. In total, 7 elements were used (or 6, if discounting tunneling as the original authors did).

Textbox 1. Content by session.

Session titles

- Session 1: Introduction to HUS Helsinki University Hospital–internet-delivered cognitive behavioral therapy program, cognitive behavioral therapy model, and generalized anxiety disorder
- Session 2: Bodily stress response, worry and relaxation
- Session 3: Worry and avoidance, intolerance of uncertainty
- Session 4: Experiential Avoidance, Core Beliefs
- Session 5: Negative beliefs about worrying, challenging worrying
- Session 6: Positive beliefs about worrying, challenging beliefs about worrying
- Session 7: Challenging worrying
- Session 8: Acceptance of worries, acceptance vs submission
- Session 9: Intolerance of uncertainty and reaching for perfection and certainty
- Session 10: Problem solving vs worrying, solvable vs unsolvable worries
- Session 11: Social skills, needs in relationships, assertiveness
- Session 12: Summarizing, warning signs, plan for the future, feedback

Textbox 2. Identified persuasive design principles.

Principles and brief example

- Reduction: simple stepped instructions; for example, worry diary or relaxation
- Tunneling: logical thematic progression
- Self-monitoring: symptom graphs
- Simulation: example stories with avatars
- Rehearsal: web-based worry diary and relaxation training
- Reminders: log-in reminders
- Normative influence: normalization of common generalized anxiety disorder features

Therapist Support

The therapists in the program were clinical psychologists, psychology students, or nurses with additional therapeutic training, all working at HUS Psychiatry. Each therapist received 1 day of training on internet delivery of CBT, text-based

communication, the intervention protocol, and Good Clinical Practice. Therapists received regular group supervision and sought consultation with a senior psychotherapist at any time.

To support patients' progress, the therapists provided empathic asynchronous feedback with written messages 4 times or more

often (if the patient requested) during the therapy. If the patient was inactive for 2 weeks, the therapist pursued contact through an SMS text message or iCBT program. If no reply arrived within a week, further contact was attempted by phone and thereafter by a letter including a 2-week deadline for continuing, after which access to therapy was discontinued.

A web-based report of live data on individual therapists was created during the study to allow for supervision of compliance with the intervention protocol and to prompt support to those failing to ask for support. The report included data on the date of the last log-in and the number of patients not contacted or logged in within the last 2 weeks. The therapist time per patient was not subject to monitoring, but each therapist treated a minimum quota of patients per dedicated working hour. On average, this quota would mean 9 to 11 minutes of working time per patient per week.

Measures

Overview

Symptoms were measured using web-based questionnaires. The primary measure of anxiety was the GAD-7; secondary measures were, for pathological worry, the Penn State Worry Questionnaire (PSWQ) and, for anxiety and impairment, the Overall Anxiety Severity and Impairment Scale (OASIS).

Patients completed the GAD-7 at the beginning of each of the first 11 sessions and at the end of the final 12th session. The 2 secondary measures were filled at the beginning and end of treatment. Each participant received an invitation for a follow-up measurement 3 months after completing the treatment.

GAD 7-Item Scale

The GAD-7 is a short, 7-item self-report questionnaire developed to measure GAD diagnostic symptom criteria of the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition [30]. Its internal consistency (Cronbach α) has generally ranged between .88 in the clinical population and .92 in the general population [36,37]. The test–retest reliability in a study was 0.83 [30]. In this study, Cronbach α was .725 before the treatment and .905 after the treatment.

Penn State Worry Questionnaire

The PSWQ is a 16-item questionnaire designed to measure pathological worry, a signature feature of GAD [38]. Internal consistency has ranged from .86 to .95 among various samples [38–40]. PSWQ sensitivity to change is good but less salient than that of GAD-7 [41]. Test–retest reliability has been inconsistent (0.67–0.93) [39,42], so a midrange score of 0.80 was our choice. In our study, the Cronbach α was .865 before the treatment and .931 after the treatment.

Overall Anxiety Severity and Impairment Scale

The OASIS is a 5-item scale developed as a brief transdiagnostic measure of anxiety severity and impairment [43]. Internal consistency has ranged from .84 to .93 in 3 large clinical samples [44–46]. OASIS's sensitivity to change has been established, but its diagnostic accuracy is low [45,47]. Test–retest reliability has been 0.73 in undergraduate samples and 0.82 in clinical samples [43,45] with a midrange value of 0.78 used. Cronbach

α in this study was .736 before the treatment and .888 after the treatment.

Adherence

We measured the number of completed sessions and the time of therapy, defined as the time between the first and last GAD-7 in-therapy measurements. Only patients who completed all 12 sessions were categorized as completers. The program introduced the main theoretical framework in the first 4 sessions, and the later sessions focused mostly on further implementation of basic principles or introduced secondary content. Hence, we subcategorized noncompleters into two groups a priori: early dropouts (those discontinued before the completion of the fourth session) and late dropouts.

Patient Characteristics

We collected patient demographics such as age, registered sex, and municipality class. The municipality class was either urban or nonurban, according to the official Finnish classification [48].

Statistical Analysis

Our data were a convenience sample of all consented patients who entered treatment after February 2016. Our desired power was 80% and type I error was 0.05 for the main tests and 0.01 for post hoc tests. When comparing 2 independent means, a requirement to detect a small effect size, a minimum of 0.2, would be achieved with a sample of 435 for main tests and 647 for post hoc tests, assuming a 45%/55% completer/noncompleter distribution. For mixed model parameters, we set significance at a conservative $P < .01$, while ensuring that Akaike and Bayesian Information Criteria [49,50] do not indicate worsening fit. The final mixed model was built in a backward stepwise manner.

The primary outcome analysis involved a linear mixed random model that allowed growth modeling to account for the changing pace of recovery at different time points during therapy, the use of all available data, and different intercept estimations for each individual. GAD-7 served as the dependent variable, and we modeled a growth curve using linear, quadratic, and cubic terms of the GAD-7 observation time. To control for the effect of *dose* of and time on therapy, we also tried a full model with the main effects and interactions of the GAD-7 observation session. We also input the main effects of gender, age, referral source, municipality class, and completion status, along with their linear combinations with time.

The ITT and noncompleter groups' effect sizes for GAD-7 were estimated with mixed model–estimated marginal means. This approach generally performs better than a pure last observation carried forward (LOCF) at handling dropout bias, especially in larger samples ($n > 400$) [51]. The method used to calculate effect sizes was that of Morris and DeShon [52] (equations 13 and 12). Calculations also used the baseline SD and observed pre–post correlation.

We calculated clinical change indexes using the LOCF values. Reliable change was defined as Reliable Change Index (RCI [53]), and recovery was defined as transitioning below the clinical cutoff on the primary outcome measure, GAD-7. The

RCI and clinical cutoff together provide stringent criteria for both response and recovery [54]. Test–retest reliability obtained from earlier normative studies allowed the calculation of the RCI. We explored recovery for those with a baseline GAD-7 score of ≥ 10 to avoid confounding recovery rates with those of patients who had already fulfilled the criterion at baseline. In reliable recovery, the patient fulfilled the criteria for both clinical recovery and RCI. Full symptomatic recovery (remission) was defined as a posttreatment score < 5 on the GAD-7.

We used SPSS Statistics 22 (IBM Corporation) for the analyses [55].

Results

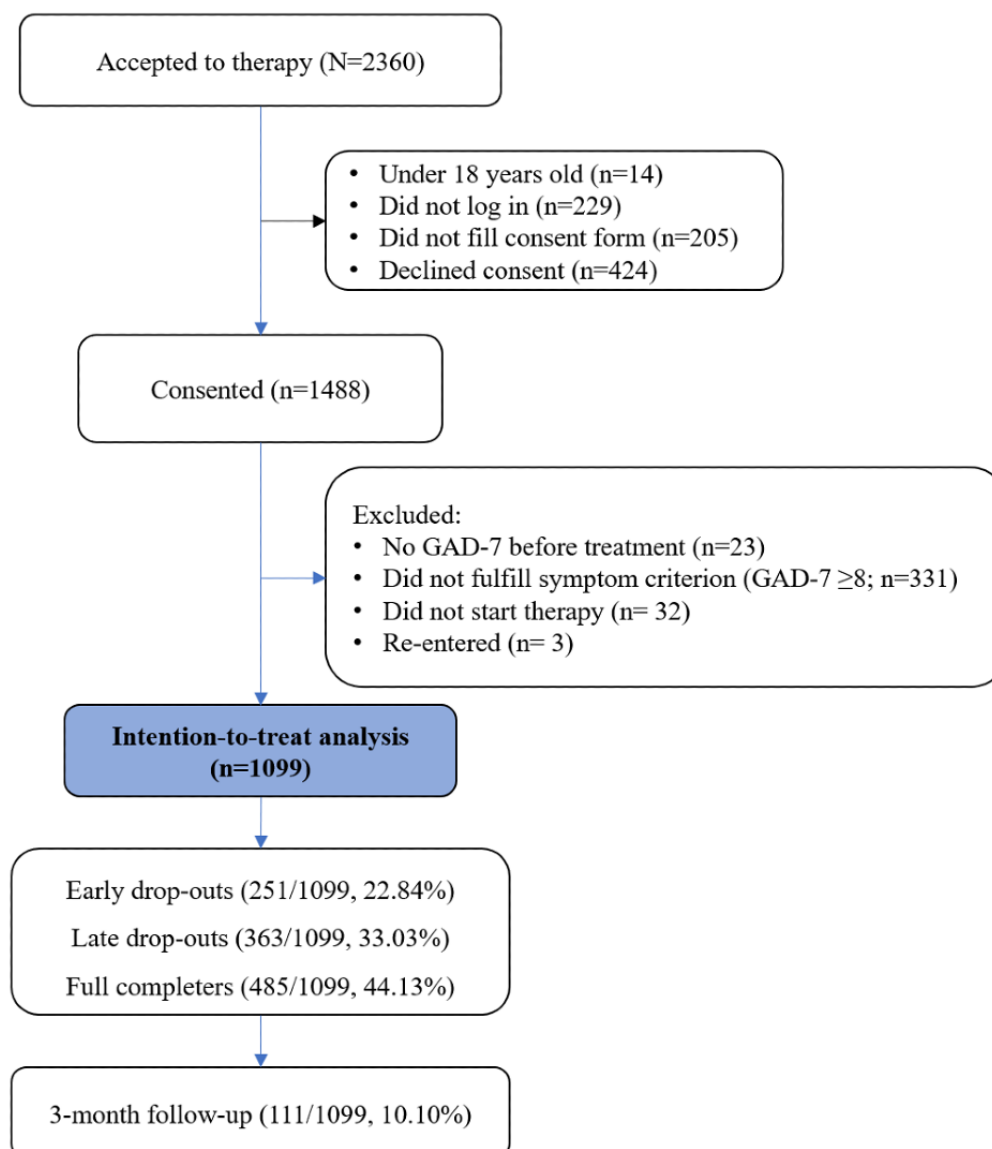

Patient Flow, Baseline Characteristics, and Adherence

Of all referrals to the clinic, those rejected during the recruitment period amounted to only 0.6%. Of the 1912 patients who completed the consent form, 1488 (77.82%) provided their consent (Figure 1).

Of the 1099 patients analyzed, 485 (44.13%) fully completed the HUS-iCBT, and a further 363 (33.03%) completed at least the first 4 sessions, meaning that 251 (22.84%) patients dropped out early. Those who completed from 4 to 11 sessions were considered as late dropouts. On average, patients completed 7.8 (SD 4.2; 65.1%) of the 12 sessions. The average time on therapy (time between pretreatment and last measurements) in the whole sample was 128 (SD 97) days, 171 (SD 95) days for completers, 36 (SD 44) days for early dropouts, and 131 (SD 84) days for late dropouts.

At baseline, completers and noncompleters differed in their proportions regarding referral source, municipality class, average age, and OASIS scores (Table 1). The average age of completers was 4.9 years higher with their average OASIS score being 0.7 points higher than the score of noncompleters. Statistically significant differences did not emerge in gender distribution or in the average GAD-7 and PSWQ scores.

Figure 1. Patient flowchart. GAD-7: Generalized Anxiety Disorder 7-item scale.

In post hoc analyses, completion was more likely among patients referred from private or occupational care (50.4%) than among those from primary care (39.1%; $\chi^2_1=9.675$; $P=.004$). Baseline OASIS scores differed significantly between early dropouts and both late dropouts ($t_{612}=4.297$; $P<.001$) and completers ($t_{734}=6.041$; $P<.001$), but not between late dropouts and completers ($t_{846}=1.625$; $P=.105$). The average baseline OASIS scores were 13.3 for early dropouts, 12.3 for late dropouts, and 12.0 for completers.

In total, 30 therapists treated an average of 37 (SD 38) study patients. Of the 1099 patients, 1097 (99.81%) received at least one message from their therapist, and 796 (72.43%) sent one or more messages to their therapist. Completers sent a message more often (420/485, 86.6% patients) than noncompleters (376/614, 61.2% patients). Therapists sent, on average, 8.4 (SD 4.7) messages and patients (those who did) sent 4.0 (SD 4.2) messages. Of those patients who did send messages, the average number of messages that completers sent (4.9, SD 4.8) was greater than that of noncompleters (3.1, SD 3.1). Therapists sent, on average, more messages to completers (11.6, SD 4.4) than to noncompleters (5.9, SD 3.1).

^cOASIS: Overall Anxiety Severity and Impairment Scale.

Primary Outcome Model

The building of the primary mixed model is described in [Multimedia Appendix 1](#) and [Textbox 1](#). The model was built backward stepwise, with all terms of interest entered into the model. Eliminated terms were gender, both in average effects and time interaction; municipality class, both in average effects and time interaction; age in average effects; and completion status, both in average effects and session interaction.

The estimated fixed and random effects on GAD-7 are given in [Table 2](#), and the model-estimated mean trajectory is shown in [Figure 2](#). According to the model, after the average time between the pre- and posttreatment observations for completers (171, SD 95 days), the main effects of time on GAD-7 would amount to an average of 3.1 (95% CI 4.4-2.7) points of

improvement. The main average effect of the session was 0.523 (95% CI 0.592-0.455) points of improvement per session, or 6.7 (95% CI 5.5-7.1) points after all 12 sessions. Time had a negative interaction with session, and over a complete therapy (12 sessions), an extra week of therapy would amount to an average of 0.20 (95% CI 0.16-0.24) points of deterioration. Older patients improved more than their younger counterparts; for example, 40-year-old patients improved on average 0.3 points more (95% CI 0.1-0.5) than their 20-year-old counterparts after an average course of therapy. Patients from private or occupational health care had similar overall symptoms as patients from student health care (95% CI -0.6 to 1.6) but milder than those from specialized psychiatric care (95% CI 1.0-3.1) and primary health care (95% CI 0.4-1.4). Patients from private and occupational health care benefited similarly as patients from

psychiatric services (95% CI -0.12 to 0.17) but more than patients from student (95% CI 0.13 - 0.46) or primary health care (95% CI 0.05 - 0.19) per month on therapy. Completers and early dropouts benefited from the treatment similarly (95% CI -0.16

to 0.35), but late dropouts benefited less (95% CI 0.16 - 0.35) per month. Estimates of random effects indicated that patients likely had individual overall symptom levels ($P<.001$).

Figure 2. Estimated mean marginal values based on linear mixed model versus observed values. Curves depict an average patient trajectory. GAD-7: Generalized Anxiety Disorder 7-item scale.

Effect Sizes

Treatment effect sizes are given in Table 3. The estimated ITT treatment effect size was 0.97, indicating a large effect on the GAD-7. The estimated scores indicated a small effect size in early dropouts (Cohen $d=0.34$) and a large effect size in late

dropouts (Cohen $d=0.85$). The treatment effect observed for the completers was very large (Cohen $d=1.39$).

At the 3-month follow-up, 111 completers were reached, which accounted for 10.1% of the whole sample and 22.9% of the completers. The observed change in the GAD-7 score was -6.8 . For secondary measures, changes were -11.3 in PSWQ and -3.9 in OASIS.

Clinical Change Indexes

Clinical change indexes based on the GAD-7 scores are provided in Table 4. After the treatment, 23.29% (256/1099) of patients achieved remission (GAD-7 score <5).

Indexes for PSWQ and OASIS were reported only for completers because noncompleters had only one observation. Reliable change on PSWQ was a change of >12 points and 40.9% (196/479) reliably improved and 1% (5/479) reliably deteriorated. On OASIS reliable change was a change of >3 points and 48.6% (233/479) reliably improved and 1.5% (7/479) reliably deteriorated.

Table 4. Clinical indexes at the final on-therapy observation.

Discussion

Principal Findings

This nationwide, free-of-charge, therapist-supported HUS-iCBT for GAD in routine care, with no predetermined maximum completion time, comprised 1099 patients referred by their physicians. To the best of our knowledge, this study has the largest reported real-world sample involving iCBT for GAD. The patients reported substantial improvement in ITT analyses amounting to effect sizes of Cohen $d=0.97$ on GAD-7; and for completers, Cohen $d=1.39$ on GAD-7, Cohen $d=1.14$ on PSWQ, and Cohen $d=1.23$ on OASIS. The full completion rate was 44.1% (485/1099), and the average session completion rate was 7.8 (65%) of the total 12 sessions. A reliable improvement occurred in 48.4% (532/1099) of the full sample. Of those with a baseline GAD-7 score ≥ 10 , reliable improvement occurred in 53.6% (479/894), with a transition to recovery achieved by 54.4% (421/894). These results seemed to be enduring for 22% (111/485) of completers who answered the follow-up questionnaires. The average change on the GAD-7 at 3-month follow-up was still -6.8 points (vs -6.1 at after the treatment).

Comparison With Earlier Work

Symptomatic Change

The change in GAD-7 score was comparable with that achieved in 3 of the 4 Australian ThisWayUp trials (Cohen $d=0.91$ - 1.18 [23,26,27]) lower than that in the fourth trial that used different inclusion criteria (Hedges $g=2.06$ and 2.10 [28]), and comparable with the Online Therapy Unit's trial (Cohen $d=1.07$ [29]). The change in GAD-7 scores in our study was also not inferior to the within-group change in a recent meta-analysis of RCTs of transdiagnostic iCBT for anxiety and depression (95% CI 0.91 - 1.22 [15]). The effect size also seems encouraging when contrasted with change in comparison with a waiting list in another meta-analysis (95% CI 0.39 - 1.01 [9]).

Interestingly, from both practical and theoretical viewpoints, the longer it took for patients to complete a given number of sessions, the less they improved. It is plausible that the effects of therapy become diluted if the patient's commitment to therapy weakens. Therefore, methods of increasing engagement in therapy seem one of the most promising ways to increase the effectiveness of iCBT for GAD.

The change in the PSWQ for completers (Cohen $d=1.14$) indicates a substantial improvement in worry. In a meta-analysis of 10 RCTs of iCBT for GAD, the ITT effect size on the PSWQ in iCBT was 0.71 [16]. Although the comparison is not direct, the results of this study agree with the existing RCT results.

The OASIS-measured anxiety-related functional impairment demonstrated a large improvement in the completers (Cohen $d=1.23$). Of the ThisWayUp trials, Mahoney et al [28] found medium to large improvements in health-related disability and functioning, as measured by the World Health Organization Disability Assessment Schedule 2.0. Similarly, a trial conducted by the Online Therapy Unit [29] found that patients had a large decrease in functional impairment after therapy, as measured by the Work and Social Adjustment Scale. The combined results

strongly suggest that iCBT for GAD can improve functional capacity.

Our completers improved faster than late dropouts, unlike those in 2 earlier studies, which showed no or negligible differences. However, significant improvement was also observed in our noncompleters, which could imply heterogeneity in this population. Feedback offered by the patients who withdrew from the Online Therapy Unit intervention also suggests that several patients may have discontinued treatment as their symptoms improved [29]. In iCBT for depression, there seems to be a subgroup of patients who benefit from the therapy rapidly and discontinue treatment prematurely [56]. These patients may regard further treatment as unnecessary. Hence, discontinuation should not be considered, by default, a failure.

Although not unequivocally proven, clinician-referred patients in iCBT tend to exhibit lower effect sizes than community-recruited or self-referred ones [13,57]. Thus, our results seem encouraging, as all patients in HUS-iCBT have been physician-referred.

Recovery and Reliable Change

In the ITT analysis using LOCF, of HUS-iCBT patients with a baseline GAD-7 score ≥ 10 , 54.4% (486/894) of patients achieved recovery. This recovery rate is comparable with that reported earlier in face-to-face CBT for GAD (51.4% [54]). Owing to differing imputation methods, we cannot directly compare our ITT results with those of Australian studies. Nevertheless, Hobbs et al [26] reported a 70% recovery rate for completers, which is comparable with our 72.7% (280/385).

Moreover, the criteria for reliable change in our study and previous studies differed, which prevented direct comparison. In one meta-analysis of RCTs of iCBT, reliable deterioration occurred in 3.1% (95% CI 1.5% - 5.9%) of patients in trials for anxiety disorders [13]; in another meta-analysis of several disorders, reliable deterioration occurred in 5.8% of iCBT patients (vs 17.4% of patients on the waiting list) [21]. In HUS-iCBT, reliable deterioration occurred in 3.73% (41/1099) of patients. Thus, HUS-iCBT for GAD also appeared to be as safe as precious treatments and safer than no treatment.

Adherence

The full completion rate in our study (485/1099, 44.13%) was similar to the rates in previous routine care trials (36%-55%) but lower than that in a meta-analysis of routine care iCBT for depression and anxiety (61%) [13]. However, RCTs are likely to inflate adherence when compared with real-world trials. For instance, ThisWayUp's trials have shown a dramatic decrease from very high full completion rates when transitioning from a research setting into primary care (75%-85% vs 38% [24]).

The proportion of completed sessions in HUS-iCBT (65%) was marginally lower than that in the earlier trials (67%-77% in ThisWayUp's and 72% in Online Therapy Unit's trials) but somewhat higher than that in the previously mentioned meta-analysis (57% [13]). Compared with ThisWayUp's program, a lower proportion of completed sessions may be expected in a therapy comprising twice as many sessions (12 vs 6). Interestingly, more patients in the HUS-iCBT completed

≥6 sessions compared with the Australian trials (61% vs 36%-55%). On the other hand, the Online Therapy Unit had slightly better results with a program of similar length both in sessions ($n=12$) and average days on therapy (135 vs our 128). Differences in the course of therapy, recruitment, and therapist protocols prevent straightforward comparison. The comparison is further hampered by the overlapping recruiting periods in the Australian trials, as the number of patients reported remains unique. Hence, the optimal number of iCBT sessions for GAD remains unknown.

Compared with our noncompletion rate (614/1099, 55.86%), face-to-face individual psychotherapy for GAD has had a low dropout rate of 17% in a meta-analysis of RCT trials [58], and a meta-analysis of nonrandomized outpatient studies on CBT for adult anxiety disorders showed a similar dropout rate of 15% [59]. However, the criteria for completion in face-to-face psychotherapy are often more lenient, such as stopping when agreed upon with the therapist or completing a minimum number of sessions [59]. Thus, the adherence numbers are not comparable and are likely to be closer to iCBTs when analyzed with an equivalent metric.

In our study, completers sent and received more messages than did noncompleters. Our data do not allow exploration of causality, but this finding may be intuitively explained by the completer's longer time on therapy. In the Online Therapy Unit's trial [29], both patients and therapists sent more messages (on average 9.6 and 20.0, respectively) than ours (4.2 and 8.4, respectively). This difference is not surprising, given the differences in intake protocol (both clinician referral and community recruitment and intake interview vs strictly a physician's referral and only referral screening in HUS-iCBT) and therapist-contact intensity (weekly messages vs minimum 4 messages per therapy). These differences may also partly explain the higher adherence in the Online Therapy Unit's trial.

Patients' Background Effects

Older patients improved more and faster than younger patients. At first glance, this seems counterintuitive, as one could presume that young, digital native patients could feel more comfortable in the digital realm than the older ones. Nevertheless, 1 of the 3 ThisWayUp's trials also found that older age predicted larger improvement [23], whereas another found no such relationship [26], and the third trial found a relationship but left its direction unreported [27]. Furthermore, in a transdiagnostic study of iCBT for anxiety and depression, older age predicted greater improvement [60], whereas in a meta-analysis of various psychotherapies for GAD, older participants improved less than younger ones [61].

Moreover, younger patients were less likely to complete the program than their older counterparts. This relationship has been a common finding in iCBT for GAD in routine care [23,26,27] but not in face-to-face psychotherapy for GAD [58]. The average age in this study was 33 years, 6 or 7 years lower than that in the 3 ThisWayUp and single Online Therapy Unit study that reported their sample ages [23,26,27,29]. Overall, research on the age issue is scarce, and what still remains obscure is how age may or may not affect the results of different modes of therapy, such as face-to-face therapy or iCBT.

Gender had no significant influence on adherence in our study, similar to the findings of Australian studies. Systematic reviews of RCTs on face-to-face psychotherapy for GAD or CBT for anxiety disorders have also found no significant gender-adherence relationship [54,58].

The full completion rate was higher among patients referred from private or occupational health (171/339, 50.4%) than among those referred from primary care (235/601, 39.1%). Their symptoms improved faster than those referred from students or primary health care. These effects could be due to patient-group differences: patients referred from occupational health are, by definition, employed and presumably have a higher average level of functioning, higher socioeconomic status, and a lower likelihood of serious comorbidities. Moreover, in our recent study, physicians in occupational health displayed more interest in sending patients to iCBT than their primary care counterparts [62], which may transfer into patients' own expectations and motivation.

Patients from nonurban municipalities were more likely to complete the therapy (73/130, 56.2%) than those from urban municipalities (412/966, 42.7%). This relationship is somewhat opposed to the findings in the 2012 report by Mewton et al [23], where patients from urban settings were more likely to complete the therapy than were those from a rural setting. The causes of this difference are unknown and are likely to include multiple recently discovered factors, such as differences in technology adoption, financial concerns, and access to treatment [63]. Nevertheless, the municipality class did not demonstrate a significant impact on symptomatic improvement in the mixed model analysis.

Design Comparison

The results of this and earlier studies in routine care are, in general, comparable despite considerable differences in setting, design, and support.

To the best of our knowledge, HUS-iCBT and the Online Therapy Unit's programs had no predetermined maximum therapy completion time, whereas ThisWayUp applied a typical fixed maximum time restriction (90 days). The time from the first to last observation on HUS-iCBT (128 days) and from the first to last log-in at the Online Therapy Unit (135 days) were comparable and longer than the typical 90 days in other trials. Although the lack of a predetermined maximum time span may support adherence during changing life situations, it could also disengage some patients and dilute therapy effects, thereby leading to an increased dropout rate. As confounding design and sample features exist, such as different numbers of sessions and differences in sample average age, the optimal time span remains unknown.

In the Australian studies, patients were referred to iCBT by their own independent clinicians, each of whom was required to register as a provider, to receive training, and to use an assessment toolkit. The Online Therapy Unit required a centralized diagnostic interview. Our HUS-iCBT only screened referrals from physicians (but not from other clinicians) with no obligatory registration or any specific assessment schema. The practice at HUS-iCBT was chosen as the middle ground to

ensure proper diagnostics while maintaining a high intake flow. To maintain a low threshold, the inclusion criteria in HUS-iCBT were purposely loose, with only 0.6% (51/8394) of all physician referrals rejected during the recruitment period, and this may have contributed to a possible patient–therapy mismatch.

In HUS-iCBT, the support was provided centrally by specially trained and supervised mental health professionals, as recommended by authors from 5 universities who argue that iCBT requires specialized expertise and processes [64]. In the ThisWayUp studies, support was provided by the referring clinicians, who rarely contacted their patients. A pre-existing alliance could compensate for the clinicians' lack of specialized training.

HUS-iCBT was free of charge for the patients, as was the treatment at the Online Therapy Unit. Patients in ThisWayUp paid approximately Aus \$49 (US \$37) for the treatment, which may have ensured motivation and therefore improved adherence [24] but may also serve as a barrier to treatment.

Strengths and Limitations

The main strengths of this study are its nationwide scope, the largest sample thus far reported, and its routine care setting. One could argue that reliance on self-report measures can inflate treatment effects, but 2 recent meta-analyses suggest that combining indexes based on self-reporting can be even conservatively biased [7,54]. Self-report measures also fulfill practical requirements for scalability.

Other routine care studies did not use PSWQ or OASIS. Their addition in our study shows that iCBT for GAD can ease pathological worry and anxiety-related impairments in routine care. Although they both offer important information, they may not be as sensitive to change as the GAD-7.

Concomitant treatments, including psychopharmaceuticals, are often offered to patients in routine care. Information on these treatments is not reliable. This limits our understanding of the possible interactions between different treatments.

Not all comorbidities may have appeared in patient documents in referrals, and depressive symptoms were not measured. This issue is particularly relevant for GAD, as its annual comorbidity with major depression is around 41% [4]. One effectiveness study also indicated that depressive symptoms could decrease treatment effectiveness [26]. The lack of depression measurement does not weaken the study's results but highlights the question of whether every one of our patients received optimal treatment.

We could not, retrospectively, reliably identify the therapist behind each message sent to the patient. We know that due to vacation periods, illness, or leaving HUS, not all messages sent to a patient may have come from the same therapist. This prevented us from analyzing the effect of the individual therapist, their profession, or other relevant training.

Only 23% (111/485) of completers were reached for the 3-month follow-up. Such high attrition limits our conclusions regarding long-term effectiveness. However, we did not include follow-up data in the linear mixed model analyses, and these limited data do not compromise the main results.

Future Research

Thus far, therapist-supported iCBT for GAD has not been compared with other active treatment forms or no treatment in routine care, making comparisons with active controls, coupled with health economic analyses, essential. Not all patients benefit from iCBT for GAD. Both transdiagnostic programs and tailoring content to individual needs have displayed promising results [15,64], although for anxiety, unguided transdiagnostic iCBTs may be less or no more efficacious than diagnosis-specific ones [19,35]. Tailored transdiagnostic treatments seem likely to be a significant trend in iCBT, but evidence for their added value still needs to be confirmed.

Adherence to iCBT for GAD seems to be lower in primary care than in RCT trials. Evidence is emerging for adapted therapist support for patients at risk for dropout [65,66] and for an optimal therapist-contact schedule for iCBT in cases of depression and insomnia [67,68]. Machine learning applications could accelerate the identification of patients at risk for dropout and accelerate proactive support. However, this venue of research is still in its infancy.

iCBT programs often retain a considerable number of text-based answers and messages. Text mining approaches could offer an exciting avenue for exploring qualitative phenomena. Such analyses could be beneficial for both theoretical research and the practical application of iCBT.

The optimal time schedules for or the number of sessions in iCBT for GAD remain unclear. Further comparison studies should seek to establish more suitable, effective, and economic combinations. Age and other demographic variables may also influence the outcomes of iCBT for GAD. To provide equally effective care for everyone, future studies should investigate how to overcome hurdles presented by demographic variables.

PSWQ and OASIS were not used in other routine care studies. They represent both diagnosis-specific and transdiagnostic processes related to GAD and anxiety in general. OASIS, a short self-rating scale, opens up a venue for further comparative research between iCBT for various psychiatric disorders. As PSWQ measures pathological worry, a theoretically important GAD feature, an in-depth psychometric examination of PSWQ may reveal important information on moderators and mediators of effectiveness.

Since the collection of our data, HUS-iCBT for GAD has adopted a novel technical platform, a predetermined maximum completion time (20 weeks), pretreatment phone calls, and weekly therapist support. These changes may have practical implications that will enable further studies.

Conclusions

This nationwide, free-of-charge, therapist-supported HUS-iCBT for GAD with no predetermined maximum completion time was effective at improving symptoms and reducing worry and functional impairment in routine care. Overall, this therapy appears to be safer than no treatment and is at least as effective as other therapist-supported iCBTs for GAD. The observed gains at the 3-month follow-up should be confirmed in future studies. Future research needs to establish comparative

effectiveness against other treatments and to optimize the benefit patients.
of iCBT for GAD in a variety of patient groups and individual

Abstract

Background: Digital interventions have gained momentum in terms of behavioral health. However, owing to lacking standard approaches or tools for creating digital behavioral interventions, clinical researchers follow widely varying conceptions of how best to go about digital intervention development. Researchers also face significant cost-, time-, and expertise-related challenges in digital intervention development. Improving the availability of tools and guidance for researchers will require a thorough understanding of the motivations and needs of researchers seeking to create digital interventions.

Objective: This study aims to understand the perceptions of behavioral researchers toward digital interventions, and inform the use of these interventions, by documenting the reasons why researchers are increasingly focusing their efforts on digital interventions and their perspectives on the perceived benefits that digital approaches can provide for researchers and intervention recipients.

Methods: We conducted semistructured qualitative interviews with 18 researchers who had experience designing digital behavioral interventions or running studies with them. A convenience sample of interviewees was recruited from among users of the Computerized Intervention Authoring System platform, a web-based tool that facilitates the process of creating and deploying digital interventions in behavioral research. Interviews were conducted over teleconference between February and April 2020. Recordings from the interviews were transcribed and thematically analyzed by multiple coders.

Results: Interviews were completed with 18 individuals and lasted between 24 and 65 (mean 46.9, SD 11.3) minutes. Interviewees were predominantly female (17/18, 94%) and represented different job roles, ranging from researcher to project or study staff. Four major themes came out of the interviews concerning the benefits of digital interventions for behavioral health: convenience and flexibility for interventionists and recipients, support for implementing evidence-based interventions with fidelity, scaling and improving access to interventions, and getting a foot in the door despite stigma and disenfranchisement.

Conclusions: Interviewees described a number of important potential benefits of digital interventions, particularly with respect to scientific rigor, scalability, and overcoming barriers to reaching more people. There are complex considerations with regard to translating behavior change strategies into digital forms of delivery, and interventionists make individual, sometimes unexpected, choices with minimal evidence of their relative effectiveness. Future research should investigate how behavioral researchers can be supported in making these choices toward usability, ease of access, and approachability of digital interventions. Our study underscores the need for authoring platforms that can facilitate the process of creating and deploying digital interventions to reach their full potential for interventionists and recipients alike.

Introduction

Background

Digital behavioral interventions, which rely on digital technologies to promote behavior change and maintain health [1], have been growing rapidly over the past several decades. Digital approaches have unique potential benefits in promoting behavioral health, especially with regard to risky behaviors and sensitive or stigmatized topics (eg, drug and alcohol use [2-4], sexual health [5,6], and mood and anxiety [7]) that many are hesitant to discuss openly [8].

However, the development of such interventions requires significant expertise, planning, and financial resources [9-11]. Researchers interested in digital interventions may need more support in areas such as design guidance, software development, and financial or other logistical considerations. However, this support must be grounded in a deep understanding of the ways that investigators are using, or hope to use, digital interventions in their research. The purpose of this 2-part qualitative investigation is to better understand the motivations, needs, constraints, and experiences of researchers who have looked to digital interventions in their work addressing behavioral health. This study was conducted as part of a redesign of the Computerized Intervention Authoring System (CIAS) platform, a web-based authoring tool for researchers [12-14]. This study includes previous and current CIAS users and CIAS-naïve users with interests in developing interventions for substance use [3,4], mental health [15], and HIV [16]. This convenience sample enabled us to investigate the experiences of researchers who have used an authoring tool to assist with the development, deployment, and scaling of digital interventions.

Objectives

In this paper (part 1), we seek to document the reasons why these researchers used digital health interventions to address behavioral health. In a companion paper (part 2 [17]), we report common barriers to the intervention creators' experience and key considerations that go into the design and implementation of digital interventions.

Methods

Overview and Ethics Approval

We conducted semistructured interviews with former, current, and potential future CIAS users, including investigators and research study staff. All methods used in this study were approved by the University of Michigan human subjects review board (HUM00171197) and Wayne State University institutional review board (IRB-19-10-1340) and were reported following the COREQ (Consolidated Criteria for Reporting Qualitative Studies) guidelines.

CIAS Platform

CIAS is an internet-based intervention authoring tool that allows users to easily build, edit, and share web-based digital interventions without needing to have computer programming experience. The CIAS Health Insurance Portability and Accountability Act-compliant platform provides researchers with the ability to develop tailored and personalized text-based interventions that can be narrated by a variety of avatars, both human and animal, capable of multiple different actions and voices (supporting >40 different languages, with male and female versions of most, and a range of accents and dialects for some of the more commonly spoken languages). For researchers, CIAS supports screening functionality to determine study eligibility, in-platform randomization to multiple conditions, custom summary report generation, on-demand data access, SMS text messaging alerts flagging specified user inputs (eg, flags for suicidal ideation), instant language translation, a visual map showing intervention flow, and web analytics. CIAS supports intervention development features such as multiple question types, natural language reflections, branching and tailoring, and integration of video content. CIAS has been used by numerous research groups to develop a variety of digital interventions, many of which have focused on stigmatized behaviors such as substance use [15,18-21]. With support from the National Institutes of Health (EB028990), our team is redesigning CIAS from the ground up. This research was conducted as part of the redesign activities.

Participant Recruitment

Interviewees were recruited via email solicitations from a purposive convenience sample of CIAS users via snowball sampling and through email to investigators familiar with conducting digital interventions. Most participants had experience with motivational interviewing (MI), an evidence-based technique to support behavior change [22], and in interventions on a variety of behavioral health topics. To be eligible to participate in this study, participants were required to be aged at least 18 years.

Study Procedures and Data Collection

Owing to the COVID-19 pandemic, all interviews were conducted via teleconference and recorded for later transcription. Interviews were conducted in single sessions between February and April 2020 by 2 trained female study team members (BMB and ANS) with expertise in user experience design and methodology and with Master's of Science in Information degrees. The 2 interviewers took field notes during the interviews, which typically lasted no more than 60 minutes. Study participants did not know the interviewers and were not given prior access to interview questions or guides; however, all participants knew they were being interviewed as part of CIAS redesign efforts. At the beginning of each interview, the interviewers read a standard script focused on information pertaining to the study, and the interviewees gave verbal consent before the interview. At the conclusion of the interviews,

interviewees completed a brief electronic survey to assess their comfort with CIAS (if they had used it previously) and collect basic demographics. Participants were neither granted access to interview transcripts for review nor asked to comment on the findings. Interviewees were offered a US \$20 check, which was mailed to their home, for each interview. Interviews were conducted until saturation was reached.

Analysis

Analysis began with a debriefing between the 2 interviewers after each interview, during which they reviewed their individual notes and gradually synthesized data across interviews, looking for patterns. Interpretations of the data and identified patterns were discussed at meetings with the full study team every other week. This stage of analysis categorized participants within the common roles they played in their interactions with the CIAS or other digital interventions. Interview recordings were then transcribed, and inductive thematic analysis was conducted by 2 coders (BMB and ANS), including an initial round of full analysis that finalized a set of patterns that became the themes

of this paper, followed by a second round of analysis that then validated these themes and confirmed connections among them. Memoing was used throughout this process.

Results

Overview

We solicited 24 former and current CIAS users for participation in this study. Of the 24 participants, the interviews were conducted with 17 (71% response rate). In addition, we solicited additional CIAS-naïve users familiar with digital interventions through email recruitment using the University of Michigan Department of Family Medicine listserv and recruited 1 additional participant. In total, we completed interviews with 18 participants. The interview duration lasted between 24 and 65 minutes (mean 46.9, SD 11.3 minutes). Interviewees were predominantly female (17/18, 94%) and represented different job roles, ranging from investigator to project or study staff. [Table 1](#) displays the aggregate interviewee characteristics, and [Table 2](#) displays brief descriptions of each interviewee.

Benefits of Digital Interventions

Overview

Our interviews revealed the perceived benefits of digital interventions from the perspective of researchers focusing on interventions for behavioral health. Grounding our interviews in the use of the CIAS platform led to themes focused on the concrete, current, or near-future capabilities of digital interventions. Interviewees most commonly pointed to four categories of potential: increased convenience and flexibility, implementing evidence-based interventions with fidelity, scaling interventions and improving access, and getting a foot in the door despite stigma and disenfranchisement.

Convenience and Flexibility for Interventionists and Recipients

Researchers described looking to digital interventions as they allow for more flexibility in where and when they are delivered. Interviewees discussed the potential for the digital approach to increase convenience and flexibility for researchers and the populations they are looking to reach. One of the researchers noted that the convenience of accessing a digital intervention is what an increasing number of generations is coming to expect of any service they receive:

We have water, we have food, and we have cell phones. Everyone is on their cell phones. Even the older generations have a phone. So, I think that CIAS is very convenient...I would like to see it a component like telemedicine is now. Telemedicine has its own phone number on the back of newer insurance cards

now...And I think that would definitely be rewarding to a lot of people. Because I see a lot of Millennials, and even the GenXers they're gravitating towards computer-based help. They're not jumping into their cars, spending \$3 for a gallon of gas to go to somebody's clinic. They're hopping online. [P10]

Evolving expectations about service delivery extended to the clinical point of view. Another researcher explained their view of how digital tools would likely support research and clinical visits in the future:

I think [CIAS] is going to allow us to deliver interventions at times that are more convenient for participants. As everything goes more mobile and more digital, being able to shoot a participant a link, enroll them in a study, shoot them a link, let them complete their follow up visits via that link, send me a text when they're done, shoot them an e-incentive. I think that's really going to change just delivering behavioral interventions in clinic and around clinic visits to delivering them, not when the client wants, so you're still on timed intervals, but when it's most convenient for the client. [P5]

However, researchers most often cited benefits for the recipients, including more choice in how they interact with the content. Recipients can complete intervention sessions wherever they are most comfortable and during a time they deem most appropriate while still staying within the allotted timeline of the intervention. This increase in flexibility may heighten the appeal of behavioral interventions to recipients, and researchers speculated that this could help with engagement:

I think a mobile intervention delivered on a computer is less threatening, and on the surface seems easier or more palatable to a research participant. "I don't have to go anywhere to do this, it can come to me at a time that's convenient to me"...The thought of coming into the office to do psychotherapy sessions is unappealing for many. But, looking at the convenience of my home at a time that is convenient for me, it may be more appealing. [P7]

Researchers were especially attuned to the needs of recipients who experienced symptoms such as fatigue, which could affect their engagement with an intervention. In these situations, interviewees had the sense that delivering interventions remotely via computers was helpful:

As far as it being remote, our participants, actually, the ones that do follow through and do their things, they love it because we're measuring their level of fatigue, so we aren't bothering them with making them come somewhere to have their visit completed. They can do it when they feel ready, feel able so it being remote is actually getting people to stay on, it's easier to get them to stay on because they don't have to go anywhere. [P11]

As we will discuss in following sections, the convenience of recipients accessing interventions from their homes is also important when addressing mental health and other sensitive or stigmatized topics.

Implementing Evidence-Based Interventions With Fidelity

Digital interventions also have the benefit of providing a structure that can support the use of evidence-based strategies with fidelity—that is, as intended or designed to ensure efficacy. Many of the researchers we interviewed were experienced in using MI and reflected on how and why they used digital interventions in concert with this approach. Digital interventions control the structure of how recipients experience the intervention, and researchers also remarked on how easily they could monitor the intervention and collect various kinds of data as recipients engage with it:

It's all programmed so there's less issues with fidelity and fidelity monitoring and so I guess that's the piece that changes CIAS, problem solving and/or developing strategies to monitor and track intervention fidelity. We still have to track delivery, so we still have to figure out "did they get it? did they complete it?" but we're not dealing with a human counselor who can kind of not follow the roadmap. [P7]

The analogy of an intervention as a road map suggests that systematic mapping of a digital intervention's user experience can serve to ossify the intervention and standardize how it is delivered to recipients. This mapping is performed once when the digital intervention is designed, and then researchers know that it will be delivered consistently each time. Therefore, interviewees indicated that improvements in fidelity could come

about not least by reducing reliance on humans, each of whom must be trained to effectively deliver the intervention:

Home visitors were mostly...they're not trained clinicians...they don't necessarily have the skills to really implement a brief motivational intervention in a way that it would be effective...so we sort of landed on CIAS where it's electronic and would be fully implemented electronically so the home visitor doesn't...have to learn how to do brief interventions. [P15]

Others similarly described how they had used digital interventions to overcome the variability inherent in training humans to deliver interventions, such as MI:

Most of the literature says that no matter how well you train people, that they don't deliver MI with high fidelity to the components that are supposed to be there at all. So, you spent all these hours and hours training people, and they still don't do it the way it's intended. So, of course, you know, having, and always doing it the same way makes a huge difference. [P1]

In addition to reliance on humans to deliver interventions consistently, researchers described challenges with training against the natural tendency to provide advice. By contrast, digital interventions were seen by interviewees as nonjudgmentally enabling a recipient to reflect on their health behaviors without the potential intrusion of another person's thoughts:

Our biggest challenge when teaching navigators...is getting them to not move into the role of "here's how to fix this and giving advice prematurely". And kind of having their own agenda. So, I think the pieces that can be done really well with CIAS are, you know, non-judgmental opportunities for a person to kind of look at their situation. [P9]

Interestingly, researchers saw an advantage in the fact that more nuanced aspects of MI, such as empathy, cannot be easily conveyed through a digital intervention. As recipients have lower expectations for warmth and understanding than they do of a human, a digital intervention may not need to meet many requirements for an effective interaction:

You can get away with a lot more on a computer-based intervention than you can with an in-person intervention. So, for instance, the idea of empathy and understanding, and warmth, and avoiding advice-giving and stuff like that, there are issues within person interaction. I don't think a lot of those are really problems with computer-based interventions. So, a computer can say "hey, wake up, go for a walk today" but if you told that to your roommate or boyfriend, that would be obnoxious, right? So, I wouldn't say that thinking is different about in-person than they are with online interventions, but the capacity of the two to kind of do the "dance" differently. [P6]

Other interviewees alluded to this dance between the intervention and the recipient, describing how they balance the

advantages and disadvantages of digital interventions to implement evidence-based strategies. For example, when using MI, there is a trade-off between the nuance a human is capable of and the difficulty in achieving consistent delivery of the intervention. Some researchers choose to sacrifice some of the former to improve the latter with a digital intervention:

The role of the avatar in this [intervention]...I think it isn't as good as a really good MI therapist delivering the intervention [using core principles like affirmations, empathy, non-judgement, no premature advice]. No, it's not, but as someone who trains people on a regular basis, you know the things that CIAS can do and do consistently, are things that I struggle to train caseworkers and patient navigators to be able to do. And I think in that sense it's a, it's a consistent step forward and an improvement...CIAS just lets you sort of balance that out [any variation in individual skill or technique] and make sure that everybody's getting some basic level of MI consistently. [P9]

Therefore, one of the key reasons that our interviewees chose to adopt digital interventions was to improve the fidelity of their evidence-based interventions through consistent delivery, monitoring, and avoidance of factors that are very difficult to manage when training humans. On the other hand, the downside of increasing structure and fidelity with digital interventions is losing the human ability to pick up on cues from the recipient, have more open-ended conversations, and adjust the intervention in response.

The Way of the Future: Scaling Interventions and Improving Access

Researchers were enthusiastic about the potential for scaling to broader populations with digital interventions in the future. This argument was typically framed from a population health perspective, as a relatively small change in behavior can have significant consequences if it can be achieved widely:

If you can reach more people and have a small change, that's important in shifting population behavior. So, digital mobile health interventions are the way of the future. [P7]

Similarly, researchers described the benefits to public health efforts if apps could bring interventions to those who are most difficult to reach:

I think it would be hugely impactful. I think a lot of the issues, or a lot of the barriers that public health faces as an industry is kind of getting people involved and actual...a lot of the issues with public health is low income and low resources for a lot of communities, and providing something so easy to use and so easy to get as an app, and allow public health professionals to communicate with so many people much easier and much, much more can make a world of difference. Program building and eliminating disease, and you know providing a more healthy lifestyle for people and kind of guiding them through that process. [P17]

One of the researchers further summarized the multilayered social factors that have resulted in populations being neglected and saw digital technologies as a way of addressing inequity:

There's this void within our community that a population is being ignored. A population that could find themselves in a mental health crisis. And they may be wheelchair bound. They may not have transportation. They may not have 24-7 care. So, a lot of the day-to-day operations of their life are online and on the phone. And it also fulfills a common item in our life. [P10]

The level of access a person has to services can also change significantly during a crisis in their personal life or their environment. In such situations, digital interventions can be more accessible and immediately available to provide tangible help if a person cannot leave their home during a crisis, as demonstrated by the global pandemic:

CIAS is catching up with the times and so to speak, providing interventions that are needed that are immediate. But in a convenient way. Like, for example, right now CIAS is needed because we're quarantined to our home [due to the COVID-19 pandemic]. Let's say for example, a person is on the verge of a break. They're in an emergency mental health crisis, they can't leave their home for whatever reason that may be. So, they can access the phone, get on the phone, and talk to somebody with real information with real resources. [P10]

With the ease of providing people access to interventions digitally, researchers highlighted the potential for scaling interventions as well as tailoring them to different people's needs:

[Digital interventions are] really scalable, you can tailor it in an infinite number of ways. [P6]

For example, recipients' literacy may be a consideration, in which case digital interventions could engage the recipients through audiovisual interaction:

I think illiteracy is an issue for some of these folks. So, I think having a survey they could participate in where they didn't have to worry about having to read things was something [important to us]. [P9]

The ability to reach people in new ways expanded researchers' thinking about new kinds of interventions. More than just translating existing interventions into digital formats, they were excited to think innovatively based on novel possibilities now afforded to them:

[CIAS] definitely broadened my ideas—like what is possible...like how many people could be reached by this. I think that especially—I am from rural Alabama and there's no way that you're ever going to hire like a—even a social worker is a stretch—but to get someone into a clinic setting who is trained and qualified to do these [assessments] is a stretch. And, you know, having an option to give someone a tablet while they're sitting there and they go through maybe a very quick screener and then they're eligible for

something. Or they're at risk for something and you're handing them something that's interactive and personalized and can give them feedback without having to have another person on the other end, I think is genius and could help a lot of people. [P16]

Some interviewees highlighted the potential for scaling access to interventions as the key reason they chose to use digital interventions:

And so, across all of those [potential benefits] for me the selling point has been getting interventions to more people more effectively. [P9]

However, we note that this potential remained largely aspirational for many researchers in our study, an indication of ongoing challenges with the development of digital interventions.

Getting a Foot in the Door Despite Stigma and Disenfranchisement

Access to health interventions is even more challenging when targeting behaviors that are stigmatized or populations who may not be comfortable seeking help. Disclosure of certain behaviors or circumstances is a significant barrier to connecting an individual with appropriate support. Several researchers mentioned that digital interventions enabled them to broach the taboo topic of substance use among pregnant and postpartum women. Therefore, by facilitating disclosure of sensitive issues such as substance use or domestic violence, digital interventions may open the possibility of intervening:

Being able to deliver an intervention online...you can send someone a link and they can go through a program on their computer, that could potentially really help them without having to disclose to a doctor or social worker or research assistant. I think that has massive implications for being able to get people help that's tailored to them. For substance use, I think it will help a lot...it has the potential in any kind of stigmatized, sensitive area, like in the doctor's office - a domestic violence screener. In any kind of healthcare setting trying to screen for any type of sensitive issue, I think it has a lot of potential to help in those areas. [P13]

Notably, disclosure was brought up in the context of both clinic and home visits. Researchers were cognizant of protecting confidentiality, whether engaging someone in a public clinical setting or via a visitor to their home. A digital intervention, even if handed over to the recipient by a human, was seen as potentially protective of their confidentiality:

We're hopeful that home visiting clients will be able to answer [sensitive] questions via an iPad, if you take away the idea that somebody else is judging you. [P2]

Researchers described intentionally deploying digital interventions to convey to recipients the confidentiality of any disclosures:

The client doesn't have to disclose if they don't want to, and that's a lot of the adapting that we're doing

is around that - making the client understand that this is confidential, that the home visitor doesn't need to know what they're putting into the program. [P15]

Barriers continue beyond screening and throughout the intervention process. Even if a potential intervention recipient can be identified (eg, through their disclosure) and linked to appropriate resources, they must be ready to accept information related to their health behavior. Therefore, the anonymity that digital interventions can afford may be helpful to an intervention itself getting a foot in the door, as one of the researchers explained within the context of engaging pregnant or postpartum individuals about their substance use:

These types of interventions, anonymous [and] in this population, do have the potential to get information and help to people who would not normally receive it because they would be too afraid to ask for it. I mean, just getting a foot in the door with these people and being able to give them psycho-education or resources at all, is a win and can really help people. [P13]

Interviewees also described using digital interventions with populations they would not have expected to reach in the past, for example, because of racial disparities or the stigma against seeking mental health services:

We're tapping into areas that we would have never thought of before. Like in terms of the disenfranchised populations [including based on their race], people who are afraid of being seen in the daylight entering into a mental health clinic. By having a phone, by having CIAS, we are getting them the help they need and we're giving them privacy...I do think we provide a comfort...I think our research becomes more and more validated because we're showing how flexible psychology and behavioral health can be. [P10]

Once an individual is engaged in an intervention, the relative neutrality of an app may enable them to dig deeper into a topic, less impeded by impression management in the presence of another human. One of the researchers working on substance use among new mothers was hopeful that switching to anonymous engagement with a digital intervention would help recipients feel more comfortable disclosing sensitive information about their behavior:

The most important thing is that CIAS allows us to have confidentiality and allows the mothers to go through the interventions anonymously. It has removed the barrier, because the intervention before...the home visitor had to go down and take the mother through it and they found that almost zero of the mothers were truthful because they didn't like talking to a person about this. So, having our little parrot narrator [avatar] bring them through it will hopefully lead to us getting accurate data for once. [P13]

As this researcher explained the ability of digital interventions to engage recipients differently, they also described the efficient progression possible by asking about certain health behaviors

to connect the recipient with appropriate resources in interactive and tailored ways:

In an in-person setting in this kind of thing, you can almost never get a straight answer if you ask somebody like “We saw that you just had a baby. Care to talk about your substance use while you were pregnant?” Like no, no one’s going to say anything about that, so you always have to come from a perspective of... “in the month before you became pregnant, what was your substance use like?” But in an anonymous format, we can kind of work around those proxy questions and get more to the meat of it, like “how are you feeling about your substance use?” “Do you want information on how you can change?” and then if so, it immediately pops up, like here’s your list of resources for your town. [A digital intervention] definitely changes the way that you can ask questions. [P13]

At the most basic level, interviewees acknowledged that intervention recipients might not even be receptive to the information provided by the intervention. In addition to removing the human interventionist and providing more privacy, digital interventions could address this issue by tailoring the information, how it is delivered, and when it is delivered:

I think one thing that CIAS has shown me is that people do appreciate the opportunity to learn information in private. And being that we thought they were absorbing or listening to what was being delivered from a person, they actually aren’t. Because when you validate the information that they should have got from a person, electronically you see that it doesn’t line up. I think CIAS has given me a new respect for being able to deliver information in a way people will receive it...since we’re using MI, one thing that’s pretty cool is that it does assess how much a person is willing to hear and it only gives them that and people tend to be interested in following up because they weren’t pressured into hearing something they didn’t want to hear and the time they didn’t want to hear it. [P5]

Some interviewees reported that digital interventions had shown marked improvement in the experiences of both researchers and intervention recipients:

We really have found CIAS to be preferable to the alternatives of both live person interview and certainly compared to survey questions without having the avatar. It just keeps people’s attention and tends to, in my experience, you know, continue to engage them in a way that they’re hopefully answering the questions more validly. [P9]

Such reports suggest that researchers have succeeded in getting their foot in the door with digital interventions, potentially even being better positioned to facilitate behavior change compared with other types of delivery. However, the use of digital interventions is still new, and research on their impact is limited.

Discussion

Principal Findings

We sought to better understand the reasons why some researchers who study topics related to behavioral health use digital interventions for lifestyle and behavior change interventions. The benefits of digital interventions that we identified among interviewees were 4-fold and included factors such as increased convenience and flexibility, fidelity to protocols, potential scalability and increased access to interventions, and the ability to reach individuals who may otherwise be unwilling to engage on matters of a sensitive nature.

Increased Convenience and Flexibility

Interviewees consistently noted that digital interventions increased convenience and flexibility for both researchers and intervention recipients. For researchers, digital interventions are set up in advance before study recruitment, and they typically run automatically without much staff involvement and oversight. For intervention recipients, depending on how digital interventions are delivered, there is potential to engage at a time and place that is convenient. Especially for sensitive issues, intervention recipients may not wish to engage in public settings and with research or clinic staff with whom they are unfamiliar.

Implementing Evidence-Based Interventions With Fidelity

Overview

The second theme that emerged from our interviews was the notion of fidelity to intervention protocols, both in terms of content and protocol fidelity. The algorithmic and automated nature of digital interventions can facilitate the delivery of content that is on schedule and consistently delivered in the same manner across intervention recipients. This protocol-based fidelity is more difficult with human interventionists.

Content Fidelity

Digital health interventions have the potential to ensure that content is delivered in the same way to all users, that is, in a nonjudgmental manner, which has been previously noted as a concern [23]. By digitally delivering content, we may be able to reduce social desirability bias. Moreover, automated interventions can finely tailor messages on a granular level in a way that is difficult for human interventionists.

Protocol Fidelity

The use of digital interventions can be tracked objectively and in detail. For example, log files and time stamps can verify when content is sent and when intervention recipients are engaged with the intervention. We can also objectively monitor measures of engagement, such as the number of times the content is accessed and the time spent engaging with content. Digital interventions allow information to be presented to recipients in a systematic way, which can allow for easier replication across various studies and with different populations, which could have a positive impact on the validity of a research study. This consistency can greatly benefit interventions that are based on

validated therapeutic techniques, such as MI, by standardizing its delivery across all recipients.

Fidelity Is Not Guaranteed

However, it should be noted that the benefits of content and protocol fidelity may not always be realized. Experienced researchers know that new threats to fidelity that are otherwise absent from face-to-face interventions exist in a digital world. Digital interventions often cannot guarantee that automated digital content is received by the correct person or that users engage with the content in the intended manner. Although technical logs can tell us that messages were sent and the amount of time spent within interfaces or on specific pages, researchers cannot guarantee that content was received or read, that the content reached the correct users, or that users attended to the content. Technical issues can also reduce the actual exposure to intervention content. Researchers new to digital interventions may not understand that routine and robust monitoring of the back end system status is an important requirement of digital interventions. Waiting on intervention recipients to report that an intervention is not properly working can lead to missed data collection and poor intervention fidelity. Being prepared to respond to system failures in a prompt fashion can reduce these potential issues. In their review of digital interventions adapting MI, Shingleton and Palfai [24] found that fidelity measures were often not reported in the literature.

Scaling Interventions and Improving Access

The third theme that emerged from our interviews was the unique potential of digital interventions to scale up and improve access to recipients. Regarding scalability, although initial costs are not insignificant for digital interventions, there is evidence that they can be cost-effective once developed [25]. However, robust data on digital interventions and cost-effectiveness are lacking [4,26-29]. From a research perspective, despite the high initial costs, digital interventions may reduce the need for costly human interventionists in research, which shifts human capital needs to technology development needs and may affect how money in research budgets is allocated. This increased potential for scalability means that population-based interventions are within better reach, and even small improvements in individual health outcomes can make big population-level improvements.

Issues related to access were especially important to the interviewees in this study. As noted earlier, digital interventions are potentially available at any time and any place. Moreover, as smartphone adoption is so ubiquitous, mobile interventions, or web-based interventions optimized for mobile devices, have the potential to reach even greater numbers than more traditional desktop-oriented programs. Although digital divide issues still persist as individuals with a lower socioeconomic status lag behind in terms of smartphone adoption, these populations with lower socioeconomic status tend to have better access to the internet via mobile phones than through computers and broadband in the home [30], which makes digital health interventions more important for reaching these populations. Digital interventions also have the potential to reach groups of people who may be hard to reach, such as those with physical disabilities, insufficient transportation, or significant time constraints. The nature of digital interventions may also increase

the potential to reach small, distributed groups of people who may have unique needs that could be too costly to support in person, such as individuals with rare diseases.

Beyond the potential to reach a greater number of people, digital interventions also have the potential to reach users in moments where they may be most efficacious [31]. For example, just-in-time adaptive interventions provide interventions at times where they may be most useful and at escalating doses that may lead to better outcomes [32]. Although most research in this area has been conducted with smoking cessation and physical activity and weight management interventions, just-in-time adaptive interventions have been previously used to intervene in sensitive behaviors such as risky substance use among adolescents and emerging adults [33]. Screening, Brief Intervention, and Referral to Treatment (SBIRT) interventions have also been used to intervene with intervention recipients at times when they may be available and receptive to interventions, such as before clinical encounters with primary care physicians or immediately following training sessions, and have been focused on topics such as substance use, intimate partner violence, and mental health [34]. These increases in convenience and flexibility for intervention recipients may yield downstream benefits to researchers and potentially translate to increased intervention engagement and completion, which may also yield positive improvements in health outcomes.

Getting a Foot in the Door Despite Stigma and Disenfranchisement

Findings from this study revealed that one perceived benefit of digital interventions for mental health and other stigmatized areas and behaviors is the opportunity to reach people concerning delicate topics when they are ready for and receptive to engaging in them. The anonymity provided by digital interventions may allow recipients to feel more comfortable disclosing sensitive information and engaging with related content. This may also afford users greater opportunities to delve into topics that they find more difficult to talk about. It is possible that this might lead to a greater level of honesty that could contribute to more successful intervention outcomes. Indeed, prior work has shown that self-reporting through digital formats can promote greater self-disclosure of undesirable behaviors and sensitive issues [8].

Future Directions

Given the range of potential advantages our interviewees described and the optimism and early gains they expressed, research is needed to understand the impact of delivering interventions digitally. For example, research should investigate the user experience from each stakeholder's point of view, identify potential unintended consequences, compare various digital and nondigital modalities for delivering interventions, and understand the disadvantages of digital delivery and how they can be addressed through careful intervention design and implementation. As mentioned in previous sections, research is needed to better understand the ways in which human-human interaction differs from human-computer interaction in terms of key factors such as perceived empathy, understanding, and friendliness.

Limitations

This study had several limitations that must be highlighted. This study was conducted as part of the redesign activities for CIAS, and therefore, it does not represent all researchers who use digital interventions for behavioral health. Moreover, our small sample size may have affected generalizability. As our convenience sample of researchers comprised CIAS users and those familiar with our redesign efforts, they may have felt compelled to aid our study activities, which could have introduced both selection bias and response bias. Finally, our focus on CIAS users meant that we only spoke to those individuals who were responsible for creating and managing digital interventions. Although many of our interviewees have conducted qualitative work with their own recipients to understand their perspectives, we did not speak directly with

recipients of digital interventions. Our findings are limited to the perceptions of digital intervention creators and study teams.

Conclusions

Digital interventions are seen by interventionists as having many benefits for both interventionists and recipients, such as greater flexibility in how, where, and when an intervention is delivered; potentially improving the fidelity of and access to interventions; and overcoming challenges of reaching populations despite stigma and disenfranchisement. More research is needed to measure the actual benefits of digital interventions and better understand whether they align with researcher expectations and hopes. A comparison of perceived and actual benefits may also inform better support for creating digital behavioral interventions that more effectively meet their potential.

Acknowledgments

This research was funded by the National Institute of Biomedical Imaging and Bioengineering at the National Institutes of Health under grant number EB028990 to SJO. The authors would like to thank Lilly Pritula and Rania Ajilat for administrative support, including manuscript editing, and the interviewees who made this study possible.

Abstract

Background: Digital behavioral interventions have become increasingly popular for their ability to support patient diagnosis and treatment, chronic disease self-management, behavior change, and adherence to recommended care. However, digital intervention development is impeded by challenges such as limited technical skills, limited access to developers, and cost. The purpose of this study is to elicit in-depth qualitative feedback from intervention developers who have interest in digital behavioral interventions but lack programming skills regarding the barriers they experience and key considerations in the design and implementation of digital interventions.

Objective: This study aims to understand barriers in the design and implementation of digital behavioral interventions, as well as to identify key considerations for researchers who are developing these interventions.

Methods: We conducted semistructured qualitative interviews with 18 researchers who had experience either designing (but not coding) digital behavioral interventions or running research studies with them. Participants were a convenience sample of users of the Computerized Intervention Authoring System platform, an existing no-code development platform for building digital intervention content, and were recruited through either direct email solicitation or snowball sampling. All interviews were conducted and recorded over videoconference between February and April 2020. Recordings from interviews were transcribed and thematically analyzed by multiple coders.

Results: Interviews were completed with 18 participants and lasted between 24 and 65 (mean 46.9, SD 11.3) minutes. Interviewees were predominantly female (17/18, 94%) and represented different job roles, ranging from researcher to project/study staff. Three key barriers in the development of digital behavior interventions were identified during interviews: lack of cross-disciplinary understanding; variability in recipients' technology access, infrastructure, and literacy; and the idea that evidence-based in-person interactions do not translate directly to digital interactions. Interviewees identified several key considerations that interventionists learned to prioritize, which have the potential to overcome these barriers and lead to successful interventions.

Conclusions: Barriers in the development of digital behavioral interventions are often created by a lack of cross-disciplinary understanding, which can lead to difficulties conceptualizing interventions, unrealistic expectations in terms of cost, and confusion about the development process. Moreover, concerns about research study participant characteristics and access to technology, as well as the translation of in-person interventions to digital, are apparent. Appropriate training in how to work with software development teams may help future digital behavior intervention creators overcome these barriers and may lead to new, exciting innovations in this space.

Introduction

Background

Digital behavioral interventions have become increasingly popular for their ability to support patient diagnosis and treatment, chronic disease self-management, behavior change and adherence to recommended care, and primary prevention [1]. They have demonstrated broad promise in terms of efficacy [2-8], but evidence for specific use cases tends to be mixed [9-11], with engagement and retention being particular challenges [9,12-14], as well as low-quality evidence [10,15,16].

There is tremendous room for innovation in this area. However, developing digital interventions is often out of reach for many research teams because of the challenges of developing relationships with software developers, the costs of custom software development, and the need for technical expertise, all of which serve as barriers to entry in this field. Critically, researchers need pilot data to access grant funding large enough to develop these types of interventions but may not be able to collect pilot data without at least a working prototype. Moreover, the constant need to update and adapt custom tools for other purposes means that research teams are constantly in the process of reinventing the wheel with each new intervention. Finally, most digital interventions are built using a particular technology stack by a particular group of developers, such that sharing or building on existing interventions is a significant challenge, even with the few apps that make their source code openly available.

No-code platforms, also known as authoring tools, may offer a solution to these challenges. Part of what has been called the no-code revolution, these platforms are designed to allow citizen developers [17] to build apps using simple graphical user interfaces. By providing templates and other structured step-by-step processes for building custom interventions, these platforms enable the creation of technology-delivered interventions without the need for computer programming or technical knowledge. For example, an increasing number of services now enable anyone to create their own website, including relatively complex functions such as e-commerce, responsive web design, and analytics. No-code platforms could similarly make the development of digital interventions faster, more accessible, and easier to edit and share by providing a framework within which researchers can build or tailor an intervention. A successful platform could be to the creation of digital behavioral interventions what Microsoft PowerPoint is to the creation of slides for a presentation: a tool facilitating an explosion of content generation.

In contrast, as with Microsoft PowerPoint, democratization of software development does not solve all challenges in the creation, testing, and implementation of digital behavioral interventions [17]. In this study, we sought to explore these challenges, grounded in the experiences of researchers who have played a range of roles with digital interventions. The

purpose of this 2-part qualitative investigation is to better understand the motivations, needs, constraints, and experiences of researchers who have looked to digital interventions in their work addressing behavioral health.

Objectives

In this paper (part 2), we seek to document common barriers reported by intervention developers, as well as key considerations, in the design and implementation of digital interventions. In a companion paper (part 1), we seek to document reasons why researchers who study behavioral health focus their efforts on digital interventions, as well as their perspectives on the perceived benefits that digital approaches afford researchers and their intervention recipients [18].

Methods

Overview and Ethics Approval

This study was conducted as part of a redesign of the Computerized Intervention Authoring System (CIAS) platform, a web-based digital behavioral intervention authoring tool for researchers. This study included previous and current CIAS users as well as CIAS-naïve users, all of whom had experience developing behavioral health interventions. We conducted semistructured interviews with these intervention creators to better understand their needs, perceived barriers to designing and implementing digital interventions, and design considerations for behavioral intervention development. COREQ (Consolidated Criteria for Reporting Qualitative Studies) guidelines were followed [19]. All methods used in this study were approved by the University of Michigan Human Subjects Review Board (HUM00171197) and Wayne State University (IRB-19-10-1340).

CIAS Platform

CIAS is a Health Insurance Portability and Accountability Act-compliant no-code web app designed to allow users to easily build, edit, and share web-based interventions without coding or other technical expertise of any kind. CIAS gives interventionists the ability to develop tailored and personalized text-based interventions that can be narrated by an animated and emotive character capable of multiple different actions and voices (supporting >40 different languages, with male and female versions of most and a range of accents or dialects for some of the more commonly spoken languages). CIAS supports intervention building features such as multiple question types, natural language reflections, branching and tailoring, and integration of video content. Further details on CIAS can be found in the part 1 companion paper [18]. With support from the National Institutes of Health (EB028990), an all-new version of CIAS (3.0) is currently being developed as an open-source and noncommercial research resource. This research was conducted as part of the CIAS 3.0 redesign activities.

Participant Recruitment

Participants were recruited via email solicitation from a convenience sample of CIAS users and researchers who have expressed interest in using CIAS, via snowball sampling, or via an email to a listserv of University of Michigan Department of Family Medicine staff members familiar with conducting digital interventions. To be eligible to participate, users were required to be aged at least 18 years.

Study Procedures and Data Collection

All interviews were conducted in single sessions via teleconference between February and April 2020 by 2 trained research staff (BMB and ANS). Participants did not have prior experience with the interviewers, nor did they have access to interview guides prior but knew that they would be participating in redesign efforts. All participants provided verbal consent, and all interviews were recorded for later transcription. Interviewers also took field notes, which were available for later analysis. Interviews were conducted until saturation was reached. Transcripts were not returned to participants for review, nor were participants asked to provide feedback regarding the findings. All participants were offered US \$20 for their participation, which was delivered in the form of a check via US mail.

Analysis

To analyze the data, the 2 study team members (BMB and ANS) debriefed after each interview. During this debrief, individual notes were compared, which were gradually synthesized across interviews. Interview transcripts underwent 2 rounds of inductive thematic analysis, which was conducted by 2 coders (BMB and ANS); the first focused on identifying patterns, which later became themes, and then a second validated themes and confirmed connections between them.

Results

Overview

We invited 24 current and former CIAS users to participate, and 17 agreed (17/24, 71% response rate). In addition, we recruited 1 additional CIAS-naïve user who was familiar with digital health interventions from the University of Michigan Department of Family Medicine. For our 18 interviews, the average duration was between 24 and 65 (mean 46.9, SD 11.3) minutes. Participants were predominantly female (17/18, 94%) and represented different job roles ranging from researcher to project or study staff. [Table 1](#) presents the aggregate interviewee characteristics, and [Table 2](#) presents the brief descriptions of each interviewee.

Barriers in Designing and Implementing Digital Behavioral Interventions

Interviews revealed three primary barriers: lack of cross-disciplinary understanding; variability in recipients' technology access, infrastructure, and literacy; and evidence-based in-person interactions do not translate directly to digital interactions.

Barrier 1: Lack of Cross-disciplinary Understanding

The first barrier commonly described by interviewees was the technical knowledge and resources required to use digital behavioral interventions. For some, this was the primary barrier: "I think the biggest barrier for many researchers is the actual building of the software itself, or how the intervention will be delivered" (P7). Building even a simple digital intervention requires the appropriate technical expertise and project management skills. Consequently, a significant amount of effort must often come from software developers who are outside the clinical research team, which increases the cost. The resources required were described by our interviewees as prohibitive, as well as difficult to anticipate:

The cost of actually developing an app is, I think, prohibitive for a lot of researchers....I think it depends also on your resources and the amount of time you have, you know, we have a small pilot grant from NIH, so we don't have a lot of resources and we don't have a lot of time and I think, I mean, I certainly didn't know going in...it just seems like everything, every piece of this, takes longer than we anticipated and the programming is a lot more intricate. [P15]

The bounds of a clinical team's technical knowledge may limit their ability to not only implement their ideas through technology but also to even envision what possibilities are available to them:

I think it's just a lack of knowledge around technology. Like, what options are available. I think that the go-to thought process when people think digital interventions is telehealth...but there's a lot more to that. So, I think just knowing that there are other options is a barrier. A lot of people are limited in that. But then once they realize that there are other options...it's accessibility to these things. Like, what is out there? How much does it cost? How do I do it? You know, a lot of the people designing these interventions aren't...they don't have a background in technology. [P16]

Conversely, those with technical knowledge who develop tools are often limited in their understanding of how interventions should be delivered. Interviewees discussed the challenges of using digital interventions that had been created without input from clinical experts:

The people who are developing these interventions are not people who deliver them. So that's a problem, I think, because sometimes it's really hard to envision what should it really look like in the development stage when you're not the kind of person who would be sitting across the table from someone, right? So like, you can't figure out what the gap is because how would you know? Because you've never been sitting across the table from someone. [P1]

As a result, interviewees found that existing software programs had significant limitations in how they could be used for developing and delivering interventions. For example, they did not allow the interviewee to edit and control important aspects of an intervention: “I think the lack of editability of the program, I think that’s the biggest thing that’s frustrating for me” (P12). Interviewees therefore indicated the need to truly combine knowledge of behavioral interventions with knowledge of technology that can deliver them. However, those who had worked closely with software developers noted the challenges inherent in this cross-disciplinary work:

That can be a barrier because oftentimes there’s disciplinary differences that challenge that experience, you know, speaking different language, computer programmers not quite “getting” behavioral intervention and the needs of the behavioral interventionist. [P7]

This interviewee also went on to explain that the level of investment in technology involves trade-offs that are commonly discussed and debated among researchers:

Particularly when we’re at conferences and seeing the work of other people, is that process of working with software engineers and developing software from the ground up is not a short process...I’ve seen animated programs that are really fun and interactive and interesting, but they also took 2 years to build...So, we’ve kind of talked about that trade-off before. Then you think about the fact that most people stop using an app or web-based type of a program, typically in a short period of time. You’ve got that huge investment in that fancy intervention software and then people are using it for a short period of time and never looking at it again, and that’s a huge investment of resources for what could be a limited return and an unknown efficacy. [P7]

The level of resources required to develop a digital intervention is a large investment and one that comes with some risk. Therefore, setting realistic expectations for timeline, cost, capabilities, and the return on investment is necessary before turning to digital interventions. One interviewee explained how they share their past experience to help other researchers adjust their expectations:

So, if they say “oh, we want a long course [for the intervention], we have multiple interventions, we have \$5,000” something like that. I will just tell them that \$5,000 is not enough, we need a lot more than that, however, no matter what you have, you can usually get something, but it may not be what you want. So, it’s \$5,000—it’s going to be crude messaging, it’s going to be texts, it’s going to be tailored audio tracks, or mailed—simple feedback. You could do that, but you’re not going to do anything fancy with video, or anything like that, for a couple thousand dollars. I guess that’s the last thing, that’s helping people to budget what kind of money they have, what kind of expectations are. [P6]

Planning and budgeting an intervention with realistic expectations can also help interventionists to think through how presentation of the content will affect intervention efficacy. Some interviewees shared their concern that the look of the digital intervention is linked to its credibility and perceived value: “Better optics might make participants take it more seriously” (P12). Interviewees therefore felt that investing in the aesthetics of the intervention could even impact engagement and efficacy.

Finally, we note that interviewees mentioned a set of technical barriers after the software development had been largely completed. As interventionists finalized, pilot-tested, and prepared an intervention for recipients, adjustments and edits still needed to be done within the code. For example, changing the terminology used on a button may seem straightforward; however, because the label on the button is hard coded into its functionality, the interventionists will not be able to change it themselves. The process of communicating every single change, large or small, and waiting for all of them to be completed can significantly extend project timelines. One interviewee described this extensive process and how experiencing it changed the way they would approach writing grants by accounting for each step in the process:

The communication [with the software development company] and the ability to sort of get something corrected just adds time to it relative to things that we could otherwise have done in-house....We would submit what we needed. They came back with things they could do easily, things that would take more time, things that would cost more money. And so that was probably several months of just sort of figuring out what was going to be feasible given the limitations of grant funding. And then probably another couple of months of back and forth finalizing items and then the student pilot tested with a couple of participants and worked out a few more glitches before we launched...But that whole process, you know again not having really done that with another company...just made me appreciate kind of, if I had to write another grant with that company how I might do it. [P9]

Digital behavioral interventions require significant knowledge from multiple disciplines, which naturally raises costs and increases the complexity of project communication and timelines. Through experience with digital interventions, interventionists get better at envisioning what they can do with technology, having appropriate expectations for a software development project, and managing costs.

Barrier 2: Variability in Recipients’ Technology Access, Infrastructure, and Literacy

Technical barriers from the recipients’ side include access to technologies such as mobile devices or Wi-Fi, literacy with these technologies, and the availability and cost of local infrastructure such as internet connection and data plans. These factors are often underestimated when digital interventions are being designed and planned and also lead to greater resources that need to be contributed by interventionists, such as supplying

Wi-Fi, data plans, or additional technical support. In addition, as operating systems (eg, Android [Google] and iOS [Apple Inc]) are updated over time, digital interventions may require recipients to install these updates on devices to ensure their continued operation.

Interviewees referenced the digital divide, the significant disparity between those who have access to technology and have fluency with technology and those who do not. Most commonly, interviewees mentioned mobile devices such as tablets (eg, iPads) and smartphones, as these are the primary technologies currently used for delivering behavioral interventions:

Not everybody has a computer. Not everybody has an iPad at home. Most—a lot of people do have smartphones, but even then, like it doesn't mean that they're going to be able to access the information or they're willing to access the information. [P2]

In order for technology to effectively facilitate a behavioral intervention, recipients must have not only access to the right device but also the appropriate technology literacy to operate and troubleshoot the device. Interviewees experienced the digital divide between themselves and the people they were trying to reach, acknowledging that the decision to use a digital intervention was a much easier one based on their own considerations compared with those for recipients:

For us, it was an easy idea for us to, you know, be like “yea, we'll do it on an iPad! No big deal.” But then, in talking to the mothers that we're potentially going to be using this behavioral intervention with, we quickly realized that a lot of these participants have probably never held an iPad in their hands before and that kind of totally changed the way we need to develop our intervention to where it's, not only are you creating your intervention, but you have to create the instructions and infrastructure in place so that they can even experience the intervention in the way that you think it's going to go. [P13]

In ensuring the right experience for intervention recipients, this interviewee alluded to the instructions needing to match their technology literacy, a consideration very similar to health literacy. With regard to infrastructure, this can include the type of internet connection accessible to a recipient in their neighborhood, as well as the data plan they have on their phones:

With our population...I know everyone has a phone but a lot of [the] women use prepaid phones with minutes. And they have...a limit on how much data they can use. [P16]

Often, the varied technological constraints can be underestimated and may not be considered when digital interventions are chosen, designed, and initially implemented:

The extent of it came up organically, like just how much we kind of took for granted when it came to technological literacy with these [participants]. I think we didn't realize that we would have to, in some cases, provide our own Wi-Fi, and that we can't just ask these [participants] for an email address to get

their feedback report, so things like that came up organically, the whole idea that we needed to know where these people were at with technology. [P13]

Interventionists also did not always consider compatibility issues based on which versions of hardware or software recipients were used. For example, an older tablet may cause more issues or not be able to run the intervention. As operating systems evolve with updates regularly released, users must download and install these updates on their devices; otherwise, the intervention may no longer run. When an intervention stops running as expected, the cause is not always obvious to the user, and they may need help troubleshooting. Although these challenges are par for the course with any software project, interventionists may not be prepared for them:

All of a sudden, we're dealing with hot spots, and intermittent access, and old computers, and updates. The versions, what we do now, Android will update a version and all of a sudden it will break, it won't work. So, our people in the field were like, “oh, it's not working, people are sitting around, the clients are getting frustrated,” and your tech people will say “we don't know what's happening, it works fine on our—,” you know. Computers are way more difficult, so those are some of the reasons people don't do it is because they don't know how. [P6]

Interviewees had learned how much extra work was required from their research team when technical challenges arose for the recipients:

For this new clinical trial, when they're going to be doing it by themselves, like it's already hard enough to get people to enroll in these studies and then for it to not work properly. And then I'm, they're going to reach out to me, my project manager, like, “well, this is not working.” And then it makes more work for them, okay, go take a screenshot of this point where it didn't work and then email it to me. It's like, oh it's a whole production. [P12]

Interviewees were therefore concerned about the effects on both the recipients and research staff. Moreover, technical difficulties with a digital intervention could stand in the way of effective behavior change, jeopardizing impact on the recipients, as well as the course of research:

I'm a little bit concerned about potential technical difficulties that they might experience that might lead to the intervention not being completed, which would then limit our ability to test the efficacy of the intervention. [P7]

Designing an intervention that meaningfully engages a recipient in the process of behavior change is challenging enough on its own, but a digital intervention adds multiple levels of technical considerations.

Barrier 3: Evidence-Based In-Person Interactions Do Not Translate Directly to Digital Interactions

The final barrier we found concerns the shift interventionists had to make from designing an in-person intervention to designing a digital intervention. Interventionists look to

technology for many perceived advantages [18]; however, interviewees pointed to the difficulty of adapting person-delivered interventions to digital forms. For example, despite the capability to program a digital narrator in CIAS so that it can adjust content in reaction to input from the user, interventionists still missed the richness of other cues they were used to relying on during in-person interactions:

Trying to translate the patient-provider interaction and the types of feedback and information that goes into that—how can you program that? [The digital narrator] is pretty much 100% scripted, he doesn't really do a lot of responding to cues. [P7]

The CIAS platform allows interventions to be delivered through a digital narrator whose voice reads out the intervention text and whose physical form appears in the interface as a human or animal. In this physical form, the digital narrator can be animated for a range of actions, such as talking, smiling, reading, waving, and pointing to items within the interface. The narrator can also ask recipients for their preferences, reactions, and thoughts at any point and can provide verbal reflections of that input (eg, “It sounds like this has been pretty hard for you”) and branch to different areas of content based on that input. However, interventions built using the CIAS platform cannot read facial expressions or body language and cannot interpret unscripted input from recipients, leading to challenges in forecasting or collecting a range of likely reactions or preferences so they can be included in the intervention:

I think part of the challenge that we've had is we're often trying to take what we would do in a face-to-face and think about how that would translate to a computerized delivery, which there's obviously going to be elements of that that are lost with the computer delivery. [The narrator] can squawk and flap his wings and make cute expressions, but he can't really interpret the non-verbal patient sitting across from him so to speak...When you're in the face-to-face setting, you obviously can use non-verbal and other types of communication to inform your thinking: looking at patients' records, looking at other sources of information, downloading meters, and other things that can be conversation start points that [the narrator], he can't necessarily do. [P7]

Although digital interventions built with CIAS allow for personalization, tailored feedback, and empathic reflections, the need for a priori entry of possible preferences and reactions is a departure from the flexibility and improvisation that is possible with person-delivered interventions:

I guess the biggest problem that I would say is that, you know, you're just in a forced choice kind of framework...So like, for example...if I were to ask you “hey, what do you think would...what would help you supervise your kid every day?” So, let's say you...rate yourself as motivated but low on self-efficacy...so, if I'm sitting across the table from you, I can just say to you, “well, what are some things you've tried?” or “what do you think would work?” and we can have an open-ended conversation. Whereas in the program,

as the developer, I have to presuppose what your likely barriers are, and put them in there, so you can click some boxes. [P1]

Interventionists, therefore, experienced greater difficulty when they approached the design of a digital intervention in the same way as a traditional human-to-human intervention. Some described the need instead for computational thinking or thinking of an intervention based on the characteristics and advantages of computers, such as logic and chunking:

But the difficult thing is to bridge that gap between what can be done in person versus what can be done online. What helps me is to think through sort of logical rules or how would you chunk things. And there are an infinite number of possibilities of what could happen in an in-person interaction. [P6]

However, as interventionists drew on behavioral theory and approaches, such as motivational interviewing (MI) [20], their expertise in applying them was primarily via human interaction, making it difficult to envision a different type of intervention. For example, interviewees pointed out that the ability to incorporate recipient responses into the course of the intervention was a key component of MI:

The most challenging thing is taking the human part out and trying to put that into mobile platforms...so, for example, like I said with MI, branching out the reflections and making it so that you could take someone's motivation and put it on a scale...that was challenging versus asking someone “hey, can I know more about this?”...I think that's a challenge...because as a human being, you could just adapt to [their response]. [P5]

The loss of nuanced reactions they were used to observing in person also meant fewer opportunities for gathering rich qualitative data:

I think, with the regular behavioral interventions that I work on it's a lot more communication with participants and like face-to-face interaction which is kind of nice because you're getting in like real-time reactions and kind of some good qualitative data. But I guess with [the digital intervention] they're doing on their own you're not kind of seeing their reaction to the actual intervention. [P3]

Human contact is, of course, not easily replicated with technology, which some interviewees saw as a significant loss:

So, the biggest thing that I would consider is, a lot of participants that I've seen in the past, the number one thing that they get out of being involved in research is that they get to talk to somebody, they get that communication, they get that personal connection. So, like if there's a chance that they're going to—in their eyes—lose that, just the way that you approach how you're going to transition it. Like, we're not going to be losing contact, we're going to still be in contact, and how you're going to be in contact. Because a lot of people that we deal with, they have severe depression and anxiety and so they participate

in these things obviously to try and you know, reduce those symptoms. But also, because they don't have anybody at home so they like seeing somebody in person. [P11]

This interviewee highlighted the potential benefits to intervention recipients, especially when working with sensitive topics and vulnerable populations, as a key consideration when choosing a digital intervention. Combining digital intervention with strategically positioned human touchpoints may also be an effective way to maintain such benefits for recipients.

However, integrating digital interventions smoothly into the experience and constraints of a recipient or an interventionist may benefit from new approaches. When designing a digital intervention, we found that interviewees often work to translate traditional interventions directly, maintaining a very similar model or approach that they had previously used in person. For example, one intervention relied on an avatar, whose role was viewed similarly to that of a human counselor helping the recipient to navigate the steps of the intervention:

We have a little [avatar of a] woman that walks you through the whole process. She kind of acts as the counselor for the participant and talks them through everything, and we build scripts for her. Kind of, build like, questions and answers and get to know the participant through CIAS. [P12]

This interviewee discussed the process of writing a script for the avatar, much like a script might be generated to support consistent human delivery of an intervention. However, achieving a flow similar to that of a natural conversation was a challenge with this approach:

I think at times it tends to, and this might be on the side of the script building and our side of putting CIAS together in the back end, but I've noticed at times that it tends to lag or, kind of lack the flow, it needs to kind of seem like a conversation. [P12]

Digital interventions need not be designed according to the traditions and best practices that have been developed with face-to-face interventions. Instead, digital interventions may be improved by envisioning new paradigms.

Key Considerations for Designing and Implementing Digital Behavioral Interventions

Overview

As interviewees shared the barriers and lessons learned from past experiences with various interventions and recipients, we identified three high-level considerations for designing and implementing digital behavioral interventions: understanding the population and context, integrating the intervention within ecologies of care, and technical staffing and preparation. A strong focus on these considerations can help address the barriers we have described previously.

Understanding the Population and Context

As discussed earlier, the process of adapting behavioral approaches to digital interactions with recipients is one of the greatest barriers to effective implementation of digital

interventions. Therefore, the first step in understanding the technological context of recipients is critical not only for ensuring appropriate access and literacy to enable intervention delivery but also for envisioning how each step of the intervention will be experienced by recipients, so that its delivery is evidence based and recipient centered. Interviewees gained this understanding through qualitative methods with the population and frontline interventionists who interact directly with the population (eg, via home visits):

In our first focus groups, we were talking to both home visitors and moms, [asking]: How comfortable are you using technology? If someone handed you an iPad and said "go through this program on your own," how comfortable would you be doing that? What are some things that would get in the way of you being able to do that? And then asking the home visitors, "when you go into a home, is there Wi-Fi? Because this is a web-based program." Things like that. And then we had them sit down and go through the program and analyze both their experience with it, just as the platform in general, and then also nitty-gritty of the wording of the content and what we're trying to accomplish. [P13]

This interviewee highlighted some of the best practices in designing digital interventions: starting the process by engaging with the population through a method such as focus groups to gather information pertinent to their experience and assessing each aspect of the intervention through their actual perspective, from the experience of interacting with the technology to clarity of the content presented. Another best practice mentioned was pilot testing, also known as usability testing, which examines how the recipient interacts with the intervention to identify how that experience might be improved:

We plan to do a small, pilot trial to test it out in home visiting, and because it's a pilot we consider [it] part of the design process where we're really looking at feasibility and acceptability, which parts work and which don't, and then we'll continue to tweak it from there. [P15]

As this interviewee points out, there must be an iterative process of testing and revising. As such, obtaining input on aspects of the design from end users should occur from the early stages of designing a digital intervention. Deeper engagement, known as participatory or community based, can involve the population in not only evaluating the intervention but also contributing ideas to its design:

I think everyone needs to do more of a community-based approach, if they can, to where they're involving the target population in the creation of [the digital intervention]. [P13]

Engaging the population in evaluation, or even design, can help address a range of concerns about how the intervention will be received. For example, interviewees mentioned that when it comes to the overall aesthetic of the intervention, "the way it looks is how seriously someone is going to take your research regardless of the content" (P14). Interviewees also made comparisons to the aesthetics of common mobile apps, such as

social media apps. Referring to a prior version of CIAS, one interviewee said:

It could just look a little bit more, you know, like the social media apps that everybody uses all the time. And like if we saw a social media app that looked like that, you'd be like "ew, what is this app, like it looks weird." I love CIAS, not to say that I hate it, I appreciate it, but I'd like a graphic redesign of CIAS to make it a little bit more appealing to the eye. [P12]

Such natural comparisons are important to consider because how an app looks and feels to a user and how the intervention content is presented can be linked to perceived value or trustworthiness of the intervention as well as the research study.

Finally, digital interventions expand the possible contexts in which recipients can be reached, changing the way they must be designed. Deciding on the geographical constraints for reaching a certain population has important implications for the intervention, and interviewees described this decision as a balance between convenience for the recipients and convenience for the research team:

Do you want to restrict it to certain geographical areas...what's your population?...Where are these people located, the time zones? Because we have people like in California. We have to consider you know, because we have to do follow up calls every six weeks after they've completed their treatment and sometimes we have to consider that they're three hours behind us, so what time might be good for them, we have to accommodate, because they are doing us a favor by participating in our study so if that means that we have to call them at 8:00 pm our time that's fine....So those are the kind of barriers, it just really depends on how widespread you want your remote study to be. [P11]

Interventionists took into consideration a range of factors about the population they wanted to reach with a digital intervention, working to understand their background, technological context, how they would interact with the digital intervention, what their expectations may be of interactive technologies generally, and how geographically distributed they may be.

Integrating the Intervention Within Ecologies of Care

Interventionists also considered how an intervention might be integrated within ecologies of care—existing services and supports, both in virtual and real-life contexts. Our interviews indicated that researchers have a range of ideas for integration but have been constrained in achieving all of the features they envision. For example, they thought recipients should be able to schedule a health appointment and even see a clinician at a distance using the same or another platform:

Having a feature that if a client wants to have a digital health appointment for something, they could set that up on their own in the [digital intervention]. They're scheduling it and it's happening on the platform. [P16]

Another potential feature mentioned was supporting patients to monitor their progress toward goals, which can include reminders, strategically timed prompts to action, or visual feedback on what it will take to meet their goals. One interviewee described the use of this approach for long-term engagement:

Have your [digital interventions] just send them text messages: "hey you set a goal for whatever, just make sure you do that today." That's the cheapest and easiest way [to improve patient compliance]. If you can tie your [digital interventions] in [with] some long-term prodding of your patients in the next week or two or three or whatever, in a way that clinicians think they're going to reap that. If the patient has been prompted to do something, the clinician thinks: "gee, the next time they come in, maybe they'll have gotten their material together and put it in the binder and developed a diet, talked to a nutritionist, or visited a grocery store, or found out more about where they can get nicotine replacement therapy." So all those I think are selling points. [P6]

Similarly, care transitions, such as leaving residential or inpatient care, are a great challenge in which technologies could provide support. Interviewees described roles for digital interventions across multiple touchpoints in one's journey with treatment for substance use:

I think I could see [digital interventions] particularly serving a role in transitions from things like residential to outpatient treatment. That's that window I think we're all still really struggling with is, how do you get [recipients] to maintain abstinence when they leave residential care? Where I think trying to build things in with brief interventions would be a great place. So, I think within the addiction treatment realm of specialized services I would see [digital interventions] as something that could help with engagement at the front end of things—to provide some early counseling in a way that facilitates retention in treatment and even enrollment in some cases. And then I think in the longer term [digital interventions] could be used for interventions that help to reduce relapse risk and facilitate uses of care. [P9]

Our interview findings suggest that even if the technology alone cannot provide meaningful interaction, the way it is integrated into other touchpoints of the research study itself can facilitate human contact that may be able to make a greater impact:

I don't think [the digital aspect of the intervention] detracts from our interaction because we still have to get to know each other over the year that they're in the study, so talking with them over the phone, and asking them really personal questions like adverse events form and things like that about their lives. [P12]

Conversely, the way the technology is used can help minimize human interaction for the purpose of protecting privacy when engaging recipients on sensitive topics:

We also use headphones. So that's something that we do to make sure that it's anonymous, because the whole idea is that people don't want to talk about these issues with their home visitors. So we're giving them an iPad so that it's just them and the iPad. [P2]

When choosing a digital intervention, it is important to remember that recipients are not likely to interact only with the technology. Integrating the digital intervention effectively within the structure of the research study, as well as the broader landscape of services and supports, will enable a good experience for recipients and may even improve impact or outcomes.

Technical Staffing and Preparation

Finalizing, testing, and preparing a digital intervention to ensure that it is ready for use is a complex process with various considerations. Our interviews revealed the extent to which research teams need to have staff available to focus on each aspect of this preparation. For example, once scripts for the avatar were written, multiple members of the research team listened to how they would be delivered by the automated voice to ensure a good experience for the recipients:

[The PI] did a lot of the scripting, like, actually what the character would say and then she and I both would put it in there and listen to it and see how it flows...I think that we really worked hard to make the language understandable and modern. We didn't use a lot of very complicated words. It is an automated voice, so we really played around with like how words sound. [P16]

The flow of audio and visual features also needed to be reviewed on the same device and in the same way that recipients would experience them. CIAS enables interventionists to design their intervention on a laptop or desktop computer while previewing what the intervention will look like (eg, on the smaller screen of a mobile device). However, such previews will not convey the full user experience, for example, leaving out touch screen interactions, which will affect how intuitively and efficiently a recipient is able to navigate through the intervention. Therefore, researchers would ensure to review the intervention on the actual device their recipients would be using:

And then I think the last step is just making sure that it looks nice on the iPad. So, just going through it as many times and listening to it. ... If I'm previewing [the intervention] on my laptop, it's not going to be the same on an iPad. [P2]

Interviewees also noted that a digital intervention may not look or perform the same across different platforms, such as tablets versus smartphones or Android versus Apple. These potential differences had implications for testing across platforms, as well as members of the research team having enough familiarity with operating different platforms so that they can troubleshoot during a study:

I have really tailored our intervention to a tablet screen. I haven't looked at it on a phone or you know...on a computer in a long time. So, I like the cross platform capability to be able to like take

something that's working on one and make sure it's going to look the same or be usable on another device—something I'm actively trying to look at right now. [P16]

I have never used any digital intervention on an Android phone, so I'm not that comfortable [troubleshooting potential problems for recipients]. I would assume that it works the same way, but I don't know. Or just things like, [the recipient's] device functionality not being the same as ours [Apple device]. [P12]

In addition to testing the intervention on an appropriate device, interventionists needed to test it on an internet connection within the community that was similar to how the recipients would be accessing the intervention. This was especially important in communities or contexts in which internet connections may be unreliable or restricted (eg, behind log-ins, paywalls, or firewalls):

I'm going to ask my [research assistants] to go out into the community, whether that's a library or to a Starbucks, or wherever and see if they can run through the intervention without getting kicked out. [P7]

One interviewee worked as a project manager and spent a significant amount of time testing all branches of the intervention logic. As she suggests, CIAS or other types of platforms could potentially provide support specifically for this type of testing:

Where I have the most experience was doing the beta testing before we could actually run it...you had to test every single branch because there is no way within CIAS to like click a button to see the flow. [P5]

Testing did not end once a study had begun. Research teams would have to ensure an adequate internet connection for individual recipients, who may be distributed across different contexts. This activity was so critical that it had been formalized as a part of study protocols:

In our protocol, we have outlined different ways to kind of go about that barrier [of having Wi-Fi]. Our participants can be all over [the state] or all over the US. They could be in places where there is just not Wi-Fi. So, our first thing is suggesting they go to a public place that has free Wi-Fi and we can help them figure that out. Is that a bookstore, or is that a little coffee shop or something, and then if they can't, then we'll direct them to our IT person and possibly work with them on getting them a mobile hotspot. [P11]

If Wi-Fi could not be guaranteed, some study teams carried data cards in the field, that is, prepaid cards that can be inserted into a mobile device for internet connectivity without Wi-Fi. The data cards were used for either a recipient's device if it did not have a data plan that could support the intervention or the research team's device when it was more cost-effective than purchasing a data plan. The data cards added to the research assistants' responsibilities for materials and troubleshooting:

So we have the data cards and we have the iPad for the site study I have actually been doing the digital intervention with. The upcoming one will be [on] their device, but still I would bring the [data] card and they would still use our iPad to do questionnaires. [P12]

The approach of providing technology for recipients was a common way to overcome the digital divide and ensure a more consistent experience for recipients. This strategy still requires sufficient staffing on the research team to provide technical support, but troubleshooting becomes significantly more straightforward. For example, one research team distributed Kindle e-readers to recipients:

We knew that technology was going to be a downfall so we have a tech personnel on call to answer any questions that need to be....They are receiving a Kindle, so if they don't have a computer, they don't have a phone, it's okay, they have the Kindle, and they get to keep the Kindle. We modify it so that it's very easy, so on the home screen it's like this is your app. [P11]

Compared with asking recipients to use their own devices, supplying devices eliminates the need to provide instructions or support for downloading because the research team can ensure that study devices reach recipients with the app already installed on them. Some research teams also allow recipients to keep study devices, either as an added incentive or to avoid the challenging logistics of collecting the devices and reusing them at the end of the study.

Many digital interventions require recipients to have email addresses so that they can set up profiles or accounts. However, research teams cannot assume that all recipients would already have their own email address, and interviewees needed to plan for research assistants to take the additional step of helping to create one when needed:

If [the recipients] don't have an email address, my research assistant works with them and she helps them create an email address just for them. [P11]

Although support for creating an email address is easy to provide, this illustrates the need to be nimble and prepared to troubleshoot and assist, which can require a significant amount of time from research staff.

Finally, interviewees described taking the time to set recipient expectations for how they will experience the intervention. This activity was described not as a training but as an orientation or a demo, indicating that the technology itself should be intuitive to use, but recipients still ought to know what to expect as with any research activity:

We're gonna talk with the participant during what we're calling "intervention orientation," where we kind of explain kind of how the intervention is going to be delivered and how it's going to work. [P7]

We've demoed it on a computer or on an iPad through a projector so that way people can see what it looks like. I've also gone in and created a short video...of what people can expect to see throughout the

intervention, because I think it's important for people when they're receiving it to know what they can expect. So like, "this is what questions will look like."... "this is what a link will look like, and this is what will happen if you click on a link." [P2]

After a research team has put considerable thought into designing their intervention and invested in the complex process of building the intervention according to their design, the key phase of ensuring that their intervention will be implemented effectively with recipients remains.

Discussion

Principal Findings

Our findings from these researchers with experience in digital intervention development are 2-fold. First, we isolated three common barriers: lack of cross-disciplinary understanding; variability in recipients' technology access, infrastructure, and literacy; and evidence-based in-person interactions do not translate directly to digital interactions.

Second, we identified three key considerations that interventionists had learned to prioritize across different types of interventions and projects: understanding the population and context, integrating the intervention within ecologies of care, and technical staffing and preparation. These considerations are important from the outset of project planning and budgeting, and focusing on them can help address the barriers. We revisit each barrier to contextualize these findings and build on what interviewees had offered as their key considerations to using digital interventions, by adding our own recommendations.

Barriers in Designing and Implementing Digital Behavioral Interventions

Lack of Cross-disciplinary Understanding

Although digital behavioral interventions are often developed by multidisciplinary teams, the nascent ideas for these programs tend to start with either clinicians or researchers who do not have experience with software development or with developers with technical backgrounds but no clinical experience. As our interviewees were interventionists and not technical developers, themes that arose from this study centered on the lack of cross-disciplinary understanding that results when nontechnical interventionists seek to develop digital behavioral interventions.

Conceptualizing Digital Behavioral Interventions

Interviewees expressed concern about the lack of technical expertise on the part of intervention creators and the effects that this may have on interventions. The ideas for digital behavioral interventions conceptualized by clinical researchers are often built on the shoulders of other interventions. For example, a researcher may see an interesting intervention that applies to 1 disease state and brainstorm ways in which it could be adapted or replicated for use in another disease state. Although this approach is common, when it is used by nontechnical clinical researchers, the new idea may unnecessarily pigeonhole new interventions by ignoring different intervention delivery modalities (eg, websites, native mobile apps, web apps, and smartphone apps), design features (eg, manual self-monitoring

and pairing with peripheral devices for objective monitoring), mechanisms for communicating content (eg, text, audio, video, and animation), or design decisions that the creator may not have considered or even be aware of.

Misaligned Expectations of Development Costs

Emerging technologies often remain out of reach for many interventionists because of their cost, which depending on factors such as complexity, novelty, and timeline, may vary greatly. Therefore, it is crucial for interventionists to align their expectations of what they want and need to develop, with the resources available to support intervention development. Misalignment with wants or needs and available resources often stem from a lack of experience with digital behavioral intervention development or the costs necessary to run and maintain an intervention, such as expenses related to hosting, security, bug fixes, and other maintenance costs. Most behavioral interventions used within research need to be implemented reliably at a scale within certain budgetary constraints. Interviewees voiced many concerns related to development costs, indicating that funds available for a given intervention development project were often far less than what was actually needed. Indeed, budget caps on federal and private research caps are often incompatible with actual market costs for high-quality software development and maintenance, which may stifle innovation. In particular, development costs are often greatest for new interventions, which are least likely to be competitive for large grant awards. Interventionists interested in advancing the state of the art in digital interventions often need to partner with technology researchers on more sophisticated and innovative interventions, often at a smaller scale, greater cost, and limited immediate ability to demonstrate impact on behavior.

Working With Software Developers

Interventionists often lack the knowledge and skills required to build digital interventions themselves and must partner with software development companies to create apps; however, doing so requires preparation that most researchers lack, at least initially. For example, even the process of identifying the right software development company can be a challenge. Some clinical researchers expressed confusion around their options when it came to hiring developers, saying that they did not understand what they should look for or how to know who to hire. In addition, before an intervention can be developed, the clinical researcher must have a clear vision and proposal for the intervention, including full details of each question, how it should be presented digitally, and an outline of all functionality. From hardware to software to the user interface, there are intricate details to a digital intervention that are time-consuming to design and will affect the quality of the intervention. Many of these details require careful decisions that researchers have not previously considered. Interviewees described lack of knowledge about what was even possible. Finally, developing and testing the intervention takes time and iteration. The processes, steps, and timelines imposed by working with a software development company can be quite lengthy and costly, growing more as researchers need even small changes made to a developed intervention. Working with outside development companies can create a disciplinary gap because those building

the intervention are not typically knowledgeable about interventions. This can lead to more back-and-forth between clinical researchers and developers to be on the same page.

Understanding the Product Design Cycle and Development Timeline

Clinical researchers who do not have first-hand experience with the product design cycle used within software development may not know how to plan their projects around it. If they do not have realistic expectations, they can then find themselves with timeline issues such as delays and budget problems associated with not locking in functional requirements and specifications in a timely manner, difficulties in making system changes because of an advanced stage of coding, or failure to include necessary components or design processes into contractual language. These can all result in digital health tools that miss the mark both for the creators who envisioned the interventions and for end users. Moreover, many digital behavioral intervention projects are behind schedule from the moment they are funded because of unanticipated contracting delays. Ensuring adequate communication with the clinical researcher, who in this case is the client for which the software is being developed, is not typically the role of a software developer, programmer, or engineer. More commonly, the responsibility for understanding the needs of the client and end user of the software lies with consultants, product managers, or user experience researchers. These types of roles specialize in overcoming cross-disciplinary communication challenges and translating between technical language and the language of, in this case, the behavioral interventionist. Unfortunately, our interviews suggest that the prohibitive costs of software development may lead researchers to work directly with those who will write the code, asking them to take on a broad range of roles that are critical to a successful software project. Working with an experienced third-party vendor, or investing in these other roles and specializations in-house, can make cross-disciplinary collaboration more effective for creating an impactful intervention, and even thoughtfully target the most difficult problems, such as engagement with technology over time.

Meeting Recipient Expectations for Digital Technology

Interviewees shared their concerns about ensuring that their intervention aligned with expectations that their recipients have for digital technologies they use in their everyday lives. Given the ubiquity of high-quality free apps and mobile websites and the technology industry's investment in the user experience of their products, consumers have high expectations for the appearance and functionality of interventions. The most prominent apps in their lives (eg, for social media, e-commerce, email, and search) are created by companies that invest considerably in the user experience, with entire departments dedicated to evaluating and continually improving the experience for their users. Apps that do not provide an experience that users have come to expect can generate disappointment, lower engagement, or abandonment.

The concerns of our interviewees echo the problem of engagement, which is well established in the literature [9,12-14,21,22] and which may be exacerbated when digital

health tools do not provide a high-quality user experience. Interventionists should therefore draw from industry best practices to meet their recipients' expectations. Asking end users of a digital intervention to interact with it, and assessing their experience, is an essential best practice [23] for ensuring the technology is user-centered and intuitive to use. For example, mockups of how the digital intervention will look can be shown in a study by Melles et al [23] or as a static image on a tablet. Users can then be asked to think aloud [24] as they review the information presented, react to the information, and describe what actions they believe they can take next. Such qualitative methods are the most effective [23] to ensure that the digital intervention is designed in a way that matches the mental model of the population. Achieving an adequate user experience can be costly, not necessarily because this requires complexity (in fact, current technology trends favor minimalism), but by investing in a user experience designer or interaction designer who will know how to meet user needs and expectations, including up-to-date standards and conventions to make it feel modern and credible. Moreover, engaging with the population as various aspects of the intervention are being designed can reveal how different design choices will affect the way they experience the intervention, providing opportunities to correct the course as needed while the intervention is still taking shape. These activities add further complexity to the timelines and budgets of software development projects we previously discussed. However, these activities are commonly adapted to fit the constraints of each project and can even save time and money when used early and strategically.

Variability in Recipients' Technology Access, Infrastructure, and Literacy

Interviewees in this study expressed many concerns about the technology access, infrastructure, and literacy of target end users, and these issues need to be considered by digital behavioral health interventionists, particularly those that work with underserved or marginalized populations. Although access to computers and smartphones may be high, access is not ubiquitous in all populations. Moreover, technology infrastructure is not equitable across the country, particularly in rural and underresourced urban settings where access to affordable, dependable, high-quality, high-speed broadband may not be readily available for all [25,26]. Furthermore, intervention-generated inequalities may arise where already advantaged populations gain greater advantage through digital interventions than do those who are less advantaged [27].

Finally, technology literacy is required to ensure that a device is connected to the internet, any peripheral devices such as a keyboard or wearable technology are paired, effective security measures such as passwords are used, and software updates are downloaded and installed in a timely manner to keep the device or intervention running smoothly. This requires a fair amount of technology literacy not only on the part of end users but also on the study staff assisting research participants to ensure adequate assistance with troubleshooting when problems arise. Regardless of the amount of advanced planning and testing, unanticipated issues with the technology will arise with any intervention, and these will affect recipients and study staff. Consequently, interventionists need to have a mechanism for

receiving reports of technical problems or difficulties. Troubleshooting problems, assisting recipients, and communicating with developers require additional effort and expertise from interventionists. Given that the interventionists perform less of the intervention delivery, their role therefore shifts more to technical training and support for recipients and ongoing communication with developers.

Evidence-Based In-Person Interactions Do Not Translate Directly to Digital Interactions

Overview

Our interviews revealed the extent to which interventionists approached the creation of digital interventions in similar ways as they had in the past with traditional methods and how they could run into challenges as a result. Although this is related to the conceptualization of the design of an intervention, which we addressed in an earlier section, we see it as a broader mindset and therefore discuss it separately. We highlight that moving analog processes and behavioral interventions to a digital world is not a 1:1 replication, nor should it be. That which is efficient and effective offline may not translate to the digital world in the same way, and the benefit of digitization means that there are potential efficiencies that can be captured with redesigned processes that are not possible in an analog world. This applies both to the front end of an intervention that is visible to research participants and also to the back-end databases and structures that run the interventions. For example, one can certainly take print materials and data collection forms and put them in a digital format as is, but this may not be the most efficient and effective content delivery solution. Moreover, given that many behavioral interventions are delivered in a face-to-face format with trained interventionists using techniques such as MI, the switch to digital platforms, which are often automated, cannot be a perfect replication. Interviewees from this study raised several concerns about the translation of in-person interventions and interactions to a digital world, including issues related to intervention design and intervention fidelity.

Intervention Design

Despite access and literacy variability among intervention recipients, one of the potential benefits valued by researchers is the ability to reach more people through the use of digital interventions at scale [18]; however, this extended reach of digital interventions comes with added complexity for planning and implementing interventions. In addition to time zone considerations, there may be other regional or cultural factors that affect how the intervention will be experienced by recipients across geographic areas. An early understanding of the potential differences between populations in different areas will enable effective design and planning. In addition, the need for tech-savviness on the part of intervention recipients introduces a level of complexity that may be off-putting for individuals less comfortable with technology. This increases the need to introduce experts in human-computer interaction and interaction design, who specialize in developing conceptual models through which users can intuitively interact with technology (eg, the desktop on a computer interface is derived from the metaphor of a physical desktop with files and folders placed upon it). In contrast to supporting intervention planning by outlining a range

of functional requirements to consider [28], focusing on user-centered conceptual models can help interventionists pivot from how they think of traditional interventions to how they might conceptualize digital interventions differently. Although some interventions try to emulate human counselors in order to provide an approach that mirrors real life, models other than that of the human counselor should be explored to effectively guide recipients through an intervention and to conceptualize how digital interventions can complement in-person services. Previous work has shown that although intervention recipients can develop a bond with an app and display open communication using this medium, the nature of the interaction is different than that with health professionals, as apps are not as able to simulate truly human qualities such as friendliness and collaboration [29]. Indeed, simulating realistic exchanges between humans and computers within the context of health issues has the potential to feel to human users as disingenuous, contrived, or overly stereotypical, which may be a deterrent to use [30]. There is evidence that suggests SBIRT (Screening, Brief Intervention, and Referral to Treatment) interventions can be at least as good as face-to-face, clinician-delivered interventions [31,32].

Interviewees often talked about the loss of ability to gauge and react to intervention recipients' responses, behaviors, and body language. The ability of automated interventions to handle such nuanced verbal and nonverbal communication is still limited; however, we note that artificial intelligence and other emerging technologies do have the potential to improve personalization and adaptivity of interventions through speech pattern recognition, natural language processing, and machine learning. These advanced technological methods can help to process the large number of possible intervention pathways and make decisions based on certain rules that are preprogrammed or learned over time, addressing the challenge articulated by some interviewees. These innovations are developing and improving rapidly and mark an important area of study at this time. Furthermore, as interventionists look to digital interventions to supplement human interaction and support, there is a critical need for continued investigation of the recipient experience. Evidence is needed to determine the extent to which technology

can convey empathy and emotional support and, if so, through which features or functions specifically. Finally, it should also be noted that although technology clearly cannot do everything that a human interventionist can do, neither can a human interventionist do everything that technology can do, and those advantages should be leveraged freely, rather than only seeking to replicate human interaction. The literature in this area includes examples of technology-delivered interventions performing equally well as human-delivered interventions [31], with similar overall acceptability [33] and greater cost-effectiveness [34].

Limitations

This study was limited, first, by our focus on the CIAS platform, given that this work was conducted within the context of CIAS redesign activities. Although the limitation on CIAS users may have potentially introduced selection and response bias, the issues raised by interviewees in this study were largely focused on considerations for developing and implementing digital behavioral interventions in general, and not on CIAS itself. Our participants described experiences across a range of behavioral interventions. We also contextualized our recommendations within the broader literature and best practices for software projects. Finally, our sample size was small; however, saturation was achieved, leaving us confident that adding additional participants to the sample would yield little new information to contribute.

Conclusions

Researchers from within the health and social sciences who wish to develop and implement digital behavioral interventions describe a consistent set of challenges. Issues resulting from lack of cross-disciplinary understanding; variability in recipients' technology access, infrastructure, and literacy; and translating face-to-face interventions into digital interactions are common across multidisciplinary teams in this space and speak to the need for better training and planning among research teams who wish to work with digital health. Finding the right expertise to include on multidisciplinary teams can help teams overcome these challenges and build off similar work that has been done, as opposed to reinventing the wheel with every new project.

Acknowledgments

This research was funded by the National Institute of Biomedical Imaging and Bioengineering at the National Institutes of Health under grant number EB028990 to SJO. The authors would like to thank Lilly Pritula and Rania Ajilat for administrative support, including manuscript editing, and the interviewees who made this study possible.

Abstract

Background: During the time surrounding the approval and initial distribution of Pfizer-BioNTech's COVID-19 vaccine, large numbers of social media users took to using their platforms to voice opinions on the vaccine. They formed pro- and anti-vaccination groups toward the purpose of influencing behaviors to vaccinate or not to vaccinate. The methods of persuasion and manipulation for convincing audiences online can be characterized under a framework for social-cyber maneuvers known as the BEND maneuvers. Previous studies have been conducted on the spread of COVID-19 vaccine disinformation. However, these previous studies lacked comparative analyses over time on both community stances and the competing techniques of manipulating both the narrative and network structure to persuade target audiences.

Objective: This study aimed to understand community response to vaccination by dividing Twitter data from the initial Pfizer-BioNTech COVID-19 vaccine rollout into pro-vaccine and anti-vaccine stances, identifying key actors and groups, and evaluating how the different communities use social-cyber maneuvers, or BEND maneuvers, to influence their target audiences and the network as a whole.

Methods: COVID-19 Twitter vaccine data were collected using the Twitter application programming interface (API) for 1-week periods before, during, and 6 weeks after the initial Pfizer-BioNTech rollout (December 2020 to January 2021). Bot identifications and linguistic cues were derived for users and tweets, respectively, to use as metrics for evaluating social-cyber maneuvers. Organization Risk Analyzer (ORA)-PRO software was then used to separate the vaccine data into pro-vaccine and anti-vaccine communities and to facilitate identification of key actors, groups, and BEND maneuvers for a comparative analysis between each community and the entire network.

Results: Both the pro-vaccine and anti-vaccine communities used combinations of the 16 BEND maneuvers to persuade their target audiences of their particular stances. Our analysis showed how each side attempted to build its own community while simultaneously narrowing and neglecting the opposing community. Pro-vaccine users primarily used positive maneuvers such as excite and explain messages to encourage vaccination and backed leaders within their group. In contrast, anti-vaccine users relied on negative maneuvers to dismay and distort messages with narratives on side effects and death and attempted to neutralize the effectiveness of the leaders within the pro-vaccine community. Furthermore, nuking through platform policies showed to be effective in reducing the size of the anti-vaccine online community and the quantity of anti-vaccine messages.

Conclusions: Social media continues to be a domain for manipulating beliefs and ideas. These conversations can ultimately lead to real-world actions such as to vaccinate or not to vaccinate against COVID-19. Moreover, social media policies should be further explored as an effective means for curbing disinformation and misinformation online.

Introduction

Background & Motivation

COVID-19 claimed the lives of 2.6 million people in the first year of its discovery [1]. In a concerted effort to reduce the cases and deaths resulting from the COVID-19 pandemic, governments and major health organizations pushed for the development and rapid distribution of COVID-19 vaccines. This process, however, has been met with online expressions of resistance vaccination [2]. In view of this concerning spread of anti-vaccine sentiment online, our work has focused on identifying the specific tactics used by both the pro- and anti-vaccine communities to spread their messages over Twitter.

Though vaccinating everyone against COVID-19 may seem to be an obvious way to prevent deaths, many people and groups oppose vaccination for several different reasons. The first compulsory vaccination was established in England by the Vaccination Act of 1853. The act faced opposition to the idea that the government should impose health legislation [3]. In current times, communities speak out against the government and assert that they have the right to decide what goes inside their bodies. Some anti-vaccine proponents fear the side effects of vaccines and refuse entirely to vaccinate themselves or their children because of rumors of autism or other medical disorders [4,5].

The Pfizer-BioNTech vaccine was the first vaccine for preventing COVID-19 to be authorized in the United States by the Federal Drug Administration (FDA). Both the FDA and European Medicines Agency (EMA) authorized the vaccine for emergency use. In 2020, the first Pfizer vaccine doses were distributed in the United Kingdom on December 8 and in the United States on December 14. Because of the rush to create the vaccine, many feel the vaccines were inadequately tested and refuse the vaccine without seeing the results of long-term studies. Additionally, some accept conspiracy theories or rumors on the vaccine. For example, one such conspiracy theory is that Bill Gates and the government created the vaccines to microchip the population for some malicious intent [6]. These are among the reasons for “vaccine hesitancy” across the world [7].

Social media has become a medium for COVID-19 vaccine discussion. Twitter is a popular platform on which government leaders, public health officials, and news organizations spread pertinent information. However, many users spread misinformation or act maliciously by conducting influence campaigns to manipulate peoples’ beliefs and ideas. Bonnevie et al [2] found that vaccine opposition on Twitter increased by 80% after COVID-19 began spreading in the United States. Misinformation is not limited to anti-vaccine users as some pro-vaccine users also share unreliable information [8]. To counter the spread of misinformation on its platform during the initial administration of the vaccine, Twitter expanded its policy by removing false and misleading tweets about COVID-19

vaccines, adding labels to potentially misleading COVID-19 vaccine information, and creating a “five-strike system” for suspending misleading accounts [9,10].

These malicious actions online are a major aspect within the field of social cybersecurity. Social cybersecurity lies at the intersection between cyberspace and human interaction. It studies how humans can be influenced by tactful messaging and connecting the right people to the right content. Key players in an online social network can conduct influence maneuvers to change users’ beliefs and affect their behavior [11]. In our study, we sought to identify the important actors in pro- and anti-vaccine Twitter communities as well as the social-cyber maneuvers they used to influence their audiences’ stances regarding the COVID-19 vaccine.

This work focused on the time period around the approval and initial administration of the Pfizer vaccine. Our objective was to determine whether there are differences between the types of social-cyber maneuvers pro-vaccine and anti-vaccine communities use toward their target audiences. We describe a methodology for determining pro-vaccine or anti-vaccine stances within tweets and identifying key players within the social network. We further used bot detection and linguistic cues to analyze the content and significance of tweets, and we evaluated how the 2 opposing vaccine communities applied social-cyber maneuvers to persuade their target audiences. Our results show how pro-vaccine messaging focused on exciting readers and explaining the vaccine issue. In contrast, anti-vaccine groups preferred to make dismaying statements and used messaging that distorted vaccine information. We also found that Twitter’s tightening of its policies on vaccine misinformation had a remarkable effect on decreasing the size of anti-vaccine communities and the prevalence of their messaging.

Related Work

Vaccine Stance Detection

The problem of identifying pro- and anti-vaccine communities has garnered the attention of several researchers who have sought to apply stance detection techniques from computer science to this task. Supervised machine learning methods developed for this problem have ranged from the use of transformer neural networks based on Google’s Bidirectional Encoder Representations from Transformers (BERT) model [12] to the use of convolutional neural networks trained on n-grams and topics detected via Latent Dirichlet Allocation [13]. More traditional community detection algorithms have also been used to find groups with overt stances on vaccines [14]. The semisupervised stance propagation technique used for our work, which has the advantage of not requiring extensive manual labelling of pro- and anti-vaccine messages, was also used to identify linguistic differences between pro- and anti-vaccine groups [15].

Pro-Vaccine and Anti-Vaccine Communities

Various studies of anti-vaccine and pro-vaccine communities have sought to identify the methods used for spreading vaccine-related messages. Different communities can have contrasting messaging characteristics depending on the nature of and support for their stances on vaccines.

In 2019, a study examining influential themes and actors within the anti-vaccine community concluded that top tweeters relied on highly networked communities led by accounts that select messages expected to have high receptivity within those communities [16]. This was different from standard messages from public officials, which tended to repeat the same information to the same communities, limiting the extent of a message's reach. In an analysis of Facebook vaccine group clusters, Johnson et al [17] observed that anti-vaccination clusters entangled more often with undecided clusters, while pro-vaccination clusters tended to be more peripheral. Furthermore, Schmidt et al [14] examined how echo chambers reinforce the opinions of groups and how involvement within these groups could be an effective way of countering anti-vaccine beliefs.

Past research has therefore found that pro-vaccine messages tend to be supported by public health officials and governments seeking to reduce the spread of infectious diseases, whereas anti-vaccine communities are more niche and maintain a smaller following. However, although pro-vaccine messages tend to stay within pro-vaccine communities, anti-vaccine messages permeate beyond the boundaries of anti-vaccine communities.

Although these past works have analyzed the themes and targeting of vaccine messaging, they have not considered the specific types of strategies carried out in vaccine-related information operations. Thelwall et al [18] tracked some of the anti-vaccine narratives spreading on Twitter, and Boucher et al [19] identified the key themes in Twitter conversations about vaccine hesitancy. However, previous research has not examined the intentions behind specific choices on the language, content, and targeting of pro- and anti-vaccine messaging. Our work breaks down the tactical value of specific types of vaccine messages and analyzes how those tactics have changed over time.

Social Cybersecurity: Influence Campaigns and Bots

A key development in the fight against online influence campaigns has been the growth of the field of social cybersecurity, a computational social science that aims to protect the security of democratic societies by studying the ways in which actors exercise manipulation on social media platforms [11]. Recognized by the National Academies as a new science [20], its key areas of research have been the study of information maneuvers, motive identification, and information diffusion, as well as the evaluation of the effectiveness of information campaigns and mitigation strategies. Though the field has most extensively focused on the spread of political disinformation,

it has more recently expanded to tackle the problem of medical misinformation [11].

Of particular concern in social cybersecurity is the existence of automated accounts on social media platforms since they are used to spread online disinformation and influence elections [21]. They have also manipulated public health discourse by propagating misinformation on topics such as e-cigarettes, diets, and medications [22]. Because of the influence of these bots on public opinion, several studies have been conducted on the use of bots for spreading vaccine information [23,24]. Before the COVID-19 pandemic, Broniatowski et al [25] examined the extent to which bots spread anti-vaccine messages, showing the high rates of vaccine content they spread and comparing it with the effects of Russian trolls, whose messages primarily sought to increase discord online. Dyer [26] determined that after Russian trolls, bots were the most prolific vaccine-related tweeters. Huang and Carley [27] found that accounts linking to coronavirus information from less reliable sites were more likely to be bots. Ng and Carley [28] also found that bots change vaccine stance more easily than non-bots. Hence, understanding the actions of automated accounts is a crucial part of vaccine-related online influence campaigns.

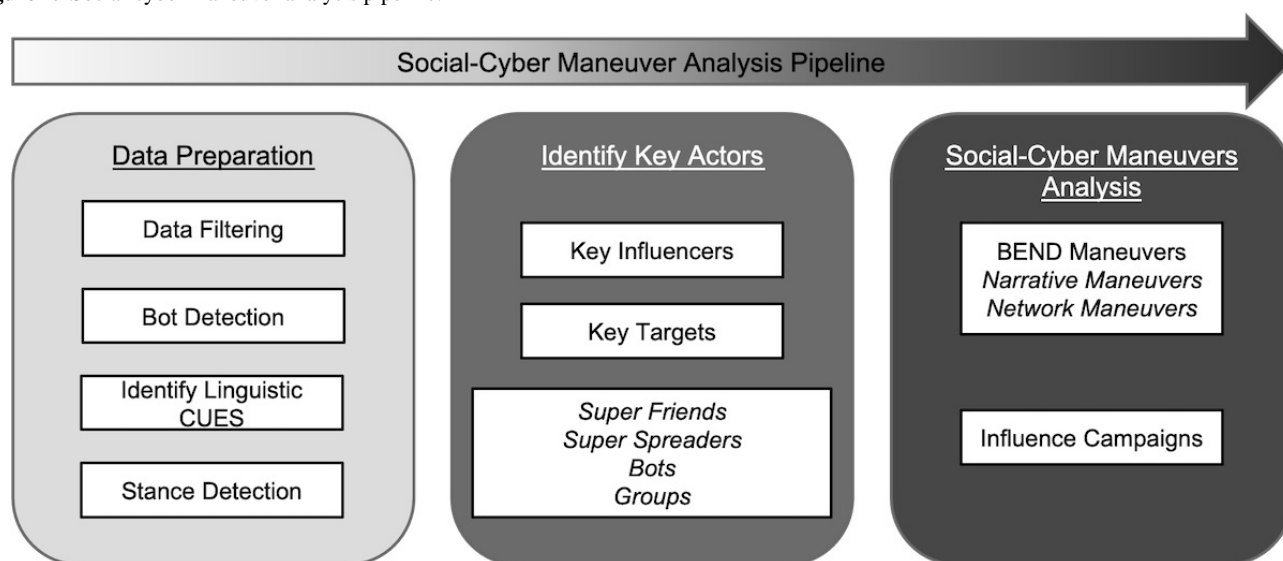

The BEND Framework

A crucial component of social cybersecurity's efforts to characterize online influence operations has been the struggle to establish the motives and tactics of those seeking to manipulate conversations in cyberspace. The BEND framework was developed to assist in the theoretical conceptualization of this problem by providing a taxonomy of 16 categories of maneuvers for conducting online influence [29]. These categories are divided into 2 types: narrative and network maneuvers. These types are further divided into positive and negative directions of influence. Narrative maneuvers focus on the information and content of messages. These maneuvers affect what is being discussed and how it is discussed. Network maneuvers focus on how the network and communities are shaped and the positions of key actors.

The BEND framework provides analysts and researchers with a way to conceptualize the tactics used in online information operations. Though this framework was discussed in reference to election manipulation [29], it has not yet been applied to vaccine-related influence campaigns.

Methods

In this work, we used a methodology similar to the pipelines in other social cyber-security studies [30]. For the social-cyber maneuver analysis, the end state is to gain a comprehensive understanding of the actors and their maneuvers used to manipulate others on social networks. The pipeline is broken into 3 parts: data preparation, key actor identification, and social-cyber maneuvers analysis (Figure 1).

Figure 1. Social-cyber maneuver analysis pipeline.

Data Preparation

Data Collection

The data used in this work are a subset of COVID-19 tweets collected from Twitter using the Twitter application

Table 1. Keywords used to collect COVID-19 vaccine-related tweets.

Filter	Keywords
Filter 1: COVID-19 tweets	coronavirus, coronavirus, wuhan virus, wuhanvirus, 2019nCoV, NCoV, NCoV2019, covid-19, covid19, covid 19
Filter 2: vaccine tweets	vaccine, vax, mRNA, autoimmuneencephalitis, vaccination, getvaccinated, covidisjustacold, autism, covidshotcount, dose1, dose2, VAERS, GBS, believemothers, mybodymychoice, thisisourshot, killthevirus, proscience, immunization, gotmyshot, igotheshot, covidvaccinated, beatcovid19, moderna, astrazeneca, pfizer, johnson & johnson, j&j, johnson and johnson, jandj

We divided the data into 3 time periods surrounding the introduction of the Pfizer vaccine: December 1-7, 2020 (the week before the rollout), December 8-10, 2020 (during the week of the rollout in the United States and the United Kingdom), and January 25-31, 2021 (6 weeks after the rollout). The 3 periods consisted of 471,962, 694,200, and 662,776 users and 935,709, 1,511,344, and 1,368,035 tweets, respectively.

Identifying Bots

Using the Tier-1 BotHunter algorithm by Beskow and Carley [31,32], we determined the probability that each user within the data set was a bot. BotHunter is a random forest regression model trained on labeled Twitter data sets. It was developed from forensic analyses of events with extensively reported bot activity, such as the attack against the Atlantic Council Digital Forensic Research Lab in 2017. This machine learning model considers network-level features (such as the number of followers and friends), user-level attributes (including screen name length and account age), and tweet-level features (such as timing and content). For this work, any score of 75% or greater was labeled as a bot to reduce the chance of false positives and ensure that the accounts classified as bots were truly bots (at the expense of missing some bots) [33].

programming interface (API) and keywords related to COVID-19. The data set was then further filtered using the vaccine-related terms shown in Table 1. Furthermore, we removed tweets from non-English speaking users from the data.

Linguistic Cues

The NetMapper software [34] was used to extract linguistic cues from the tweet text. These are metrics helpful in identifying a tweet's sentiment and author's emotional state [11]. Examples of these cues include the frequency of positive and negative terms, types of pronouns, emojis, and others. These tweet attributes are used to identify BEND maneuvers and actors participating in such maneuvers.

Organization Risk Analyzer - PRO Software

The Organization Risk Analyzer (ORA)-PRO software [34] is a dynamic meta-network analysis tool used extensively in this study to examine and characterize key actors, conversations, and the overall structure of the Twitter data. Key features used included a network data visualization tool, stance detection function, Twitter analysis report, and the BEND and Community Assessment report.

Stance Detection

We used the stance detector [35] built into ORA-PRO to divide the data set into the pro-vaccine and anti-vaccine communities. This stance detector starts with a set of hashtags that the user initially labels as pro- and anti- with respect to an issue. The stance detector uses these hashtags to label the stance of the

Twitter accounts that used them. The algorithm then uses the concept of influence propagation to label the stance of users who did not use any of the pre-labeled hashtags. This propagation through the user communication network proceeds by repeating 2 steps. First, users with a known stance are used to determine the stances of some of the hashtags that have not yet been labeled. In this step, hashtags that are used overwhelmingly by users of one stance over the other are accordingly assigned that stance. In the second step, hashtags with a known stance are used to determine the stances of some of the unlabeled users. Users who have overwhelmingly used hashtags of one stance rather than the other are labeled with that stance. Additionally, both steps allow stance to spread directly from user to user. In both steps, unlabeled users who

are predominantly connected to users of the same stance are assigned that stance.

The algorithm also provides a confidence level for each stance classification. After running the stance detector on our data, pro-vaccine users had a mean confidence level of approximately 99% to 100% for each time period. However, the anti-vaccine users for the before, during, and after rollout periods had mean confidence levels of 84%, 85%, and 67%, respectively. [Table 2](#) shows the number of users classified by stance for each time period and the number of tweets by these communities. There were noticeably fewer anti-vaccine users and tweets than pro-vaccine users and tweets. Though the stance detector also identified neutral nodes, we excluded them from this study.

Table 2. The number of users labeled as pro-vaccine and anti-vaccine, along with the number of tweets by users of each stance after running the stance detector.

Time period	Users labeled by stance detection		Number of tweets by users of each stance	
	Pro-vaccine	Anti-vaccine	Pro-vaccine	Anti-vaccine
Before rollout	216,156	36,609	186,726	31,200
During rollout	195,334	47,566	292,607	55,406
After rollout	430,278	19,519	338,035	30,560

Examining Key Actors and Social-Cyber Maneuvers

We used reports within ORA-PRO to gain insight on key actors, individual tweets, BEND maneuvers [36], and the entire network. We ran the reports and analyzed each of the 3 time periods on each of the subsequent stance communities. By examining an entire time period, we observed the interactions of the users between those of opposing or neutral stances. Then, by focusing on the individual communities by stance, we conducted a more fine-grained analysis.

ORA-PRO's Twitter report allows us to identify and analyze key agents or actors, hashtags, tweets, and other Twitter attributes on Twitter data. Key actors are useful in understanding who are the most influential entities and what are the most influential conversations. The first type of key actors we observed was super friends, or users that exhibit frequent 2-way communication with others, such as reciprocal mentioning or retweeting. The second type that we examined was super spreaders. These users generate content that is shared often, facilitating the diffusion of information across the network. We then extracted the list of tweets and hashtags for each of these key actors for further inspection.

Additionally, the Twitter report identified valuable tweets. In this study, we specifically focused on the most propagated tweets within a data set. These are tweets that have the highest combined values for retweets, replies, and quotes. This information aided in understanding social-cyber maneuver narratives and actions.

The ORA-PRO software uses NetMapper's linguistic cues as input for detecting BEND maneuvers in tweets using the BEND and Community Assessment report. Of the most propagated tweets, we used this report in conjunction with manual labeling to gain insight into the social-cyber maneuvers used within our data sets.

In our analysis, we organized the BEND maneuvers into 1 of 6 application categories based on the similarity of the maneuvers: developing the narrative, emotional influence, countering the narrative, affecting leaders, making or growing groups, or dissolving or reducing groups ([Table 3](#)). These represent macro-level actions occurring as a result of multiple BEND maneuvers. We observed these combinations over time to identify a concerted effort to influence target audiences of their stances. We labeled the narratives and actions for the 100 most propagated tweets for each stance community within each time period and grouped them into these application categories.

Table 3. BEND maneuvers organized into application categories.

BEND maneuver and application categories	Maneuvers
Narrative maneuvers	
Developing narrative	Engage, explain, enhance
Emotional influence	Excite, dismay
Countering narrative	Distract, dismiss, distort
Network maneuvers	
Affecting leaders	Back, neutralize
Making groups	Build, boost, bridge
Reducing groups	Neglect, narrow, nuke

Results

Key Actor Overview Overtime

Key Influencers: Super Friends and Super Spreaders

We used ORA-PRO to calculate the super friends and super spreaders for the 3 data sets for each time period and identified the types of entities that fell into each of these categories.

The top 10 super friends throughout the 3 data sets were predominately pro-vaccine, though varied in the types of actors. All of the top 10 super friends identified before the rollout were unverified Twitter accounts and relatively low-profile users. ORA classified all of the tweets as pro-vaccine, and 3 of them, we identified as amplifier bots [37]. During the rollout, the top 10 included several anti-vaccine users and a single neutral stance user. Of the 3 bots on the list during this period, 2 news bots emerged alongside one of the pro-vaccine bots from the before period. At 6 weeks later, several higher-profile users from health and government organizations appeared as super friends. These

included the World Health Organization, the India Ministry of Health, and the India Official COVID Response account.

Except for one instance, the top 10 super spreaders were either classified as pro-vaccine or neutral within the 3 data sets. All of the users before and during the rollout were high-profile verified Twitter accounts. During these 2 periods, the super spreaders were primarily health organizations, vaccine manufacturers, news organizations, and senior government leaders. After the rollout, the types of accounts identified as super spreaders changed. Though a couple of news organizations and health-related accounts remained on the list, the users were more community leaders or professionals with a substantial reach, such as actors or journalists.

Bot Influencers

The BotHunter results revealed that anti-vaccine agents consisted of a higher percentage of bots than the pro-vaccine agents (Figure 2). Though anti-vaccine bots decreased over time, the number of bots remained relatively higher than the total percentage of pro-vaccine bots of the same time periods.

Figure 2. Percentage of bots by stance by time period.

We calculated the number of bots within the top 100 super spreaders and super friends (Figure 3). The high percentage of super friends shows that users are interacting with the bots and engaging in 2-way communications. The super spreaders show that bots are effectively diffusing tweets through the network. These bots have managed to connect with users on Twitter, which makes them susceptible to the information or

disinformation that these bots can be posting. Furthermore, the data show a noticeable decline in the number of anti-vaccine influencers after the rollout. Super spreaders, for example, reduced from 15 and 16 bots during the first 2 periods to only 4 after the rollout. This difference is likely a result of the Twitter policy against anti-vaccine disinformation enacted mid-December 2020 [9].

Figure 3. Number of bots in top 100 influencers.

BEND—Narrative Maneuvers

Using ORA-PRO, we identified the most propagated messages for each of the stances and periods. We then identified and

evaluated how narratives manifested themselves as maneuvers to persuade others. This section provides a cumulation of narrative BEND maneuvers observed within each of the communities.

Pro-Vaccine Communities—Narrative Maneuvers

Pro-vaccine communities had varying messages before the vaccine rollout. Many of them were *excite* messages, defined as messages that elicit a positive emotion such as joy or excitement. Users posted positive tweets about the vaccine's approval and then encouraged others to get their vaccine when it became available. At the same time, many users also attempted to compel others to curb the growing number of COVID-19–related illnesses and deaths using the *dismay* maneuver. This is messaging to elicit negative emotion such as sadness or anger, to warn users of the consequences of not getting the vaccine. Health officials and organizations used the maneuver, *explain*, which is to educate on a topic using details and relevant facts, to inform the science behind the vaccine and build confidence in its use. To counter vaccine myths, users used the *dismiss* maneuver, the maneuver used to downplay anti-vaccine information as either irrelevant, inconsequential, or foolish. Many users also *dismissed* many of the fears that stemmed from the vaccine's rapid development. These maneuvers were typically followed up with *explain* maneuvers that attempted to debunk these myths using scientific evidence or detailed forms of justification. Finally, users would *enhance* their pro-vaccine ideas or encourage their views with the support of prominent actors or interesting content. Many, for example, tweeted and quoted articles about 3 former US Presidents volunteering to get the vaccine to promote trust in the vaccine.

During the rollout, pro-vaccine communities continued to post similar types of messages as in the week prior. Many users expressed *excitement* about the first person to receive the Pfizer vaccine, a 90-year-old woman from the United Kingdom leading the vaccine rollout. Other types of optimistic *excite* messages included those from users of various countries approving and purchasing vaccines as well as many *excited* at the sight of the logistics vehicles containing the vaccines within the distribution process. Additionally, pro-vaccine proponents also added to their *explain* messages about how the vaccines work by emphasizing the vaccine's effectiveness after the first dose and

supporting the overall narrative with charts and results from the vaccine trials during the development process. Furthermore, medical professionals made efforts to *engage* with their more hesitant audiences to instill confidence in the vaccine and encourage them to get vaccinated.

After the rollout, messages continued to *explain* science-backed research for the development, safety, and efficacy of the vaccine to build trust in its use while countering anti-vaccine myths and narratives. Pro-vaccine users during this period showed general *excitement* and optimism about how the vaccine will benefit themselves, their families, and their communities. There were general *excite* tweets about the authorizations and distributions of the vaccine worldwide. Individuals also spread *excite* messages about finally getting the vaccine, getting an appointment for the vaccine, or just desiring to get the vaccine. Many users combined these messages with the *engage* maneuver by taking ownership of the vaccination process by setting the example as a vaccinated individual and encouraging others to also get vaccinated.

Throughout these periods, pro-vaccine communities engaged in hashtag hijacking by tying pro-vaccine narratives to hashtags intuitively associated with anti-vaccine messages. By adding #antivax, #antivaxxer, and other similar anti-vaccine-related hashtags to their tweets, pro-vaccine communities used these hashtags in large numbers to draw attention to pro-vaccine messages with anti-vaccine keywords (Table 4). In one case, they used it to *enhance* the pro-vaccine messages, typically by attaching this hashtag to pro-vaccine *explain* messages intended for vaccine hesitant users. In another case, hashtag hijacking tied the hashtag to satirical messages related to anti-vaccine individuals' actions. The pro-vaccine message *distorts* the anti-vaccine message with a quote or a reply or somehow ties their narrative to a specific anti-vaccine incident. Furthermore, in some uses of the hashtags, pro-vaccine users *engaged* anti-vaccine users to condemn or insult them for either spreading disinformation or other anti-vaccine behavior.

Table 4. Hashtag hijacking: usage count of anti-vaccine–related hashtags by pro-vaccine users.

Hashtag	Before rollout (n=2218), n	During rollout (n=1221), n	After rollout (n=768), n
antivaccination	0	26	5
antivaccine	55	47	68
antivax	457	281	247
antivaxer	5	3	0
antivaxers	26	11	13
antivaxx	83	54	63
antivaxxer	133	39	62
antivaxxers	1459	760	310

Anti-Vaccine Communities—Narrative Maneuvers

In the week leading up to the vaccine approval and distribution, users were already expressing their COVID-19 anti-vaccine views on social media. The most popular types of messages were the emotionally appealing *dismay* messages about side

effects from the vaccine. Anti-vaccine users shared messages about how the vaccine causes female infertility, destroys the immune system, or leads to death. These messages were further *enhanced* with references to scientists, doctors, former Pfizer representatives, and politicians. In many of these messages, the side effects were *explained* using plausible arguments and

pseudoscientific methods and information. To counter pro-vaccine messages, anti-vaccine proponents attempted tactics such as *dismissing* the vaccine effectiveness, suggesting that a person's immune system is more than sufficient against the virus. They also countered with the *distract* maneuver, which uses misdirection by making other topics seem more important. In one example, the 3 US Presidents volunteering for the vaccine mentioned earlier sought to build confidence. However, opponents of the vaccine focused on *distracting* their audiences with negative political news from the Presidents' pasts relations with China. These insinuated negative links between the Presidents and the country where the virus first began to spread. In another narrative, messages specifically targeting pro-life supporters described the use of fetal cells derived from an abortion during the vaccine development process. These began as *dismay* messages to anger pro-life supporters about its use and then was supported with *explanations* on how the different vaccines used the fetal cells in different phases of the process, making some vaccines more ethical than the others. Proponents then *enhanced* these messages by attaching supportive messages from major religious organizations.

During the rollout, anti-vaccine narratives continued to emphasize many of the negative aspects of the vaccine. Still, many *dismaying* messages about the vaccine side effects dominated anti-vaccine conversations. New *explaining* messages to support these *dismaying* claims included citing the vaccines' published lists of adverse effects and a cost-benefit analysis on the benefits versus the severe reactions resulting from getting the vaccine. Again, these were *enhanced* and validated with statements from medical professionals and scientists. Additional *dismaying* messages emerged as popular during this early period. Topics included news reports for the vaccine causing false positives for HIV, government cautions for allergic reactions to the vaccines, claims that the vaccine is not Halal certified under Islamic dietary laws, and negative experiences from those who participated in the vaccine trials. *Distort* messages, or discussion that alters the main message, helped anti-vaccine messages counter many positive pro-vaccine narratives and propagate anti-vaccine conspiracy theories. They countered the scientific facts about the construct of the vaccine with the lack of peer-reviewed literature to support it, spread manipulated images of Dolly Parton purporting that the vaccine caused her to have Bell's palsy, and suggested that the mRNA vaccines contain nanobots and can change a person's DNA. Furthermore, general anti-vaccine messages from both medical and nonmedical users within this community *engaged* online to express their distrust with the vaccine and recommend not getting the shot without knowing the long-term safety data.

After the rollout, the decrease in anti-vaccine users resulted in spreading fewer anti-vaccine messages. By this time, Twitter removed many anti-vaccine users and their messages for violating their policy on spreading false or misleading COVID-19 vaccine information. The messages that remained, however, were still primarily *dismaying* and *distorting* messages about the adverse side effects and deaths resulting from vaccinations. Despite the Twitter policy, several *distorting* conspiracy theories such as vaccines connecting one's body to cryptocurrency and altering DNA still appeared in the data set.

Furthermore, users continued to *engage* their audiences more practically by expressing hesitancy for a quickly developed vaccine without data on its long-term effects.

BEND—Network Maneuvers

Using the messages, we identified instances of the communities engaging in network maneuvers. Network maneuvers alter the structure of the network by encouraging connections or disconnections between users. In Twitter, one effective tool and indication of a network maneuver is the use of mentions. These types of maneuvers, however, can exist without them.

There were several ways that pro-vaccine communities engaged in network maneuvers. The most common maneuvers were *building* and *boosting*, used for creating a group or to grow the size of a group, respectively. The primary goal for pro-vaccine communities was to urge others to get the vaccine under the premise that the more people who supported and received the vaccine, the sooner the pandemic would end. Simultaneously, these groups engaged in the counter maneuver of *narrowing* and *neglecting* to reduce the size of or marginalize the opposing anti-vaccine community. One of the most effective actions for group reduction was using the *nuke* maneuver to dismantle or show the appearance of a dismantled anti-vaccine community. Twitter attempted this maneuver when it created its policy against COVID-19 vaccine disinformation, affecting the entire after-rollout period data set. Another common network maneuver was *backing*, which is an action that increases the importance of leaders or creates new leaders. Pro-vaccine users showed support for government officials, leaders in the medical field, health organizations, and vaccine manufacturers with positive messages and references to these leaders or organizations.

The anti-vaccine community conducted similar network maneuvers to the pro-vaccine community. They aimed to *build* and *boost* their group and reduce the pro-vaccine community using *narrowing* and *neglecting*. This community, however, did not have as many leaders as its opponents. The few that they *backed* included critics of pro-vaccine policies such as an ex-Pfizer vice president, politicians, and scientists who petitioned against the vaccine for safety concerns. Anti-vaccine users, however, had a large selection of leaders that they attempted to *neutralize* or decrease in importance. These opposing leaders were largely the same people and organizations the pro-vaccine community *backed*.

Social-Cyber Maneuvers Applications Over Time

The different narratives and BEND maneuvers from each stance community were associated with one or more application categories. Though each community used different content for their messaging, they used roughly the same techniques. Many of these techniques are used in combination over time to develop more impactful influence campaigns.

Over time, pro-vaccine communities consistently used mostly positive narrative content in their messaging while applying a pattern of developing their narrative, using emotional influence, and countering the opposing community's narrative (Figure 4). *Excite* messages combined with the narratives about the approval, distribution, and administration of the vaccine were

were often fake or pseudoscience. Furthermore, we found that directly countering anti-vaccine narratives became less common over time as the number of anti-vaccine messages decreased and the primary pro-vaccine narratives became prevalent.

Figure 4. Social-cyber maneuvers and narratives for top 100 most propagated pro-vaccine tweets.

[illegible]

structure. The result was the decrease in accounts that typically propagated offensive disinformation and subsequently large amounts of anti-vaccine tweets.

Across the 3 time periods, the anti-vaccine community also used different combinations of the maneuvers and application to sway their audience (Figure 5). They primarily developed their narrative and countered pro-vaccine messages using multiple maneuvers, heavily relying on the negative emotional influence using *dismaying* messages to highlight the side effects, long-term effects, and conspiracy theories. Anti-vaccine users also aimed to affect the relationships of leaders of both communities. They aimed to discredit the leaders of the

effect type of messages emerged as the dominant narrative. Because of the decrease in messages, it would be difficult to speculate about the types of anti-vaccine maneuvers that may have otherwise prevailed during the later period.

Figure 5. Social-cyber maneuvers and narratives for top 100 most propagated anti-vaccine tweets.

[illegible]

Principal Findings

to effectively *nuke* the anti-vaccine community by reducing the size of the online community and the quantity of anti-vaccine messages.

The majority of top super spreaders and super friends for each of the analyzed time periods were pro-vaccine users. Government leaders, medical organizations and professionals, vaccine manufacturers, and, in the later period, less-mainstream community leaders emerged as pro-vaccine leaders, effectively reaching a higher number of users and engaging in more 2-way conversations. Additionally, bots had a sizeable presence within each community. We observed a larger percentage of bots within the anti-vaccine community than the pro-vaccine community, and among the top 100 key influencers for each community over time, the anti-vaccine community had more bots as super spreaders and super friends. Before Twitter's vaccine disinformation policy, they reached as high as 24% and 16% of the top 100 anti-vaccine super friends and super spreaders, respectively, before the rollout. The anti-vaccine community

utilized bots to a greater extent to *build* their communities and spread their narratives than did the pro-vaccine community, effectively positioning them as key influencers among anti-vaccine users.

Pro-vaccine users repeated many of the same maneuvers throughout each time period, varying in different narratives that emerged as the rollout occurred. Many of the maneuvers were positive or growth-type maneuvers. They developed narratives around science-based facts *explaining* the safety and effectiveness of the vaccine and emotionally influencing narratives that *excited* their audiences about the health and societal benefits of everyone receiving the vaccine and, to a lesser extent, *dismayed* them with the fatal consequences of not vaccinating. Many of the topics used to develop these narratives were also used to counter anti-vaccine messages. As many anti-vaccine conversations revolved around side effects and conspiracy theories, pro-vaccine proponents rebutted with facts to *explain* the errors in these messages. These narratives were used consistently by highly connected leaders within the community and actors that maintained a high profile apart from Twitter, such as government leaders, news organizations, and medical professionals. Pro-vaccine users tended to *back* government officials and health organizations with positive messaging to build confidence in the proponents of the vaccine as well as the vaccine itself.

Throughout each of the time periods, the anti-vaccine community used similar maneuvers to those the pro-vaccine community used but with a greater frequency of the negative or reducing-type maneuvers. They developed focused narratives and countered pro-vaccine messaging to increase hesitancy and doubt. Their most consistent technique was using *dismaying* messages of the adverse side effects, the uncertainty of the long-term effects, and vaccine deaths. Conspiracy theories about the vaccine also added to the anti-vaccine narrative. Users attempted to *neutralize* pro-vaccine leaders by discrediting them and their associated messaging, and they *backed* leaders who criticized the vaccine and encouraged others not to get the vaccine.

Finally, as the host for the pro-vaccine and anti-vaccine engagements, Twitter is in a unique position with the ability to filter the discussion on their platform. Their policy to remove misleading and false anti-vaccine *nuked* the anti-vaccine community by significantly reducing the number of anti-vaccine users and tweets that had grown at the time of the rollout. The social media site made a policy to fight disinformation, which resulted in supporting the pro-vaccine effort to reduce the size of the anti-vaccine community and messaging.

Limitations

One major limitation was the ability for the stance detection to separate the nodes into pro-vaccine and anti-vaccine communities. First, many pro-vaccine maneuvers use neutral hashtags. Second, anti-vaccine mean confidence levels for each

time period were lower than those for pro-vaccine, with the after-rollout data only reaching as high as 67%, even after multiple iterations of hashtag labeling. Third, hashtag latching made stance selection difficult as some hashtags commonly used for pro- or anti-vaccine messages were used to gain the attention of members of the other community. Therefore, further study is required for improving the separation between pro- and anti-vaccine agents and tweets.

A second limitation is the ability of ORA-PRO to detect BEND maneuvers. This required manual verification of select entities within the data set. Newer versions of ORA-PRO continue to refine the metrics to better identify some of the maneuvers, especially network maneuvers, that occur over time. The results of this study inform the specifications and thresholds for improving the software.

Finally, many tweets and users that existed during the initial data collection were either deleted or suspended due to Twitter Rules violations. This made it difficult for observing historical tweets with their associated images and videos as well as visualizing tweets with replies and mentions within the Twitter environment.

Conclusions

In this paper, we analyzed how pro-vaccine and anti-vaccine communities around the initial COVID-19 vaccine administration attempted to persuade others of their stance under the BEND maneuvers framework. The BEND maneuvers allowed us to examine the different techniques used by each community. We observed the actions of different types of key actors within the different groups and analyzed their varying techniques. Additionally, we examined the main concepts and messages of tweets tweeted within each community and the extent they acted as each of these social-cyber maneuvers. These maneuvers were combined into application categories to gain a macro-level understanding of how the maneuvers were used in combination as an overarching influence campaign over time.

Real world events influence online discussions, and over time, the changes in these conversations reflect changes in beliefs. In this case, the efforts of these 2 communities can lead users to either vaccinate themselves against COVID-19 or not, possibly changing the direction of the pandemic. Future work should look at how these changes in beliefs mobilize into changes in behavior. Furthermore, though many influencing actions result from users interacting with other users, the policies that govern the use of social media can impact the size of a community and their ability to spread their narrative throughout the network. Therefore, research to regularly detect and evaluate the effectiveness of social-cyber maneuvers and make pointed network structure alterations based on specific narratives is needed to understand the consequences of different interventions and implement better policies to impact influence campaigns on social media.

Acknowledgments

Abstract

Background: Per- and polyfluoroalkyl substances (PFAS) are environmental contaminants that have received significant public attention. PFAS are a large group of human-made chemicals that have been used in industry and consumer products worldwide since the 1950s. Human exposure to PFAS is a growing public health concern. Studies suggest that exposure to PFAS may increase the risk of some cancers and have negative health impacts on the endocrine, metabolic, and immune systems. Federal and state health partners are investigating the exposure to and possible health effects associated with PFAS. Government agencies can observe social media discourse on PFAS to better understand public concerns and develop targeted communication and outreach efforts.

Objective: The primary objective of this study is to understand how social media is used to share, disseminate, and engage in public discussions of PFAS-related information in the United States.

Methods: We investigated PFAS-related content across 2 social media platforms between May 1, 2017, and April 30, 2019, to identify how social media is used in the United States to seek and disseminate PFAS-related information. Our key variable of interest was posts that mentioned “PFAS,” “PFOA,” “PFOS,” and their hashtag variations across social media platforms. Additional variables included post type, time, PFAS event, and geographic location. We examined term use and post type differences across platforms. We used descriptive statistics and regression analysis to assess the incidence of PFAS discussions and to identify the date, event, and geographic patterns. We qualitatively analyzed social media content to determine the most prevalent themes discussed on social media platforms.

Results: Our analysis revealed that Twitter had a significantly greater volume of PFAS-related posts compared with Reddit (98,264 vs 3126 posts). PFAS-related social media posts increased by 670% over 2 years, indicating a marked increase in social media users’ interest in and awareness of PFAS. Active engagement varied across platforms, with Reddit posts demonstrating more in-depth discussions compared with passive likes and reposts among Twitter users. Spikes in PFAS discussions were evident and connected to the discovery of contamination events, media coverage, and scientific publications. Thematic analysis revealed that social media users see PFAS as a significant public health concern and seek a trusted source of information about PFAS-related public health efforts.

Conclusions: The analysis identified a prevalent theme—on social media, PFAS are perceived as an immediate public health concern, which demonstrates a growing sense of urgency to understand this emerging contaminant and its potential health impacts. Government agencies can continue using social media research to better understand the changing community sentiment on PFAS

and disseminate targeted information and then use social media as a forum for dispelling misinformation, communicating scientific findings, and providing resources for relevant public health services.

KEYWORDS

PFAS; per- and polyfluoroalkyl substances; social media; public perceptions

Introduction

Background

Per- and polyfluoroalkyl substances (PFAS) are a large class of manufactured chemicals that have been widely produced and used in industry and consumer products such as nonstick cookware, water-repellent clothing, stain-resistant fabrics, carpets, and other items since the mid-20th century [1-3]. The most commonly studied PFAS are perfluorooctanoic acid (PFOA) and perfluorooctane sulfonic acid (PFOS) followed by perfluorohexane sulfonic acid and perfluorononanoic acid. Chemical companies and other industry manufacturers began phasing out the use and manufacture of the PFOA and PFOS variants in the early 2000s [2,3]. However, PFAS persist in the environment, especially in certain foods, water sources, people, and wildlife worldwide owing to their long biological half-lives [4]. Some communities nationwide have been and likely will continue to be exposed to drinking water contaminated with PFAS owing to both new and historical exposure [4-7]. Research examining the impact of PFAS has varied; however, some studies indicate that exposure to certain PFAS may increase the risk of some cancers and have negative health impacts on the endocrine, metabolic, and immune systems [3,5-7]. In recent years, PFAS as environmental contaminants have received significant public attention owing to emerging evidence of widespread PFAS contamination, the development of new state and federal drinking water PFAS guidelines, and a handful of newly released PFAS-focused documentaries and news stories [8-13].

One way to assess and understand the increase in public attention to PFAS is to investigate PFAS-related activity on various social media platforms. Social media is a broad term used to describe web-based platforms that allow individuals as well as representatives of institutions (such as news media, government agencies, nongovernmental organizations, and advocacy groups) to publish content and connect with other users. Widespread adoption of social media apps has fundamentally changed the way the public disseminates and shares information [14]. In the past decade, social media platforms have been used to monitor disease outbreak patterns and communicate information to the public during emergency responses for bubonic plague, swine flu, seasonal influenza, and West Nile virus disease [15-21]. As today's digital activity increases, the use of social media platforms to find and share information about public health issues continues to grow.

Some studies have explored the use of social media to communicate information about emerging health concerns such as the health effects of e-cigarettes [19-22]. A recent study [21] observed that Reddit posts included an abundance of requests looking for healthy alternatives to e-cigarettes and that Twitter

posts tended to focus on information seeking related to regulations and policy debates around e-cigarettes. Variation in information seeking and discussion by platform suggests that some platforms may be more successful than others for government agencies in the reach and delivery of public health information and interventions. Therefore, it is important to analyze data from different social media platforms to gain a better understanding of social media users' perceptions of PFAS.

Objectives

Although we are not aware of any studies investigating PFAS-related social media activity, we believe that observing American social media users' attitude toward PFAS across various platforms has the potential to help government agencies better understand public concerns, prevent and address the spread of misinformation, respond to new PFAS-related incidents, and develop targeted communication and outreach efforts, as demonstrated in other studies targeting different health issues [23,24]. This social media research aims to increase understanding of the public's perception of PFAS and inform how best to reach affected communities with the appropriate health information and environmental health prevention services. The public receives health information from various sources and stakeholders. It is important to understand how perceptions of and dialogue about those sources may affect government agencies' ability to effectively communicate health information. By conducting social media research and analysis of PFAS-related posts, government agencies and other partner organizations may become better equipped to respond to public concerns, questions, and requests.

This study has three objectives: (1) to understand how social media is used to share, disseminate, and engage in public discussions of PFAS-related information in the United States; (2) to identify common themes within PFAS-related mentions across social media platforms; and (3) to identify how social media engagement relates to various news events to better anticipate when and where to target outreach efforts using social media.

Methods

Data Collection

We first selected seven social media platforms—Facebook, Twitter, Reddit, YouTube, Nextdoor, Imgur, and Pinterest—that are likely used by the public to share environmental health-related information and investigated the availability and quality of data from these platforms across a recent 2-year window from May 1, 2017, to April 30, 2019. We focused our analysis on a 2-year window based on 2 primary factors. The first is an increase in media attention to PFAS in late 2017. The second is the dynamic and fluid nature of social media

environments and the internet more broadly. Accordingly, we focused on a recent 24-month period that would enable sufficient time to identify patterns. Owing to the identified challenges in the collection, processing, and comparison of the data associated with these disparate social media platforms, we tailored our data collection to focus on Twitter and Reddit, the 2 platforms that provided access to data and metadata, allowing us to achieve the study objectives. We extracted the data on August 7, 2019, for Twitter (N=98,264) and Reddit (n=3126) through the use of NetBase (NetBase Solutions Inc), a third-party software vendor that facilitated access to the platforms' full-stream application programming interfaces (eg, *firehose* application programming interfaces), which included all publicly available content (ie, not content from private accounts) featuring our identified key terms defined below within our specified time frame. On the basis of the scope of our research questions, we did not collect PFAS-related content posted from countries other than the United States.

Ethics Approval

The data used for this study were based on publicly available information only and, thus, the study was determined to be exempt from the Centers for Disease Control and Prevention Institutional Review Board approval.

Variables of Interest

Our key variable of interest was posts on PFAS or common alternatives, including PFOA, PFOS, and the hashtag derivatives of each term (#PFAS, #PFOA, and #PFOS) across social media platforms. These key term variables were selected based on their more prominent volume and use as identified in an initial exploration of PFAS-related key term frequency during the same time frame on Google Trends (data accessed on June 19, 2019).

Posts were classified as either original posts or engagement posts. Original posts were defined as first-instance comments. Engagement posts were secondary posts in the form of a reply or comment (including retweets on Twitter) to an original post. We acknowledge that these types of posts are different; however, we chose to aggregate at the *engagement* level so that engagement could be compared across platforms. On the basis of the study goals, additional variables of interest included post type, Twitter *likes*, date of post, and PFAS event or geographic location of social media user. Below are the key variables and their associated definitions.

- PFAS post (binary): a post, tweet, or comment on social media platforms that uses one or more of the terms PFAS, PFOA, or PFOS
- Post type (binary): original posts refers to first-time comments. Engagement posts refers to any reply, comment, or retweet that responds to or engages with an existing comment. The engagement ratio is the proportion of engagement posts to original posts. Engagement posts are defined similarly across different social media platforms, although they may be referred to with platform-specific language (eg, a retweet on Twitter)
- Likes (count): specific to Twitter data, likes indicates the number of Twitter users that clicked on like on a tweet
- Date (continuous): the day, month, or year of a tweet, post, or comment
- Geography (categorical): the national jurisdiction location of a PFAS-related post

Although original posts measure message reach, engagement posts measure interactive dialogue among social media users. Engagement ratio is defined as the proportion of engagement posts to original posts, which is an indicator of the degree of engagement by users via replies to, comments on, or retweets of an original post. For example, an engagement ratio of 2 suggests that users were 2 times more likely to reply to, comment on, or retweet an existing post than to generate an original post.

We manually reviewed 3 random samples (n=500) of the data sets to identify keywords or phrases for cleaning irrelevant or misleading data. This manual review was used to implement rule-based removal of similar irrelevant or misleading content throughout both data sets. Irrelevant data accounted for <1% of Twitter (254/98,264, 0.26%) and Reddit (18/3126, 0.58%) data. Examples of removed content included advertisements for various cookware products with marketing language such as *PFOA-free* and irrelevant posts of *PFAs*, an acronym for *protection from abuse* referencing an unrelated domestic violence abuse order.

Quantitative Analysis

We analyzed and identified unique attributes of public engagement across each platform. We used descriptive statistics, including counts and frequencies of the key quantitative variables, to assess the incidence of PFAS discussions and to identify time, geographic, and entity patterns. We explored PFAS-related posts over time to identify spikes and assess their association with PFAS-related events. We obtained maps of tweets and Reddit posts by geographic area using a data visualization package (ggplot2) in the statistical software R (R Foundation for Statistical Computing) [25].

The purpose of the geographic analysis was to demonstrate which states had the highest number of PFAS-related posts broken down by original and engagement posts, count percentage, and the engagement to original post ratio for each state. Understanding geographic patterns in PFAS-related posts more broadly can help government agencies develop future outreach efforts.

That said, geographic metadata are not always provided by a given social media platform. For this analysis, we identified geographic information for tweets based on state-level geographic data available in an individual user's profile. However, Reddit data did not provide geographic metadata for users' posts. To approximate geographic concentrations of Reddit data, we built a complementary proxy using text analysis of geographic subreddit identification (eg, *r/Michigan*) and user mentions of specific jurisdictions. To complement geographic approximation, we also conducted a scan of post titles that directly referenced a specific geographic location. Although not providing an exact comparison, geographic analysis through these 2 approaches provided insight into potentially underlying differences in PFAS conversations by geography. To account

for population variance across states, we normalized the data using 2010 census data to provide a proportional jurisdiction ratio of per 100,000. Our dissimilar approach to obtaining geographic information, coupled with variance in sample sizes between the 2 platforms, is likely to influence geographical findings and related conclusions.

Qualitative Analysis

We used the constant comparison method based on grounded theory [26,27] to inductively analyze posts and comments, coupled with deductive analysis to identify and analyze major discussion themes on social media platforms. A total of 3 people used Microsoft Excel to individually open code 3 subsets of randomly sampled text (1500 in total; 500/1500, 33.33% per subset) for common themes, cross-validation, and collective refinement of themes. Through an iterative process, some coding categories were collapsed into larger concepts until no further themes emerged in the subsequent analysis, suggesting that we had reached saturation of themes. The team subsequently developed search criteria with a unique set of keywords for each theme based on the initial open coding process (see the *Thematic Analysis* section for example keywords for each theme). Themes were not mutually exclusive and, therefore, each unit of analysis had the potential to be counted across multiple themes.

Mixed Methods Analysis

As a follow-up to the qualitative analysis, we conducted a series of regression analyses to test whether posts containing words from the search criteria established in the qualitative analysis differed from one another and from posts that did not use the search criteria in terms of their level of engagement on the Twitter and Reddit platforms. Search criteria were used to separate posts into thematic groups, and the relationship between these nonexclusive groups was established on two indices measuring user engagement: categorization as a reply to an original post and number of *likes* on Twitter. The data set used for comparison included only social media users of the Twitter and Reddit platforms. The level of analysis was posts and comments, and the unit of analysis was comment or post and not individual users.

The analyses consisted of a logistic regression to examine the effect of the 3 thematic groups on a binary outcome of original posts versus engagement posts. In other words, the logistic regression analysis compared each of the 3 themes to one another in terms of the relative quantity of engagement posts to original posts (ie, level of engagement). In addition, we conducted a Poisson regression analysis to look at the effect of the same predictors on a count outcome representing the number of *likes* that a tweet received on Twitter, a secondary indicator of user engagement. As *likes* is a metric that is unique to Twitter and the sample of Reddit data was much smaller than the Twitter sample, these follow-up mixed methods analyses were limited to the Twitter data. We were unable to conduct the same analyses among Reddit data as we did not have access to upvote or downvote information, a measure used to demonstrate that a user likes or dislikes a post. Furthermore, the smaller number of posts for Reddit provided much lower statistical power than the Twitter data, and the limitation for post length for Twitter and not for Reddit limited our ability to compare the 2 platforms.

Results

Platform Volume, Post Type, and Term Use

As seen in Table 1, there were a total of 101,390 PFAS-related posts on Twitter and Reddit during the 2-year window. Twitter had a significantly greater volume of PFAS-related posts compared with Reddit (98,264 vs 3126).

Understanding PFAS-related term use clarifies how social media users were interfacing with PFAS-related conversations on social media. Among Twitter data, social media users used the term *PFAS* in 73.81% (72,528/98,264) of all posts compared with *PFOA* (21,545/98,264, 21.93%) and *PFOS* (10,183/98,264, 10.36%). Given that a post may include multiple terms, the aggregate total resulted in a value of >100%. We saw a different pattern of term use among Reddit posts whereby users most mentioned the term *PFOA* (1767/3126, 56.53%) followed by *PFAS* (1540/3126, 49.26%) and *PFOS* (974/3126, 31.16%; Figure 1).

Table 1. Counts of observations by social media platform.

	Original posts, n (%)	Engagement posts ^a , n (%)	Total, n (%)
Platform			
Twitter (tweets)	36,795 (37.44)	61,469 (62.55)	98,264 (100)
Reddit (posts)	424 (13.56)	2702 (86.44)	3126 (100)
Total	37,219 (36.71)	64,171 (63.29)	101,390 (100)

^aEngagement posts include all replies and retweets.

Figure 1. Key term distribution across all posts by social media platform (Twitter: N=98,264; Reddit: N=3126). PFAS: per- and polyfluoroalkyl substance; PFOA: perfluorooctanoic acid; PFOS: perfluorooctane sulfonic acid.

Timing and Event Analysis

Overview

The volume of posts over time underscores a collective rise in interest in and awareness of PFAS. Driving this increase were

9 notable spikes in the volume of public discussion of PFAS (3 on Twitter and 6 on Reddit). We evaluated the data retrospectively and conducted text analysis to determine the primary PFAS-related topics and events mentioned in the posts associated with the spikes (Figure 2).

Figure 2. Number of per- and polyfluoroalkyl substance (PFAS)-related Twitter and Reddit posts by date with annotated events. EPA: Environmental Protection Agency.

Twitter Spikes and Events

The 3 primary spikes in PFAS-related discussions on Twitter occurred in May 2018, July 2018, and February 2019. The content analysis of posts during these periods revealed that the

spike in May 2018 was attributed to the high volume of posts about the US Environmental Protection Agency (EPA) National Leadership Summit (which happened in May 2018). In July 2018, a smaller but notable spike occurred that was attributed to discussions of a ProPublica article on government responses

to PFAS [28] and a local news article about the PFAS water contamination in Parchment, Michigan [29]. Finally, the spike in February 2019 corresponded with the release of a PFAS action plan by the EPA and greater national-level reporting on PFAS by mainstream publications, such as *The New York Times* articles on PFAS exposure in military families [30] and government response [31]. In several instances, spikes occurred simultaneously or were slightly delayed across platforms, indicating the potential for a sustained discussion over time and across platforms of critical PFAS events.

Reddit Spikes and Events

The 6 primary spikes in PFAS-related discussions on Reddit occurred in June 2017, May 2018, August 2018, November 2018, January 2019, and March 2019. The June 2017 spike was primarily related to the publication and release of a peer-reviewed study in *Environmental Pollution* on PFAS exposure in the mid-Ohio River Valley from 1991 to 2012 [32]. The spike in May 2018 was attributed to the high volume of posts about the US EPA National Leadership Summit. A noticeable spike in Reddit activity in August 2018 was related to the publication of 2 different media articles. One was from *ProPublica* on government response [28], the same article found in the Twitter July 2018 spike. The other article was from *MLive*, a local Michigan news site, focused on governmental action toward PFAS contamination [5]. The reprinting of the *ProPublica* article [28] by CNBC on November 12, 2018, led to an increase in Reddit activity, with numerous users posting links to and comments about the article within the subreddit *r/news*. Another noteworthy increase in PFAS-related Reddit activity was largely in response to a peer-reviewed study published in January 2019 in the *Journal of Exposure Science*

and *Environmental Epidemiology* on serum concentrations of PFAS and exposure-related behaviors in African American and non-Hispanic White women [33]. Finally, the March 2019 spike was associated with 2 media articles on the regulatory process of the EPA and PFAS exposure in military families from *The Guardian* [34] and *The New York Times* [30], respectively.

Geographic Analysis

Twitter Geographic Analysis

We examined the pure volume of tweets, including both engagement and original, irrespective of state population, revealing that 15.83% (15,560/98,264) of the tweets occurred in Michigan followed by New York (7765/98,264, 7.9%), District of Columbia (DC; 6822/98,264, 6.94%), California (6075/98,264, 6.18%), and New Hampshire (4262/98,264, 4.34%). However, this measure of pure tweet volume does not account for differences in population sizes across jurisdictions. Figure 3 incorporates data from the 2010 US census to provide a normalized comparison of tweets per 100,000 people by state. Once normalized, DC rose to 1133 tweets per 100,000, nearly 4 times that of New Hampshire with 323 tweets per 100,000. The remaining three top-ranking states were Michigan, Vermont, and Rhode Island with 157, 112, and 56 tweets per 100,000, respectively.

Table 2 highlights the engagement ratio for the top 5 jurisdictions with the highest number of tweets per 100,000 population. Among the 5 jurisdictions with the highest PFAS-related Twitter volume per 100,000 population, New Hampshire displayed the highest engagement ratio (2.71) followed by Rhode Island (2.52), DC (1.23), Michigan (1.2), and Vermont (0.9).

Figure 3. Choropleth of tweets per 100,000 people by state.

Table 2. Top 5 jurisdictions with the highest number of tweets per 100,000 population and engagement ratio.

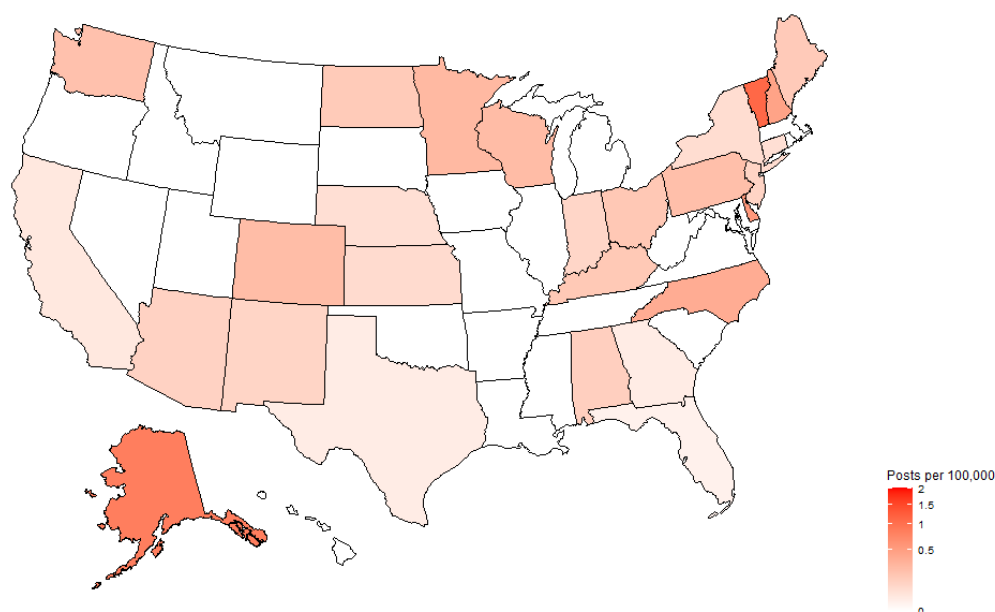

Jurisdiction	Tweets per 100,000 population, N	Original posts, N	Engagement posts, N	Engagement ratio
District of Columbia	1133.74	3057	3765	1.23
New Hampshire	323.74	1149	3113	2.71
Michigan	157.43	7059	8501	1.2
Vermont	112.99	372	335	0.9
Rhode Island	56.15	168	423	2.52

Reddit Geographic Analysis

Of the 3126 posts in the Reddit data set, 443 (14.17%) contained jurisdictional information, allowing for geographic analysis. The remaining 85.83% (2683/3126) did not have any information for geographic linking. The top five states for PFAS-related posts by pure volume, including both original and engagement posts, were Michigan (206/443, 46.5%), North Carolina (35/443, 7.9%), Pennsylvania (28/443, 6.3%), Ohio (19/443, 4.3%), and Minnesota (14/443, 3.2%). The top jurisdictions by Reddit posts per 100,000 population were

Michigan (2.08), Vermont (1.12), Alaska (0.84), Delaware (0.56), New Hampshire (0.46), North Carolina (0.37), Minnesota (0.26), and Wisconsin (0.25; [Figure 4](#)).

[Table 3](#) highlights the engagement ratio for the top jurisdictions with the highest number of Reddit posts per 100,000 population. Minnesota displayed the highest engagement ratio (6) followed by North Carolina (4), Michigan (3.29), Vermont (2.50), and Wisconsin (1.80). The engagement ratios for Alaska, Delaware, and New Hampshire could not be computed (N/A in [Table 3](#)) as the number of original posts was 0 for these states.

Figure 4. Choropleth of Reddit posts per 100,000 people by state.**Table 3.** States with the highest number of Reddit posts per 100,000 population and engagement ratio.

Jurisdiction	Reddit posts per 100,000 population	Original posts, N	Engagement posts, N	Engagement ratio
Michigan	2.08	48	158	3.29
Vermont	1.12	2	5	2.50
Alaska	0.84	0	6	N/A ^a
Delaware	0.56	0	5	N/A
New Hampshire	0.46	0	6	N/A
North Carolina	0.37	7	28	4
Minnesota	0.26	2	12	6
Wisconsin	0.25	5	9	1.80

^aN/A: not applicable.

Thematic Analysis

We identified the following three topics as the most prevalent themes, ordered from most to least commonly mentioned: (1) social media users discuss PFAS as an immediate public health concern, (2) social media users desire clarity on government agencies' roles related to PFAS, and (3) social media users discuss general mistrust of PFAS-related information.

Social Media Users Discuss PFAS as an Immediate Public Health Concern

We defined this theme, hereafter abbreviated as *PFAS are a health concern*, by the volume of posts discussing the health impacts of PFAS. Some of the thematic excerpts included a discussion of the products known to contain a PFAS derivative and their associated health effects. Examples of keywords associated with this theme included *hazard*, *crisis*, *threat*, *exposure*, *dangerous*, *unsafe*, and *risk*. Many social media users believe that PFAS are dangerous human-made chemicals that contribute to wider environmental and health issues. A significant portion of the posts associated with this theme included dialogue on the discovery of new PFAS contamination sites across the country, *breaking* news articles or studies reporting new locations with high concentrations of PFAS, and concerns for potential adverse health effects from personal exposure to PFAS. In addition, social media posts containing this theme often implicitly or explicitly expressed a lack of clarity on PFAS health effects or uncertainty on where to access relevant health information. Discussions often included questions for clarification or requested links to PFAS-related information.

Social Media Users Desire Clarity on Government Agencies' Roles Related to PFAS

We defined this theme, hereafter abbreviated as *clarity on government agencies' roles*, by the volume of posts mentioning government agencies (eg, state and local health government and federal agencies) and discussing the need for government leadership for PFAS-related community outreach and dissemination of standardized information. Examples of keywords associated with this theme included *enforce*, *state*, *regulate*, *mitigate*, and *protect*. Social media users largely engaged with PFAS discussions as it related to a desire for more government participation at the local, state, and federal levels.

Users frequently connected PFAS-related issues and concerns to contaminated water and drinking water supplies and called on the government for more active support in producing evidence-based science to identify and protect the public from further PFAS exposure. The public's confusion and uncertainty on various agencies' roles in PFAS-related activities provides an opportunity for government agencies to ensure their messaging outlines how the actions they are taking will protect public health.

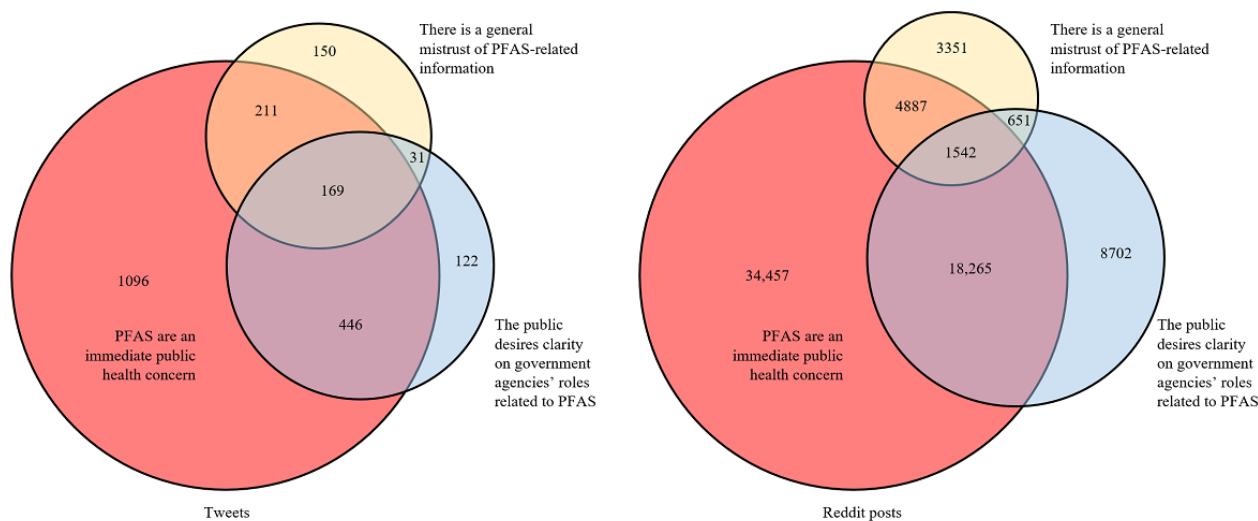

Social Media Users Discuss General Mistrust of PFAS-Related Information

We defined this theme, hereafter abbreviated as *mistrust of PFAS information*, by the volume of posts discussing mistrust of the available information related to PFAS. Examples of keywords associated with this theme included *corrupt*, *greed*, *litigation*, and *accountable*. In the last decade, there has been an exponential increase in scientific literature on the health effect of PFAS and many ongoing changes in PFAS information, in part because of jurisdictional attempts and successes in changing health exposure thresholds [3,5,10]. The data suggest that many social media users felt unable to determine the credibility of certain sources of PFAS information, particularly when conflicting information is presented by media outlets and various sources. Many users commented on the potential for political bias in journalism, often looking for authoritative sources of scientific information. Social media users often sought to expand their knowledge by discussing PFAS-related information with other users and expressed an overarching frustration based on the need to piece together accurate PFAS information.

Twitter Thematic Analysis

Of the 98,264 tweets, 59,151 (60.2%) received the *PFAS are a health concern* code, 29,160 (29.68%) received the *clarity on government agencies' roles* code, and 10,431 (10.62%) received the *mistrust of PFAS information* code. Of the 98,264 total tweets, 71,855 (73.12%) received *at least* one thematic code, and the remaining 26,409 (26.88%) received no code. As seen in Figure 5, approximately 47.33% (46,510/98,264) received exactly 1 code, and 24.22% (23,803/98,264) received 2 codes. Approximately 1.57% (1542/98,264) received all 3 codes. See the *Thematic Analysis* section above for clarification of theme definitions.

Figure 5. Overlap of tweets or Reddit posts containing at least one thematic code (Twitter: N=98,264; Reddit: N=3126). PFAS: per- and polyfluoroalkyl substance.

Reddit Thematic Analysis

Of the 3126 posts in the Reddit data set, 1922 (61.48%) received the *PFAS are a health concern* code, 768 (24.57%) received the *clarity on government agencies' roles* code, and 561 (17.95%) received the *mistrust of PFAS information* code. Of the complete Reddit data set of 3126 posts and comments, 2225 (71.18%) received at least one code, and 901 (28.82%) received no code. See the *Thematic Analysis* section above for clarification of theme definitions.

As shown in Figure 5, approximately 43.76% (1368/3126) received exactly 1 code, and 22% (688/3126) received 2 codes. Approximately 5.41% (169/3126) received exactly 3 codes.

Mixed Methods Analysis

Posts that received the *PFAS are a health concern* code were 1.59 times as likely as other PFAS-related posts to be categorized as engagement (ie, a reply, comment, or retweet that responded to or engaged with an existing comment) rather than volume (ie, an original post that did not reply, comment, or retweet a previously existing comment). Posts that received the *clarity on government agencies' roles* code (odds ratio 1.35,

95% CI 1.31-1.39) and *mistrust of PFAS information* (odds ratio 1.36, 95% CI 1.3-1.42) code were also significantly more likely to be categorized as engagement rather than volume (Table 4).

Post hoc tests showed that posts related to the theme *PFAS are a health concern* were significantly more likely to be labeled as engagement posts compared with posts categorized into the other 2 themes. However, the themes *clarity on government agencies' roles* and *mistrust of PFAS information* were statistically equal in their relative levels of engagement.

The number of *likes* for a post ranged from 0 to 1447 within the data set. As shown in Table 5, a post categorized as *PFAS are a health concern* was 1.78 times as likely to receive *likes* compared with other PFAS tweets. Tweets categorized as *mistrust of PFAS information* were 1.35 times as likely to receive *likes*. However, the *clarity on government agencies' roles* theme received 94% as many *likes* (incident rate ratio=0.94; $P=.001$) when compared with other PFAS-related tweets. Furthermore, when conducting 2-way post hoc comparisons across themes, we found that all themes were statistically significantly different from one another in terms of how often they received *likes* by Twitter users.

Table 4. Logistic regression results of engagement on thematic categories.

Variable	Values			
	Estimate (SE)	Z	P value	OR ^a (95% CI)
Intercept	0.12 (0.01)	11.26	<.001	— ^b
PFAS ^c are a health concern	0.46 (0.01)	34.11	<.001	1.59 (1.54-1.63)
Mistrust of PFAS information	0.31 (0.02)	13.65	<.001	1.36 (1.3-1.42)
Clarity on government agencies' roles	0.3 (0.01)	20.12	<.001	1.35 (1.31-1.39)

^aOR: odds ratio.

^bOdds ratio not provided for intercept.

^cPFAS: per- and polyfluoroalkyl substance.

Table 5. Poisson regression results of likes on thematic categories.

Variable	Values			
	Estimate (SE)	Z	P value	IRR ^a (95% CI)
Intercept	−2.25 (0.02)	−135.40	<.001	0.11 (0.1-0.11)
PFAS ^b are a health concern	0.57 (0.02)	31.09	<.001	1.78 (1.71-1.84)
Mistrust of PFAS information	0.30 (0.02)	12.74	<.001	1.35 (1.29-1.41)
Clarity on government agencies' roles	−0.06 (0.02)	−3.27	.001	0.94 (0.91-0.98)

^aIRR: incident rate ratio.

^bPFAS: per- and polyfluoroalkyl substance.

Discussion

Social Media Data Usability for Public PFAS Interest Analysis

There were several challenges identified in the collection, processing, and comparison of data associated with the original 7 disparate social media platforms we sought to evaluate. Owing to data access restrictions on Nextdoor, we could not collect any PFAS-related mentions at all on the platform nor could we capture aggregated or descriptive statistics of PFAS mentions from the platform. On Pinterest, we ran into limitations collecting PFAS mentions with required metadata (eg, time and regions across the United States), which removed the data's potential comparative value. Attempts at data collection on YouTube and Imgur did not reveal substantial user mentions of PFAS-related key terms during the period of analysis. The full sample from YouTube included <300 videos, and Imgur featured a single post.

Although Facebook can be a valuable data source for analyzing social media use, Facebook only enables data to be collected from preidentified public pages. Therefore, we determined that it was not appropriate to include Facebook data in this untargeted analysis that aimed to explore and analyze the general patterns and uses of social media for PFAS-related topics. Given these challenges, we focused our analyses on two platforms—Twitter and Reddit—based on similarities in metadata and relatively large sample sizes.

Use Trends Across Social Media Platforms

Social media data provide a lens to understand perceptions about rising public health phenomena (see the *Limitations* section for further discussion of social media user population representativeness). Comparing the availability of PFAS-related data and metadata on different social media platforms and the Twitter and Reddit findings, our analysis indicates variation in post volume by platform. Our research over the 2-year period shows increasing public dialogue on PFAS. Although there are several other platforms that can contain meaningful insights into public perceptions of PFAS, for this analysis, Twitter and Reddit were the most appropriate for understanding geographic trends and theme sentiment. Although Facebook is the most widely used social media network [35] and can be a valuable data source for analyzing social media use, Facebook only enables data to be collected from preidentified public pages. Therefore, Facebook data can be suitable for a targeted research

approach whereby researchers first select specific public Facebook pages associated with topics of interest and then collect data from those pages. This data retrieval restriction limits the use of Facebook for broad identification of related content across the entire platform and detecting general use trends.

The rising volume of posts across Twitter and Reddit and the growing visibility of PFAS across local and national news suggest an increasing interest in PFAS-related information. Considering each of the social media sources initially examined for this study, Twitter was the predominant platform for PFAS-related posts, likely owing in part to its ease of use in sharing ideas, real-time information, and trending news. However, despite having a relatively larger proportion of original posts, users engaged more frequently with Reddit posts, suggesting a more interactive platform. On the basis of our content analysis, Reddit users often provided their impressions, opinions, and perceptions of PFAS-related topics with other users. Individuals using Reddit to discuss PFAS tended to engage in follow-up discussions with the goal of gaining additional factual or anecdotal information or to provide additional resources. These differences in posts across social media platforms provide an initial understanding of the ways in which government agencies can further investigate PFAS sentiment among social media users. Through the themes that this research identified, our findings suggest that social media posts can help provide insight into some portions of the public's accurate or inaccurate understanding of PFAS-related information and determine some gaps in public knowledge.

Geographic and Event Trends

Understanding the prevalence of PFAS-related posts by jurisdiction provides a measure for PFAS public health professionals, organizations, and federal agencies to provide tailored intervention information, remediation, and community outreach by jurisdiction. The geographic data revealed a pattern of high-volume PFAS-related posts among jurisdictions affected by PFAS contamination during the time frame. Our analysis suggests that individuals living in jurisdictions with recent PFAS events appeared to be more engaged with web-based discussions that included continuous and active coverage of PFAS events by local news outlets. DC, New Hampshire, and Michigan were the top-ranked jurisdictions based on posts per 100,000 across both platforms. Much of the social media dialogue associated with Michigan and New Hampshire was related to PFAS

contamination incidents or sites such as Parchment in Michigan and Pease International Tradeport in New Hampshire.

Thematic Trends

Our analysis revealed that many posts described the contaminants as a public health threat and national crisis, especially among those living in PFAS-affected communities. As more individuals become aware of and are affected by PFAS, there is a growing sense of urgency to understand the health impacts and protective behaviors associated with PFAS exposure. This is exemplified through the predominant theme found in our analysis—*PFAS are a health concern*. Our findings suggest that both Twitter and Reddit were used to question, share, engage with, and react to evolving information related to discovered PFAS contamination. This is underscored by individual desires for access to concrete and reliable evidence-based information about PFAS and their impacts on human health and the environment.

Our results showed a notable overlap between *PFAS are a health concern* and *clarity on government agencies' roles*. Some posts stressed the notion that scientific, academic, and environmental communities could play a positive and significant role in shaping future PFAS responses and interventions by acting both as scientific experts and trustworthy resources for answering outstanding questions on both health and environmental risks. These findings present an opportunity for government agencies to provide scientific information, answer questions, and correct misperceptions. American social media users are particularly interested in understanding what is being done to mitigate exposure, the potential human health effects, and obtaining information on tangible steps individuals can take to manage their own risk. Although there is still much to be known about PFAS, our findings suggest that there is an unmet need among the public for clarity on who is leading the charge in scientific discoveries, cleanup and protection, and dissemination of scientific health-related information. Given the core theme *clarity on government agencies' roles*, government agencies have an opportunity to play a lead role in developing and distributing materials to the public on what is known about PFAS detection and to effectively communicate what remains unknown. This will not only provide PFAS information but also demonstrate the agencies' roles as it relates to PFAS and health. Furthermore, by capitalizing on social media's interactive format, government agencies can communicate information in these forums in a way that reflects audience preferences, stimulates conversation on relevant critical topics, and provides content that can be tailored to each platform's application.

On the basis of our findings, individuals and communities negatively affected by PFAS feel uninformed and subsequently excluded from proposed or in-progress solutions. There is a strong desire on social media for a trusted source of PFAS-related health information on everything from breaking news and events to longer-term response plans.

Our analysis found that PFAS content is best created with a lens that acknowledges sensitivities within current public perceptions. It is preferred that outreach efforts and scientific findings ensure clarity in word choices and accurate framing of hot topics to mitigate disinformation and encourage social media users'

engagement. Dissemination strategies may be developed through partnerships with trusted scientific and academic organizations to dispel misinformation and demonstrate collaborative active leadership on the topic. In this way, continuous and ongoing evaluation of PFAS-related social media discussions may be advantageous, especially as new discussions arise across social media platforms and further communication materials are developed and deployed nationally. On social media platforms, government agencies can demonstrate real-time awareness of current PFAS-related issues and provide diverse content to address geographically specific concerns. By better understanding social media user interests, concerns, opinions, and perceptions of PFAS, environmental health professionals will be better equipped to uncover innovative ways to inform and engage citizens on important environmental health topics.

Limitations

There are several limitations to our analysis. First, differences may exist between social media users and the general population [36], so our findings should not be extrapolated to the general population. Second, given the jurisdictional patterns found when sorting by our engagement ratio measure, we believe this measure has several inherent flaws. Most notably, it indicates instability among small population jurisdictions, as seen with several small states that were among the top 5 when measured by engagement ratio but not among the top 5 when measured by original post volume and original post volume by 100,000 people. In addition, our Reddit data were substantially truncated because of the lack of geographic indicators in the metadata. This resulted in a small sample size and more volatility in the geographic analysis across this platform. As events were determined post hoc, there was an inherent collinearity between the geography and event measures, resulting in potentially inflated SEs and very little improvement in the predictive value of the outcome. The location-masking tools and decisions to opt out of location information may also have had an impact on the geographic analysis. The length of posts allowed by Twitter also differed from what is allowed by Reddit, which limited our ability to compare results between platforms. Third, we must acknowledge the potential existence of social media *bots*—an autonomous account or network of accounts that posts and shares content according to specific predetermined rules—within the evaluated data sets that was not an immediate focus of this research effort but nevertheless may have had an impact on the spread of PFAS-related information [37]. Finally, data generated by social media platforms create unique research challenges, primarily as social media platforms create an exceptionally dynamic data environment. Specifically, across social media platforms, content is being created, disseminated, reacted to, and interacted with constantly and in real time. At any moment, a new or returning user can view a video, like a post, unlike a post, post a comment, or delete a previous comment. Thus, this dynamic communication environment presents challenges to those conducting research with its data as the data represent a finite snapshot in time rather than a continuous cumulative capture.

Conclusions

On the basis of the analysis of social media posts and activity, we find that PFAS are perceived as an immediate public health concern and there is a growing sense of urgency to understand this emerging contaminant and its potential health impacts on social media. Twitter is the predominant platform among the 7 investigated social media platforms for PFAS-related posts based on the pure volume of key terms mentioned during the 2-year time frame of the analysis. However, despite Twitter having a relatively larger proportion of original posts, Reddit posts were more frequently engaged with by users, suggesting a more interactive rather than passive platform. Some social media users seek to understand long- and short-term health risks

and access reliable PFAS information to make personal decisions that mitigate health risks. All of this underscores an opportunity for a robust public health response. Government agencies can continue using social media research to better understand the changing public sentiment on PFAS and the critical topics of interest among affected communities and then use social media as a forum for dispelling misinformation, communicating scientific findings, and providing resources for relevant public health services. Through these findings on geographic and event-based trends in PFAS-related discussions, government agencies and other partner organizations are better equipped to disseminate targeted PFAS-related scientific information and conduct community outreach.

Acknowledgments

The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention/Agency for Toxic Substances and Disease Registry. The use of trade names is for identification only and does not imply endorsement by the Centers for Disease Control and Prevention/Agency for Toxic Substances and Disease Registry.

Authors' Contributions

HT, CG, LL, AP, GV, and AG conceived and designed the study. AG and BG collected the data. AG, BG, and HT were involved in data analysis. HT, CG, LL, AP, GV, AG, BG, EH, CMR, and RDR were involved in interpreting the results. EH, AG, and BG drafted the initial manuscript. All authors provided critical comments and edited, revised, and approved the manuscript in its final form for submission.

Abstract

Background: In November 2018, a Chinese researcher reported that his team had applied clustered regularly interspaced palindromic repeats or associated protein 9 to delete the gene *C-C chemokine receptor type 5* from embryos and claimed that the 2 newborns would have lifetime immunity from HIV infection, an event referred to as #GeneEditedBabies on social media platforms. Although this event stirred a worldwide debate on ethical and legal issues regarding clinical trials with embryonic gene sequences, the focus has mainly been on academics and professionals. However, how the public, especially stratified by geographic region and culture, reacted to these issues is not yet well-understood.

Objective: The aim of this study is to examine web-based posts about the #GeneEditedBabies event and characterize and compare the public's stance across social media platforms with different user bases.

Methods: We used a set of relevant keywords to search for web-based posts in 4 worldwide or regional mainstream social media platforms: Sina Weibo (China), Twitter, Reddit, and YouTube. We applied structural topic modeling to analyze the main discussed topics and their temporal trends. On the basis of the topics we found, we designed an annotation codebook to label 2000 randomly sampled posts from each platform on whether a supporting, opposing, or neutral stance toward this event was expressed and what the major considerations of those posts were if a stance was described. The annotated data were used to compare stances and the language used across the 4 web-based platforms.

Results: We collected >220,000 posts published by approximately 130,000 users regarding the #GeneEditedBabies event. Our results indicated that users discussed a wide range of topics, some of which had clear temporal trends. Our results further showed that although almost all experts opposed this event, many web-based posts supported this event. In particular, Twitter exhibited the largest number of posts in opposition (701/816, 85.9%), followed by Sina Weibo (968/1140, 84.91%), Reddit (550/898, 61.2%), and YouTube (567/1078, 52.6%). The primary opposing reason was rooted in ethical concerns, whereas the primary supporting reason was based on the expectation that such technology could prevent the occurrence of diseases in the future. Posts from these 4 platforms had different language uses and patterns when they expressed stances on the #GeneEditedBabies event.

Conclusions: This research provides evidence that posts on web-based platforms can offer insights into the public's stance on gene editing techniques. However, these stances vary across web-based platforms and often differ from those raised by academics and policy makers.

Introduction

Background

The clustered regularly interspaced palindromic repeats (CRISPR) or CRISPR-associated protein 9 (Cas9) genetic scissor is a revolutionary gene-editing technology for the life sciences, for which its creators were awarded the 2020 Nobel Prize in Chemistry [1]. However, much remains unknown about the long-term effects of applying CRISPR in *human gene editing* (HGE), and experts in ethics and policy have particularly cautioned against its use in *germline gene editing* (GGE) to influence the genetic code of a human embryo [2,3]. However, in November 2018, a Chinese researcher, Jiankui He, reported that his team applied this tool to delete the *gene C-C chemokine receptor type 5* from embryos and claimed that the 2 newborns would benefit from lifelong immunity from HIV infection. This event, which is often referenced as #GeneEditedBabies in the web-based domain, has raised widespread concerns in the scientific community about HGE, especially GGE, for numerous reasons, which include but are not limited to biological safety and ethical implications [4-6].

The experiments of Jiankui He violated Chinese regulations and ignored international ethical norms [7]. Most criticisms against his actions concentrated on assertions that the experiments (1) were unnecessary as existing treatment strategies can sufficiently block HIV paternal transmission without the risk of GGE [8] and (2) violated the protocols required for general genetic procedures [9], expressing a concern that off-target editing can lead to dangerous and unpredictable mutations [10,11]. To expedite global cooperation on science and its governance, an international commission comprising experts from 10 countries released a guidance report in September 2020 on how to determine whether such an application is sufficiently well-developed for clinical use [12].

However, the worldwide debate has focused primarily on the perspective of academics and policy makers. By contrast, little is known about how the public, who are often influenced by geographic region and local culture, perceived this event, as well as these issues more generally. Gaining intuition into the public's perspectives on these matters is critical to understanding social norms and expectations for potential beneficiaries and victims. In this respect, the public's perspective is a core component in determining resource allocation, political policies, and participation in clinical trials, all of which influence the development and adoption of such technologies as they evolve [13,14].

To date, research on public attitudes has mainly applied survey methods to investigate hypothetical personal opinions regarding gene-editing techniques [15-18], and few have considered this specific actual event. At the same time, web-based social media platforms have become an essential medium for billions of people to learn about and comment on trending events, including

#GeneEditedBabies, in a timely manner, making them an ideal resource to study public perception. Web-based social media platforms accommodate speech from wide demographics, and the discussions and expressions therein are not controlled by predefined questionnaires. Thus, they may effectively reduce the bias in the data [19]. As a result, over the past decade, user-generated content from web-based social media platforms has been increasingly relied upon to study the public's attitudes regarding a broad range of topics, including weight stigmatization [20], antivaccination [21], lung cancer screening [22], the Brexit referendum [23], and political debates [24]. A total of 3 recent studies of web-based data investigated the #GeneEditedBabies event; however, they were limited in that they either focused only on sentiment [25] or relied on data from only 1 web-based platform [26,27], which, as we show in this study, paints an incomplete and likely biased picture.

Objective

In this work, we present a substantially broader investigation into the public's perceptions of the #GeneEditedBabies event through the lens of four popular social media platforms known to be influenced by different cultures and demographics: *Sina Weibo* (based in China), *Twitter*, *Reddit*, and *YouTube*. Specifically, we apply topic modeling to >220,000 posts to analyze what had been discussed about this event across these platforms and examine how these topics changed over time. Our results indicate that the main topics were related to news; the technique itself; posting words on the web; and discussions from the perspectives of disease, risk, laws, ethics, and scientific literature. We also observed that certain topics have clear temporal trends based on the heat of the relative discussions. On the basis of the topic analysis results, we further design a codebook to annotate 2000 randomly selected posts from each platform, which we use to investigate how web-based posts supported, opposed or held a neutral stance on this event. The results indicate that the public's web-based posts had much more divided stances toward this event than toward those of academics, although the former varied across platforms with different language patterns.

The findings of this study indicate that society can learn about the public perception of controversial events using web-based data; however, we must be careful about drawing conclusions from any single platform.

Methods

Overview

Our research focused on the data that were collected from four popular and publicly accessible web-based platforms with user bases from different regions and backgrounds: *Sina Weibo*, *Twitter*, *YouTube*, and *Reddit*. The internal review board at our university designated this project as non-human subjects research and exempt from review. All posts presented in this

paper have been rephrased for privacy concerns and demonstration purposes.

Data Preparation

As the #GeneEditedBabies event was instigated by a Chinese scientist, it is natural to examine how people reacted to this event on Sina Weibo, the most popular microblogging platform with 500 million users in China [28]. The data from this platform have been applied to investigate a broad range of topics, including suicide prediction [29] and the mining of characteristics of patients with COVID-19 in China [30].

Twitter and YouTube are web-based platforms with a broader international basis, where approximately 20% of their users are from the United States, and the other 80% are from other countries [31]. Owing to its instant posting feature, Twitter has been recognized as an ideal platform for tracking people's comments or attitudes toward social events over time [32,33]. YouTube, a web-based video-sharing platform that enables users to upload, view, rate, and comment on videos has also become a valuable resource for studying the public's stances [34,35].

Reddit is a social news aggregation, web content rating, and discussion website, with approximately 50% of users from the United States [36]. Reddit users are more likely to write longer posts and generate deeper discussions on specific topics than users from other platforms. In addition, most Reddit users reportedly have a college degree [37].

We acknowledge that the users who mentioned the #GeneEditedBabies event do not necessarily represent the general population in each platform and, thus, may not represent the same demographics as those previously mentioned. However, because of the wide coverage of their user base, we believe that the posts on these platforms can provide intuition into the public's stance regarding the #GeneEditedBabies event in a cross-regional and cross-cultural manner [38].

To collect data, we defined a set of keywords that were related to the #GeneEditedBabies event: *jiankui he*, *gene-edited babies*, *crisper babies*, 贺建奎, 基因编辑婴儿, and their variations. Given that each platform has distinct application programming interface (API) use policies and that we initiated data collection 3 days after the event (November 29, 2018), we relied upon several different strategies to collect data. Specifically, we used the Twitter streaming API to continuously collect data from the Twitter stream and used the Twitter search API to fetch the data that were generated before the initial data collection date. For the other web-based platforms, we used their search APIs to collect data. We collected data from November 26, 2018, to October 19, 2019; aggregated the data on each platform; and removed duplicates. For Twitter, YouTube, and Reddit, we focused only on posts written in English.

Topic Analysis

To characterize what has been discussed in the #GeneEditedBabies event and provide a basis for the following stance annotation, we conducted a topic analysis of all collected data using structural topic modeling (STM) [39]. STM is a topic modeling framework that can leverage document-level

meta-information (eg, publication date and author) to improve inference and qualitative interpretability. However, because of language differences, it is challenging to generate topics by applying a single model to all the data. In addition, as many posts and comments in YouTube data do not have a well-defined posting date (eg, *one month ago*), we could not accurately build temporal trends for this platform's topics. As a result, we applied STM on Twitter and Reddit data sets together to (1) extract general topics, (2) analyze topic trends, and (3) compare topic differences; we applied STM on Sina Weibo and YouTube data sets to extract only general topics separately. We believe that temporal analysis can help understand how related news triggered the public's discussions on web-based social media platforms.

We removed stop words, punctuation, and numbers and replaced words with their stems before applying STM. As STM is based on unsupervised learning, we relied on exclusivity and semantic coherence to select the optimal number of topics K^* by running STM, with each candidate for the number of topics ranging from 5 to 25. Exclusivity corresponds to the distinctiveness of words with the highest probabilities in the topics, whereas semantic coherence measures the probability of co-occurrence of these words in a topic. As large exclusivity often results in small semantic coherence and vice versa, an ideal choice of K^* should strike a balance between these 2 measures. To do so, we first selected the 3 topic number candidates for K^* that exhibited the largest proportion of topics, with scores within 1 SD of the mean for the metrics of interest. The mean score was calculated for all the candidate topic numbers. We then manually compared and selected the number of topics that resulted in the most interpretable topics through the authors' observations and discussions.

Stance Annotation

Overview

Topic analysis can provide a high-level picture of what has been discussed in general. However, it cannot precisely tell whether people support or oppose this event. Therefore, after topic analysis, we conducted a stance analysis to further investigate how web-based posts from different platforms reacted to this event.

Coding Question

To identify and analyze the stance of web-based users in the #GeneEditedBabies event, we randomly selected 2000 posts from each platform for annotation. We designed a codebook for data annotation based on reading, independently summarizing, and collectively discussing the topic analysis results among the authors (CN, ZW, CY, and ZY) of this manuscript. We formulated 2 annotation tasks for each selected post. First (question 1 [Q1]), we asked what the post's stance was toward this event and let annotators select one of the following options: *no clear stance*, *support*, *oppose*, or *neutral*. As the distinction between *no clear stance* and *neutral* stances can be somewhat nuanced, we instructed annotators that a post with a *neutral* stance must explicitly balance between supporting and opposing stances.

If the answer to Q1 was different from *no clear stance*, we then asked annotators to perform a second task (question 2 [Q2]) to identify what issues the post raised when expressing its stance. Q2 was a nonexclusionary multi-option question, in which annotators were instructed to choose any of the following options based on the instructions of the codebook: (1) *techniques* (eg, considering the development of science or technologies),

(2) *ethics*, (3) *laws*, (4) *judging Jiankui He* (eg, on his education, appearance, or ambition), (5) *judging the organization* (eg, He's institute or country), (6) *others* (eg, those not listed above, but the missing aspect should be recorded), and (7) *no reasons are mentioned*. Table 1 presents several examples along with their answers.

Table 1. Examples of posts with answers to the questions posed in the annotation tasks.

Post examples	Platform	Q1 ^a choice (suggested)	Q2 ^b choice (suggested)
“年轻有为，反正我不会这个技术。(He is young and promising; I do not understand this technology anyway)”	Sina Weibo	Support	Techniques and judging Jiankui He
“The first gene-edited babies claimed in China—The Mainichi https://t.co/uNL0QFfdur ”	Twitter	No clear stance	N/A ^c
“I mean Nazi scientists went to hell in a tote basket but produced some of the most influential research of the 20th century.”	Reddit	Neutral	Techniques and ethics
“It sounds like any other mad scientist story.”	YouTube	Oppose	Judging Jiankui He

^aQ1: question 1.

^bQ2: question 2.

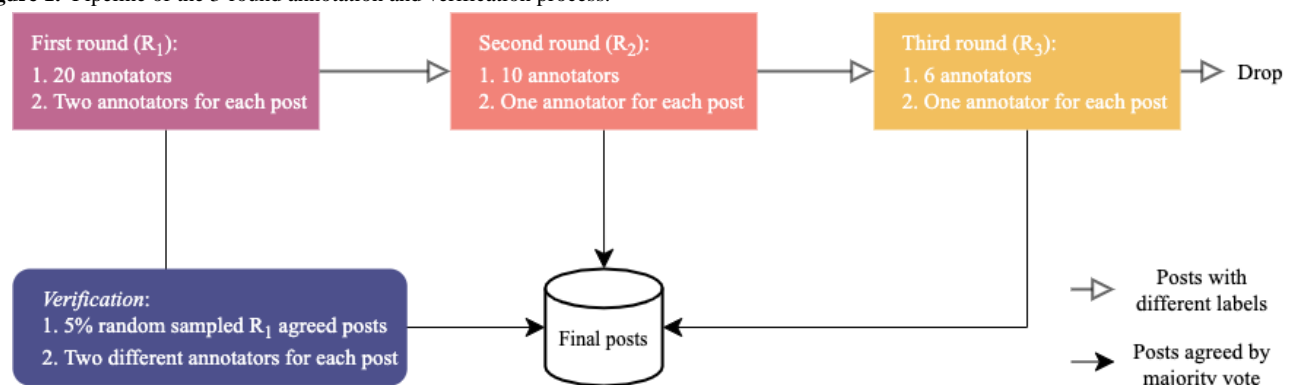

^cN/A: not applicable.

Annotation Strategies

As the languages used in the 4 platforms are either Chinese or English, we recruited 20 college students who were fluent in both languages to annotate the data. We selected bilingual annotators to reduce bias in stance judgment induced by differences in the language spoken. Before assigning the task,

we provided the codebook and tutorial examples to train the annotators and discuss with them. Once they were comfortable with the requirements and the task, we proceeded to formal data annotation. As stance is subjective, to ensure the annotation quality, we conducted 3 rounds of *verification* for Q1, the single option question. Figure 1 shows the annotation and verification processes.

Figure 1. Pipeline of the 3-round annotation and verification process.

A total of 8000 posts from 4 platforms, with 2000 posts per platform, were labeled in our annotation. In the first round (R_1), we randomly partitioned 20 annotators into 10 groups of 2 annotators each and assigned each group to 800 selected posts (200 from each platform). After annotation, we compared the labeling results within the groups. When 2 annotators labeled a post with the same stance, the task for the post was considered complete. We calculated the inner-annotator agreement between the 2 annotators in the first round using the Cohen κ score.

Instead of requiring 2 annotators to select the same options in Q2, which would be very challenging, we calculated a weighted score for each option based on their answers as follows:

represents the score of option o_j in post p_i , i is the post number from 1 to 800, j is the option number from 1 to 7 (see the abovementioned coding questions), A_k represents the set of options that annotator k chooses, and K is the total number of annotators who labeled post p_i :

We sent all posts with conflicting stance labels into a second round of annotation (R_2) for tie-breaking purposes. In this round, we selected another 10 annotators as adjudicators. If a post received 3 different stance labels in 2 rounds of annotation, we sent it to the third round of annotation (R_3) for further tie breaking. Multiple rounds of annotation can reduce manual effort and improve efficiency. However, some posts received

2 stance labels in R_1 , whereas some other posts received 4 stance labels in R_3 . It is possible that the posts that received the same stance labels in R_1 could obtain different labels from 2 (different) annotators, which may have made the annotations unreliable. To examine the extent to which such cases existed, we randomly selected 5% of such posts and assigned them to 2 annotators who had yet to label them for a verification process.

For posts with stances settled beyond R_1 , we extracted the answers to Q2 from the 2 annotators who determined their final stance label. Once we calculated the weighted score $\frac{1}{M} \sum_{i=1}^M s_i(o_j)$ for each option o_j in each post p_i , from Q2, we estimated $\frac{1}{M} \sum_{i=1}^M s_i(o_j)$, the probability that an issue (corresponding to option o_j) was raised in a web-based platform regarding a particular stance. $\frac{1}{M} \sum_{i=1}^M s_i(o_j)$ was calculated as follows:

$$\frac{1}{M} \sum_{i=1}^M s_i(o_j)$$

Where M represents the total number of labeled posts for a platform, and L represents the number of options in Q2.

Stance Language Analysis

After comparing the stance differences across the 4 platforms, we continued to examine how the language used in the posts differentiated supporting and opposing stances across the platforms. To perform this analysis, we focused on annotated data with only supporting or opposing stances. We removed stop words and extracted the lemma form of each word. We then calculated the saliency [40] $s(w)$ for a word w in each platform as follows:

Table 2. A summary of the data set collected for this study^a.

Platform and users	Post type	Posts	Posts per user, mean (median) ^b	Post length, mean (SD) ^c
Sina Weibo				
2800	Microblog	4941	1.8 (1)	81.4 (76.8)
83,265	Comment	131,126	1.6 (1)	16.6 (17.5)
Twitter				
24,960	Tweet	47,147	1.9 (1)	14.1 (4.2)
Reddit				
866	Submission	3205	3.7 (1)	71.0 (324.6)
11,678	Comment	22,417	1.9 (1)	43.3 (65.9)
YouTube				
31,237	Comment	48,172	1.5 (1)	36.1 (60.4)

^aOn the basis of the properties of each platform, the posting type varies.
^bRepresents the average number (median) of posts per user in each platform.
^cRepresents the average word count (SD) of each post.

Topic Analysis

Topics on Twitter and Reddit

On the basis of our criterion, we set K^* to 15 for the topic analysis. We refer the reader to [Multimedia Appendix 1](#), Tables S1-S3, for further details. [Table 3](#) reports on the 15 extracted

$$\frac{1}{M} \sum_{i=1}^M s_i(o_j)$$

In the abovementioned equation, t refers to either a supporting or opposing stance, and p represents the probability of w within the data corpus. The larger the saliency value, the more informative the word is for differentiating among stances. We retained the 50 most informative words for each platform. For each selected word w , we used the relevance score [41] to determine how informative it was to a stance t , which is defined as follows:

$$\frac{1}{M} \sum_{i=1}^M s_i(o_j)$$

In the abovementioned equation, λ is used to control the trade-off between the word frequencies within a stance and the word importance in distinguishing 2 stances. Here, a small λ highlights rare but exclusive words for a stance, whereas a large λ highlights frequent but not necessarily exclusive words for the stance. In this study, we set $\lambda=0.6$, as suggested by Sievert and Shirley [41].

Results

Data Preparation

[Table 2](#) summarizes the data collected for this study. Within the first round of annotation, the inner-annotator agreement was 0.44 (SD 0.11), which indicated moderate agreement. The median number of posts published by each author was 1 for all platforms, suggesting that most users only had one post or comment in our data set.

topics; the most representative words; expected topic proportions (the probability of each topic in all the posts); and the 5 summarized themes, which were summarized by authors (CN and ZY) by manually reviewing the posts with the highest probability, and the difference in topical prevalence between

Twitter and Reddit. The most representative words per topic were based on the rank ordering of their probabilities.

Table 3. Topics, top words, and the 5 summarized themes.

Theme and topic	Top representation words	ETP ^a	Difference (SD) ^b

^aETP: expected topic proportion.

^bDifference represents the difference in the prevalence of the topic between Twitter and Reddit, where a positive (negative) value suggests a topic was more frequently discussed on Twitter (Reddit). All the differences were significant with $P < .001$ according to a 2-tailed paired t test.

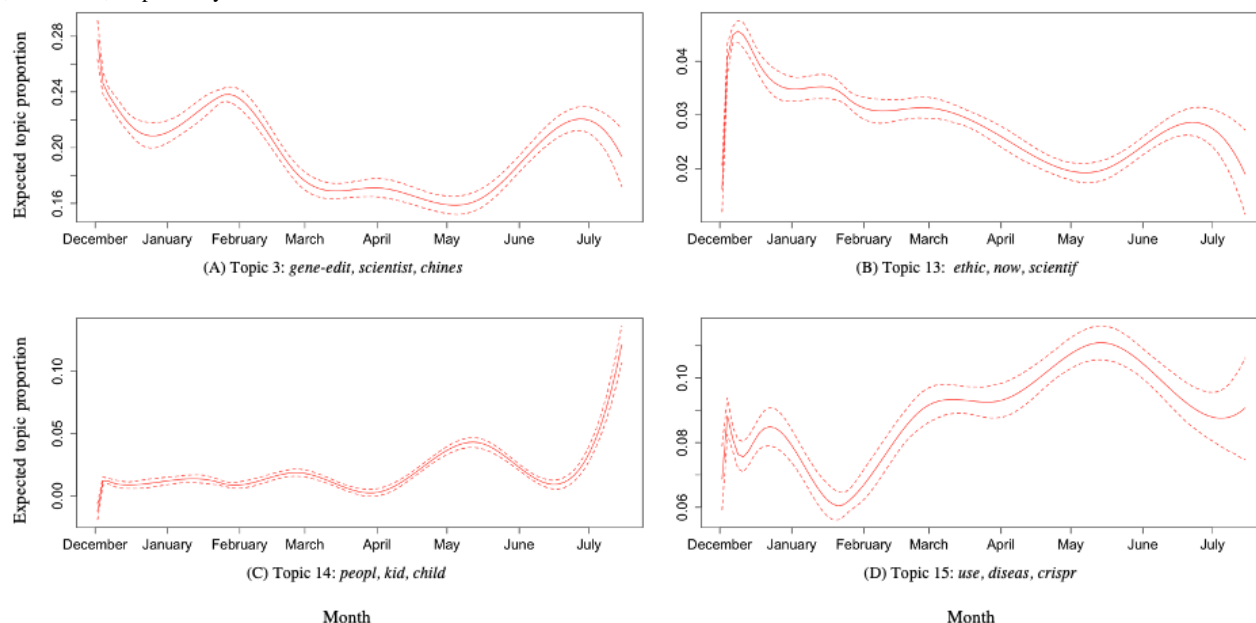

Five themes were generated by the authors: *communications* (topics refer to regular web-based chatting), *discussions* (topics related to the discussion of this event), *gene editing* (topics of gene editing technique), *news* (topics of #GeneEditedBabies), and *posting on the web* (topic of common web-based communities' words). Topics with positive (negative) scores were more often discussed on Twitter (Reddit). For example, it can be seen that topic 12 from the *gene-editing* theme exhibited the highest score, followed by topics 3, 4, and 10, which are all part of the *news* theme. This suggests that Twitter is more dedicated to the sharing of news. By contrast, topic 14 exhibited the lowest negative score, a topic in the *discussion* theme about people and children. Topics 11, 9, and 5 of the

communication themes also exhibited negative scores, which suggests that they were more likely to be mentioned on Reddit as well. The above findings clearly demonstrate the different topics on the 2 platforms.

Topic Temporal Trend Analysis

Figure 2 illustrates the temporal trends for the 4 representative topics derived from Twitter and Reddit. We interpreted the trends by manually examining the posts with the largest probabilities for each topic during a specific period. Note that the scale of the y-axis for each topic that we selected in Figure 2 varies because of different expected topic proportions (Table 3).

Figure 2. Topic temporal trends for 4 topics generated by applying structural topic modeling on Twitter and Reddit data. The solid line represents the mean expected topic proportion and the dashed lines represent 1 SD. The x-axis corresponds to the posting time, whereas the y-axis corresponds to the expected topic proportion obtained from structural topic modeling. (A) to (D) represent the monthly changes in the expected topic proportion of Topic 3, 13, 14 and 15, respectively.

Topic 3 (in Figure 2) mainly refers to the scientist Jiankui He in this event. After the beginning of the event, the popularity of this topic decreased sharply but then experienced an increase in February 2019. This increase corresponded in time to a rumor that *Chinese gene-editing scientist missing amid rumors of arrest: report says Chinese scientist He Jiankui has been arrested* on Twitter. He again attracted attention in the news in June 2019 because of an announcement by Denis Rebrikov at the Kulakov National Medical Research Center in Moscow, who was planning to repeat his experiment once he obtained official approval [42].

Topic 13 communicates the public's concerns about the event (eg, legal issues). This topic experienced a decreasing trend as the #GeneEditedBabies event became outdated. However, it experienced a peak around May 2019 because of an article published in the journal *Nature: CRISPR babies: when would the world be ready?* [43], which stirred a discussion on Reddit.

The temporal trend for topic 14, which focuses on human rights and was more likely to be discussed on Reddit, exhibited an increasing trend, with a local peak during May 2020 when a Reddit user shared an article with the title of *What we risk as humans if we allow gene-edited babies: a philosopher's view* [44], which received >600 comments. The popularity of this topic continued to rise rapidly in July 2020, perhaps because of the news of *Five couples lined up for CRISPR babies to avoid deafness* [45], which received numerous retweets on Twitter.

Topic 15, which focuses on gene-editing technology, grew over time, with a peak around May 2019. The peak of its popularity appeared to coincide with news related to how gene editing helps cure disease. For example, 1 such news story posted on Twitter in May 2019 was *Researcher Brian Liau and his team combine CRISPR gene-editing technology with chemical profiling to tease out acute myeloid leukemia mechanisms* [18].

Topics on YouTube and Sina Weibo

We also applied STM to YouTube and Sina Weibo data sets to generate $K^*=15$ topics using the same criteria for processing Twitter and Reddit data sets, respectively. The three most popular topics on YouTube were summarized as visual arts (*video, gattaca, and episod*), thoughts (*want, get, and think*), and human evolution (*human, speci, and evolut*). The top three popular topics on Sina Weibo were news (*事情 event, 科研 research, and 国际 international*), science (*科学 science, 科学家 scientist, and 成果 result*), and concerns (*法律 law, 胚胎 embryos, and 人体 human*). Other topics on YouTube included mentions of race and culture (keywords: *tan, skin, cultur, hair, and racist*), and general thoughts (*peopl, talk, feel, and understand*). By contrast, Sina Weibo included topics presenting strong negative emotions, such as strong opposition to the event (*出生 born, 死 death, 可怜 pity, 毁灭 destroy, 人性 humanity, and 危害 danger*) and the discussion on inequity between the rich and poor (*穷人 poor, 富人 rich, 普通人 normal people, and 小白鼠 experimental mice* [used as a metaphor]).

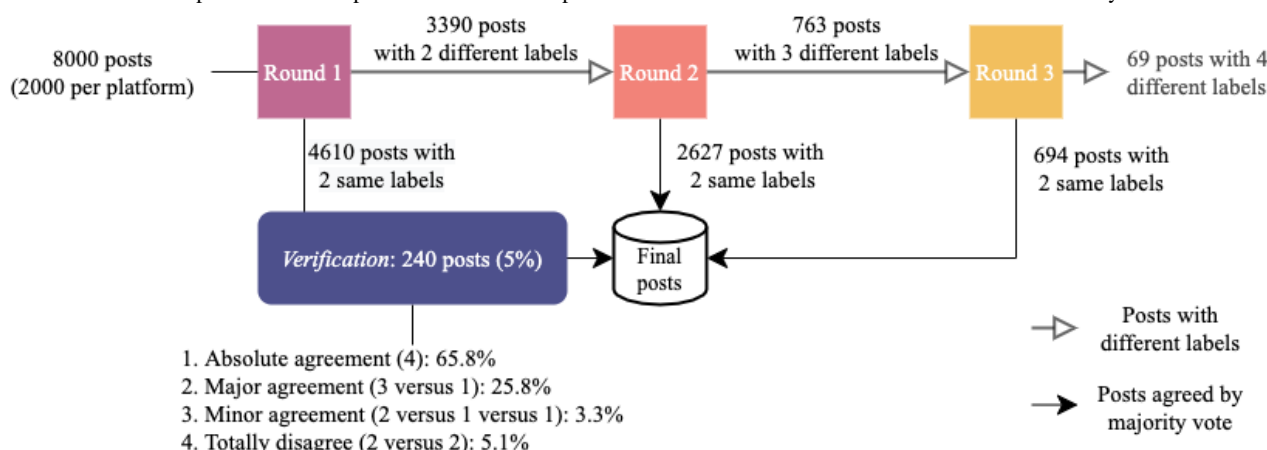

Stance Analysis

Annotation Results

Figure 3 illustrates the labeling process. Both annotators agreed in 57.62% (4610/8000) of the posts that were labeled in the first round. After the second round of annotation, 3 annotators remained in disagreement on 22.51% (763/3390). The 9% (69/763) of posts that were annotated with 4 different options were removed because of the inability to reach any consensus. Regarding verification, 65.8% (158/240) of the examined posts received the same labels as the first round (ie, absolute agreement); 25.8% (62/240) received 1 different label (ie, major agreement); 3.3% (8/240) received 2 different labels (ie, minor agreement); and only 5.1% (12/240) received 2 of the same

labels, which differed from the original, suggesting a reliable labeled data set for further analysis.

Figure 3. The annotation process for 8000 posts. Note that the 69 posts with 4 different labels were removed from further analysis.

Stance Distribution

We calculated the number and percentage of each stance in each platform among the posts that clearly had a stance in the annotated data. The percentage of removed posts with *no clear stance* was 42.8% (853/1993) on Sina Weibo, 59% (1174/1990) on Twitter, 54.4% (1070/1967) on Reddit, and 45.6% (902/1978) on YouTube. Although all 4 platforms generally contained more opposing stances than other stances, the ratios of those stances were quite different. Specifically, Sina Weibo and Twitter exhibited similar rates of opposition (approximately 84.91% [968/1140]); however, Sina Weibo's rate of support was almost double that of Twitter (37/816, 4.5%). In contrast, Reddit and YouTube had much lower (higher) rates of opposition (support) at 61.25% (550/898; 257/898, 28.62%) and 52.6% (567/1078; 405/1078, 37.6%), respectively. Sina Weibo exhibited a lower rate of neutral stance (70/1140, 6.1%) than the other 3 platforms (all of which were around 10%). It is notable that, although both Twitter and YouTube have broader international user coverage, YouTube exhibited a more divided stance toward #GeneEditedBabies. We suspect this may be because of the fact that YouTube presents its content in videos, such that users can comment under them and share conflicting ideas in an irrelevant manner. By contrast, Twitter is more akin to a news (re)distribution center, where it is difficult to support a deep discussion.

Although a post-level analysis of stance may be biased by superusers who publish substantially more posts than others, we found that within the annotated posts with a clearly expressed stance, >95% of users had only 1 post (Sina Weibo: 1005/1057, 95.08%; Twitter: 726/755, 96.16%; Reddit: 822/858, 95.8%; and YouTube: 965/1012, 95.35%), and no users had >5 posts. This indicates that the influence of superusers on our findings based on randomly sampled data is limited.

Concern Analysis

Supporting Stance

Figure 4 shows that *techniques* were the primary consideration when posts supported the #GeneEditedBabies event on each web-based platform. The rates of Sina Weibo and YouTube posts supporting this event were slightly >50%, whereas those

for Twitter and Reddit were closer to 40%. A qualitative examination of the related posts suggests that users believed the event could help advance scientific knowledge for clinical trials using gene-editing technologies and, thus, create an opportunity to cure severe diseases and benefit humans in the future. A Sina Weibo user commented the following:

解剖学最早也是反人类的，遭到大多数人的反对，[...]，恭喜先生走出新的世界纪录。(Anatomy was also anti-human at the earliest and was opposed by most people, [...], congratulations to Mr. for stepping out of the new world record.) [post 1, Sina Weibo]

It should be noted that *no reason* was the second most selected option for Q2 on YouTube (76.5/467, 16.4%), Sina Weibo (23/114.5, 20.1%), and Twitter (14.5/38.5, 37.7%) and the third most selected option for Reddit (51/311, 16.4%). The difference in *no reason* ranking within the platforms may be as Reddit discussions are more likely to compose longer posts than the discussions on the other 3 web-based platforms (Table 1) and, thus, have more of a chance to share reasons in their posts. Ethics was another critical consideration when posts supported this event on Reddit (66.5/310.5, 21.4%), YouTube (73/467, 15.6%), and Sina Weibo (17/114.5, 14.8%). The users in these posts did not believe that this event lacked ethical concerns. Instead, these users intimated that the event could help patients with genetic diseases. The two posts indicated the following:

It's not morality, it's cowardice to seek permission from 30 governing bodies before taking every step. [...] No risk, no reward. [Post 2, Reddit]

Nice work! [...] If you can help parents with a genetic disorder have a healthy baby, I don't understand why people are so upset. [Post 3, YouTube]

We also found posts expressing a supporting stance directly based on the aspects of Jiankui He or organizations (eg, He's institute or country); posts on Sina Weibo and Twitter tended to talk about Jiankui He himself, whereas Reddit and YouTube tended to say more of his organizations. The following two posts offer examples in these categories:

总有人要付出代价。如果你不迈出第一步，后面的人就永远不敢前进。(There is always someone who has to pay the price. If you don't take the first step, the ones behind will never dare to move forward.) [Post 4, Sina Weibo]

China will leave us behind because we refuse to edit human genes like this. [Post 5, YouTube]

Some Reddit and YouTube posts supported this event as they believed it could help push forward new strategies and regulations for gene therapy, as indicated in post 3.

Figure 4. The reasons for supporting stances within 4 platforms.

Opposing Stance

Figure 5 illustrates the distribution of the issues identified in each platform for the opposing stance. Although there were many comments without any reason, especially on Twitter, ethics was the primary concern for Reddit (259/724, 35.8%), YouTube (235/714, 32.9%), and Sina Weibo (376.5/1258.5, 29.92%). A YouTube opposer said the following:

Who owns the rights to products and technologies? [...] I don't think it's been adequately addressed, nor is there transparency in the scientific community about it. [Post 6, YouTube]

The fact that the technique is relatively new and could lead to many unknown and serious issues was another consideration in Reddit (209/724, 28.9%), YouTube (204/714, 28.6%), and Sina Weibo (179/1258.5, 14.22%). A Redditor wrote the following:

Genes are complex. So, if it doesn't work, it's as if you're not fighting the infection properly and there's a higher risk of dying. [post 7, Reddit]

However, Sina Weibo had more posts and insults (240.5/1258.5, 19.1%) that were not directed at the event or the technology but were only directed at the individual (Jiankui He). One such quote is as follows:

说白了，还是利益熏心!! 一身的铜臭味!! (To be straightforward, (He) was too greedy and only cared about the money!) [post 8, Sina Weibo]

Notably, Twitter is quite different from the other platforms in that the major considerations mentioned in this platform were laws (151/806.5, 18.7%), organizations (132/806.5, 16.4%), and ethics (131.5/806.5, 16.3%). Techniques (83/806.5, 10.3%) had a smaller percentage than those exhibited in Sina Weibo and much less than on YouTube and Reddit. A possible explanation for this phenomenon is that many users directly tweeted the news without attaching their own commentary, whereas the discussions on the other platforms were more likely to comment under either video or other posts.

Figure 5. The reasons for opposing stances within 4 platforms.

Language Analysis

Figure 6 illustrates the word clouds for each platform, with a larger font size indicating a more informative word.

Figure 6. Salient words for supporting (green) and opposing (red) stances within each web-based platform. A larger font size suggests a higher relevance of the associated word in the corresponding stance and platform. Note that all words presented here are in their lemma form.

Sina Weibo

The most informative terms used by Sina Weibo supporters were 试管婴儿 (in vitro fertilization), 自然选择 (natural selection), 癌症 (cancer), 时代 (time), good, 日心说 (heliocentrism), 宣扬 (advocate), 骄傲 (pride), 核弹 (nuclear bomb), and 医药 (drug). These people argued that the event might be part of natural selection, and from an ethical

perspective, there might be no difference between in vitro fertilization and gene-edited babies because of human intervention. Some people believed this was good and that society should be proud as they have the potential to cure diseases such as *cancer*. Others argued that gene editing was similar to dual use technologies [46], such as *nuclear* technology, which could be used to create bombs but also be beneficial for energy development; eventually, it would be

accepted just as heliocentrism. By contrast, opposers were more likely to mention words related to law or stakeholders, such as 基因编辑 (gene edit), 广东省 (Guangdong province), 央视 (CCTV), 非法 (illegal), 明令禁止 (clearly forbidden), and 审查 (governance). It should be noted that 吐 (throw-up) is a common Chinese term in Sina Weibo that expresses an emotion in strong opposition.

Twitter

Supporters used many positive words such as *exciting*, *OK*, *innovation*, *protect*, and *enhance*. We found that male contraceptives were also mentioned as they, together with gene editing babies and other findings, were reported as the most exciting innovations of 2018, and the link to the web-based version of this report received many retweets. By contrast, people with an opposing stance used words that were more relevant to this event specifically, such as *baby*, *geneedit*, *scientist*, *china*, *illegal*, *death*, *break*, *halt*, *stop*, *rule*, and *risk*. In this regard, Twitter shared similarities with Sina Weibo in that opposers from both platforms quote news or web-based links (eg, *http*, *cnn*, *cnet* on Twitter and *http* and *CCTV* in Sina Weibo).

Reddit

Posts on Reddit were more multidimensional and tended to be more thoughtful than posts on other platforms. Supporters discussed this event from the perspective of religion, using terms such as *conservative*, and argued that they did not see any religion-related issues. They also mentioned *hereditary*. They believed that this technology could be used to cure autism or certain predispositions. They also used positive terms such as *effective* and *efficient*. In addition, these supporters likened this technique to the increase in deaths when automobiles were first introduced. The words in the supporting stance also demonstrate that Reddit posts were likely to write deep or scientific, dialectical explanations to express supporting opinions. By contrast, the opposing views included words such as *read*, *bring*, *datum*, *unknown*, and *add*, expressing their concerns about the unknown effects that such a technique might bring to the human gene pool. These opposers also used more technical terms such as *germline*, *off target*, *protein*, *allele*, *reproduction*, *deletion*, and *intervention*. Many of them believed it was dangerous, comparable with the strong opposing emotion word 吐 (*throw up*) used on Sina Weibo.

YouTube

The posts on YouTube invoked a very different language style compared with posts on other platforms. For example, supporters used the term *successful* in expressing their supporting stance and argued that gene-editing techniques will make people healthier and live longer, just as vaccines do today. Although the supporters also used terms that appear to be in opposition, such as *despite*, *greedy*, *harmful*, and *struggle*, a closer examination of the related posts showed that these posts presented 2 stances but with a solid preference for a supporting stance. By contrast, opposers on YouTube were more likely to use dramatic words such as *zombie*, *machine*, *extinction*, and *inferior* and conspiracy-related words such as *assume*, *fake*, and

lie. When talking about the law issue, these posts tended to use the word *jail*.

In summary, a comparison of informative terms shows a clear distinction in the language used in these 4 platforms. Moreover, the difference in language occurred in both the supporting and opposing stances toward this event. A possible explanation for this distinction is that it may be an artifact of user populations with different cultures or demographic backgrounds. We believe that this further supports the need to consider the public's stance from multiple diverse web-based platforms to form a more comprehensive picture. There are certainly other possible explanations, such as the fact that these differences may be because of the political stances or related screening policies of each individual platform. However, further investigation is necessary to determine whether this conjecture is correct.

Discussion

Principal Findings

This study introduced a novel, cross-cultural, and cross-regional investigation of the public's stance toward the #GeneEditedBabies event by using data from 4 popular web-based social media platforms. We found that the platforms focused on different topics and that some had clear temporal trends around the news associated with this event and related techniques. In addition, we found that opposition to this event was high in general; however, the stances varied across platforms. Among the discussions that expressed a clear stance, Twitter exhibited the largest percentage of posts (701/816, 85.9%) in opposition, followed by Sina Weibo (968/1140, 84.91%), Reddit (550/898, 61.2%), and YouTube (567/1078, 52.59%). The main reasons people supported this event were as the techniques were thought to be scientific advances that have the potential to cure debilitating genetic diseases. By contrast, the main reasons for opposition were ethical and legal concerns. The variation we observed may stem from the differences in the cultural and demographic backgrounds of the user base in each platform.

Comparison With Prior Work

Earlier Stance Analysis on Gene Editing

Our findings regarding Sina Weibo and Twitter are aligned with a conclusion in a recent survey of responses to a hypothetical, norm-violating application of gene-editing technology that such applications would *invite public backlash that can spill across national boundaries* [47]. However, as we demonstrated, Reddit and YouTube still had a substantial proportion of posts supporting this event. Other survey-based studies have also found that people tend to have supporting but cautious attitudes toward HGE. For example, 1 study showed that adults from Australia were comfortable with editing human and animal embryos but only for research purposes and to enhance human health [48]. Similarly, Japanese users generally accepted the use of genome editing for disease-related genes; however, many were concerned about its risks [49]. Although many Dutch adults responding to a survey considered the risks of GGE to be substantially greater than its benefits, they may approve of using GGE if it is sufficiently safe and effective and used for a

disease instead of enhancement [50]. In addition, another survey based on the responses from 1537 participants across 67 countries (87% of whom were White and mainly from the United States, Australia, Canada, and the United Kingdom) found that respondents generally supported GGE for medical applications, and resistance was mainly reported by people with religious beliefs or working experience in genetics [51].

However, as a recent review of nationally representative public opinion surveys summarized [52], many of these surveys did not capture the views after the #GeneEditedBabies event, *which could have raised awareness of HGE or affected views of edits among public*. In addition, the authors of the review advocated collecting more data from around the world to capture the views of different segments of populations. In this regard, our multiplatform investigation provides more insight into how people with different cultures and from different regions discussed this event, findings that can help fill the gap in this field.

Analysis of the Event Using Web-Based Data

Several studies have investigated public discussions using data from social platforms. For example, Calabrese et al [53] examined the perceptions of CRISPR on the web through the application of a semantic network analysis of Twitter messages, and Müller et al [26] analyzed tweets about CRISPR or Cas9 technology and trained machine learning models to classify tweets. However, these studies used data from Twitter only, which was not easily accessible in mainland China. Moreover, they focused on the sentiment of tweets (eg, positive or negative) and the type of subject (eg, applying the technology to humans as opposed to other organisms) instead of the stance (eg, in support or in opposition) and greater understanding of concerns (eg, why hold this stance?). Furthermore, the #GeneEditedBabies event was not the main focus. Zhang et al [27] compared the differences in language used to discuss gene editing before and after this event on Sina Weibo. Liu and Lapata [54] conducted a sentiment analysis of news reports and tweets about this event that were collected from Google, Baidu, Sina Weibo, and Twitter about this event. However, all of these investigations are fundamentally different from ours in that they selected various platforms for data collection and focused solely on sentiment analysis, which is insufficient to characterize the stance expressed in a comment.

Web-Based Multiplatform Data Analysis

Multiplatform studies are useful for reducing the bias caused by a single platform or a small amount of data. In particular, multiplatform data resources can enrich analysis and optimize the training results of classifiers [55,56]. For example, Schifanella et al [57] leveraged the contextual information carried by visuals to decode the sarcastic tone of multimodal posts by using images and texts from Instagram, Tumblr, and Twitter. In addition, most multiplatform data analyses targeted a particular topic, such as travel (eg, discussion about hospitality and tourism [58]), business (eg, the preferences and discussions of e-cigarette users [59]), and health (eg, a study of symptoms of depression and anxiety of American young adults [60]). Our study contributes to this area of research by using multiplatform data to conduct a reasonable and comprehensive analysis of

stances across various cultures, regions, and network environments.

Limitations and Future Work

However, there are certain limitations in our study that can serve as the basis for future research. First, although we focused on 4 popular publicly accessible platforms, there are other major web-based platforms (eg, Facebook), the data of which could be used to enrich the analysis. Second, the set of keywords we relied upon was limited to the names of the event and the scientist. Although we believe that these are likely to cover most of the perspectives that can be detected, we did not conduct a pretest to confirm if this was the case. Third, we calculated the percentage of stances based on randomly selected posts and showed that superusers had a limited impact on our findings. Future work may consider directly sampling all users to avoid this issue. Fourth, although our annotated data set is sufficiently large to obtain insight into the public's stance, it would be interesting to conduct stance temporal trend analysis with more labeled data. Finally, our findings reflect only the opinions of people who use web-based social media platforms to express their stances on this event. It is necessary to investigate how their perspectives relate to people who do not post on social media.

This project laid the foundation for a wide array of future studies. First, to analyze the language used, we applied a saliency word cloud to show the differences in language among posts from different stances and platforms. Alternative methods, such as semantic networks [61], could be considered in future work to investigate a different perspective of topic modeling; for example, the relationships among the words. Second, it would be useful to determine whether the public's stance on gene editing changed as a result of this event. A way by which this could be accomplished would be to compare posts about gene-editing technology before and after the #GeneEditedBabies event across social media platforms. Third, although we focused only on post-level content for analysis, it will be useful to attach conversations, such as the comments under the posts in each platform, to enrich this research.

Implications and Conclusions

This study has several notable implications. First, this study shows that web-based social media platforms can serve as efficient tools for tracking people's reactions to a series of news regarding a public event in a timely manner. However, such reactions can vary depending on the platform from which the posts come. Using multiplatform data to study public events can help to obtain a more comprehensive understanding of people's stances worldwide. Second, web-based posts exhibit more divided stances on, understandings of, and interpretations regarding a cutting edge but controversial technique than those expressed by academic professionals. This adds further weight to the need to listen to public voices and increase public engagement in policy formation beyond the scientific community [6]. Finally, the public's observed stances and the factors that web-based posts considered can both help guide the development of promotional materials to improve awareness and understanding of this technique for posts on different

platforms [62] as well as take public concerns more fully into account.

Although we focused on studying the public's stance regarding this specific event, our annotation methods and analysis

strategies can be readily adapted to investigate other social events (eg, Black Lives Matter or presidential elections) and public health promotions (eg, cancer screening or COVID-19 vaccination) in a cross-cultural or cross-regional manner.

Abstract

Background: Puff Bars are e-cigarettes that continued marketing flavored products by exploiting the US Food and Drug Administration exemption for disposable devices.

Objective: This study aimed to examine discussions related to Puff Bar on Twitter to identify tobacco regulation and policy themes as well as unanticipated outcomes of regulatory loopholes.

Methods: Of 8519 original tweets related to Puff Bar collected from July 13, 2020, to August 13, 2020, a random 20% subsample (n=2661) was selected for qualitative coding of topics related to nicotine dependence and tobacco policy.

Results: Of the human-coded tweets, 2123 (80.2%) were coded as relevant to Puff Bar as the main topic. Of those tweets, 698 (32.9%) discussed tobacco policy, including flavors (n=320, 45.9%), regulations (n=124, 17.8%), purchases (n=117, 16.8%), and other products (n=110, 15.8%). Approximately 22% (n=480) of the tweets referenced dependence, including lack of access (n=273, 56.9%), appetite suppression (n=59, 12.3%), frequent use (n=47, 9.8%), and self-reported dependence (n=110, 22.9%).

Conclusions: This study adds to the growing evidence base that the US Food and Drug Administration ban of e-cigarette flavors did not reduce interest, but rather shifted the discussion to brands utilizing a loophole that allowed flavored products to continue to be sold in disposable devices. Until comprehensive tobacco policy legislation is developed, new products or loopholes will continue to supply nicotine demand.

KEYWORDS

tobacco; policy; social media; e-cigarette; twitter; mHealth; dependence; addiction; nicotine

Introduction

From 2011 to 2019, current e-cigarette use among US high school students increased from 1.5% to 27.5% [1], prompting the US Surgeon General to declare a youth vaping epidemic. An appealing aspect of e-cigarette use to adolescents was the availability of flavors [2]. Among this population, initial use of flavored e-cigarettes is associated with progression to current e-cigarette use [3].

Driven by the results of the 2019 National Youth Tobacco Survey (NYTS) and other reports of increased use of tobacco products by youth, the US Food and Drug Administration (FDA) took action to address this epidemic in December 2019 by raising the federal minimum age for sale of tobacco products (including e-cigarettes) from 18 to 21 years and by prioritizing enforcement against illegal flavored (eg, fruits) e-cigarettes [4,5]. Likewise, many US states have enacted legislation to restrict flavored e-cigarettes [6]. In an effort to balance

considerations for adult smokers trying to quit cigarettes, the federal flavor ban was focused on cartridge-based products, such as those sold by JUUL (JUUL Labs)—at the time, the device used by a majority of youth who were current e-cigarette users [1].

However, the actions by the FDA may have resulted in unintended consequences. In the case of e-cigarette-related policy, loopholes allowed for disposable devices such as Puff Bar to continue to be sold, even in prohibited flavors. Puff Bars are single-use, disposable, flavored e-cigarette products. The

design and packaging of Puff Bar are similar to those of JUUL (Figure 1). Puff Bar e-cigarettes come in 25 different flavors (eg, strawberry banana). There is evidence that Puff Bar is targeting its products and advertisements to youth. For example, the company produced flavor pods (Puff Krush) that are advertised as an “add-on” for JUUL pods following JUUL’s removal of most flavors from the US market, which were extremely popular with youth [7]. In 2020, the NYTS reported that the use of disposable e-cigarettes among current high school users increased by approximately 1000% from 2019 [8].

Figure 1. Puff Bar and JUUL comparison. Left: Puff Bar device; right: JUUL device.

On July 13, 2020, Puff Bar announced that they were ceasing online sales in the United States [9]. One week later, the FDA announced that it issued warning letters to 10 companies, including Cool Clouds Distribution, Inc (Puff Bar’s parent company), to remove their products from the market, citing their introduction after the 2016 deeming rule bringing all tobacco products under the authority of the FDA [10]. Puff Bar was also cited for marketing their product as a modified risk tobacco product without FDA approval [10]. However, evidence suggests that Puff Bar sales were continuing despite the FDA warnings. For example, at the time this article was written, the Puff Bar website still had a “store locator” function [11] listing retailers across the US.

The continued sales of flavored products in disposable devices may be contributing to youth use of products containing high levels of nicotine. In contrast to contemporary products that contain freebase nicotine, Puff Bar e-cigarettes contain nicotine salt formulations (similar to JUUL) that deliver nicotine in a quickly metabolized and palatable manner, with nicotine concentrations as high as 5% [12,13]. Research indicates that

users of JUUL’s higher nicotine level products (ie, 5%) experience symptoms of dependence and acute nicotine effects [14]. Likewise, nicotine dependence in past-month adolescent e-cigarette users is significantly associated with increased nicotine concentrations [15]. Thus, despite the intended goal of reducing youth tobacco use through legislative and policy activities, unintended loopholes allowed youth to access the same products, just in a different form.

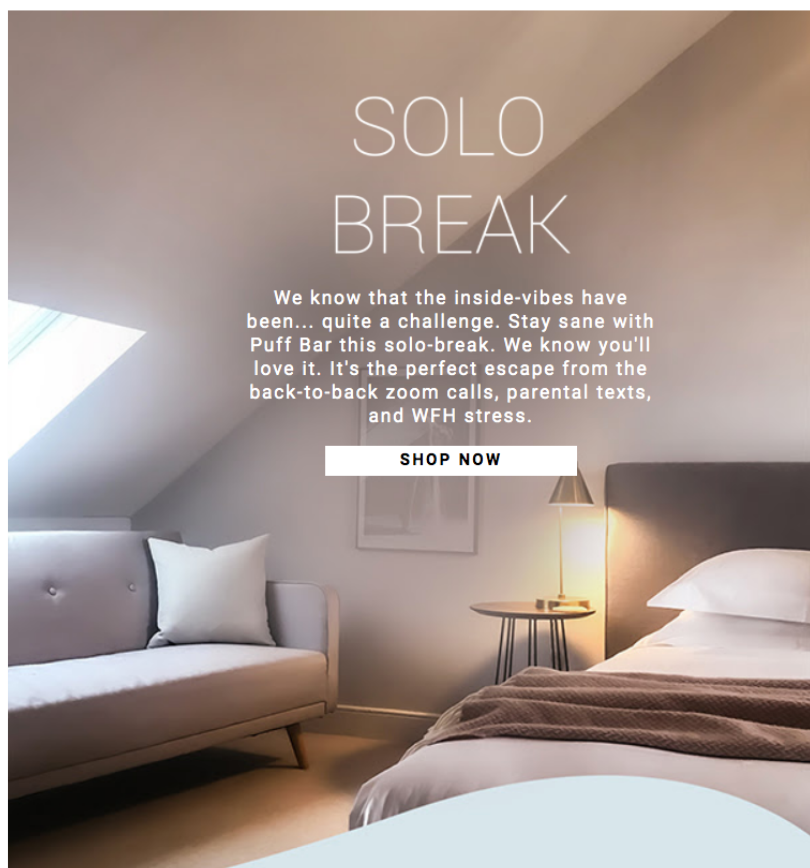

Research has consistently found that e-cigarette discussions on social media platforms can quickly diffuse marketing messages, activate brand awareness, and reach large numbers of adolescents [16-18]. An analysis of videos on TikTok, a social media platform particularly popular with younger populations [19], found that the 10 most popular videos depicting Puff Bar were viewed between 2.8 and 42.4 million times and that 2 of the videos depicted clear youth-related content (eg, an underage youth purchasing a Puff Bar) [20]. Additionally, during the COVID-19 pandemic social distancing restrictions, Puff Bar released an advertisement picturing a bedroom and suggested that their products would allow for escape from “back-to-back

zoom calls, parental texts, and WFH [work from home] stress” (Figure 2) [21].

With growing risk of adolescent use of disposable e-cigarette devices, studying Puff Bar on social media may offer insight into topics of discussion and trends that are emerging [22]. Twitter has become a valuable source of publicly observable data for public health practitioners to better understand attitudes toward e-cigarette use, advertisements targeted to youth, and discussions of tobacco regulations [23-26]. Pew Research has also found that Twitter users tend to be younger than the overall

US adult population [27]. Specifically, Puff Bar-related discussions on Twitter may give insight into how these products are being used as an alternative to products that fall under federal and state restrictions. Evaluating the potential impact of legal actions related to e-cigarettes will provide important information to the public health community. Thus, this study sought to examine Puff Bar-related discussions on Twitter to identify themes related to tobacco policy as well as unanticipated outcomes of legal and regulatory loopholes, such as effects from continued use of flavored, high nicotine concentration salt formulations, for use in future research.

Figure 2. Puff Bar advertisement during global pandemic.

Methods

Sample Selection

We used the Real-time Inveillance of Twitter Health Messages software framework to collect Twitter posts (ie, tweets) containing the terms “puffbar” or “puff bar” for 1 month from July 13, 2020, to August 13, 2020 [28]. The Real-time Inveillance of Twitter Health Messages allows for real time collection of all publicly available tweets matching a specified set of keywords through Twitter’s filtered data stream application programming interface. This start date aligned with the date Puff Bar announced ceasing online sales in the United States [9]. This resulted in 13,304 tweets, of which 4785 (36%) were retweets and 8519 (64%) were original tweets.

We obtained a 20% random subsample of original tweets (n=2661) for human coding; this process has previously

demonstrated to be both feasible for human qualitative coding and generalizable to the full data set [28].

Ethical Approval

The University of Pittsburgh Institutional Review Board (IRB) determined that the proposed activity is not research involving human subjects as defined by DHHS and FDA regulations (STUDY19080214).

Codebook Development

We developed a codebook based on a hybrid process that included consideration of our research question, prior analysis of e-cigarette discourse on Twitter [14,29], tobacco policy, and an inductive analysis of 100 relevant tweets that were not included in the final sample. First, we included a code for relevance to the research topic of Puff Bar-related discussions (relevant). Tweets that did not contain the disposable e-cigarette Puff Bar as the main topic (eg, “I go to my car to get my puff

bar and somebody left me a rose on my car. I can't stop smiling!") were deemed not relevant.

Relevant tweets were coded for topics informed by 2 areas of research, which were nicotine dependence and tobacco policy. Topics for nicotine dependence included language that suggests dependence on Puff Bar and signs of nicotine addiction or withdrawal related to Puff Bar use. These categories were informed by prior research that examined similar content posted about JUUL [14]. Topics for tobacco policy included whether

posted content were commercially marketing Puff Bar or a business selling Puff Bar, references to purchasing a Puff Bar, references to underage use of Puff Bar, regulations of Puff Bar, price of Puff Bar, references to Puff Bar flavor, and references to other e-cigarette products. The codebook was validated through analysis of 100 relevant tweets that were not included in the final sample by 2 experienced Twitter coders. Following this, the final codebook was codified, presenting clear definitions and examples for each code (Table 1).

Table 1. Definitions for categorical codes and example tweets. Examples are paraphrased.

Code and subcode	Definition	Examples
Tobacco policy	Puff Bar in relationship to laws or regulations that could affect use of Puff Bar	
Commercial	Marketing for Puff Bar or shops selling Puff Bar	<ul style="list-style-type: none"> Check out what our customers are saying about Puff Bar Disposable Pod device!
Black market	Reference to illegal purchase of a Puff Bar or buying a knockoff	<ul style="list-style-type: none"> Yo the puff bar black market is wild I hope the govt knows they created both the fake puff bar prob & the fake the oil problems all by themselves
Buying	Concretely obtaining or trying to obtain Puff Bar	<ul style="list-style-type: none"> Can I get a puffbar on Instacart? Got a free puff bar at the gas station :)
Underage use	Underage use (ie, under 21) of Puff Bar	<ul style="list-style-type: none"> I wish I could explain to you guys how flabbergasted I am to have just met a 5 year old child 2/ a puff bar...he talked about disposable vapes for 5 minutes & rated various flavors This little boy really asked if I could buy him a puff bar and when I did, he went goat and then says I can't get it anymore I'm sorry
Regulations	Regulations on Puff Bar (cannot buy, cannot access, etc)	<ul style="list-style-type: none"> Why do I gotta be 21 to buy myself a puff bar FDA calls for removal of fruity and disposable Puff Bar vapes devices
Price	Price of a Puff Bar	<ul style="list-style-type: none"> Anyways does anyone wanna paypal me 16 dollar so I can buy a fucking puff bar Maaan I shouldn't have hit ur puff bar bc now my ass is spending \$15-20 every other week on nic
Flavors	Flavors of Puff Bar	<ul style="list-style-type: none"> Strawberry banana puff bar is just vaping a gogurt Peach ice and lychee seemed to be the favorite/most popular flavors
Other products	Other vaping products, including Puff XXL or JUUL	<ul style="list-style-type: none"> Checkout the newest Puff XXL 1600 disposable device Why did nobody tell me that air bars get me more puffs than a puff bar plus they r cheaper
References to COVID-19	Use of Puff Bar during the pandemic	<ul style="list-style-type: none"> I hate when my puff bar starts spitting at me. C'mon bitch were in a pandemic!
Dependence	Puff Bar in association with words that specify dependence on Puff Bar	
Puff bar as a meal	Puff Bar as a meal or in place of food, using terms such as meal, breakfast, lunch, or dinner	<ul style="list-style-type: none"> My power meal today: one puff bar plus an energy drink Had a whole lychee puff bar as all of my meals today. I'm thriving babeey
Losing access	Not being able to use Puff Bar to an external factor such as losing it or the battery dying	<ul style="list-style-type: none"> On 4 hour drive and my puff bar completely died I lost my puff bar for an hour and found it in my bra. Whoops
Self-report	Self-report of being addicted or dependent on Puff Bar	<ul style="list-style-type: none"> Just tried a puff bar and I'm definitely addicted Bought myself a puff bar. Time to bring back my nicotine addiction
Does not last	Using up Puff Bar quickly	<ul style="list-style-type: none"> I've never been able to make a puff bar last more than 48 hours Another day. Time for another puff bar
Acute nicotine effects	Puff Bar in association with words that specify acute nicotine effects	<ul style="list-style-type: none"> My puff bar got me buzzing like a bee That puffbar feeling - lightheadedness
Quitting or withdrawal	Quitting Puff Bar or experiencing signs of nicotine withdrawal from lack of Puff Bar	<ul style="list-style-type: none"> I have a problem, so after this puff bar runs out, I'm NOT buying another one Only positive of being at my parents house is that i finally quit my puffbar quarantine habit

Coding Procedures

The tweets were coded by 2 independent individuals, with adjudication of disagreements by a supervising researcher. The coders were provided with the tweet text and a URL link to each tweet. During the coding process, all relevant tweets that were publicly available at the time of coding were viewed on Twitter so that visuals in the tweet (eg, images, videos, and emoji) could also be assessed. The text from unavailable tweets was still included in the coding and thematic analysis to preserve comprehensiveness of the original data. The codes were not mutually exclusive.

We calculated interrater reliability using the Cohen κ , and disagreements were adjudicated between the 2 coders. In instances where the coders could not reach consensus, the lead author had final determination. After 4 rounds of independent double coding (100 tweets each round), interrater reliability was considered good to excellent (Cohen κ =0.71-1.00) for all categories [30]. The remaining tweets were split between the 2 coders for independent coding.

Analysis

We calculated descriptive statistics for each coding category and used a thematic content analysis approach to analyze qualitative data [31]. To conduct the content analysis, the coders wrote annotations and memos throughout the coding process and highlighted specific words or phrases within tweets that exemplified the themes. The coders then met with supervising researchers to synthesize themes with salient examples from the observed data.

This study was approved by the University of Pittsburgh Institutional Review Board. To protect tweeters from identification, all examples provided in the text and tables are paraphrased versions of original tweets.

Results

Of the random sample of tweets ($n=2661$), 80.2% ($n=2123$) were coded as relevant to the research question. Of these relevant tweets, 698 (32.9%) tweets discussed topics relevant to tobacco policy (Table 2). In table 2, the percentages for subcodes are presented as the percent of tweets within total tweets for that code.

Table 2. Frequencies of coding categories for relevant tweets ($n=2123$). Categories are not mutually exclusive; therefore, proportions will not always add up to 100%.

Code and subcode	Frequency, n (%)
Tobacco policy	698 (32.9)
Flavors	320 (45.9)
Regulations	124 (17.8)
Buying	117 (16.8)
Other products	110 (15.8)
Black market	31 (4.4)
Price	36 (5.2)
Underage use	24 (3.4)
Commercial	20 (2.9)
Dependence	480 (22.6)
Losing access	273 (56.9)
Self-report	110 (22.9)
Puff bar as a meal	59 (12.3)
Does not last	47 (9.8)
Quitting or withdrawal	52 (2.4)
Acute nicotine effects	50 (2.4)
References to COVID-19	11 (0.5)

The most frequent themes relevant to tobacco policy were references to Puff Bar flavors ($n=320$, 45.9%; eg, “I bought a peach ice puff bar and it is so yummy”). There was a similar prevalence of references to buying Puff Bar ($n=117$, 16.8%; eg, “setting my alarm to go the puff bar store tomorrow morning”) and other products ($n=110$, 15.8%; eg, “a puff bar only lasts me a day so switched to viva. Last 3+ days”).

Approximately 22% ($n=480$) of the tweets referenced dependence in the context of Puff Bar. A majority of these tweets referenced losing access to Puff Bar ($n=273$, 56.9%; eg, “on a long drive and my puff bar died. Send help. Im so upset”). Another theme was users tweeting about their Puff Bar lasting less than 48 hours due to frequent use ($n=47$, 9.8%; eg, “I wonder why I can’t breathe yet I go through a puff bar in 2 days”). Additionally, approximately a quarter ($n=110$, 22.9%)

of tweets referencing dependence involved the user self-reporting dependence on Puff Bar (eg, “I need a puff bar so bad, but I will stay strong. I want to get rid of this mf addiction”).

Users also reported acute nicotine effects, such as feeling a buzz or high when using Puff Bar ($n=50$, 2.4%; eg, “this puff bar lightheadedness feels so good”). Users reported other symptoms related to nicotine, such as headaches (eg, “is my headache a sign of coronavirus or my puff bar addiction?”) and upset stomach (eg, “I hit my puff bar until my stomach hurts everyday haha”).

Discussion

Principal Findings

This study examined Puff Bar-related discussions on Twitter to identify themes related to tobacco policy and dependence. Despite federal regulations and FDA warnings against Puff Bar, the results of this study suggest that the purchasing and use of Puff Bar products are still being discussed on social media. Discussions of Puff Bar flavors were prevalent, accounting for a plurality (45.9%) of tweets classified as relevant to tobacco policy; these products are circumventing a federal ban designed to protect youth from the appeal of nicotine products. Similarly, the second most common theme was focused on regulations ($n=124$, 17.8%). As a result, the outcome of the FDA ban of e-cigarette flavors did not reduce demand, but rather shifted more attention to different e-cigarette brands that utilize a loophole for disposable devices.

We found similar dependence and acute nicotine effect themes as prior research on JUUL products and cigarettes, such as self-report of dependence, frustration over losing access to the device, compulsive use, and self-reports of physical effects of nicotine exposure including suppression of appetite [14,32]. Again, this suggests that despite legislative and policy activities to reduce youth access to and use of flavored, high nicotine-containing and dependence-forming products, they continued to be available due to exploitation of loopholes. The fact that high school students’ use of disposable e-cigarettes such as Puff Bar increased by 1000% from 2019 to 2020 is evidence that these loopholes can contribute to continued use of e-cigarettes by youth.

Due to new federal tobacco policies, discussions about Puff Bar offer a view into topics relevant to tobacco policy including e-cigarette regulations and how they might affect access to Puff Bar (17.9%) and buying Puff Bar (16.8%). The results suggest that while the legality of Puff Bar sales might be recognized and discussed by Twitter users, people continue to purchase them even though the products are banned in the United States. This is especially alarming considering that commercial content (ie, posts by retailers) were very low (2.9% of tobacco policy tweets, 0.9% of all relevant tweets) when compared with other e-cigarette research [33,34].

The results of this study align with data from the NYTS that demonstrate a shift to disposable e-cigarettes following FDA tobacco policies. While the federal flavor ban was enacted to curb youth e-cigarette use, it is unfortunate that exemptions

created loopholes to allow continued access to flavored products. While outside the scope of this study, future research should consider identifying what types of accounts are posting this content. Specifically, understanding whether commercial tweets are being posted by Puff Bar users, commercial vendors, news organizations, or others could help to better inform counter messaging or preventive measures. Additionally, it would be valuable for researchers to be guided by a framework that can address both legal and health concerns. For example, legal epidemiology, the scientific study and deployment of law as a factor in the cause, distribution, and prevention of disease and injury in a population, might inform stronger and more comprehensive policies [35]. Legal epidemiology involves the three following components: (1) legal prevention and control—the study and application of laws and legal practices as interventions to prevent disease and injury and as enablers of effective public health administration; (2) legal etiology—the study of laws and legal practices as causes of disease and injury; and (3) policy surveillance—the ongoing, systematic collection, analysis, and dissemination of information about laws and other policies of importance to health [36]. In combination with continued real time inveillance of e-cigarette discussions, this framework could help better understand how tobacco policy (eg, age or flavor restrictions) and implementation can affect health outcomes.

Puff Bar acknowledged that their products were excluded from the FDA regulation banning most flavors. On February 21, 2020, Puff Bar posted on their official blog a lament about federal regulations “determined to eliminate vaping as a whole” stating that “disposable devices like Puff Bars and e-liquid used in refillable tank systems can still carry flavors like fruits and desserts” [37]. These, and other similar arguments, have been used by JUUL in order to continue promoting their products, particularly through advertisements targeted to adolescents [38]. Puff Bars—which have now resumed sales—have become the latest device to replace previously banned tobacco products. Until we are able to develop comprehensive tobacco policy, new products that capitalize on policy loopholes will continue to supply the demand for nicotine, particularly by adolescents through targeted advertisements or flavored products. We suggest that a framework such as legal epidemiology could offer a unique lens to understand the confluence of tobacco policy and health outcomes, helping inform policy makers to better understand and strengthen the practical implications of tobacco policies.

Limitations

The results of this study should be considered in the context of the following limitations. Twitter users are not representative of the general population, although it is frequently used by adolescents and young adults [27], a population that also frequently uses e-cigarettes. While interpretation of tweets using qualitative analysis can be subjective, we minimized subjectivity by using a systematic coding procedure and the use of experienced Twitter coders; nonetheless, these tweets are discussion of purchasing, rather than the act itself. We also did not use location data; thus, there is the possibility that some tweets are by non-US users. Finally, our results are constrained by the keywords and time period used in our search parameters.

Future research could expand these parameters to widen the scope of the investigation.

Contribution to Literature

Here, we summarize the key findings of our research: (1) laws and regulations around e-cigarettes are rapidly changing in response to increased concern about the use of the products by youth, and prior research suggests the focus of flavor bans on devices such as JUUL may have created a policy loophole that was filled by disposable devices such as Puff Bar; (2) however, it is not yet known how Puff Bar is being used as an alternative to traditional e-cigarettes that fall under federal and state restrictions; (3) our analysis of tweets related to Puff Bar suggests that the FDA ban of e-cigarette flavors did not reduce interest, but rather shifted the discussion to brands utilizing a loophole for disposable devices and suggests the importance of

using a framework such as legal epidemiology when researching and evaluating tobacco policy.

Conclusion

This study found similar dependence and acute nicotine effect themes in Puff Bar-related discussions on Twitter compared to prior research on JUUL and cigarettes [14]. We also found that discussions about Puff Bar on Twitter provided insight into topics relevant to tobacco policy, including flavors, e-cigarette regulations, and purchasing Puff Bar. Our results, in conjunction with evidence by the NYTS and other data sources, suggest that the FDA ban of e-cigarette flavors did not reduce demand, but rather shifted the supply to brands utilizing a loophole for disposable devices. Until comprehensive tobacco policy legislation is developed, new products or loopholes will continue to supply nicotine demand.

Acknowledgments

We would like to thank Erica Barret for coding of tweets and Michelle Woods for editorial assistance. This work is supported by grant R01CA225773 from the National Cancer Institute. Technical infrastructure was supported through National Science Foundation award numbers ACI-1548562 and 1445606, at the Pittsburgh Supercomputing Center. The funding agencies had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; or decision to submit the manuscript for publication.

Abstract

Background: TikTok is a microvideo social media platform currently experiencing rapid growth and with 60% of its monthly users between the ages of 16 and 24 years. Increased exposure to e-cigarette content on social media may influence patterns of use, including the risk of overconsumption and possible nicotine poisoning, when users engage in trending challenges online. However, there is limited research assessing the characteristics of nicotine poisoning–related content posted on social media.

Objective: We aimed to assess the characteristics of content on TikTok that is associated with a popular nicotine poisoning–related hashtag.

Methods: We collected TikTok posts associated with the hashtag #nicsick, using a Python programming package (Selenium) and used an inductive coding approach to analyze video content and characteristics of interest. Videos were manually annotated to generate a codebook of the nicotine sickness–related themes. Statistical analysis was used to compare user engagement characteristics and video length in content with and without active nicotine sickness TikTok topics.

Results: A total of 132 TikTok videos associated with the hashtag #nicsick were manually coded, with 52.3% (69/132) identified as discussing firsthand and secondhand reports of suspected nicotine poisoning symptoms and experiences. More than one-third of nicotine poisoning–related content (26/69, 37.68%) portrayed active vaping by users, which included content with vaping behavior such as vaping tricks and overconsumption, and 43% (30/69) of recorded users self-reported experiencing nicotine sickness, poisoning, or adverse events such as vomiting following nicotine consumption. The average follower count of users posting content related to nicotine sickness was significantly higher than that for users posting content unrelated to nicotine sickness ($W=2350.5$, $P=.03$).

Conclusions: TikTok users openly discuss experiences, both firsthand and secondhand, with nicotine adverse events via the #nicsick hashtag including reports of overconsumption resulting in sickness. These study results suggest that there is a need to assess the utility of digital surveillance on emerging social media platforms for vaping adverse events, particularly on sites popular among youth and young adults. As vaping product use–patterns continue to evolve, digital adverse event detection likely represents an important tool to supplement traditional methods of public health surveillance (such as poison control center prevalence numbers).

Introduction

TikTok is a social media platform that has gained millions of followers and now has brand recognition comparable to that of other well-known social media platforms, such as Facebook, YouTube, and Twitter [1]. TikTok users post, share, and rank microvideos or short clips (between 15 seconds to 3 minutes in duration), with the potential for their content to go viral depending on the level of user interactions, shares, hashtags, and subject matter [2]. In 2021, TikTok reported 1.2 billion monthly active users, and 1.5 billion monthly active users are projected for the end of 2022 [1,3]. It was one of the fastest growing social media platforms, with over 2 billion total downloads since its launch [3]. Approximately 60% of monthly TikTok users in the United States are between the ages of 16 and 24 years [4]—a demographic that is at risk for tobacco initiation and uptake [5]. Additionally, the platform has also been identified as a source of pro-tobacco and tobacco product sentiment [6,7].

Uptake of electronic nicotine delivery systems, as well as patterns of use, can be impacted by social interactions that occur in digital environments as a result of exposure to marketing content, influencers, and other pro-nicotine product sentiment shared by users [8,9]. Increased social media use among adolescents can lead to increased willingness and intention to use e-cigarettes, with reported positive and normative perceptions [10]. Concurrent with the rise in popularity and high rate of adoption among youth and young adults on emerging social media platforms such as TikTok, the increased popularity and use of electronic nicotine delivery systems has given rise to a vaping epidemic [11,12]. For example, from 2016 to 2018, there was a 2.9% increase in smoking prevalence among young adults aged 18 to 24 years in the United States, and more than one-quarter of 10th graders reported having used an electronic nicotine delivery system product [13]. Due to this appeal, vape manufacturers and web-based sellers reportedly use TikTok influencers and direct marketing and selling of electronic nicotine delivery system products on the platform, although public health and tobacco control advocates have also attempted to use TikTok for health promotions warning about the risks of vaping [14].

One of the consequences of increased use of electronic nicotine delivery systems has been the rise in nicotine-related adverse events and poisoning, which was highlighted by the 2019 outbreak of lung injury associated with use of e-cigarette or vaping products that led to 2807 hospitalizations or deaths in the United States [15]. Nicotine poisoning refers to the toxic effects of nicotine consumption that are beyond an individuals' tolerance. Poisoning causes nonspecific symptoms such as nausea, vomiting, tremors, and increased heart rate in early phases and severe symptoms such as shock, low blood pressure, and even paralysis in later phases [16]. Complicating this public safety risk, nicotine poisoning and other electronic nicotine delivery systems adverse events have increased [17,18], partially

due to the introduction of new nicotine products, some of which still require market authorization by regulatory agencies [17]. Most nicotine poisoning research and product surveillance is based on data from government consumer safety organizations (eg, US National Electronic Injury Surveillance System) or poison control centers [19], with only a few studies [20] using social media surveillance to detect adverse events. *Nic sick* is a term that has been used to refer to these adverse effects by users on various social media platforms who post content related to nicotine sickness [21] and can be used as a keyword to curate user-generated self-reporting about nicotine sickness topics and lived experiences.

While TikTok is a platform that can promote and share beneficial health-related content and possibly mobilize public health campaigns [22-24], it can also spread harmful information [25], including content that promotes the use and overuse of electronic nicotine delivery systems to its large audience of youth and young adults [18,26,27]. For example, recent published studies [28,29] that examined health information videos on TikTok observed that the overall quality of health information can vary based on the source of content and that users should be selective and cautious when viewing such content. Additionally, the findings of systematic thematic analysis in 2021 [7] showed that a majority of electronic nicotine delivery system-related TikTok videos portrayed electronic nicotine delivery system-use positively. Another study [30] found that disposable electronic nicotine delivery system product content was popular among TikTok users. Therefore, due to the growing popularity of electronic nicotine delivery system content on the platform, in addition to the high burden of nicotine consumption and risk of nicotine adverse events among TikTok youth and young adults [31], we aimed to expand on prior research by examining the specific characteristics of nicotine poisoning-related TikTok content.

Methods**Ethics**

All information used in this study was posted publicly, and the study did not involve any interaction with users. User identifiable information was removed.

Data Collection

The hashtag #nicsick was originally selected for review based on news and media reports on the popularity of the term for users' self-reporting experiences and topics associated with nicotine sickness [21]. The selection of #nicsick as the hashtag for data collection was confirmed by conducting preliminary manual searches with the TikTok in-platform search function for keywords, terms, and hashtags that were used in videos discussing nicotine sickness content. In addition, we conducted preliminary Google Trends search terms analysis to assess if there were any queries or topics related to the *nic sick* terminology set for the study period, which did not reveal any

specific terms for further keyword or hashtag data filtering. TikTok videos with the hashtag #nicsick were collected retrospectively in May 2021 by first using structured searches on the platform without any user log-in credentials, with no personal search history and with cookies disabled. The URLs and metadata (eg, date, time, username, favorites) associated with retrieved TikTok videos using the hashtag #nicsick were collected and saved using an algorithm (Python, version 3.7.0) and an automated web browser and automation tool (Selenium, version 3.141.0; SeleniumHQ). In addition, the videos were also downloaded and saved for content analysis.

Data Analysis

Content analysis of TikTok videos collected was conducted by VP, TM, and MN. The videos were manually annotated (using binary classification—whether the video depicted nicotine poisoning or nicotine sickness or not) and then inductively coded for specific themes that emerged, such as showing active vaping, specific adverse events, or nicotine sickness experiences (Table 1). Furthermore, based on prior research studies [7,32,33] that have conducted content analysis on TikTok videos, we also coded the following metrics and associated metadata: (1) user engagement (views, likes, comments, shares, followers, verification); (2) video characteristics (duration, caption, text

on screen, subtitles, music); and (3) video type (original, duet, stitch). An *original* video is a microvideo uploaded by a TikTok user and is the primary source of user-generated posts on the platform. A *stitch* integrates the user's own video into another user's original video by clipping and integrating scenes from the original video which allows the sharing of existing videos in combination with new user-generated content. A *duet* video builds on another user's original video, with a new video recorded alongside the original as it plays and is mainly used for user reaction videos. VP, TM, and MN coded posts independently and achieved high intercoder reliability ($\kappa=0.96$). For inconsistent results, senior author TKM was consulted.

After open inductive coding based on our coding schema, videos with nicotine poisoning content were grouped into main thematic categories: (1) firsthand and secondhand reporting of suspected nicotine sickness symptoms (eg, nausea, headache, cough, stomachache, and regurgitation); (2) videos displaying actual poisoning-related adverse events; and (3) videos displaying active vaping while discussing nicotine sickness-related content. The 2-tailed independent sample *t* test and Wilcoxon rank-sum test were used to compare the engagement metrics of videos with and without active nicotine sickness-related content. All statistical analyses were conducted using RStudio (version 3.6.1). A *P* value<.05 was considered statistically significant.

Table 1. Coding scheme for videos.

Theme and subtheme	Coding scheme
Nicotine sickness symptom reporting (firsthand or secondhand)	
Yes	<ul style="list-style-type: none"> Videos of users discussing specific symptoms related to nicotine sickness, such as vomiting, nausea, burning sensation in throat, headache, and fatigue, during or after nicotine use Users discussing nicotine sickness symptoms of self or friends, family, and neighbors Users discussing clinic/hospital/emergency room visits for alleged nicotine sickness symptoms Videos of users seeking suggestions to overcome nicotine sickness symptoms
No	<ul style="list-style-type: none"> Posting videos on news posts related to nicotine sickness Videos on nicotine sickness symptoms by users or public health organizations to create awareness about nicotine sickness Videos unrelated to nicotine sickness using the hashtag #nicsick Videos with jokes or sarcasm about nicotine sickness
Displaying poisoning-related adverse events	<ul style="list-style-type: none"> Videos with users displaying symptoms related to nicotine sickness or poisoning
Actively vaping	<ul style="list-style-type: none"> Users actively vaping while discussing nicotine sickness-related content in the video

Results

A total of 134 TikTok videos with #nicsick were collected, but 2 videos were inaccessible due to user privacy settings and were excluded from analysis. After manual annotation, we confirmed that 52.3% (69/132) of videos included content discussing nicotine sickness, poisoning, or adverse event symptoms, of which 52 were original videos, 16 were stitches, and 1 was a duet. Of these 69 videos, 36.23% (n=25) were posted in the year 2020 and 63.77% (n=44) in 2021; and the earliest was posted on January 12, 2020, and the latest was posted on May 24, 2021. The videos that were unrelated to nicotine sickness—reporting primarily depicted content related to vaping

behavior and other topics, but nevertheless, included the hashtag #nicsick.

Videos with content related to nicotine sickness discussed specific symptoms, such as vomiting, nausea, burning sensation in throat, headache, and fatigue, during or after nicotine use. Apart from posting videos with content on nicotine sickness experiences, users also asked for suggestions on how to overcome nicotine sickness symptoms from other TikTok users who may have previously experienced similar adverse effects following nicotine consumption. More than one-third of the videos with nicotine poisoning content (26/69, 37.68%) portrayed active vaping (including extreme vaping behavior such as vaping tricks, nicotine overconsumption, attempts at performing vaping challenges) and 43.5% (30/69) recorded

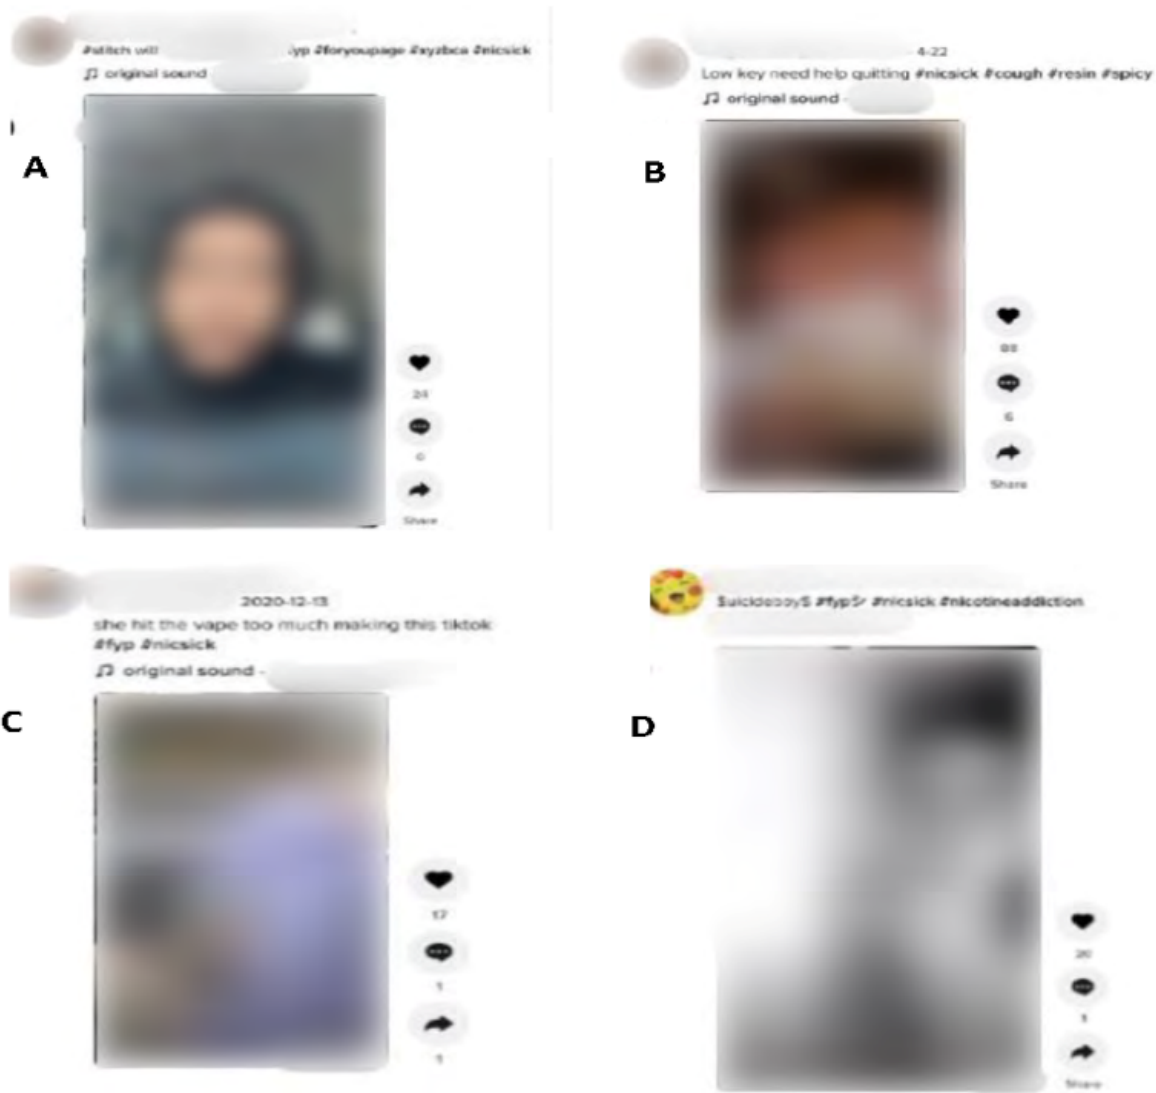

users experiencing nicotine sickness, poisoning, or adverse events, such as vomiting after nicotine consumption. While the first category of videos with only mentioned users experiencing various adverse effects during or after nicotine consumption,

the second category of videos recorded the adverse effects, such as vomiting, nasal discharge, vigorous coughing, directly in the video (Table 2; Figure 1).

Table 2. Descriptions of #nicsick examples (deidentified).

Theme	Definition	Example
Firsthand (self) and secondhand reporting of nicotine sickness symptoms.	A user reporting one or more suspected nicotine sickness symptoms (nausea, cough, regurgitation, etc) currently or in the past.	Figure 1A is a screenshot of a TikTok video in which the user describes their own experience with nicotine sickness
Users displaying adverse events related to nicotine poisoning.	A user exhibiting one or more adverse events (regurgitation, cough, etc) related to nicotine poisoning.	Figure 1B and Figure 1C is a screenshot of a TikTok video in which the user describes their own experience with nicotine sickness Figure 1B shows a user experiencing nasal discharge. Figure 1C shows user vomiting on the side of the road after making a TikTok.
Users actively vaping	A user actively vaping on video.	Figure 1D is a screenshot of a TikTok video in which the user is seen actively vaping using an electronic nicotine delivery systems device.

Figure 1. TikTok video screenshots with signal for nicotine sickness (“nicsick”; user information concealed and images blurred).

A total of 67 TikTok users posted the 69 videos with nicotine sickness content, of which 66 users were unique, while only 1 user (with a follower count of 2487) posted 3 videos, with 2 of them discussing adverse events after nicotine consumption. The

63 videos with content unrelated to nicotine sickness were posted by 60 users, of which 57 user IDs were unique, while 3 users posted 2 videos each. Upon comparing the user IDs, we

found that 3 users had posted signal and nonsignal videos using the hashtag #nicsick.

Videos with nicotine sickness content had 4415 mean views, 548 mean likes, 4 mean shares, 16 mean comments, and a mean user follower count of 19,485, and videos unrelated to nicotine sickness had 52,117 mean views, 1958 mean likes, 31 mean shares, 30 mean comments, and a mean user follower count of 8669. The follower count of users posting content related to nicotine sickness was significantly higher ($W=2350.5$; $P=.03$) than that of users posting content unrelated to nicotine sickness. The mean differences for views ($W=1688.5$; $P=.45$), likes ($W=1780$; $P=.56$), shares ($W=1733$; $P=.36$), and comments ($W=1811.5$; $P=.66$) between videos with nicotine sickness content and those without were not statistically significant.

The mean duration of videos with nicotine sickness content was 23.68 seconds (range 4–62 seconds) and the mean duration of videos displaying active vaping (12.23 seconds) was significantly shorter ($P<.001$) than that of videos without active vaping (30.60 seconds). However, videos displaying nicotine sickness symptoms were longer in duration (28.57 seconds) than those not displaying nicotine sickness symptoms (19.92 seconds), albeit the comparison did not meet the threshold set for statistical significance ($P=.08$).

Users who posted first- or secondhand experiences with nicotine poisoning often did not explicitly or implicitly discourage others from engaging in harmful vaping behaviors such as overconsumption. Instead, users posting with the hashtag #nicsick appeared to actively participate in trending vape tricks or challenges. Some of the phrases heard in TikTok videos included “nic-sick check” and “where’s my JUUL” while users intentionally engaged in vaping behavior to generate TikTok trends (ie, how TikTok uses a hashtag or a song to group together viral trends within the app).

Discussion

Principal Findings

We found that TikTok users openly discussed their experiences, both firsthand and secondhand, with nicotine poisoning and related adverse events via the #nicsick hashtag. This includes users promoting extreme vaping behavior, discussion of users’ direct experiences with adverse events, and explicit video documentation of adverse events that appear to elicit user attention and reaction. We also found that users were more likely to create original videos as opposed to stitches and duets, which allow users to imbed and combine existing videos into their own TikTok post, which can often result in higher user engagement [34]. User engagement metrics of the videos in our study indicated moderate and lower compared to general metrics for popular TikTok videos, although some popular creators have had higher levels of engagement and mean follower counts. Additionally, the duration of videos depicting adverse events or nicotine poisoning symptoms was marginally longer than those that did not, indicating that videos depicting adverse events may need to be longer in order to provide sufficient details on the reported nicotine sickness experiences versus videos that simply reported or portrayed general vaping behavior.

These emerging forms of microvideo-based social interactions have the potential to change ways in which susceptible youth and young adults receive vaping-related behavior cues. For example, phrases heard in TikTok videos in this study included “nic-sick check” and “where’s my JUUL” and were associated with intentional overconsumption of nicotine products that also appeared to increase user engagement. TikTok’s *For You Page* also personalizes content based on user viewing history and can lead to a continuous cycle of exposure to trending vaping videos, including those in this study that portrayed overconsumption. Characteristics of TikTok videos, including use of hashtags, trending sounds, and video duration, may also represent crucial opportunities for the introduction of targeted health education and promotion to warn young users about the documented harms of vaping, particularly if they are already experiencing and self-reporting adverse events [35].

Yet, it is important to note that the impact of these videos on actual knowledge, attitudes, and behaviors of social media users associated with the appeal, uptake, and use of electronic nicotine delivery systems remains unclear. Vaping themes detected in this study seem to demonstrate that users may be promoting harmful vaping practices, which in turn has the potential to encourage overconsumption or dangerous nicotine use behavior. For example, popular internet challenges, including vape challenges, are rapidly circulated through TikTok—some may greatly harm the health of participants or encourage others to engage in similar behavior [25]. However, the motivations of these users to post #nicsick videos and the reason why they may or may not become viral require further study, particularly in the context of how the risk of electronic nicotine delivery system–related adverse events may be increased. We also found that there was no clear indication that users experiencing nicotine sickness were committed to quitting despite their sickness or poisoning, although a few user videos included individuals expressing a desire to quit. Instead, users using #nicsick appeared to be actively participating in trending vape tricks or challenges, which then led to overconsumption followed by one or more adverse events, which they then posted.

Combating the youth vaping epidemic requires scrutiny of how new interactive media, such as TikTok, serves as a source of vaping-related information and a source of peer influence among young user communities. Traditional poisoning and adverse event surveillance systems, such as the National Poison Data System and the US National Electronic Injury Surveillance System, may fail to capture these less severe cases captured on social media platforms, thereby underrepresenting the morbidity burden of nicotine poisoning [19]. Hence, social media platforms such as TikTok, may represent an important data source that can be used to help identify the burden of user-reported nicotine exposure and poisoning.

Our study narrowly focused on identifying and characterizing how nicotine poisoning–related content is created and shared through TikTok’s microvideo posts. Future studies should focus on examining the complex interplay between user exposure and the appeal of TikTok pro–tobacco and vaping content, the dynamics of how this content is shared and propagated on these networks, how it impacts real-world use patterns and vaping behavior, and finally, how these factors may impact safety and

health issues, such as adverse events. Though TikTok's policies state that content which offers the purchase, sale, trade, or solicitation of tobacco products (including vaping products) is prohibited [36]. Our study results indicate that content related to excessive or potentially dangerous smoking or vaping behavior does not fit this criterion, although the utility of removing such content is also unclear.

Limitations

We used a single platform and a fixed data collection period. Hence, the results may not be representative of all nicotine sickness content on social media. While TikTok is a popular social media platform, the demographics of TikTok users may not reflect those of the general population of electronic nicotine delivery system users. Furthermore, study data were limited to results for videos queried and returned by TikTok's internal search function, which may further limit generalizability. We used a single hashtag, #nicsick, based on a combination of open-source news reports, manual searches, and a preliminary Google Trends analysis to justify inclusion and due to the narrow focus of the study on nicotine sickness-related content. Hence, this study might have missed capturing additional nicotine sickness content with other hashtags that may have focused on specific electronic nicotine delivery system products, vaping behavior and challenges, and other nicotine and vaping-related topics with content related to nicotine sickness or adverse events. Furthermore, we did not cross-validate user-generated content with other data sources of nicotine sickness reports or cases, such as data from poison control

centers, and we did not explore user interaction or social network characteristics of web-based user networks where videos with nicotine poisoning content was shared, viewed, or interacted with, via favorites or comments, in-depth. Future studies should conduct more comprehensive and large-scale data analysis of nicotine-related adverse events on TikTok compared with those on other social media platforms. Future research can explore further analysis of characteristics of videos including hashtags, trending sounds, and video duration, which may help curate targeted health education and promotion against vaping use.

Conclusion

While we observed discussions and experiences with nicotine poisoning and adverse events on TikTok, further research is needed to assess how this unique social media risk environment impacts user perceptions about the known harms of vaping and which health promotion strategies can be tailored for youth experiencing vaping-related adverse events. Although other electronic nicotine delivery system-promoting content on TikTok may influence tobacco use behavior, #nicsick-specific content represents user-generated experiences directly associated with adverse events or poisoning due to nicotine overconsumption, which could be an alternative form of surveillance to better characterize this likely underreported public health issue. Supplementing traditional surveillance methods with infodemiology and infoveillance approaches can help in capturing the nicotine sickness cases that are not reported to poison control centers and assess the growing health burden due to nicotine use more appropriately.

Acknowledgments

This study was funded by the University of California Tobacco-related Disease Research Program (T29IP0465 and T29IP0384). We thank Cortni Bardier for her useful discussion, input, and assistance during the project.

Data Availability

Raw data supporting the conclusions of this paper will be made available by the authors, without undue reservation.

Authors' Contributions

ZL collected data. VP, TM, and MN conducted data analyses. All authors contributed to the design, formulation, drafting, completion, and approval of the final manuscript.

Conflicts of Interest

TKM serves as editor in chief for JMIR Infodemiology. ZL, MN, and TKM are employees of the startup company S-3 Research LLC. Abstract

Background: A critical unmet need for underserved patients with diabetes is regular access to sufficient support for diabetes self-management. Although advances in digital technologies have made way for eHealth applications that provide a scalable path for tailored interventions for self-management of chronic conditions, health and digital literacy has remained an obstacle to leveraging these technologies for effective diabetes self-management education. Studies have shown that the availability of coaches helps to maintain engagement in internet-based studies and improves self-efficacy for behavior change. However, little is known about the substances involved in these interactions.

Objective: This study aims to compare the content of conversations between patient-coach pairs that achieved their self-management goals and those that did not. The context is a clinical implementation study of diabetes self-management behavior change using Health360x within the practices of the Morehouse Choice Accountable Care Organization in the Atlanta metro area. Health360x is a coach-assisted consumer health information technology designed to support self-management skills acquisition and behavior among underserved, high-risk patients with diabetes.

Methods: We provide a novel analysis of the discursive emphasis on patients and coaches. We examined transcripts of visits using a structural topic model to estimate topic content and prevalence as a function of patient and coach characteristics. We compared topics between patient-coach pairs that achieved diabetes-related self-management goals and those who did not. We also estimated a regression in which utterances are the units, the dependent variable is the proportion of an utterance that is about a given topic, and the independent variables are speaker types and explored other themes.

Results: Transcripts from 50 patients who were recruited and consented, starting in February 2015, were analyzed. A total of 44 topics were estimated for patient-coach pairs that achieved their intended health goals and 50 topics for those who did not. Analysis of the structural topic model results indicated that coaches in patient-coach pairs that were able to achieve self-management goals provided more contextual feedback and probed into patients' experience with technology and trust in consumer information technologies. We also found that discussions around problem areas and stress, support ($\beta_{\text{Coach}}=.015$; $P<.001$), initial visits ($\beta_{\text{Coach}}=.02$; $P<.001$), problems with technology ($\beta_{\text{Coach}}=.01$; $P<.001$), health eating goals ($\beta_{\text{Coach}}=.01$; $P=.04$), diabetes knowledge

($\beta_{\text{Coach}}=.02$; $P<.001$), managing blood sugar ($\beta_{\text{Coach}}=.03$; $P<.001$), and using Health360x ($\beta_{\text{Coach}}=.003$; $P=.03$) were dominated by coaches.

Conclusions: Coach-facilitated, technology-based diabetes self-management education can help underserved patients with diabetes. Our use of topic modeling in this application sheds light on the actual dynamics in conversations between patients and coaches. Knowledge of the key elements for successful coach–patient interactions based on the analysis of transcripts could be applied to understanding everyday patient–provider encounters, given the recent paradigm shift around the use of telehealth.

KEYWORDS

self-management; structural topic modeling; coaching; diabetes; minority populations; mobile phone

Introduction

e-Patients are a relatively new breed of informed health consumers comprising 61% of all adults in the United States using technology to *equip, enable, empower, and engage* with relevant health-related information [1]. Despite increasing access to wireless and mobile technology among minority and vulnerable populations, there is still a higher trend in the adoption of digital health technologies among disproportionately advantaged groups, such as young, White males [1–3]. It is known and well-accepted in the disparities research community that health and digital literacy are barriers to the increased use of eHealth technologies among minority and vulnerable populations. These obstacles include lack of perceived value, technologies creating more work, materials not in appropriate reading levels to make informed health decisions, lack of cultural relevance (ie, accessing sources in their respective language), and privacy and trust concerns [4]. These barriers are a function of individual characteristics, including socioeconomic status, education, and less access to change agents, among other factors that are associated with higher rates of attrition in internet-based studies [5–7]. Higher rates of attrition are even more noticeable among minority and underserved populations, who are also disproportionately challenged by intervention factors, including usability problems, complexity, and ease of discontinuance [4]. The net result is a lack of diffusion of innovations among vulnerable populations and a worsening of disparities in health outcomes [8], that is, the uneven adoption of digital health innovations by minority and other vulnerable populations because of health and digital literacy exacerbates existing disparities in health.

An area where there is an agreement in the literature is that health and digital literacy are obstacles to the use of eHealth technologies for implementing tailored health interventions that support self-management of chronic conditions, particularly diabetes [7]. A typical example for diabetes is the challenge with the delivery of appropriate and effective diabetes self-management education (DSME) to vulnerable populations. Multiple studies have found that diabetes DSME is associated with improved diabetes knowledge and self-care behavior [9], improved clinical outcomes such as lower hemoglobin A_{1c} [10], lower self-reported weight [11,12], improved quality of life [13], healthy coping [13,14], and lower costs [15]. Diabetes education is associated with increased use of primary and preventive services and lower use of acute, inpatient hospital services [16], and patients who participate in DSME are more

likely to follow best practice treatment recommendations, particularly among the Medicare population. A critical issue and unmet need for underserved patients living with diabetes is the regular access to sufficient support for effective diabetes self-management. Better outcomes were reported for DSME interventions that were longer and included follow-up support, that were culturally appropriate and age appropriate, and that were tailored to the individual psychosocial needs and behavioral preferences [17,18].

Prior studies indicate that the availability of a trusted partner (coach) helps to improve user experience with health technology for DSME, including perceived relevance and ease of use [19], among vulnerable populations who face health and digital literacy barriers and higher rates of attrition. The support of a coach improves engagement with technology, and accountability improves adherence to and self-efficacy for behavior change [20]. In this patient–coach relationship, coaches are not intermediaries between patients and health information but serve as an apomediary, that is, a guide to relevant information and services for the patient [19]. Much has been theorized about what leads to successful patient–coach relationships; however, what is less understood is the content of patient–coach interactions.

In this paper, we aim to evaluate the discursive emphasis on patients and coaches engaged in DSME. To do so, we will leverage self-reported patient data and >100 hours of recorded transcripts from a clinical implementation study of Health360x, a coach-assisted consumer health information technology (CHIT) designed to support diabetes self-management skills acquisition and behavior for underserved, high-risk patients living with diabetes [19]. The platform is available as a web application and mobile app and includes functionality for improving health literacy and self-efficacy through access to a health coach, a social network of peers, a curriculum of DSME materials, and a health tracker that can record blood pressure, BMI, physical activity, and self-management goals.

In what follows, we provide some background on the study from which the data were generated. We then provide a novel analysis of the discursive emphasis on patients and coaches from transcripts of visits using a structural topic model (STM) to estimate topic content (ie, characteristic words in a topic) and prevalence (ie, proportion of an utterance that is related to a topic) as a function of patient and coach characteristics. We conclude with a discussion of our results, limitations, and

directions for future work on the use of coach-assisted CHIT for DSME.

Methods

Transdisciplinary Collaborative Center Project

Longitudinal data and transcripts of patient-coach interactions were taken from a clinical implementation study of Health360x, a coach-assisted CHIT designed to assist with chronic illness care through behavior change [19,21]. It is important to note that as an implementation study, there was no intervention or control arm as the goal of the study is not to make generalizations to a broader population [22]. The research design of the study focused almost exclusively on external validity. As such, countless hours were spent working with clinical practices through focus groups and plan-do-study-act cycles to ensure clinical readiness. The goal of the transdisciplinary collaborative center was to study the implementation across several clinics that are part of the Morehouse Choice Accountable Care Organization (MCACO).

Health360x was developed at the Morehouse School of Medicine and evaluated within the MCACO. MCACO is a physician-led integrated delivery model participating in the Medicare Shared Savings Program offered by the Centers for Medicare and Medicaid Services Innovation Center [23]. The MCACO partner practices care for a disproportionate share of high-need, complex populations and endure extraordinary challenges in managing the use, with comparatively limited resources. The Health360x implementation at MCACO was nested within the MCACO's Centralized Care Coordination model. This synergistic approach represents a *health system* where an African American majority patient population spends time and receives primary health care.

To determine health practice readiness for inclusion in the study, key individuals within the practice were identified for a focus group. For a clinic to participate, their front office manager, practice manager, lead physician, and (optionally) patients living with diabetes were required to participate in this focus group. The goal of this focus group was to delineate patient experiences and practice workflow for patients living with diabetes. Findings from focus group discussions were then used to identify and address issues around recruitment, signup, and visits through a plan-do-study-act cycle from select practices. In total, we recruited between 3 and 5 individuals across 5 sites for a total of 25 individuals for these focus groups.

Health coaches from within and outside of clinical practices were also recruited. The preferred characteristics included the following: (1) certified by Americans With Disabilities Act with the tool *Fundamentals of Diabetes Care*; (2) previous experience with living with diabetes either directly or through providing care for a family member or patient; (3) health care professionals with previous experience in educating patients living with diabetes; and (4) soft skills, including being considerate, responsible, dependable, and understanding within their community. A total of 4 health coaches were recruited by participating in health practices. This included 3 foreign-trained physicians, including 1 man in his late 30s whose second

language was English, and 2 female physicians in their late 30s who were native English speakers. The final coach was a licensed practical nurse in her late 50s. All coaches identified as Black, with 50% (2/4) of coaches identifying as African and the others as African American.

Health coaches interacted with a slate of patients identified through the MCACO practices and established communication with the practice to facilitate patient self-management support. Approximately 20-30 patients across 4 practices were selected, obtained consent from, and trained on the use of Health360x to report outcomes of self-efficacy; overall health, including blood pressure, blood glucose, exercise, sleep, and quality of life; and satisfaction with care. A total of 200 patients were screened for being at high risk of living with diabetes. A total of 100 patients were excluded as they did not meet the eligibility criteria for the study or were part of a clinical site that was ultimately deemed *not* practice ready, leaving 100 patients to be allocated the intervention.

Ethics Approval

This study was approved by the Morehouse School of Medicine Institutional Review Board (approval number 674).

Inclusion Criteria

Included in the study were adults living with diabetes at high risk of complications and mortality, as defined by the presence of obesity or overweight status ($\text{BMI} > 25 \text{ kg/m}^2$); tobacco use; history of depression; systolic blood pressure $> 140 \text{ mm Hg}$ and diastolic blood pressure $> 90 \text{ mm Hg}$; hemoglobin $\text{A}_{1c} > 7\%$; recent hospitalization or emergency room visit for uncontrolled diabetes or hypoglycemia; history of renal disease defined as estimated glomerular filtration rate $< 60 \text{ mg/mmol}$; and history of heart attack, angina, claudication, or cerebrovascular disease.

Training

Health coaches were required to complete 4 sessions of training. These sessions included training on diabetes knowledge, diabetes management and prevention, cultural competencies of the target population, working with low-literacy populations, patient recruitment and retention, confidentiality, and familiarity with data collection tools. Coaches were also required to complete web training and certification by the American Association of Diabetes Educators titled *Fundamentals of Diabetes Care*. Finally, the coach training sessions also included hands-on training on Health360x.

A total of 6 hours of training sessions were required to be completed by patients before the start of participation. The training was conducted at the Morehouse School of Medicine and covered the role of health coaches as navigators; the use of Health360x, glucose meter, blood pressure monitor, and pedometer; and process for downloading data. Patients with access to a computer or personal smartphone compatible with Health360x were instructed on how to access or download the app. Those patients who did not have access to a computer or personal smartphone that is compatible with the mobile app relied on a kiosk at the practice that was accessible when they visited their coach. The Health360x application access and training were completed through a combination of YouTube

videos, and a handbook detailing steps for using the application was also provided to patients.

Patient and Coach Visits

The health coach met with patients at the practice during scheduled visits. The purpose of each visit was to advance the patients' self-efficacy for self-management of their diabetes. During the initial visit, patients were asked to select individual diabetes-related self-management health goals around being active, healthy coping and eating, monitoring, problem solving, reducing risky behaviors, and taking medication. At each subsequent visit, coaches ascertained the barriers the patient experienced through the use of motivational interviewing. Once these barriers were identified, incremental steps to address them, which the patient suggested or agreed with, were made. Techniques such as behavioral contracting were incorporated into the process. All interactions between patients and coaches were between 20 and 40 minutes. All meetings were digitally recorded and transcribed using a third-party transcription service. As a rule, initial schedules for interactions were every 2 weeks for the first 2 months and then monthly for 4 months.

Statistical Analysis

Primary Outcome in Transdisciplinary Collaborative Center Study

The primary outcome of interest in the study was self-efficacy for behavior change, which is a predictor of intention and behavior. Self-efficacy was measured using a self-reported 10-point General Self-Efficacy Scale at each follow-up visit. A patient was determined to have achieved their self-efficacy goals if they self-reported a score ≥ 7 .

Sample Size

Our sample size calculation was based on a systematic review and meta-analysis that included 85 high-quality published studies of internet-based behavioral health interventions with a total sample size of 43,236 patients [24]. On average, interventions with more extensive use of theory were associated

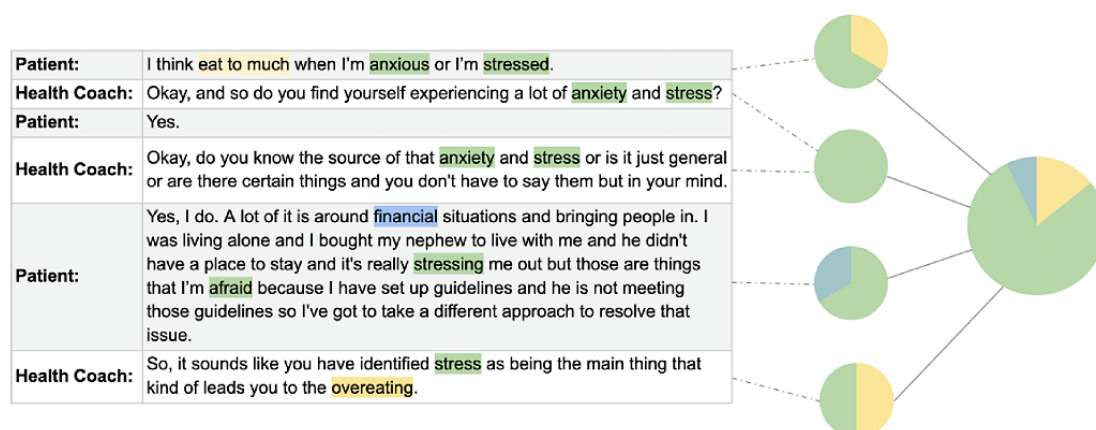

with increases in effect size ($P=.049$). Interventions based on the theory of planned behavior tended to have substantial effects on behavior (Cohen $d=0.36$, 95% CI 0.15-0.56). Health360x was designed with particular attention to the incorporation of theory-driven behavioral change techniques such as an enriched information environment (current diabetes knowledge and curriculum), self-monitoring with color-coded feedback, goal setting, identifying barriers, and problem solving. Our a priori power analysis indicated that a minimum sample size of 97 was required to detect an anticipated effect size of 0.36, assuming a desired power and significance level of 0.8 and 0.05, respectively. Therefore, we recruited 100 patients for this study.

Topic Modeling

To explore the substance of conversations between patients and coaches, we used a topic model. This statistical machine learning method identifies common themes in a corpus of documents, or in our case transcripts, and is based on the intuition that particular words are associated with particular topics. Formally, each utterance in a conversation is represented as a vocabulary multiset with corresponding word counts (also referred to as a document-term matrix). Each word in this vocabulary has some associated probability that it belongs to a given topic. If we think of a conversation as representing a random mixture of topics that are in turn defined by a set of characteristic, high-probability words, we can infer latent topics.

Topic modeling has been shown to reliably uncover conversational topics from transcripts between patients and providers in clinical settings [25,26]. Figure 1 provides a visual example of how this works from a snippet of the conversation between a patient and a health coach. Characteristic words are highlighted in yellow, green, and blue and correspond to eating, anxiety, and finances, respectively. Taken together, we can see that this conversation is about anxiety and stress, leading to overeating. However, the snippet can be further broken down, and a topic model estimates the proportion of the conversation that corresponds to each of these topics based on the observed vocabulary.

Figure 1. Example topic proportions and assignment.

We use an STM [27] for 2 main reasons: first, the STM extends traditional probabilistic models such as the Blei et al [28] latent

Dirichlet allocation and the Blei and Lafferty [29] Correlated Topic model to incorporate document metadata into the analysis

of latent topics. This was done by defining a generative process that produces *documents*, that is, utterances, with associated data, given document-topic and topic-word distributions, and using a variational optimization algorithm to estimate topic model parameters. Each conversation and utterance was made up of different proportions of the estimated topics. Incorporating speaker metadata into our topic modeling allowed us to explicitly model the association among patients, coaches, and topics of conversation, that is, the way the characteristics of patients and coaches were associated with the proportion of a specific topic in a given utterance. In our topic model, we included the speaker's age, gender, and race and ethnicity, as well as that of the person they are speaking with and whether the speaker was a coach. We estimated a regression in which utterances were the units, the dependent variable was the proportion of an utterance that is about a given topic, and the independent variables were speaker types.

The second reason we used the STM relates to what is a common subjective decision made when using topic models: the number of topics to estimate. This decision was generally arbitrary. To avoid any human-injected bias in our analysis, we leveraged a data-driven approach to select the number of topics based on the identification of *anchor* words that exist in a document only if the document is about a specific topic. The Mimno and Lee [30] algorithm automatically selects distinctive and probable anchor words from which a number of topics can be reliably estimated. As the authors of the STM indicate in their documentation of their software in R (R Foundation for

Statistical Computing), the primary advantage of this approach is that the number of topics to be estimated is automatically selected by the algorithm.

Results

Patient Sample Characteristics

A total of 100 high-risk patients with diabetes were recruited, and they consented to participate in this study from February 2015 over 5 years. Of the 100 patients, 18 (18%) patients were lost to follow-up before starting any coaching sessions, leaving 82 (82%) patients with at least 1 and as many as 11 follow-up visits. A total of 195 patient-coach follow-up visits were completed throughout the study, with an average of 2.35 (SD 1.98) follow-up visits per patient and 4.79 (SD 5.77) goals per patient. Of the 82 patients, 3 (4%) patients specified 1 diabetes-related self-management health goals, 18 (22%) patients specified 2 goals, 15 (18%) patients specified 3 goals, 8 (10%) patients specified 5 goals, 4 (5%) patients specified 7 goals, 1 (1%) patient specified 8 goals and another 15 goals, and 1 (1%) remaining patient specified 24 goals. Of the 82 patients who participated in the study, transcripts were analyzed for 51 (62%) patients. Digital recordings for the remaining 38% (31/82) of patients were of bad quality and, therefore, were not uploaded or corrupted during transcription. Most patients were Black and African American (45/51, 88%) and between the ages of 45 and 65 years (40/51, 78%). [Table 1](#) provides a complete breakdown of patient demographic characteristics. [Textbox 1](#) provides a sample of diabetes-related self-management goals.

Table 1. Patient demographic characteristics (N=51).

Textbox 1. Frequency of the number of health subgoals.**Health subgoals**

- Exercise longer
- Cope with diabetes
- Get support from my medical team
- Get support from my family and friends
- Get preventive help
- Stop smoking
- Check my feet
- Lose weight
- Get blood pressure under control
- Learn to have a safe pregnancy
- Follow my eating schedule better
- Eat better food
- Overeat less often
- Check my blood sugar more often
- Miss fewer blood sugar checks
- Do my blood sugar checks on time more often
- Prevent high blood sugars
- Treat high blood sugars
- Prevent low blood sugars
- Treat low blood sugars
- Manage diabetes when sick
- Miss fewer medications

Structural Topic Model**Preprocessing**

In total, our corpus included >17,000 talk turns, that is, an utterance or spoken statement in a conversation. To explore differences between topics of conversation between patient–coach pairs that achieved their health goals and those that did not, we split the corpus into successful patient–coach pairs (achieved) and patient–coach pairs that did not achieve the intended health goals (not achieved). This left us with 7196 talk turns in the achieved corpus and 9644 talk turns in the not achieved corpus. We then preprocessed each corpus using the `textProcessor` function in the STM R package to remove punctuation, stop words, numbers, and stemming. This produced a final document-term matrix with 6737 talk turns and a vocabulary of 1444 terms for the achieved group and 8663 talk turns and 1952 terms for the not achieved group. Patients represented more talk turns, that is, spoke more, in both the

achieved and the not achieved groups, 60% (4318/7196) and 63% (6076/9644), respectively.

Topical Content

A total of 44 topics were estimated for patient–coach pairs that achieved their intended health goals and 50 topics for those who did not. In line with common practice, our approach to assigning labels to topics began by reviewing topic model outputs to identify potential topics based on the coherence of characteristic word forms. We then reviewed the high-scoring conversations for each topic to determine the topic labels. Where there was a clear topical theme in the first N talk turns, we validated the topic label. In general, a clear theme emerged within the first 30 talk turns. A review of high-scoring talk turns was completed collaboratively by 4 reviewers until a consensus on topic labels was reached. Of the 44 topics estimated for the achieved group, 13 (29%) coherent topics emerged, as presented in [Textbox 2](#). [Textbox 3](#) provides the results for the second STM of the not achieved group, which produced 10 coherent topics.

Coaching and Contextual Feedback

We found quite a bit of overlap between topics of discussion between the 2 groups (eg, healthy eating, diabetes knowledge, and sleep). However, we found more coherent, that is, meaningful, topics that capture coaching in the achieved group versus in the not achieved group. Further investigation of high-scoring talk turns and the broader conversation that they were a part of provides many examples of coaches providing contextual feedback and incorporating this feedback into the patient's strategy. [Multimedia Appendix 1](#) provides 2 examples of such conversations. In the first example, which is taken from a high-scoring conversation on healthy coping and strategies, we see that after the coach first probes the source of anxiety and stress that is leading to overeating, acknowledges the patient's feelings, and contextualizes how their anxiety and stress lead to overeating, only then does the coach start discussing a plan to reduce overeating by focusing on the identified stressors. The next sample conversation was around healthy eating. The coach begins the conversation by recentering the patient around the goal of getting their blood sugar down

through exercise and healthier eating habits. The conversation quickly zeroes in a specific challenge in implementing this strategy: not eating on a regular schedule as the patient was not hungry at regular mealtimes. Only then does the coach provide contextualized feedback around what, when, and how much to eat.

User Experiences With CHIT

Another clear theme in our analysis of the topic model results was conversations around user experiences with CHIT. We found that CHIT use in the not achieved group focused almost exclusively on technical issues and how to use Health360x. [Multimedia Appendix 2](#) provides 2 examples from the not achieved group. In the first example, the coach expresses frustration with technical issues that require troubleshooting Health360x during a demonstration with a patient. The second example is from a conversation in which the patient and coach work together to reset the password (a common theme throughout the study was remembering passwords) and then updating the patient's health record on Health360x.

Conversely, the topic on the use of CHIT in the achieved group contained multiple examples of coaches probing user experiences with technology. [Multimedia Appendix 3](#) provides 3 examples of coaches asking probing questions on CHIT use in the achieved group. These questions ranged from familiarity with technology and use of the internet to how trusting the patients are of consumer information technologies, including sharing their health and other information on those tools. What we found to be particularly interesting is that we did not find a topic in the achieved group that resembled issues with using Health360. This suggests that understanding a patient's experiences with technology can lead to better coaching around the use of technology. This, in turn, can lead to better engagement with CHIT, self-management behavior changes, and health outcomes.

Who Dominates Topics of Conversation: Patients or Coaches?

In the achieved group, we found that healthy eating was much more likely to be discussed by patients. The average proportion of conversations about healthy eating across all patient and coach interactions, that is, $E(\text{topic prevalence})$, was 0.026 or 2.6%. Being a coach was associated with an increase of 4.9% ($\beta_{\text{Coach}}=.049$; $P=.02$) in the healthy eating topic proportion of a given utterance. The average proportion of conversations around follow-up visits and coaching in the form of goal assessment and progress across all visits was 3.4% and 0.8%, respectively. Being a coach was associated with an increase of 3% ($\beta_{\text{Coach}}=.03$; $P=.007$) and 0.3% ($\beta_{\text{Coach}}=.003$; $P=.01$) in the proportion of utterances related to follow-up visits and coaching in the form of goal assessment and progress. All other coherent topics in the achieved group were equally as likely to be discussed by either coaches or patients.

Conversations in the not achieved group were dominated by coaches. This included a 1.5% increase in the proportion of an utterance on problem areas, and stress and support ($\beta_{\text{Coach}}=.015$; $P<.001$; $E[\text{topic prevalence}]=0.012$), a 2.4% increase related to initial visits ($\beta_{\text{Coach}}=.024$; $P<.001$; $E[\text{topic prevalence}]=0.012$), a 1.3% increase around problems with technology ($\beta_{\text{Coach}}=.013$; $P<.001$; $E[\text{topic prevalence}]=0.012$), a 0.8% increase in health eating goals ($\beta_{\text{Coach}}=.008$; $P=.04$; $E[\text{topic prevalence}]=0.03$), a 1.7% increase in the proportion of diabetes knowledge ($\beta_{\text{Coach}}=.017$; $P<.001$; $E[\text{topic prevalence}]=0.02$), a 3% increase in speaking about managing blood sugar ($\beta_{\text{Coach}}=.03$; $P<.001$; $E[\text{topic prevalence}]=0.02$), and a 0.3% increase in speaking about using Health360x ($\beta_{\text{Coach}}=.003$; $P=.03$; $E[\text{topic prevalence}]=0.03$). A total of 2 exceptions were the proportion of an utterance on medication ($\beta_{\text{Coach}}=-0.008$; $P=.009$; $E[\text{topic prevalence}]=0.02$) and social determinants ($\beta_{\text{Coach}}=-0.02$; $P<.001$; $E[\text{topic prevalence}]=0.012$), which were positively associated with patients.

[Figures 2](#) and [3](#) present the mean difference in topic proportions as a function of whether the speaker was a coach or a patient, that is, which topics were more likely to be discussed by coaches versus patients. Also included in the plots are CIs indicating a statistically significant difference between the 2 groups. Although we found quite a bit of overlap between topics of discussion between the 2 groups, plotting the mean difference in topic proportions across all coherent topics indicated that conversations in the achieved group were equally distributed between patients and coaches. However, topics of conversation between patients and coaches in the not achieved group did not include 0 in their 95% CIs, indicating that these topics were dominated, and therefore more likely to be driven, by coaches.

Figure 2. Mean difference in achieved topic proportions—patients versus coaches. BP: blood pressure; HIPAA: Health Insurance Portability and Accountability Act; IT: information technology.

Figure 3. Mean difference in not achieved topic proportions—patients versus coaches. HIPAA: Health Insurance Portability and Accountability Act.

Discussion

Principal Findings

In this paper, we present the results of a novel analysis of the discursive emphasis on patients and coaches. The dialog is derived from an implementation of Health360x, a coach-assisted CHIT designed to support diabetes self-management skills acquisition and behavior for underserved, high-risk diabetic patients. Thematic analysis of conversations clustered using STM results of patient-coach interactions indicates that in patient-coach pairs that were able to achieve self-management goals, coaches provided more contextual feedback and probed into patients' familiarity with technology and use and trust of consumer information technologies. We also found that topics of conversation between successful patient-coach pairs were equally distributed, whereas discussions with patients who were unable to achieve enhanced self-efficacy for diabetes-related self-management were dominated by coaches.

Limitations

There are a few limitations of the analysis presented in this paper. First is the small corpus of transcribed conversations. As with all machine learning algorithms, the more training data, the better the models perform. Typically, topic models are used on corpora with tens of thousands of talk turns; however, we analyzed significantly less (approximately 17,000) talk turns. With that said, the methodological novelty of this paper is the incorporation of covariates into our estimation of topic models using the STM. Although we had a smaller than expected corpus, we found that we could reliably identify latent topics in comparatively smaller corpora by incorporating metadata into topic modeling. Transcription of the sessions was also outsourced and included errors, which may have further limited the overall information content of the transcripts.

A second potential limitation is that there are subjective decisions that go into creating a topic model that can influence topic outputs. The number of topics estimated as well as decisions around preprocessing (eg, removing stop words, stemming, and lemmatization) can influence topic model coherence and stability [31-33]. We addressed the subjectivity of arbitrarily selecting a number of topics by automating the number of topics to be estimated; however, another approach is to estimate and compare topic models with different topic sizes for stability across models. Finally, evaluations of preprocessing on topic model outputs are needed within the context of the STM used in this paper.

Another limitation relates to the lack of power in our analysis. The sample size calculation of 97 participants for this study was based on an effect size with a *P* value that is effectively .05. Moreover, our analysis of discursive analysis included transcripts from only half of the estimated sample size. To assess whether patient characteristics influence retention and transcript quality, we ran a logistic model regressing whether we had at least one session recording of high enough quality for analysis of patient characteristics. The results are presented in [Multimedia Appendix 4](#). Patient characteristics, including gender, age, insurance status, and willingness to use the internet, were not significantly different between patients whose session

recordings were retained and those whose session recordings were not.

A final limitation was related to the training of coaches, which was naturally limited. Coaches did not receive extensive training in cognitive behavioral therapy or motivational interviewing. Our training built the coaches' existing skills and provided additional tools to help with an appreciative inquiry. In the future, we will use these learnings to provide more uniform training for health coaches.

Comparison With Prior Work

A need exists to better understand how DSME might be delivered within primary care, the outcomes that can be achieved, and the training and system changes needed as a result [34]. Effective face-to-face multicomponent interventions require skilled primary care workers and activated patients coupled with tailored training and self-help systems, resources, and materials [35]. These interventions for diabetes self-management are complex, and their effectiveness is in large part determined by dynamics within the patient-provider relationship [36,37]. Where these relationships are 1-sided, that is, focus on what the patient *should* be doing, and do not account for a patient's circumstance, strategies for encouraging diabetes-related self-management behaviors will be ineffective [38].

Patients stand the best chance of developing skills to actively participate and take responsibility in the management of their chronic condition when they receive personalized coaching. Polonsky and Fisher [39] provided a conceptual model of how the frequency of feedback, personal meaningfulness, clarity, guidance and support, and patient characteristics influence diabetes-related feedback and affect patient engagement and behavior change. The way each of these elements should be personalized for diabetes-related coaching to be effective is beyond the scope of this comparison with prior work. What is relevant is that our analysis of the discursive emphasis on patients and coaches provides a novel approach for quantifying the substance of these relationships. Examples of coaches providing contextual feedback, probing patient experiences with technology, and engaging in back-and-forth conversations are all indicators of tailored coaching. However, what remains less clear is how we can relate these conversations to clinical outcomes and how we can quantify the additional benefit that technology provides in addition to tailored coaching. These 2 questions are the focus of subsequent projects and manuscripts.

Our study also contributes to prior work by providing new and important insights into the usability and effectiveness of mobile health interventions targeting older African American patients living with diabetes. This underserved population has traditionally been considered not amenable to the use of technology to manage their health [4]. In addition, we present novel methods that can be used to understand (and predict) what is happening in patient-coach interactions. These methods enable the analysis of themes in text at scale using techniques that minimize the amount of human-injected bias into qualitative studies.

Conclusions

Coach-facilitated, technology-based DSME can help address critical issues and unmet needs for underserved patients with diabetes around accessing sufficient support regularly. A variety of factors influence the efficacy of coaching; however, cultural expectations must be further explored, given the growing diversity among patients and the health care workforce prevalent

today. Our use of structural topic modeling in this application is novel, and it creates an opportunity to introduce this technique into everyday patient-provider encounters, particularly in a post-COVID-19 world in which there has been a paradigm shift around the use of telehealth. The opportunity to create outputs that guide further physician action and patient action could drive better patient engagement and overall patient health outcomes.

Authors' Contributions

PP and E Ofili conceptualized the project. PP and MYI contributed to the development of the project. E Olorundare, MM, and MB led the investigation. EAM conducted the data curation. MYI conducted the formal analysis. PP and E Ofili led the investigation. MYI contributed to writing the manuscript and preparing the original draft. PP and E Ofili completed the finding acquisition. All authors have read and agreed to the published version of the manuscript.

Conflicts of Interest

E Ofili is the Founder and Chief Science Officer for AccuHealth Technologies, a technology startup which holds the patent for the Health360x platform. AccuHealth Technologies was not involved in the design and analysis of the study.

Abstract

Background: The digital divide refers to technological disparities based on demographic characteristics (eg, race and ethnicity). Lack of physical access to the internet inhibits online health information seeking (OHIS) and exacerbates health disparities. Research on the digital divide examines where and how people access the internet, whereas research on OHIS investigates how intersectional identities influence OHIS. We combine these perspectives to explicate how unique context–device access pairings operate differently across intersectional identities—particularly racial and ethnic groups—in the domain of OHIS.

Objective: This study aims to examine how different types of internet access relate to OHIS for different racial and ethnic groups. We investigate relationships among predisposing characteristics (ie, age, sex, education, and income), internet access (home computer, public computer, work computer, and mobile), health needs, and OHIS.

Methods: Analysis was conducted using data from the 2019 Health Information National Trends Survey. Our theoretical model of OHIS explicates the roles of internet access and health needs for racial and ethnic minority groups' OHIS. Participant responses were analyzed using structural equation modeling. Three separate group structural equation modeling models were specified based on Black, Latine, and White self-categorizations.

Results: Overall, predisposing characteristics (ie, age, sex, education, and income) were associated with internet access, health needs, and OHIS; internet access was associated with OHIS; and health needs were associated with OHIS. Home computer and mobile access were most consistently associated with OHIS. Several notable linkages between predisposing characteristics and internet access differed for Black and Latine individuals. Older racial and ethnic minorities tended to access the internet on home and public computers less frequently; home computer access was a stronger predictor of OHIS for White individuals, and mobile access was a stronger predictor of OHIS for non-White individuals.

Conclusions: Our findings necessitate a deeper unpacking of how physical internet access, the foundational and multifaceted level of the digital divide, affects specific racial and ethnic groups and their OHIS. We not only find support for prior work on the digital divide but also surface new insights, including distinct impacts of context–device access pairings for OHIS and several relationships that differ between racial and ethnic groups. As such, we propose interventions with an intersectional approach to access to ameliorate the impact of the digital divide.

Introduction

Background

The benefits of eHealth, or the use of the internet to facilitate health behaviors (eg, online health information seeking [OHIS]) [1], are counteracted by the digital divide. The digital divide was first used to emphasize that racial and ethnic minorities and individuals of lower socioeconomic status did not adopt new technologies to the same extent as White individuals or those of higher socioeconomic status [2]. Obtaining physical access to new technologies and, thus, web-based health information remains a paramount obstacle, particularly for Black or African American (hereafter *Black*) and Latino or Latine or Hispanic (hereafter *Latine*) individuals [3]. This is problematic, as racial and ethnic minorities are more likely to live in areas of concentrated poverty that coincide with limited health care access [4-6]. Systematic inequalities in internet access and health care for racial and ethnic minorities reinforce one another, such that those who would potentially benefit the most from OHIS are often unable to access it.

However, internet access (hereafter *access*) is not monolithic and comprises the use of different devices (eg, smartphone or computer) in various contexts (eg, at home or in public) [7]. Although mobile devices are increasingly more accessible than computers, they can be harder to navigate because of their smaller interfaces [8]. Publicly accessible devices may extend access to those who do not own such devices; however, they often entail irregular availability, which can compound poor health outcomes for minority groups [9]. Recognizing the multidimensionality of access [7] is key to understanding how access via a myriad of devices in various contexts differentially influences OHIS. Furthermore, positioning the digital divide as a health disparity is imperative to developing effective interventions [10]. As such, this study uses data from the 2019 Health Information National Trends Survey (HINTS), also known as HINTS 5, Cycle 3 [11], to bolster theoretical models of OHIS with a nuanced conceptualization of access. We also advance the perspective that the digital divide is a health disparity by applying an intersectional focus to examine how relationships with access and OHIS differ across racial and ethnic groups.

Theoretical Framework: OHIS Model

The internet has become one of the most common ways of accessing health information [12]. Health information seeking refers to those actions that individuals use to search for information about their health, risks, illnesses, and health-protective behaviors [13]. When conducted on the web (ie, OHIS), seeking out health information can positively affect health outcomes by improving the quality, expense, and efficiency of health care [10]. In addition, OHIS has demonstrated that individuals are more willing to comply with their health decisions [14]. However, those with limited access to OHIS may not experience its benefits. Health disparities faced by low-income and minority communities may be magnified by the digital divide [3,15]. However, when underserved communities are provided the means to participate in OHIS, they gain more health knowledge [16]. Thus,

understanding how the digital divide affects OHIS is imperative to enhance the impact of interventions aimed at increasing access among these communities.

The digital divide first highlighted that certain groups of people (eg, racial and ethnic minorities and individuals of low socioeconomic status) lagged in adopting new technologies. This gradual diffusion represents the first-level factor of the digital divide, which has been situated in issues related to ownership, availability, and affordability of the technology [17]. Recent studies have identified additional second-level factors that may also impede technological adoption (eg, skills) [15,18]. Although the focus of OHIS has shifted away from access as some suggest that it has become democratized [19], we argue that it has not been democratized across devices and contexts of use as the lack of physical access remains an obstacle for marginalized groups [3,20]. Moreover, access is heterogeneous, as people can access the internet on multiple devices and at various places [7,21]. Even in populations with saturated home access, disparities can persist for other points of access and the cost to maintain them [7]. Thus, a nuanced conceptualization of access can respond to criticism that the digital divide suggests a simple binary between those who have access and those who do not [22].

Notably, some scholars have applied this multifaceted conceptualization of access to predict the likelihood of web-based activities (including OHIS). Hassani [23] found that people engaged in more OHIS as they increased their points of access (eg, home and work vs only home). Similarly, Mossberger et al [24] found that home computer access is vital to reap the benefits of web-based activities such as OHIS. Although the authors highlight the potential for mobile devices to attenuate the impacts of the digital divide, mobile access alone did little to minimize these impacts in low-income areas. Reisdorf et al [21] also suggest that simply increasing access does not lead to equal results across different contexts. However, these studies investigated OHIS as one of many web-based activities; as such, they were not grounded in theoretical models of OHIS. Moreover, studies that focused on OHIS [25,26] did not examine the impact of specific devices or contexts of use; instead, they examined the number of access points overall.

Furthermore, scholarship in this area has seldom disaggregated these connections by racial and ethnic groups. Studies that include race and ethnicity self-categorization as predictors of web-based activities [21] can unearth patterns of devices and contexts of use, such as Black (vs non-Black) individuals using mobile devices more often [24]. However, disparities among intersectional identities may still be overlooked, such as how age and race may interact to affect technology use [27]. Therefore, it is unclear where disparities in OHIS exist among intersectional identities.

Previous OHIS theorizing [14,28] highlights several factors that influence health-seeking behaviors. As such, our model includes predisposing characteristics (age, sex, education, and income), access (home computer, work computer, public computer, and mobile), health needs, and OHIS (Figure 1). Our model also focuses on the foundational level of the digital divide (ie, access). As such, our nuanced conceptualization of access helps

to fill the empirical gap in OHIS research on the first-level digital divide [29]. Thus, this study offers 2 primary contributions. First, we apply a multidimensional conceptualization of access along dimensions of the context of use (eg, at home vs in public) and device type (eg, smartphone

vs computer) to theoretical models of OHIS. Second, we disaggregate our models by race and ethnicity to examine how they manifest differently across racial and ethnic groups. We explicate the relationships between predisposing characteristics, access, and health needs in our model.

Figure 1. Initial online health information seeking model.

Antecedents of OHIS

Predisposing Characteristics

First, we posit associations between OHIS and predisposing characteristics. Younger individuals are more likely than older individuals to be able to navigate web-based platforms to seek out web-based health information [30,31]. Females are often expected to seek out health information because of their social roles as family caregivers [23,32]. Furthermore, education and income are generally positively associated with OHIS [33,34], as individuals with low education or income are inhibited from participating in OHIS because of low literacy [5]. Thus, we propose the following hypothesis:

Hypothesis 1 (H1): Demographic variables—age, sex, education, and income—will be associated with OHIS.

Internet Access

Expanding our understanding of OHIS, we extend prior conceptualizations of access [7,21,23] and examine access by considering context and device. *Context* refers to the physical environment in which users engage in OHIS, and *device* refers to the physical technology used to engage in OHIS. We focus on four of the most common context–device pairings: home computer, work computer, public computer, and mobile (which can be used across contexts). People seek health information on the web on several devices and at several places [23]. Owing to the extent that computers and mobile devices entail different technological constraints [8], and context structures media use [35], it is crucial to consider how different context–device pairings relate to OHIS.

First, *home computer* access involves computer use at home. It facilitates the availability of OHIS in a private setting where people spend most of their time [23]. However, because of the large cost of computers, ownership trends reflect the digital divide: White individuals are more likely to own home computers than Black and Latine individuals [3,7].

Second, *work computer* access involves computer use in the workplace. Individuals may not own these devices and likely would not pay for access, making it less expensive than home-computer access. However, work computer access requires employment that involves or entails access to computers [36]. The workplace is also a less frequented and private setting than the home [23,37].

Third, *public computer* access involves computer use in public facilities [3]. Such access can be inexpensive (if not free) and occurs in typically accessible public places, enabling access for individuals who cannot afford devices with internet access [21]. However, public computer access is contingent on a variety of factors, including the hours, locations, and resources of public facilities, which restrict the availability of such services [5].

Finally, *mobile* access involves the use of mobile devices (typically smartphones) in a variety of contexts. Mobile devices allow users to connect to public Wi-Fi and data networks, enabling OHIS in a variety of public, private, and (uniquely) mobile places (eg, on the bus) [38]. However, the small size of the mobile interface may restrict more intensive tasks [8], such as OHIS.

Overall, we expect that access will be related to predisposing characteristics and OHIS. Older individuals are less likely to access the internet [7,39], and males tend to access the internet more than females [18]. Education and income are positively correlated with access [40,41]. These differences may be linked to literacy and resources, allowing certain groups to maintain [7] and navigate access [10]. Furthermore, OHIS, by definition, is contingent on internet access [42,43]. With these considerations in mind, we propose the following hypotheses:

Hypothesis 2 (H2): Predisposing characteristics (ie, age, sex, education, and income) will be associated with access.

Hypothesis 3 (H3): Access will be positively associated with OHIS.

However, it is unclear how our nuanced conceptualization of access (ie, 4 discrete context–device pairings) may differentially

affect OHIS. Thus, we pose the following research question (RQ):

RQ1: Which access pairings have the most consistent associations with OHIS across racial and ethnic groups?

Health Need

We conceptualize health needs as the extent to which individuals perceive that they require current or chronic medical attention. The likelihood that one may endure chronic illness is linked to group identities along the lines of age, gender, education level, and income [44]. When avoidable health differences in treatment, access to treatment, mortality, and diseases correlate with group identity, a health disparity occurs. Older individuals report greater health needs than younger individuals [45]. Although health disparities among males and females differ based on the illness, males may be more confident in their ability to maintain their health and report lower health needs [46]. Braveman et al [44] highlight that education level and income are important health determinants that predict health needs. Finally, individuals who perceive their health to be poor often demonstrate motivation to find health information on the web [28,33]. Thus, we propose the following hypotheses:

Hypothesis 4 (H4): Predisposing characteristics (ie, age, sex, education, and income) will be associated with health needs.

Hypothesis 5 (H5): Health needs will be positively associated with OHIS.

Race and Ethnicity

This study holds that existing racial and ethnic disparities exacerbate the impact of the digital divide on health disparities [22]. As such, we investigate how these inequities may affect OHIS. We explore whether hypotheses linking predisposing characteristics with OHIS (H1), access (H2), and health need (H4) differ across racial and ethnic groups. First, race and ethnicity may interact with age, sex, education, and income to predict OHIS as unique disparities in health and technology have been observed within groups that have intersecting predisposing characteristics and racial and ethnic group identities [41]. Next, race and ethnicity may interact with access to predict OHIS. Fang et al [47] provide illustrative insights, highlighting that age was a strong predictor for access but that this effect was exaggerated for some racial and ethnic minorities. Finally, race and ethnicity may interact with health needs to predict OHIS. For example, Black and Latine individuals are more likely to live in low-income areas [4,6], which is associated with exacerbated health needs [48]. As such, this study foregrounds the persistent racial and ethnic disparities in the United States to understand access and health needs from an intersectionality perspective [49].

In addition, race and ethnicity may interact with access (H3) and health need (H5) to influence OHIS. Regarding access, even when Black and Latine individuals access the internet at similar rates as White individuals, such access is often marked by greater insecurity [39]. Similarly, even with similar levels of health needs, racial and ethnic minorities may avoid seeking out web-based health information if they possess lower health

and technology literacy [50,51]. Overall, our study uses previously tested models of OHIS [14,28,50-52] and seeks to extend previous theories by applying a multidimensional conceptualization of access and testing the fit of the model across racial and ethnic groups. These intersectional considerations, heightened by higher rates of internet insecurity [39] and greater health needs [4,6] because of systemic inequality, beg the following question:

RQ2: How will the relationships between predisposing characteristics, access, health needs, and OHIS differ across different racial and ethnic groups?

Methods

Sample

To test our model, we used data from the 2019 HINTS, also known as HINTS 5, Cycle 3 [11]. HINTS is an annual, nationally representative survey that asks participants about their engagement with health information. Data were collected between January 2019 and April 2019. A total of 5438 individuals responded to the survey. However, of the 5438 responses, 191 (3.51%) responses were deemed ineligible by HINTS because of partial completion, leaving 5247 (96.49%) individuals. Participants who did not complete the self-categorization variables for each model were excluded (Black and White: 420/5247, 8%; Latine: 487/5247, 9.28%). In addition, participants who did not complete all model variables were excluded (Black and White: 446/5247, 8.12%; Latine: 408/5247, 7.78%). Taken together, the sample size for the final models' group was 4381 (based on Black and White self-categorization) or 4352 (based on Latine self-categorization). Owing to these different sample sizes, we report demographics and correlations for the 5247 individuals deemed eligible by HINTS. Only the variables presented in the *Measures* section were used for the purposes of this study; all other variables were excluded. Data are available in [Multimedia Appendix 1](#). More information regarding the methodology can be found in the 2019 HINTS methodology report [53].

Ethical Considerations

An institutional review board approval was not requested because the analysis for this study was conducted using secondary data. All HINTS data sets, including the one used for analysis in this study, have been approved through expedited review by the Westat Institutional Review Board, and subsequently deemed exempt by the U.S. National Institutes of Health Office of Human Subjects Research Protections [54].

Participant Demographics

Demographic data were used to assess predisposing factors. Participants were aged 56.58 (SD 16.88) years on average. Approximately 56.62% (2971/5247) of the participants self-categorized as female, and 41.16% (2160/5247) self-categorized as male. Race and ethnicity were operationalized in comparison with those who did not self-categorize as the respective racial or ethnic group as individuals who self-categorize ethnically as Latine may still self-categorize racially as White or Black. Of the 5247 individual, 3727 (71.03%) self-categorized as White, and 1100

(20.96%) did not; 847 (16.14%) self-categorized as Black and 3980 (75.85%) did not; and 716 (13.64%) participants self-categorized as Latine and 4044 (77.07%) did not. The remaining individuals did not disclose their sex, race, or ethnicity. Participants' level of education was measured on a

5-point scale from *less than high school* (score=1) to *postbaccalaureate degree* (score=5), and participants' annual income was measured on a 7-point scale from *US\$0 to US \$19,999* (score=1) to \geq *US \$200,000* (score=7). See [Table 1](#) for a summary of participant demographics.

Table 1. Participant demographics.

Demographics	OHIS ^{a,b}

Internet Access

Participants reported how often they access the internet on a computer at home, at work, in a public place, and on a mobile device. A single item was used to measure each mode of access. Items were measured on 3-point scales, including *not applicable or never* (score=0), *sometimes* (score=1), and *daily* (score=2). There were varied responses for home computer (mean 1.14, SD 0.84), work computer (mean 0.70, SD 0.90), public computer (mean 0.16, SD 0.39), and mobile (mean 1.27, SD 0.85) access.

Health Need

Health needs were operationalized as perceived general health [14]. Thus, it was measured with a single item: "In general, how would you say your health is?" The item was measured on a 5-point scale from *excellent* (score=1) to *poor* (score=5; mean 2.58, SD 0.94). As measured, greater values represent greater health needs or poorer general health.

OHIS Measure

Participants reported using a single item, whether they used a computer, smartphone, or other electronic means to look for health or medical information for themselves in the past 12 months. Responses were *no* (score=0) or *yes* (score=1; mean 0.71, SD 0.45).

Statistical Analysis

The initial demographic data were cleaned and analyzed using SPSS Statistics (version 27, IBM Corporation; [Multimedia Appendix 1](#)). Three group structural equation modeling models were specified based on the Black, Latine, and White

self-categorization using Mplus 8.4 (Muthen and Muthén) [55]. Owing to the dichotomous outcome, diagonally weighted least squares mean and variance adjusted estimators were used instead of maximum likelihood to estimate the models, and odds ratios (ORs; vs standardized coefficients) were used to interpret relationships with OHIS. These models evaluated relationships between predisposing characteristics, access, health needs, and OHIS (H1-H5) and determined the access pairings most predictive of OHIS (RQ1). To test differences across racial and ethnic groups (RQ2), we constrained individual paths and compared each model with its respective baseline model, using chi-square tests for difference testing to account for the diagonally weighted least squares mean and variance estimation method.

Results

Model Fit

Our proposed models grouped by Black, Latin, and White self-categorization displayed poor fit statistics [56]. Modification indices suggested the addition of correlations between all the access variables. Individuals who partake in OHIS are likely to do so in multiple ways [23,57]—thus, these correlations were incorporated into the models ([Figure 2](#)). The resulting models yielded appropriate fit statistics [56] for all 3 models, grouped by Black (root mean square error of approximation [RMSEA]=0.026; comparative fit index [CFI]=0.997; standardized root mean square residual [SRMR]=0.008), Latine (RMSEA=0.021; CFI=0.998; SRMR=0.007), and White (RMSEA=0.026; CFI=0.997; SRMR=0.007) self-categorization.

Figure 2. Final online health information seeking model.

Theoretical Model

First, we examined whether predisposing characteristics were associated with OHIS (H1). Age was negatively associated with OHIS, and education was positively associated with OHIS across all models and groups. Income was positively associated with OHIS for individuals who self-categorized as White (OR 1.122, 95% CI 1.048-1.202; $P<.001$), non-White (OR 1.121, 95% CI 0.989-1.271; $P=.02$), non-Black (OR 1.124, 95% CI 1.052-1.201; $P<.001$), and non-Latine (OR 1.123, 95% CI 1.051-1.200; $P<.001$). Sex was negatively associated with OHIS, such that White (OR 0.572, 95% CI 0.513-0.638; $P<.001$), non-Black (OR 0.591, 95% CI 0.530-0.660; $P<.001$), Latine (OR 0.601, 95% CI 0.474-0.762; $P=.009$), and non-Latine (OR

0.656, 95% CI 0.581-0.741; $P<.001$) females were more likely to engage in OHIS. These findings lent partial support for H1.

Next, we investigated whether predisposing characteristics were associated with access (H2) and whether access was associated with OHIS (H3). Age was negatively associated with all forms of access for all the models and groups. Education was positively associated with all forms of access for all models and groups, except public computer access for Latine individuals ($\beta=.087$; $P=.10$). Income was positively associated with home computer access, work computer access, and mobile access—but negatively associated with public computer access—for all models and groups. Sex was negatively associated with mobile access for all models and groups and negatively associated with work computer access for Black individuals ($\beta=-.097$; $P=.003$),

such that females who self-categorized with these groups accessed the internet more frequently than males within these context–device pairings. However, sex was positively associated with home computer access for individuals who self-categorized as White ($\beta=.071$; $P<.001$), non-Black ($\beta=.074$; $P<.001$), and non-Latine ($\beta=.063$; $P<.001$) as well as public computer access for individuals who self-categorized as non-Black ($\beta=.035$; $P=.04$) and non-Latine ($\beta=.033$; $P=.048$), such that males who self-categorized with these groups accessed the internet more frequently than females. This provided partial support for H2.

Turning to OHIS, mobile and home access were positively associated with OHIS across all models and groups. Public computer access was positively associated with OHIS for non-White (OR 1.307, 95% CI 0.706-2.418; $P=.04$) individuals. Finally, work computer access was not associated with OHIS in any model and for any group. This provided partial support for H3. Regarding RQ1, mobile and home computer access were associated with OHIS more consistently across groups than public computer access and work computer access.

Then, we examined whether predisposing characteristics were associated with health needs (H4) and whether health needs were associated with OHIS (H5). Age was positively associated with health needs across all models and groups. Education and income were negatively associated with health needs across all models and groups, except for the relationship between education and health needs for non-White ($\beta=-.061$; $P=.08$) and Black ($\beta=-.072$; $P=.06$) individuals. Sex was not associated with health needs for any group. This provided partial support for H4. Turning to OHIS, health needs were positively associated with OHIS across all models and groups apart from non-White (OR 1.182, 95% CI 0.958-1.458; $P=.07$) and Latine (OR 1.091, 95% CI 0.869-1.369; $P=.58$) individuals. This provided partial support for H5.

Intersectional Differences

Finally, we investigated whether significant differences in H1 to H5 emerged for different groups (RQ2). We found that certain

relationships between predisposing characteristics and access differed for each type of access; all reported relationships were significant at $P<.05$. Significant differences emerged for the relationship between home computer access and age, income, and sex. The negative association with age was stronger for non-White, Black, and Latine individuals. The positive association with income was stronger for non-White and Black individuals. The association with sex was stronger for non-Black individuals; males were more likely to have home computer access than females among non-Black individuals. Significant differences also emerged for the association of work computer access with age and sex. The negative association with age was significantly stronger for non-Latine individuals. The association with sex was stronger for Black individuals; females were more likely to have work computer access than males among Black individuals. Next, the negative association between public computer access and age was stronger for non-White and Black individuals. Finally, the positive association between mobile access and education was significantly stronger for non-White and Latine individuals.

Other relationships also differed across racial and ethnic groups. For predisposing characteristics and OHIS, sex had a stronger negative association with OHIS for non-Black and White individuals, such that the gap between females and males engaging in OHIS was greater for these groups. For access and OHIS, home computer access had a significantly stronger positive association with OHIS for White, non-Black, and non-Latine individuals. Mobile access had a significantly stronger positive association with OHIS for non-White individuals. There were no significant differences in other dimensions of access or health needs. [Tables 5-7](#) display the ORs and standardized coefficients for the final models, and our general analysis scripts are available in the [Multimedia Appendix 1](#).

Discussion

Principal Findings

This study applied a nuanced conceptualization of access to theoretical models of OHIS and identified how relationships with OHIS differed between racial and ethnic groups (ie, Black, Latine, and White individuals). We found partial support for all hypotheses, and results regarding the RQs provided deeper insight into the predicted relationships. By examining access as 4 unique context–device pairings, we found that home computer and mobile access were most consistently associated with OHIS. In addition, disaggregating models by racial and ethnic self-categorization identified different patterns between predisposing characteristics and access for different groups, highlighting how the digital divide affects intersectional groups.

Our findings suggest that predisposing characteristics are associated with OHIS for different racial and ethnic groups (H1). Education was positively associated with OHIS, and age was negatively associated with OHIS. These findings align with previous research, such that those with more education and younger individuals are more likely to possess the skills to navigate web-based platforms [30,31,33,58]. However, income only had a positive association with OHIS for individuals who self-categorized as White, non-Black, or non-Latine. Although education and income are often correlated with OHIS [9,59,60], our findings suggest that education may better index the foundational knowledge necessary to take advantage of web-based health information. Finally, although females sought out health information more frequently than males [23,32], this pattern did not hold for those who self-categorized as Black. This may reflect how factors of socioeconomic status are typically stronger determinants of access to technology and health services for racial minorities than sociodemographic factors [44,61].

Our findings also suggest that some predisposing characteristics are associated with access for some racial and ethnic groups (H2). Age was negatively associated with all forms of access.

Older individuals used all 4 context–device pairings less frequently than younger individuals, which may indicate their use of nondigital means (eg, print media and interpersonal) to obtain health information [47]. Females of all groups accessed the internet on mobile devices more frequently than males, as well as work computers among Black individuals. However, White males (vs females) accessed the internet on home computers more frequently. Although males and females may have similar access overall [62], combining a multifaceted conceptualization of access with an intersectional approach highlights that disparities in access based on sex are grounded in devices and contexts of use, as well as race and ethnicity. White males and females are more likely to access the internet on home computers and mobile devices, respectively, suggesting that internet access may be a zero-sum game, such that having access in one place reduces the need to have access elsewhere [21]. However, this trade-off did not emerge for other groups, suggesting important boundary conditions based on race and ethnicity [61]. Furthermore, income and education consistently demonstrated a positive association with access, as maintaining access requires sustainable resources afforded by income and education [7]. However, income was negatively associated with public computer access, suggesting that individuals with lower income may be more reliant on public resources to access the internet [39,57].

Our findings generally confirm that access is associated with OHIS (H3). As suggested by previous research [14,28,50-52], OHIS is unlikely without a means to access the internet. Specifically, mobile access was positively associated with OHIS for all groups, suggesting that the ubiquity of mobile phones may help bridge this particular gap of the digital divide [3,5,21]. Home computer access was also associated with OHIS for all groups. Public computer access was positively associated with OHIS for non-White individuals. Work computer access was not associated with OHIS across all groups. These findings are corroborated by the fact that certain contexts of OHIS (eg, home computer and mobile) provide a level of privacy that other contexts do not [23,37], thus facilitating searches for private

health information. Our results highlight that certain groups (particularly non-White individuals) face access disparities based on affordance and maintenance of that privacy [7,63].

Predisposing characteristics were also associated with health needs (H4), such that older individuals and individuals with less education and income were more likely to describe their health as poor. Older individuals and individuals with less education and income often face barriers to quality health options [44]. However, education was not significantly associated with health needs for Black and non-White individuals. Research on minority groups (eg, Black individuals) finds that educational advancement may not overcome the aggregated stress of marginalization, which contributes to negative health outcomes [64]. However, sex was not associated with health needs for any group, likely because of counterbalancing of health issues that disproportionately affect males and females separately [45].

Furthermore, those with greater health needs were more likely to partake in OHIS, apart from non-White and Latine individuals (H5). Past research has found that greater health needs are associated with increased OHIS among Latine individuals [58]. However, our findings support previous findings that Latine individuals may be less trusting of health information on the web and may rely on different (eg, interpersonal) means of seeking out health information [65]. Reconciliation of these contradicting findings may be a result of area, as the national sample is not limited to patterns that may only exist in larger cities with more resources to provide access [58].

Finally, our exploratory analyses provide insight into RQ2; however, additional research may be required to fully explicate certain patterns in our model in which stronger relationships were detected for specific racial and ethnic groups. In terms of access, several relationships were stronger for Black individuals. Greater income was associated with more frequent home computer access across all groups; however, this relationship was stronger for Black (vs non-Black) individuals. Income inequality among Black individuals appears to be a stark determinant of home computer access [39]. Individuals with higher income can afford the cost of maintenance that comes with home computer access, which is apparent across the models [7]. However, Black individuals with lower income may face additional hurdles to home computer access, such as living in areas without the infrastructure to support maintenance [3]. Similarly, the negative relationship between age and public computer access was stronger for Black (vs non-Black) individuals. The restricted availability of public computers [5] and limited accessibility of web-based platforms for older individuals [7] may be particularly profound for Black individuals. As Black individuals have been historically disadvantaged in access, both community resources and technological skills of the older generation may be stunted [5,39]. Furthermore, the relationship between sex and access differed, such that Black females reported more frequent access via work computers than Black males. In contrast, non-Black males were more likely to use home computers. For specific sex, racial, and ethnic groups, finding access to the internet via 1 mode may be sufficient, which could reduce the need to have access elsewhere [21]. Finally, non-White (vs White)

individuals, or racial and ethnic minorities in general, demonstrated a stronger negative relationship between age and home computer access and a stronger positive relationship between education and mobile access. Older racial and ethnic minorities tend to have less access to the internet [39], including at home. Although racial and ethnic minorities lag in home computer ownership, the stronger relationship with education and mobile access may be interpreted as a route to attenuate the digital divide or as exacerbating the digital divide within racial minority groups. As such, lower education levels seem to inhibit access more intensely among Latine individuals.

In addition to access, the relationship between sex and OHIS differed, such that non-Black (vs Black) females demonstrated a stronger association with OHIS. The extent to which females relieve the burden of family health knowledge [32] may differ across racial and ethnic groups, as these groups are often disproportionately affected by health disparities [4,6]. Moreover, the positive relationship between home computer access and OHIS was weaker for non-White (vs White) individuals, whereas the positive relationship between mobile access and OHIS was stronger. Mobile devices remained a key factor not only for establishing access for racial and ethnic minorities [3] but also for OHIS. Although the mobile interface may be more difficult for tasks such as OHIS [8], having at least one point of access is critical for web-based health behaviors [9,24]. Although some OHIS research suggests that access has been democratized [19], the above results highlight the overlap in health and technology disparities for racial and ethnic minority groups [4-6].

Contributions

Our first contribution—applying a multidimensional conceptualization of access to theoretical models of OHIS—revealed that different context–device pairings offer distinct OHIS profiles. Mobile and home computer access were more consistently associated with OHIS than work computer and public computer access. This implies that privacy is important when assessing the digital divide, as home computers and mobile devices can be used in more private contexts [23,37]. Furthermore, for racial and ethnic minority participants, the link between home computer access and OHIS was weaker, and the relationship between mobile access and OHIS was stronger. These differences primarily emerged in the non-White versus White models because of reduced power in the other models and the fact that Black individuals were included as non-Latine individuals (and vice versa). Racial and ethnic minorities may rely more on mobile (vs home computer) access for OHIS because of the lower cost and flexibility of mobile devices [66]. Public and work computer access were not consistently associated with OHIS, although public computer access was generally associated with OHIS for non-White individuals. Contexts that typically do not require ownership may provide access for groups that lack other means of access. Discrepancies among home computer, work computer, public computer, and mobile access highlight that devices and contexts of use do not provide access equally [7].

Our second contribution was to unpack the digital divide using an intersectional approach, as it is crucial to understand which

groups have limited access to the internet. We found discrepancies in access for specific groups. Older individuals who self-categorized as a racial or ethnic minority engaged in less frequent home and public computer access. Older (vs younger) individuals and racial and ethnic minorities (vs majorities) tend to access the internet less frequently [39], and we find that this gap is magnified for home and public computer access. In addition, for non-White (vs White) individuals, there were stronger positive relationships between education and mobile access, as well as mobile access and OHIS. Although formal education may minimize the digital divide via mobile access, disparities in access to the education needed to operate the devices should also be considered. Discrepancies between predisposing characteristics, access, health needs, and OHIS for different racial and ethnic groups demonstrate the need for future OHIS theorizing to adopt an intersectional approach.

Practical Implications

This study supports the criticism that the digital divide is not a dichotomy between access and lack thereof [22]. In response to this criticism, interventions combating the digital divide must consider how context–device access pairings can be leveraged among specific racial and ethnic groups. Home computer and mobile were the most frequently used means of access and were both consistently positively related to OHIS. This implies that people typically engage in OHIS on home computers or mobile devices. As such, improving access within these contexts may be valuable for interventions to support OHIS across racial and ethnic groups. Our findings suggest that work and public computer access are less ideal for OHIS. These pairings may lack accessibility [5] or privacy [23,37]. The association between public computer access and OHIS for racial and ethnic minorities could be explored further as a means of increasing OHIS for Latine and Black individuals. Work and public computer access remain important to the extent that increasing access points overall supports OHIS [21,25,26]. However, public computer access may also replace more expensive yet more private modes of access (eg, home computer). In general, interventions could reinforce existing strengths (eg, home computer and mobile access) or bolster existing weaknesses (eg, work and public computer access).

These 2 courses of action can also apply to future interventions aimed at addressing the digital divide and OHIS among specific groups. For racial and ethnic minorities, we found weaker positive relationships between home computer access and OHIS and stronger positive relationships between mobile access and OHIS. Interventions can strengthen the established relationship between mobile devices and OHIS or bolster the weaker link for home computer access. Although home computer access is considered a more easily navigable interface [8], it may not be scalable, given its cost. As such, interventions with limited financial resources may benefit from working with providers of web-based health information to develop mobile-friendly interfaces to make health information more accessible.

Furthermore, this study shines a spotlight on older racial and ethnic minorities, who experienced consistent discrepancies in access and may have the highest health needs. The negative relationship between age and public computer access was stronger for Black individuals, suggesting a drop-off in public computer access for older Black adults. As public computer access was associated with OHIS for racial and ethnic minorities, future interventions could increase the accessibility of public computers for older Black adults, with attention toward local libraries and community centers in predominately older Black neighborhoods [5]. Overall, a deep understanding of current community strengths must be balanced with efforts to provide equitable access to web-based health information to not overlook the key interactions between multiple social positions that create compounding experiences of oppression [67].

Limitations and Future Research

Some limitations should be considered when interpreting these findings. This study used secondary cross-sectional data. Thus, potentially relevant variables (eg, mobile use at home vs at work vs in public) were not measured, and causality or directionality cannot be determined. Future research could measure additional constructs and use longitudinal designs. In addition, this analysis used self-reported data. Future work could use log and GPS data in tandem to paint a more accurate picture of OHIS. Furthermore, our primary outcome variable (OHIS) was dichotomous, and other variables (eg, access) were trichotomous or single-item measures. Future research should use continuous variables for OHIS and access to better capture the temporal variety of digital media use. Finally, we did not examine second-level digital divide variables (eg, experience, perceived utility, beliefs, and skills) [28,50,51,68,69]. However, before receiving and interpreting information, those who seek information on the web must choose a device and context to seek that information.

Conclusions

This study holds that a nuanced conceptualization of access is necessary to understand how the digital divide differentially affects racial and ethnic groups. Our theoretical model identified variables that predict OHIS while distinguishing the type (ie, device) and location (ie, context) of access, testing these associations for different racial and ethnic groups and examining intersectional characteristics among these groups (ie, age, sex, education, and income). By interlacing a thorough understanding of the first-level digital divide with an awareness of the unique impacts of the digital divide for specific groups, we further theorize on OHIS and suggest important considerations for more targeted interventions. As we continue to understand the complexities of the digital divide and its relationship with health, racial, and ethnic disparities, our perspective highlights how web-based health resources may not be accessed by those who need them the most.

Abstract

Background: Monitoring eating is central to the care of many conditions such as diabetes, eating disorders, heart diseases, and dementia. However, automatic tracking of eating in a free-living environment remains a challenge because of the lack of a mature system and large-scale, reliable training set.

Objective: This study aims to fill in this gap by an integrative engineering and machine learning effort and conducting a large-scale study in terms of monitoring hours on wearable-based eating detection.

Methods: This prospective, longitudinal, passively collected study, covering 3828 hours of records, was made possible by programming a digital system that streams diary, accelerometer, and gyroscope data from Apple Watches to iPhones and then transfers the data to the cloud.

Results: On the basis of this data collection, we developed deep learning models leveraging spatial and time augmentation and inferring eating at an area under the curve (AUC) of 0.825 within 5 minutes in the general population. In addition, the longitudinal follow-up of the study design encouraged us to develop personalized models that detect eating behavior at an AUC of 0.872. When aggregated to individual meals, the AUC is 0.951. We then prospectively collected an independent validation cohort in a different season of the year and validated the robustness of the models (0.941 for meal-level aggregation).

Conclusions: The accuracy of this model and the data streaming platform promises immediate deployment for monitoring eating in applications such as diabetic integrative care.

KEYWORDS

deep learning; eating; digital watch

Introduction

Background

The technological progress of wearable devices, such as smartwatches and wristbands, has made them an integral part of our lives [1]. Wearable devices provide rich, high-frequency, and longitudinal information for symptoms or activities relevant to improving patient diagnosis, care, and treatment. Being able to identify specific relevant activities, such as food intake, in a

way that places a minimal burden on that person has the potential of increasing efficiency of monitoring and patient satisfaction. For example, current diabetes management using basal and bolus insulin regimens requires a high level of patient engagement. One-third of patients with type 1 or type 2 diabetes report insulin omission or nonadherence at least once in the past month, and one of the cited reasons is being too busy [2]. In this scenario, passively collected digital sensor data from consumer wearable devices could be an ideal approach for supplementing the sensor and patient-provided data collected

by specialized connected care diabetes devices. Apart from diabetes, a variety of diseases have been linked to poor eating habits, including heart diseases, obesity, high blood pressure, and other leading causes of death [3,4]. The ability to monitor eating behavior on a continuous basis is central to improving the care and treatment of these conditions.

Related Works

The current literature includes studies of automatic food intake detection using a variety of sensors (Table 1), such as audio, motion, and specialized sensors for chewing and swallowing detection, mounted on different parts of the body such as wrists, head, ears, and neck [5-11]. Although published results are encouraging and indicate the feasibility of automatic food intake detection, advancement in data collection and analytics is still in need. First, most of the existing studies have been conducted in the laboratory [12-15], whereas data on eating in the

free-living environment is more difficult to obtain and infer. Second, if a study is conducted in a free-living condition, it is challenging to obtain accurate ground truth. Typically, such ground truth is obtained through food diaries or questionnaires, and the failure to memorize eating times impedes establishing accurate models [16,17]. Third, because of the cost of wearable watches, participant recruitment, and data extraction, pioneering studies so far are very limited in size, typically covering dozens to hundreds of hours of records in total (Table 1) [18]. For example, Farooq and Sazonov [19] took a total of 23 hours of records >10 individuals in a free-living environment to study the effectiveness of accelerometers in detecting eating. A study that is comparable in size to this one is the Sharma et al [9] study, which contained 1413 hours of records. Finally, this study distinguishes itself from the above studies by its longitudinal follow-up of weeks. This allowed us to update the models for each device user as the data collection proceeded.

Table 1. Representative literature with relatively large size of data on eating detection.

Objective

Our objective is to develop a prospective, noninterventional, observational study that addresses the above challenges in detecting events of food intake based on passively collected motion sensor data from wearable devices in free-living conditions. We also aim to test the performance of the deep learning algorithms in detecting eating using this data. To this end, we developed a specialized app that allows the recording of eating diaries by simply tapping on the smartwatch and automatic streaming of the accelerometer and gyroscope data into the cloud computing platform. A total record of 3828.25 hours (1658.98 in the discovery cohort and 2169.27 in the validation cohort), encompassing 6 types of eating utensils (forks, knives, spoons, glass, chopsticks, and hands), provided us with deep data for developing models that infer eating behavior in the general population. We develop models that have an area under the curve (AUC) of 0.951 for detecting an entire meal event. We also show the potential to fine-tune more accurate personalized models. A prospective, independent cohort further validated the model. The accuracy of this model supports its immediate readiness to be deployed in clinical trials such as connected diabetes care devices and other therapeutic areas.

Methods

Recruitment and Ethics Approvals

The inclusion criteria of participants in the study were as follows: (1) aged ≥ 18 years; (2) living in the United States; (3) an Eli Lilly employee working in a Lilly office in Indianapolis,

United States; (4) willing to wear an Apple Watch, which is provided for this study and which will be used to collect data from the device motion sensors and logs of events of food consumption; (5) owning a Lilly iPhone and willing to pair it with the Apple Watch provided in this study and to use an app developed for this study to facilitate transfers of motion sensor data; (6) having an internet connection with access to a secure password-protected Wi-Fi at home for the duration of the study; and (7) willing to not use another wrist-worn personal device (eg, Apple Watch) for the duration of this study. The exclusion criteria were as follows: (1) experiencing from hand tremors or involuntary arm movements, (2) currently being a smoker, (3) participation in any other study involving wearable devices that may interfere with the conduct of this study at any point during participation in this study, and (4) being involved in the planning or conduct of this study or being a member of the Machine Learning and Artificial Intelligence team of the Advanced Analytics and Data Sciences group at Eli Lilly. The study has been approved by the Eli Lilly Review Board (study number: 2019-8193) and reviewed by the Western Institutional Review Board (WIRB protocol number 20190878), and all participants have provided written consent to this study. The informed consent form is provided in [Multimedia Appendix 1](#).

Instruments

The purpose of this study is to develop a data streaming system and algorithms that could automatically collect and detect eating events based on passive monitoring of motion sensor data from wearable devices in free-living conditions. The terms used throughout this paper are outlined in [Textbox 1](#).

Textbox 1. Terminology and notations used in the paper.

Terms and explanations

- Window
 - A segment from the data used as the model input (typically 5 minutes in this study)
- Moving step
 - The size of the stride between 2 consecutive windows
- Session
 - A session is a consecutive recording from the watch; a single day can have multiple sessions.
- Region
 - A segment of data within a specific time range
- Aggregation
 - The methods that we use to determine the inference of a region based on its related windows
- n
 - A cutoff helping to determine if a meal region is inferred correctly or if a region is false positive
- False positive regions
 - A region containing at least n false positive data windows
- (Hourly) false positive detection rate
 - (Number of the false regions–number of the positive regions)/total sample hours

Our goal is to detect eating activity based on data from motion sensors embedded in wearable devices to minimize the risk of privacy invasion. Eating activity in humans involves potentially distinguishable movements—hand-to-mouth gestures. A total of two motion sensors—accelerometer and gyroscope—were used for the position and orientation sensing in digital watches (Figure 1B). We used the Apple Watch Series 4, which is equipped with both sensors. We programmed the watch to extract sensor data using a standard application programming interface (API), which can be seamlessly paired with an iPhone to facilitate data flow and retrospective labeling. This study has been approved by the Eli Lilly Western Institutional Review Board, and participants' information was deidentified before analytic research. Eating dairy is in general recorded by 2 simple tappings of *begin* and *end* on the Apple Watches. Compared with previous eating diaries, this method facilitates accurate recordings of the eating region.

Participants were asked to log all events of food intake regardless of the type of food or beverage consumed or the manner in which it is consumed (eg, with or without utensils, sitting down, standing, or walking), except while driving. Specifically, they were asked to log each region of food intake if she or he estimated that it would involve >3 bites or sips (movements to bring the food to one's mouth) and would last for >2 minutes. Activities such as taking oral medications, using chewing gum, or taking a few sips of water did not need to be logged. Although many people wear a watch on a nondominant arm, in this study, we asked the participants to wear the study Apple Watch on the arm that they consider dominant for eating purposes. This choice is motivated by the available literature indicating that the food intake detection algorithms using motion sensor data from the dominant arm provide better performance than those using data from the nondominant arm, whereas using sensor data from both arms does not improve performance significantly [5].

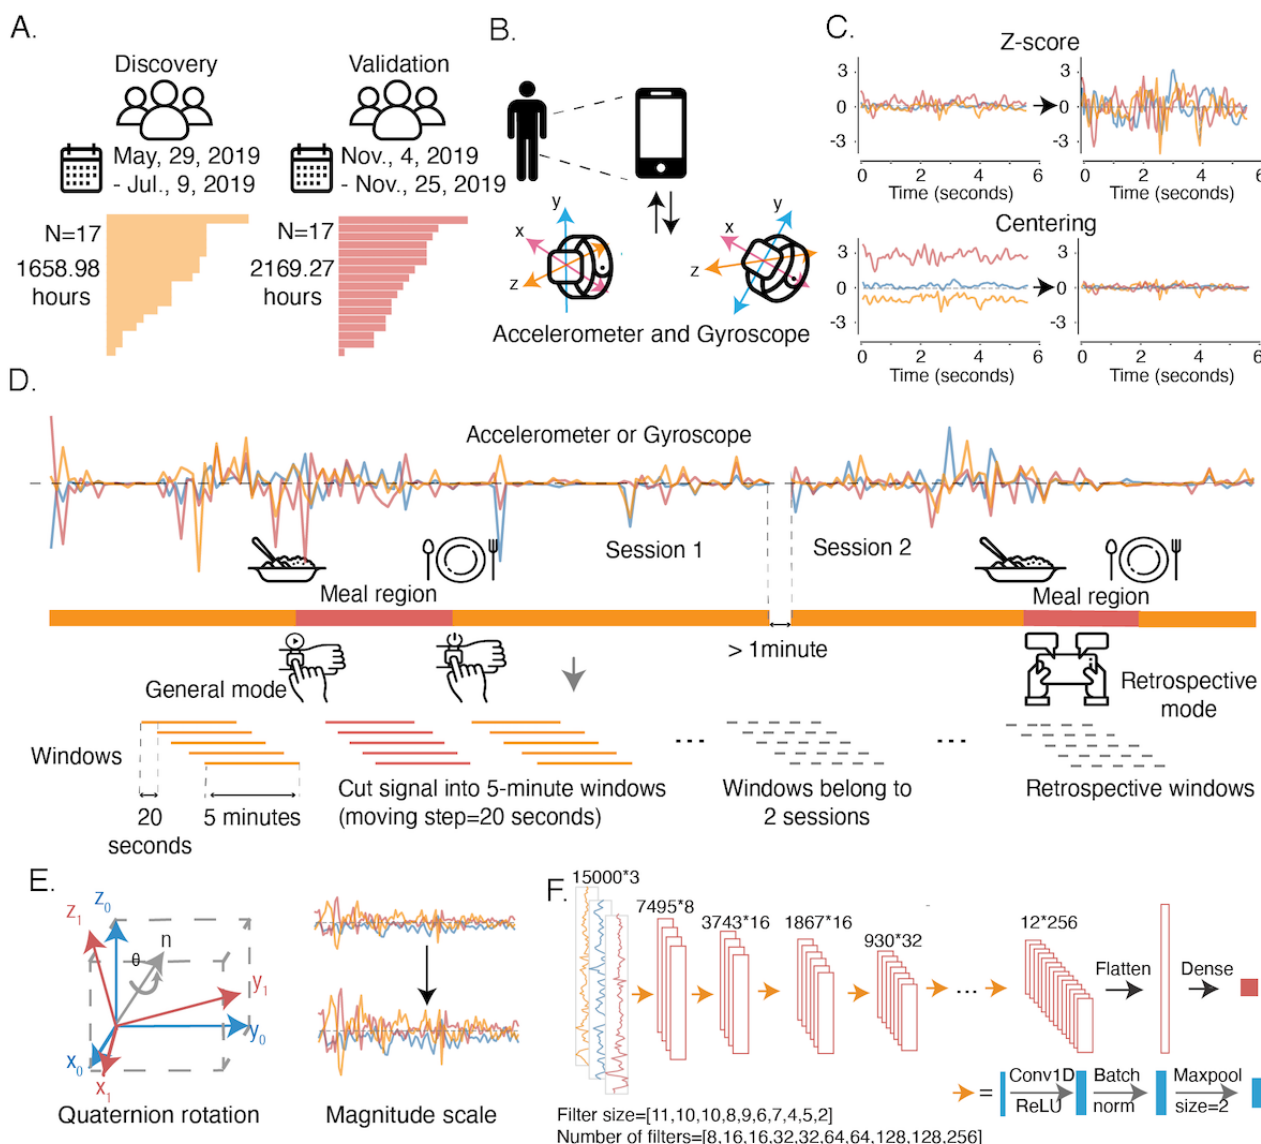

We recruited 2 independent cohorts. The first cohort included 17 individuals, deidentified before data analysis—02CE, 064F, 08A5, 0D51, 0FA7, 11FD, 1453, 16A9, 1B55, 2257, 2BAF, 305B, 32B1, 375 D, 3e5f, 4561, and 47B7—and spanned between May 29, 2019, and July 7, 2019. The second cohort included 17 individuals—766F, 7D71, 7FC7, 8473, 94CD, 9979, A07B, AE7F, B0D5, BED9, C385, CA87, D189, D3DF, DF8D, E1E3, and E68F—and spanned between November 4, 2019,

and November 25, 2019. For each participant, we longitudinally collected a maximum of 20 (discovery cohort) and 22 days (validation cohort) of their daytime activities, with a median of 9 and 11 days, respectively. This provided a total of 1658.98 hours of data in the discovery cohort and 2169.27 hours of data in the validation cohort (Figure 1A). The discovery cohort included 162 days of samples in total, where each individual was allowed to take different numbers of days of experiments varying from 1 (eg, participant 1453) to 20 (eg, participant 2257; Multimedia Appendix 2, Figure S1). The validation cohort included 193 days of samples in total, with the experiment days varying from 1 (eg, participant A07B) to 22 (eg, participant CA87; Multimedia Appendix 2, Figure S1).

Data were recorded at a frequency of 50 Hz and were segmented into individual files by the combination of collection date and participant ID. It is common to see multiple sessions in a single file (Figure 1D and Textbox 1), corresponding to consecutive recording periods in a single day. Approximately 25.3% (41/162) of the samples contain >1 session in the discovery cohort, and approximately 68.9% (133/193) of the samples in the validation cohort have at least two sessions (Multimedia Appendix 2, Figure S1C). The data are presented in a timewise fashion of 20 features, including acceleration and rotation rate ($accl_x$ for acceleration at the x-axis, $accl_y$ for acceleration at the y-axis, $accl_z$ for acceleration at the z-axis, $gyro_x$ for gyroscope at the x-axis, $gyro_y$ for gyroscope at the y-axis, and $gyro_z$ for gyroscope at the z-axis), utensils (binary labels of utensils, fork, knife, spoon, glass, chopstick, and hand), ground truth labels (*tag* for all eating tags, *tagTimely* for eating tags that are done when eating happens, and *tagRetro* for retrospectively recorded taggings), session (*sesid*), timestamp (*ts*), and the local time (*tod*). We determined whether a positive tag should be considered in the training by *tagTimely*, a binary feature indicating whether the tag is labeled during mealtime.

The data collection platform will also enable the participants to retrospectively log approximate times of meals if they forget to log them in a timely manner. The choice of collecting ground truth classification labels through participants' logs is also motivated by the fact that a potential future activity detection system deployed in real life may collect some amount of personalized training data to fine-tune the inference model to individual characteristics.

Figure 1. Overview of data collection and streaming for meal activity analysis. (A) Data comes from two cohorts: 17 participants in the discovery cohort with 1658.98 hours of data and 17 participants in the validation cohorts with 2169.27 hours of data. (B) Signals were collected by 2 sets of sensors, accelerometer and gyroscope, in Apple Watch and paired with iPhone. (C) Z score and centering normalization were conducted for each of the x, y, and z axes for each window. (D) The gyroscope and accelerometer provide continuous signals on the x, y, and z axes over time. There are 2 modes to record meal time. The general model recording starts and stops by tapping the button on the Apple Watch. Retrospective mode allows the participant to type in the rough meal time with the iPhone after having a meal. For each record, we took 5-minute windows with a moving step of 20 seconds. The windows with >2.5 minutes of mealtime will be labeled as eating activity. Windows belonging to 2 sessions are removed. (E) Two augmentation methods, quaternion rotation and scaling the signal magnitude, apply to each data window. (F) Deep learning network structure.

Data Cleaning

A couple of noncompliances appeared to have come from the misunderstandings of the guidance. For example, participant 4561 presented very short sampling regions on June 6, 2019 (Multimedia Appendix 2, Figure S2A). It appears that she/he recorded only the mealtime. Another noncompliance was observed in the close-to-zero signals in accelerometer and gyroscope data for a long region of time; for example, 47B7_2019-06-07 (Multimedia Appendix 2, Figure S2B). This identification number follows the format of participant ID_date. It is likely that participants took off their watch during these time regions. We further removed individuals or days without eating records (eg, 2257_2019-06-27). Communications with participants indicated that they were incorrectly annotated.

For the discovery cohort, participants 064F, 1453, and 08A5 were excluded from this study because of an overwhelming number of retrospectively annotated meals (>50%; Figure 2A), which indicates potential poor data quality of these days. Records from these participants are also removed as the sampling times are <3 hours in a day, as they are possibly not compliant with the instructions that require wearing the watch during day time: 4561 (May 30, 2019, and June 6, 2019), 305B (June 11, 2019), 47B7 (June 7, 2019, and June 1, 2019), 2257 (June 27, 2019), 375 D (June 7, 2019), 32B1 (June 18, 2019), and 0D51 (June 11, 2019). Of the 17 individuals, 14 (82%) individuals remained to consider in the model development for the global model. The personalized models were fine-tuned and evaluated on the 86% (12/14) of individuals with ≥ 7 samples:

02CE, 0D51, 0FA7, 11FD, 16A9, 1B55, 2257, 32B1, 2BAF, 305B, 4561, and 47B7.

For the validation cohort, based on the same exclusion rules, we also kept 82% (14/17) of individuals and removed

participants 9979 (3/3); 94CD (8/11), who had an overwhelming number (>50%) of retrospectively recorded meals; and 7D71 (0/0), who failed to label the meal times in all dates. Then, we removed 15 person days with a total duration of <3 hours and another 55 person days, which did not contain any meal times.

Figure 2. Summary of the meal regions. (A) Describes the meal number of each individual in the discovery cohorts and the validation cohorts. The bars are sorted by the total number of the meals and comprise two types of model labeling: label during eating (in-time, the blue bars) and label by retrospect (retrospective, the orange bars). (B) Summarizes the meal numbers per day excluding the retrospectives. (C) Shows the distributions of the duration (in minutes) of the meals for the discovery and the validation cohorts, excluding the retrospective meals. (D) Plots the distributions of the starting times of the meals in these 2 cohorts, and the dashed lines correspond to smoothed curves describing the counts. (E) Distribution of the numbers of the meals with different utensils in the discovery and the validation cohorts. (F) Statistics of the meal lengths (in hours) for different utensils in the discovery and the validation cohorts.

Data Preprocessing

All the data were cut into 5-minute (300 seconds) windows with a moving step of 20 seconds from the start of each date of data based on the record length. The label for each 5-minute data window was determined by the proportion of mealtimes: if the window has >2.5 minutes (150 seconds) labeled as mealtime, then the label of the window is 1 (positive examples); otherwise, it is 0 (negative examples). There were 3 additional conditions that generated -1 labels, which were excluded in both training and evaluation (Figure 1D). The first one is when the current window belonged to 2 different sessions; the second is that the window included the records whose tagRetro (retrospectively recorded eating) was not 0 or missing, which means these tags were recalled by the users after their meals. Third, extremely short periods of eating <3 minutes were excluded as they could have disrupted the fairness of evaluation. A total of 282,942 windows were generated according to this preparation method

from the discovery cohort, and 13,498 of them were positive. As the data were highly unbalanced, we applied an oversampling: we randomly selected N records from the positive examples with replacement, where the N is the number difference between the negative examples and the positive examples.

Model Training and Evaluation

The general training and evaluation strategy was cross-validation, a commonly used scheme that ensures sufficient test examples. In each test, we randomly selected 21% (3/14) of individuals for the test set, 18% (2/11) of individuals for the validation set, and the rest 64% (9/14) of individuals as the training set. Models were trained and tuned on the training and the validation sets, and we evaluated the performances on the test set. We also trained 5 models for each test, which came from 5 random splits on the training set and the validation set while maintaining the 3 final test individuals unchanged. The

final inference scores for the evaluations were the averaged ensemble of the 5 models.

We experimented separately based on accelerometer and gyroscope data, and then we assembled the inference scores using the 2 types of data by taking the average. Experiments are organized in the following order: input data, normalization methods, and augmentations. In each step, we selected the best-performing model for the next experiment. For the fine-tuned personalized model, we first trained a model using all the data in the discovery set, excluding the individual that was the target of fine-tuning. Then, we fine-tuned the model for 2 additional epochs on 60% of the days of the target individual, using another 20% of the days as validation and the last 20% of the days as the test set. Across all experiments, the evaluation was conducted on the testing set with the original class imbalance.

Model Architecture

The backbone of the models is a deep convolutional neural network, comprising 10 building blocks and a fully connected layer for the output listed in [Multimedia Appendix 2](#), Table S13 and [Figure 1F](#). Each block contains a convolutional layer, a batch normalization layer, and a maxpooling layer. The number of filters grows progressively from 8 to 256 (8,16,16,32,32,64,64,128,128, and 256). The sizes of the filters follow (11,10,10,8,9,6,7,4,5, and 2). The network receives both the 3-channel inputs from the accelerometer or the gyroscope and the 6-channel inputs when using them together. The weights of the network are trained by an Adam optimizer [21], the most popular parameter optimizer, with a learning rate of 0.00003 and a binary cross-entropy loss function as the training target is binary. To combat overfitting, we applied a callback function to retrieve the weights from the epoch of the best performance on the validation set. These selected weights were then applied to the test set to evaluate the model performance. We trained a total of 5 epochs. The kernel was initialized with Glorot uniform. The abovementioned parameters were selected empirically and then searched around the empirical values.

Normalization and Data Augmentation

We tested two normalization methods: centering and z score normalization ([Figure 1C](#)). The outputs of centering were the subtraction between the original values and the averages, and the z score normalization required a calculation based on the following formula, where the μ is the average, and the σ is the SD.

To combat overfitting, we applied 2 augmentation methods ([Figure 1E](#)). The first was scaling the signal magnitude by multiplying a randomly selected number from a uniform distribution in (0.8, 1.2). The second was rotating the signals by multiplying a quaternion rotation matrix, which mimics the situations where the same record is taken in different reference frames. First, we randomly generated a set of coordinates (x , y , and z) and defined a reference frame by calculating the basis vectors.

Then, we randomly seeded a rotation angle from $(0, 2\pi)$, and calculated as follows:

The rotation matrix, which multiplies to the original acceleration or gyroscope signals, were then defined as follows:

Evaluation Metrics

The model performances were evaluated on the ensembled inference scores and by a series of metrics, including the area under the receiver operating characteristics curve and the area under the precision–recall curve (AUPRC). Using the information of true positive TP , true negative TN , false positive FP , and false negative FN , we evaluated the weighted F_1 score and the relating precision and recall scores [22], where i is the index of the class, and the w_i =number of class i samples/total sample numbers is the proportion of the class i .

Precisions came from $TP/(TP+FP)$, and recalls came from $TP/(TP+FN)$. We also calculated weighted accuracy following the method in the studies by Dong et al [7] and Sharma et al [9]:

where w is the ratio of the number of negatives over the number of positives.

All the metrics were calculated by the corresponding functions in scikit-learn.

Comparison With DeepConvLSTM

We applied DeepConvLSTM [22] based on the official Pytorch implementation. We used a filter size of 32, and the number of hidden units in the long short-term memory was 64. Details of the structure and the parameters are listed in [Multimedia Appendix 2](#), Table S14. We used the Adam optimizer and binary cross-entropy loss function.

Statistical Significance Analysis

For model comparison, in each test of inference, we first calculated the ratio (denoted as R) of the positive (label=1) to the negative examples (label=0) and then randomly selected 1500 positive 5-minute windows and $1500R$ negative windows. We repeated 100 times to estimate the P values.

Code Availability

The code is attached with the submission ([Multimedia Appendix 3](#)) and can be runnable with Python 3.6.12 and Keras 2.2.4.

Data Availability

On the basis of consent forms, Eli Lilly can share data with regulatory authorities (Food and Drug Administration) in the

United States, the ethical review board overseeing this study, and the researchers at other institutions who wish to analyze the data in this study.

Results

Deep Learning Accurately Classifies Eating Activity in 5-Minute Windows on Previously Unseen Individuals

We first analyzed the data from the discovery cohort. Raw data were collected from the accelerometer and gyroscope from the Apple Watch at a frequency of 50 Hz and streamed to Amazon Web Service [23]. Each time point was labeled with a meal tag (1 denoted the meal region and 0 denoted non-meal time). Participants were asked to specify the start and the end of the mealtime and whether this region was recorded at the time of the meal or retrospectively. Most (126/162, 77.8%) of the daily records lasted approximately 8 to 15 hours, representing the daily activity time when the participants wore the watches (Multimedia Appendix 2, Figure S1B). The participants are likely to begin their records from 7 AM to 9 AM (Multimedia Appendix 2, Figure S1D) and end at 7 PM to 9 PM (Multimedia Appendix 2, Figure S1E), which is consistent with the expected daily activity time. A participant could have 1 to 7 eating events within a day, with the vast majority having between 1 and 4 eating events per day. Approximately 75% of the meals would last for <20 minutes. The start and peak times of the meal events were shown at the expected breakfast, lunch, and dinner times (Figure 2).

With the generated 5-minute windows (Figure 1D), we constructed a 1D (along the time axis for both input and output) deep learning model (Figure 1F) with 3 channels as input (x, y, and z axes of accelerometer or gyroscope; 6 channels when giving both accelerometer and gyroscope information). On the basis of the cross-validation described in the *Methods* section, our work showed an average AUC of 0.825 (SD 0.073; Figure 3D and Figure 4C) and an average AUPRC of 0.437 (SD 0.096), with the baseline (same value predictions for all data points) of 0.053 (Multimedia Appendix 2, Figure S3C and Figure 4D). When including the retrospective meals in prediction, our model showed stable performances with an average AUC of 0.813 (SD 0.067) and AUPRC of 0.440 (SD 0.077, baseline 0.065). In comparison, we adapted DeepConvLSTM on this data set [22], which achieved an average AUC of 0.797 (SD 0.065) and an average AUPRC of 0.294 (SD 0.072; Figure 3E) on the nonretrospective meals. This demonstrated that the techniques integrated into this approach could substantially improve over a state-of-the-field method.

We identified the factors that affect performance. First, based on the 5 models trained on the random splits of the training set, assembling the inference values from the output of the last fully connected layer, by taking the averages in each test, can significantly improve the performances in all the experiments ($P<.001$; Figure 3B-Figure 3D; Multimedia Appendix 2, Figure S3A-3C). Second, building the model on gyroscope data can achieve better performances than using accelerometer data or both. The average AUC and AUPRC of the gyroscope model are 0.02 to 0.05 higher than the other alternatives (P values for AUCs $<.001$; P values for AUPRCs $<.001$; Figure 3B and Multimedia Appendix 2, Figure S3A; Multimedia Appendix 2, Tables S1 and S2). Third, choosing correct input data normalization methods may be helpful. Centering normalization improved the model performance by 0.002 on the AUC and 0.01 on the AUPRC (P values for AUCs=.29; P values for AUPRCs=.10), whereas, with the z score normalization, which may compress the original ranges of the signals, the performances will drop by 0.01 and 0.04 on the AUC and AUPRC (Figure 3C and Multimedia Appendix 2, S3B; Multimedia Appendix 2, Tables S3 and S4). This is likely to reflect the fact that the magnitude of the signal is critical to the model, whereas the directions of the watch (ie, reflected as the overall shift of an axis) are not relevant. Fourth, data augmentation, including the quaternion rotation of the signals in space and scaling the signal magnitudes, might improve the model performance. Rotation and scaling can provide >0.01 improvement on both AUCs and AUPRCs for a single model, although not statistically significant (P values for AUCs=.33; P values for AUPRCs=.17). When considering the ensemble model that aggregates 5 models generated using different random seeds, the magnitude scaling gives better but not significantly better performance both on AUC and AUPRC (P values for AUCs=.26; P values for AUPRCs=.88; Figure 3D and Multimedia Appendix 2, Figure S3C; Multimedia Appendix 2, Tables S3 and S4). Adding in local time did not improve the performance (Tables S1 and S2).

To retrieve the performances of each individual, including the previously excluded ones, and generate the baselines for evaluating the improvements of our following fine-tunings on the personalized models, we also used the leave-one-subject-out approach to calculate the AUCs and AUPRCs. For each individual, the model was trained on all the other data except the one left out. The average AUC for the ensemble model was 0.818 (SD 0.104), and the average AUPRC was 0.419 (SD 0.162, Figure 4A and Figure 4B; Multimedia Appendix 2, Table S7). Visualization of the inferences of two dates of records: data on June 24, 2019, from 0FA7 and data on June 10, 2019, from 3E5F show consistency with the eating and noneating behaviors (Figure 4E and Figure 4F).

Figure 3. Evaluation of model performance on 5-minute windows of the discovery cohort. (A) Models were built by gyroscope data only, accelerometer data only, and gyroscope+accelerometer data. Next, we tested the centering and normalization of each axis of the data. Intensive data augmentation was applied to the data on the fly. For each method, 5 models were trained by resampling the training and validation data and they were assembled for evaluation. (B) Presents the performance comparisons of different data selections. (C) Presents the performance comparison of different normalization methods applied on the gyroscope model. (D) Presents the performance comparisons of the augmentation methods based on the centering model, where Quart refers to the quaternion rotation augmentation, and Scale refers to scaling the magnitude. (E) Comparison of the performances between DeepConvLSTM and the method presented in this paper. AUROC: area under the ROC curve; AUPRC: area under the precision–recall curve; CNN: convolutional neural network; ROC: receiver operator characteristic.

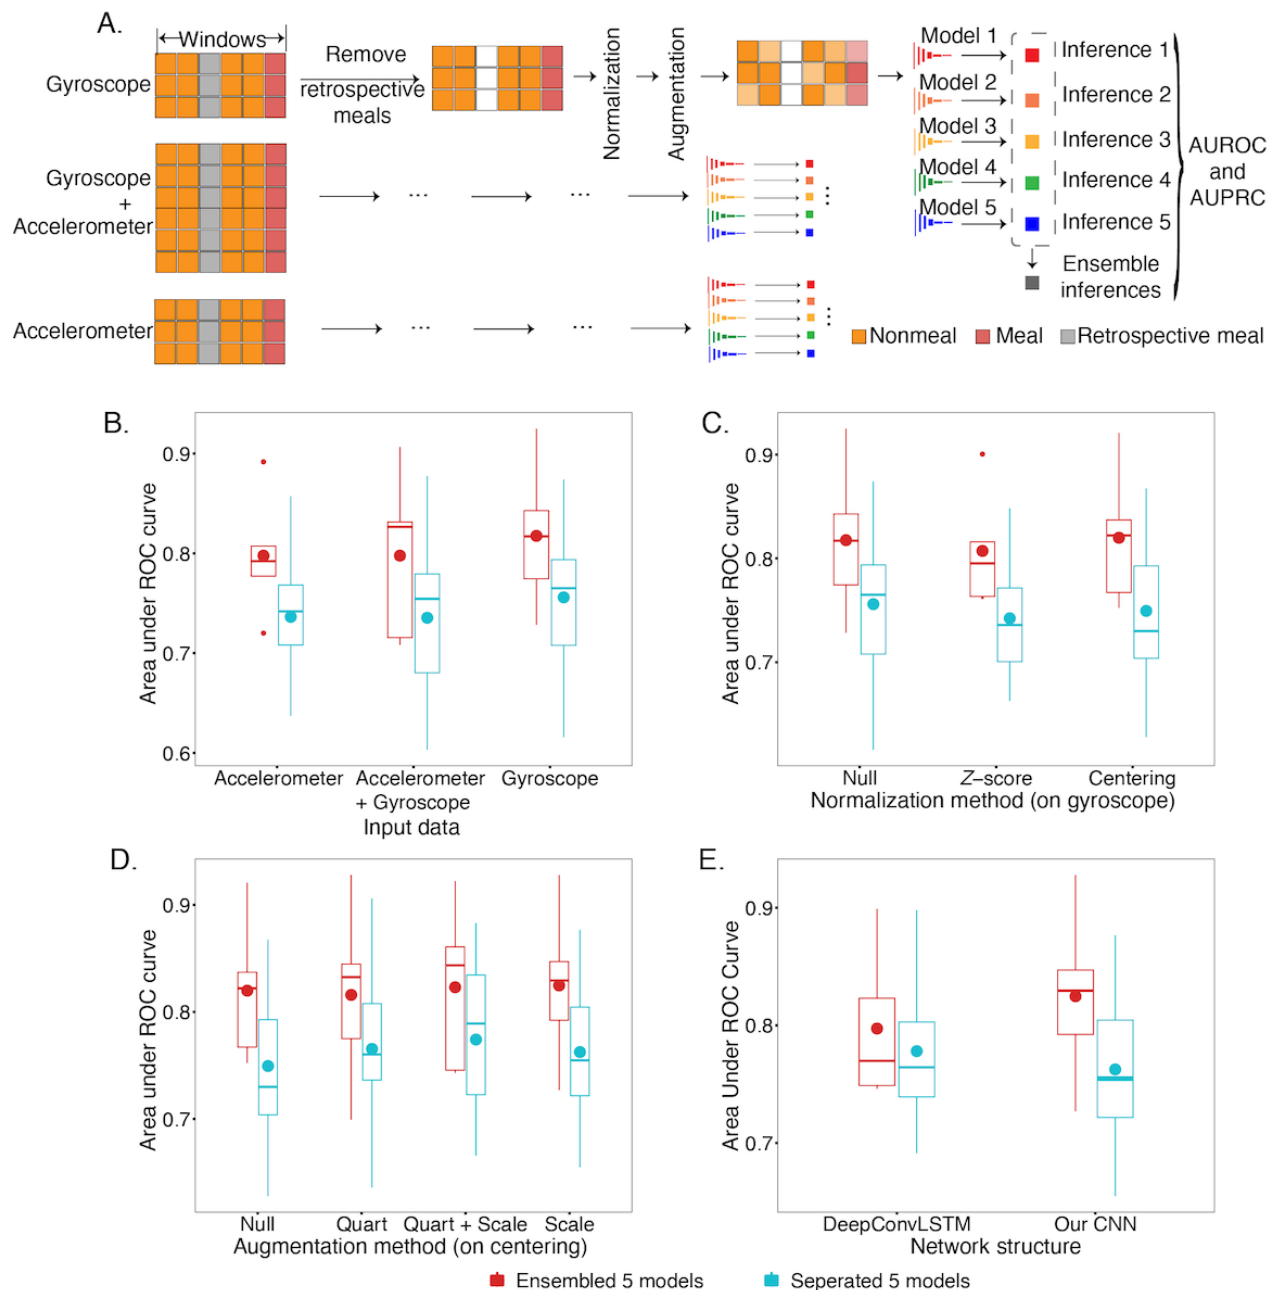

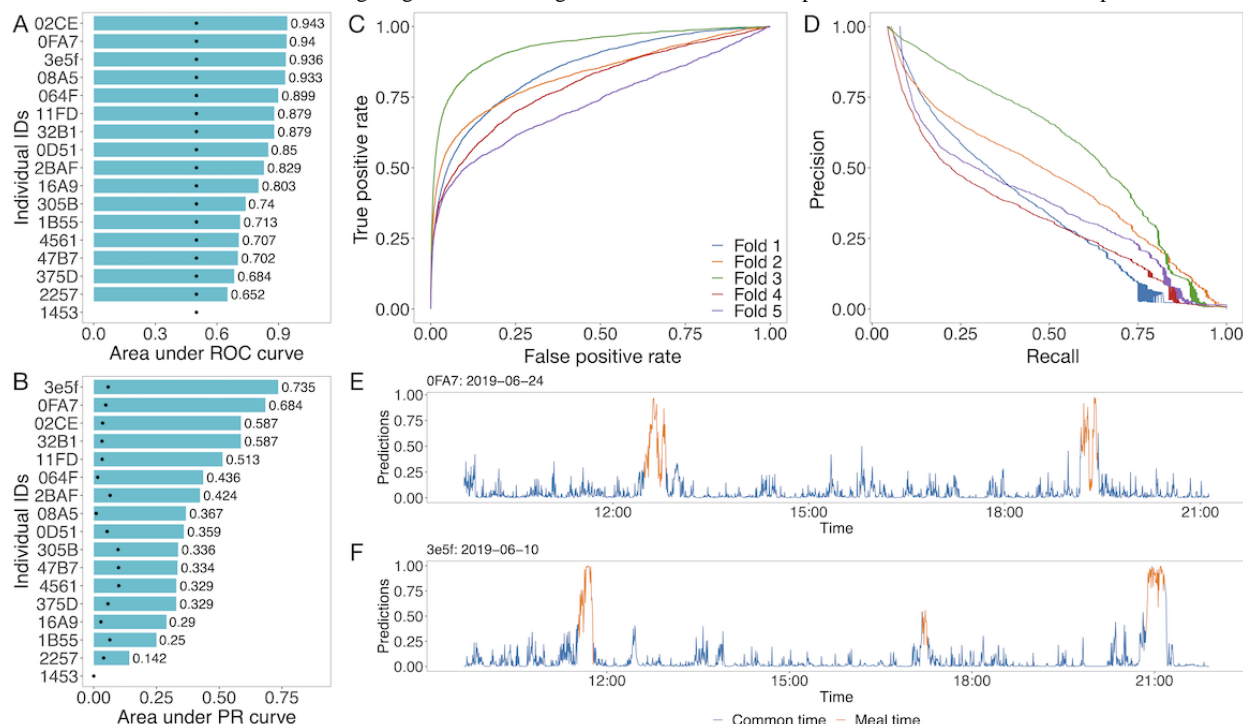

Figure 4. The evaluations of the selected best model: convolutional neural network backbone trained with the centering normalized gyroscope data using magnitude scaling. (A and B) show the leave-one-subject-out results of the model on the discovery cohort, evaluated both in the area under the curves and area under the precision–recall curves. The black points in (B) are the baselines for the individuals. As 1453 does not have any positive samples after excluding the retrospectives, its value will be empty. (C) is an area under the ROC curve, and (D) is a precision–recall curve for the cross-validation from the ensemble model, respectively. (E and F) give the inferences of the 2 dates of records, where the blue segments denote the signals of the non-meal time, and the orange segments are the signals of the mealtime. PR: precision recall; ROC: receiver operator characteristic.

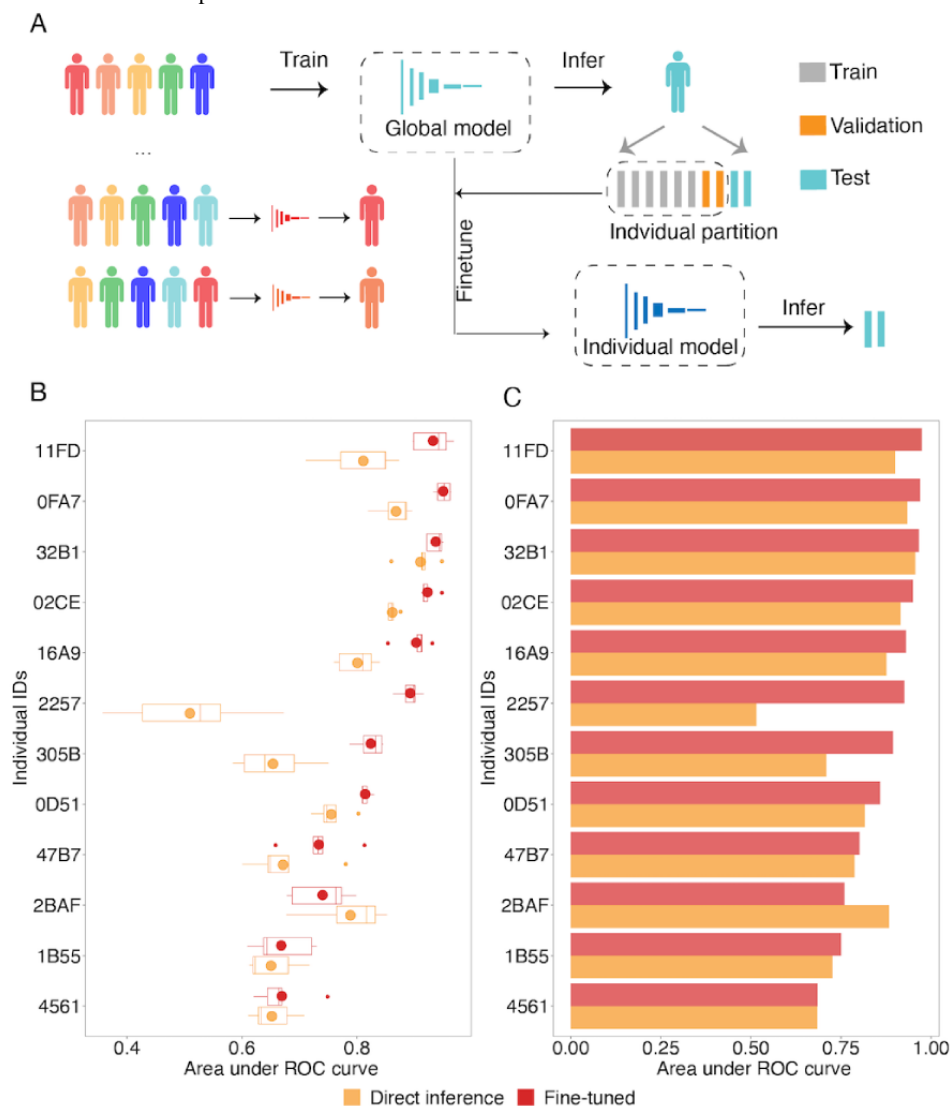

Fine-tuning of the Personalized Model Improves Performance

This longitudinal data allowed us to explore whether it is possible to construct personalized models for eating and further improve model performance (Figure 5A). The global models served as the fine-tuning starting points for the individuals of interest (Figure 4A and Figure 4B). This study design mimics an important utility of the models in real life, where we adopted an existing model to a previously unseen person and asked whether we could improve the inference on this individual by observing some data for this individual.

Comparing the performance of the global model on this individual versus the fine-tuned model, we found that other than 1 individual (2BAF), the fine-tuned personalized models showed better performance than directly applying the population models on the specific individuals. The AUC on average improved for the fine-tuning model to 0.872 (SD 0.099), with an average weighted F1 (the average weights were 0.059 and 0.941 for positives and negatives, respectively) score of 0.938 (SD 0.048), an average precision of 0.945 (SD 0.045), and an average recall of 0.934 (SD 0.049; Figure 5B and Figure 5C; Multimedia Appendix 2, Tables S8 and S9).

Figure 5. Evaluating fine-tuning to generate individual models on the discovery cohort. (A) For a specific individual under investigation, we first trained 5 global models using all other individuals by resampling the training and validation set for the deep learning training process. Next, we split records of the individual of interest by days into training, validation, and test sets and fine-tuned the global model using the training and validation set. We evaluated the performance by the area under the ROC curve for both the global and the individual fine-tuned models for (B) 5 separated models and (C) ensemble models. ROC: receiver operator characteristic.

Aggregation of Multiple Windows Reaches Near-Perfect Detection of Meal Events

We then evaluated the model performance on the original mealtimes. We conducted three experiments on cross-validation of the discovery cohort: (1) the prediction for whole meals (Figure 6A), (2) the prediction within 5 minutes or 10 minutes after the meal starts (Figure 6B), and (3) the false calls within an hour (Figure 6C). For all nonretrospectively recorded meal events, we calculated the average score during each meal event. For calculating scores for the negative regions, we randomly selected a series of negative regions whose lengths and numbers were matched to the meal events. The scores for the negatives were generated by taking the averages of the windows within the selected regions. The models achieved an AUC of 0.951 (SD 0.018) by this aggregation, and the corresponding weighted F1 score (weights were 0.464 and 0.536 for positives and negatives, respectively), precision, and recall were 0.877 (SD 0.037), 0.8890 (SD 0.027), and 0.879 (SD 0.035), respectively

(Figure 6D; Multimedia Appendix 2, Table S10). Including the retrospective, meals would result in a similar AUC of 0.951 (SD 0.017), with the corresponding weighted F1 score of 0.858 (SD 0.040, weights for positives and negatives were 0.5).

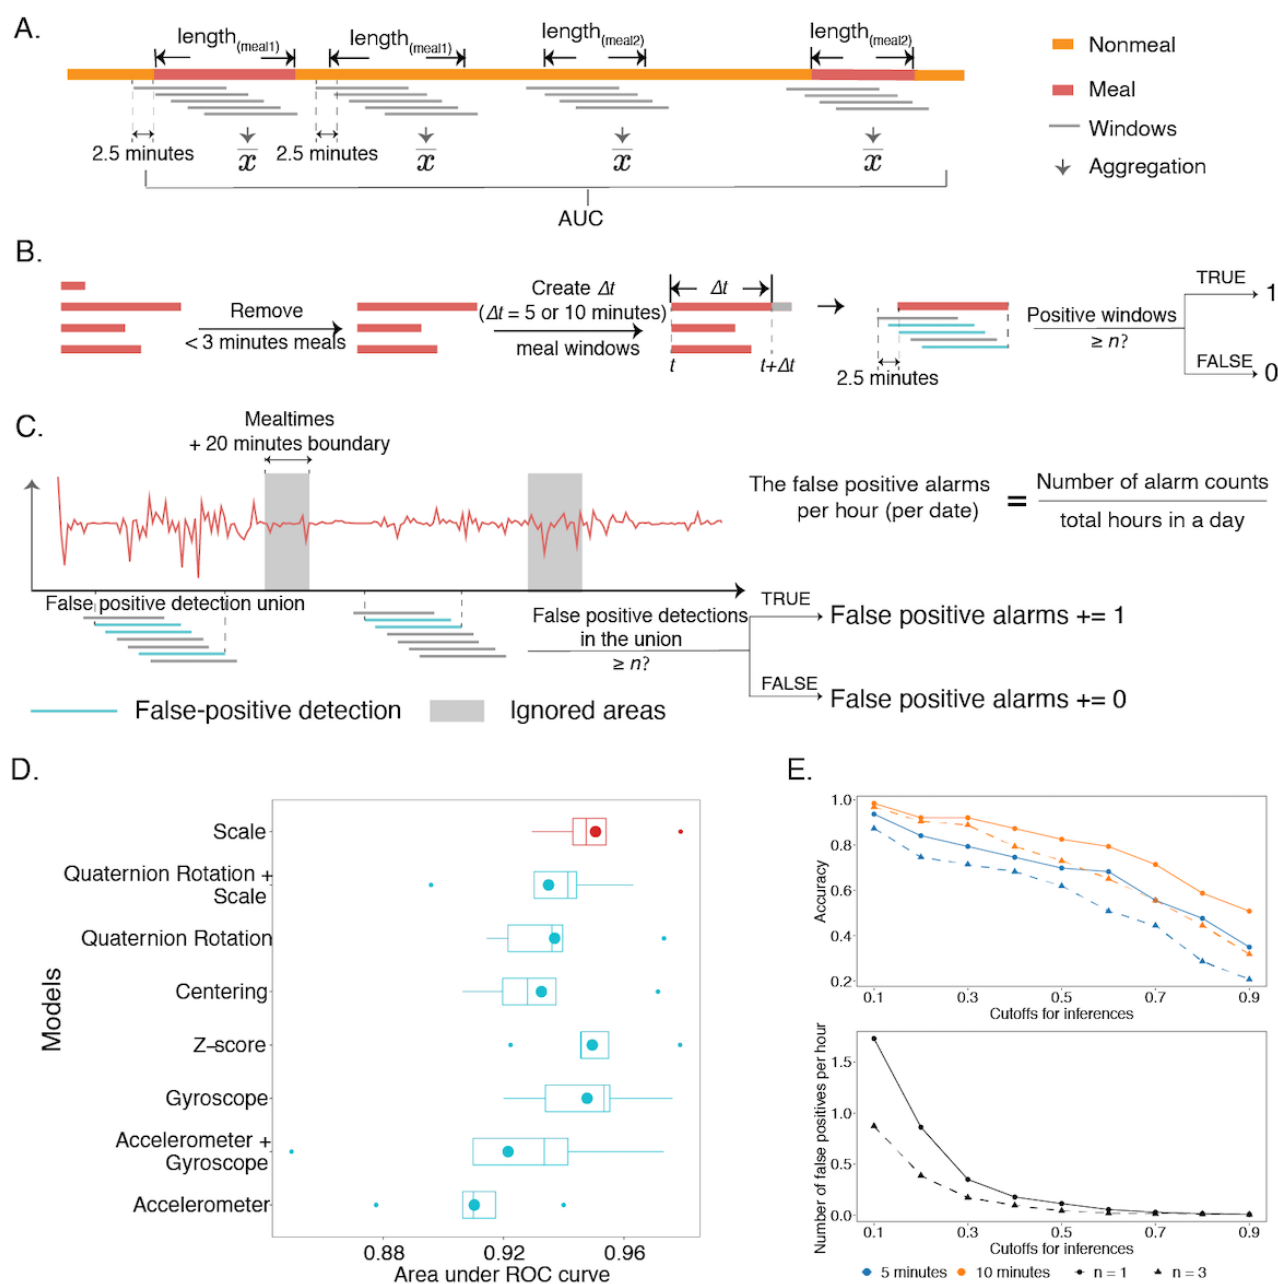

For prediction on the 10-minute or 5-minute after meal start, we used the accuracy (ie, how many mealtimes were correctly inferred) for evaluation (Figure 6E; Multimedia Appendix 2, Tables S11 and S12). In this case, we were interested in how we could choose a criterion so that most meals could be detected within 5/10 minutes. We used a moving step of 10 seconds and defined a window to be positive if the prediction score was >0.3 . If >3 windows were predicted to be positive in 5/10 minutes, we alarmed a *call*. Using these criteria, we reached a recall rate of 0.889 for 10 minutes, and the result remained robust in the 5-minute test, cutoffs of prediction score between 0.4 and 0.6, and the number of windows we used to alarm the call.

Next, we calculated the number of false positive predictions per hour of negative regions. For each hour, we had a total of 360

chunks (with a moving step of 10 seconds). The corresponding false positive prediction was 0.172 per hour; that is, 1 to 2 times of false positives in a whole day of activity. Again, this result

was robust against the cutoff defining a positive window and the number of windows needed to alarm a call.

Figure 6. The results of the aggregations on the entire meals and on the specific time regions after meal start. (A) Aggregation to produce meal-level detection performance. (B) A preprocessing step removed meals that were <3 minutes and created 5- or 10-minute windows for positive examples to evaluate recall rate. (C) Nonmeal regions were used to calculate false positive alarms using the 5-minute windows and the same criteria as what was used to define positive inferences in calculating the recall rate. The gray areas denote the mealtimes with the 10-minute boundaries at the start and the end, where the windows are out of consideration. (S) Shows the evaluations of the aggregations on the entire meals. The boxplots comprise the AUCs from the average inferred scores of the ensemble models in the cross-validation, and the experiments (models) are the same as those in Figure 3A. The point in each box denotes the corresponding average AUC. (E) indicates the results of the aggregation on the 5- and 10-minute meals after starting and on the entire negative signals. The lines show how the detection accuracy and the hourly false positive numbers (the black lines) change along with the cutoffs. The orange lines show the results for the 10-minute meals, and the blue lines are the 5-minute meals. The shape of the points represents the choice of N, where the circles/solid lines are N=1, and the triangles/dashed lines are N=3. AUC: area under the curve; ROC: receiver operator characteristic.

Generalizability to an Independent Validation Cohort Collected in a Different Season

Although the first batch of the data was collected in the summer, we proceeded to collect a second validation cohort in winter, 6

months later, by recruiting 17 new individuals. By splitting the discovery cohort data into 5 sets of training and validation data, we first finalized 5 models for the first cohort; then, we directly applied these models to the validation cohort for inferences. Next, we applied the scheme of the whole meal predictions to

the validation cohort, both on the data with and without the retrospective meals. Without any further tuning, the model achieved a meal-level AUC of 0.941 on the validation cohort for the nonretrospective meals, with a 0.870 weighted F1 score (the weights were 0.445 and 0.555 for positives and negatives,

respectively), a 0.878 precision, and a 0.871 recall. With the retrospective meals, the meal-level AUC and the weighted F1 score were 0.920 and 0.846, respectively (the weights for positives and negatives were 0.5). The performances of our work in this study are listed in [Table 2](#).

Table 2. List of the performances in this study.

Experiments	Area under the curve	Area under the precision–recall curve	Weighted F1 score
Cross-validation of our model on 5-minute windows	0.825	0.437	N/A ^a
Cross-validation of our model on 5-minute windows, including the predictions on retrospective meals	0.813	0.440	N/A
Cross-validation of DeepConvLSTM [22] on 5-minute windows	0.797	0.294	N/A
Leave-one-subject-out approach of our best model on 5-minute windows	0.818	0.419	N/A
Fine-tuning the personalized model	0.872	N/A	0.938
Cross-validation of our model on the original mealtimes (discovery cohort)	0.951	N/A	0.877
Cross-validation of our model on the original mealtimes, including the predictions of retrospective meals (discovery cohort)	0.951	N/A	0.858
Predictions of our model on the original mealtimes (validation cohort)	0.941	N/A	0.870
Predictions of our model on the original mealtimes, including the predictions of retrospective meals (validation cohort)	0.920	N/A	0.846
Accuracy of detecting the eating in 10 minutes	0.889	N/A	N/A
False positive detections per hour	0.172	N/A	N/A

^aN/A: not applicable.

Discussion

Principal Findings

In this study, we presented a large, in-the-field, digital eating detection study of eating activity. Deep learning algorithms experimented with a diverse array of augmentation, preprocessing, and architectures allowed us to narrow down the algorithm into one with a performance of AUC of 0.825 to infer previously unseen individuals for a single 5-minute window. When evaluated on the entire meal regions, this AUC was 0.951. We further validated the algorithm in an independently time-lapsed cohort collected in a different season (6 months later, winter) and achieved a meal-level performance of 0.941 AUC without further tuning. This design can potentially result in models that are more or at least similarly generalizable than data collected consecutively in the same season. This represents the first study that harbors a validation cohort in this field.

Compared with other studies that focus on population-wise models [9,13,24–26], the longitudinal weeks of follow-ups of the data set presented in this study allowed us to further explore the possibility of personalized models for detecting eating activity. It is widely recognized that eating motions differ substantially in a population by gender, culture, and certainly individual habits. This fine-tuning scheme produced an average AUC at 0.872, corresponding to a 0.89 success rate in calling back an eating event within 10 minutes. This substantial improvement in performance points to the direction toward personalized eating monitoring in the dietary research field.

Records of the local time, as well as the utensils used for each meal, also allow us to glean insight into their influences on our model ([Multimedia Appendix 2](#), Figure S4). We found that food taken with hands had relatively poor performance (AUC=0.812; [Multimedia Appendix 2](#), Figure S4B). In addition, we found that false positive rates are relatively high between 6 AM to 7 AM and 9 PM, indicating potential morning and evening activities mimicking eating movement ([Multimedia Appendix 2](#), Figure S4C). Future studies incorporating different characteristics of utensils as well as whole daily activity logs might have the potential to further improve the performance.

Limitations

We acknowledge several potential limitations of this study. First, we excluded smoking individuals, for whom the inference task could become more complicated as the motion of smoking shares a certain similarity with the motion of eating. Second, we only included healthy individuals, which may not be representative of the population of movement disorders such as ataxia and Parkinson disease. In addition, we did not collect the data for the nondominant hand. The weaker and noisy signals may significantly affect our model built on dominant hand data. Potentially, combined with additional devices such as ear- and chest-anchored devices and video ([Multimedia Appendix 2](#), Table S15 [27–31]), in future works, we will be able to combat such limitations. We used a total of 34 individuals in the study. Although we observed strong predictions across individuals, larger collections focusing on more individuals but less longitudinal follow-up might further complement the information provided in this study. Furthermore, we used 50

Hz data in this study for optimizing battery performance in collecting data. It is yet to be evaluated how higher Hz data contribute to performance with the development of the devices.

Future Works and Conclusions

This study and the API developed here open several future directions that are worth exploration. For example, how do digital indicators differ for populations coming from different cultural backgrounds? Does handedness affect model construction and performance? And how much will the model

be affected if one wears the device on his or her nondominant hand? Answering these questions will need large-scale studies with a large number of participants, and the API and data streaming platform developed in this study will become a convenient tool for this purpose. The accuracy of the models developed in this study satisfies immediate deployment needs in clinical settings to monitor eating behavior and give guidance to treatment regimen adjustment accordingly. We envision the digital streaming platform will be widely integrated into a variety of clinical trials in the near future.

Authors' Contributions

BZ, JS, BR, and HF contributed to the study design, device design, and data streaming. KD, JS, YG, and BR contributed to data analytics. YG drafted the manuscript. KD and LC were responsible for the figures. BR contributed to conducting and analysis planning.

Conflicts of Interest

BZ and HF are current Eli Lilly and Company employees. JS and BR were Eli Lilly and Company employees when the work was conducted. KD and LC were Ann Arbor Algorithms, Inc employees when this study was conducted. YG serves as the scientific adviser for Eli Lilly and Company on this study.

Abstract

Background: Sleep influences moods and mood disorders. Existing methods for tracking the quality of people's sleep are laborious and obtrusive. If a method were available that would allow effortless and unobtrusive tracking of sleep quality, it would mark a significant step toward obtaining sleep data for research and clinical applications.

Objective: Our goal was to evaluate the potential of mobile sensing data to obtain information about a person's sleep quality. For this purpose, we investigated to what extent various automatically gathered mobile sensing features are capable of predicting (1) subjective sleep quality (SSQ), (2) negative affect (NA), and (3) depression; these variables are associated with objective sleep quality. Through a multiverse analysis, we examined how the predictive quality varied as a function of the selected sensor, the extracted feature, various preprocessing options, and the statistical prediction model.

Methods: We used data from a 2-week trial where we collected mobile sensing and experience sampling data from an initial sample of 60 participants. After data cleaning and removing participants with poor compliance, we retained 50 participants. Mobile sensing data involved the accelerometer, charging status, light sensor, physical activity, screen activity, and Wi-Fi status. Instructions were given to participants to keep their smartphone charged and connected to Wi-Fi at night. We constructed 1 model for every combination of multiverse parameters to evaluate their effects on each of the outcome variables. We evaluated the statistical models by applying them to training, validation, and test sets to prevent overfitting.

Results: Most models (on either of the outcome variables) were not informative on the validation set (ie, predicted $R^2 \leq 0$). However, our best models achieved R^2 values of 0.658, 0.779, and 0.074 for SSQ, NA, and depression, respectively on the training set and R^2 values of 0.348, 0.103, and 0.025, respectively on the test set.

Conclusions: The approach demonstrated in this paper has shown that different choices (eg, preprocessing choices, various statistical models, different features) lead to vastly different results that are bad and relatively good as well. Nevertheless, there were some promising results, particularly for SSQ, which warrant further research on this topic.

Introduction

Background

Sleep is important for well-being and plays a key role in people's mood and their risk for mental health problems such as depression. Therefore, obtaining a reliable picture of people's sleep quality critical for the study, prevention, and treatment of mood disorders. However, most of the existing methods are based on obtrusive techniques, either asking participants to wear dedicated technological devices (in the laboratory or otherwise) or to self-report their sleep patterns in a sleep diary. Therefore, both methods are burdensome for individuals and are not appropriate for long-term monitoring. If a method that is capable of unobtrusively tracking a person's sleep quality is developed, it would mean an important leap forward. One potential solution is the use of smartphones that have become ubiquitous in today's society. Approximately 76% of adults in countries with advanced economies have a smartphone [1], a device equipped with several sensors that automatically record user behaviors, some of which may be considered sleep-related ones. This study aims to examine to what extent automatically recorded information with smartphones—known as mobile sensing—can be used to predict self-reported subjective sleep quality (SSQ), mood, and the risk of mood disorders in the form of depression.

Sleep quality can be measured either in terms of subjective, self-reported sleep quality or can be captured with objective measurements such as polysomnography (PSG) and more recently actigraphy. Subjective and objective sleep quality are only weakly related [2-4] because they measure different aspects of sleep quality, namely physical sleep quality (objective) or a person's perception of sleep quality (subjective). However, they are both predictive of moods [5-7] and mood disorders [8-10]. Given the obtrusiveness of objective measurement methods and their adversity to use over long periods, we focus on predicting SSQ. Therefore, the primary outcome of this study is to measure SSQ with mobile sensing. As a secondary outcome, given the relevance of sleep quality for moods and mood disorders, we will examine to what extent mobile sensing is capable of predicting moods in terms of the daily negative affect (NA) and risk for mood disorders in terms of depression symptom severity. Thus, the underlying mechanism (and the underlying data on which this mechanism relies) is the relation between sleep and mental health.

Related Work

In most studies, an accelerometer is used to detect smartphone movements that are seen as synonymous with participant movements in bed [11-14]. Such movement detection is also used in commercial sleeping apps, such as Sleep as Android [15], Sleep Cycle [16], and Apple's native health app. Accelerometers can be used for movement detection with and without instructions to the participants. For example, researchers can instruct participants to place their smartphone next to or under their pillows. However, for the sake of ecological validity, this is usually not recommended. Another seemingly straightforward feature indicating sleep is whether the smartphone is being used (ie, screen on/off events) [14,17]. These screen events have proved useful for detecting circadian

rhythms and people's temporal sleep preferences [18]. A more contextual feature comes from the light sensor; ambient light indicates whether a room is dark and thereby helps determine whether a participant is sleeping [12,19,20]. Similarly, a microphone can pick up ambient sound, thereby confirming whether a participant is in a quiet environment [11,14,20].

Early efforts were made, for example, using location (GPS), contextual (sound and light), physical activity (accelerometer), and communication data (text and call logs) to infer SSQ measured with the Pittsburgh Sleep Quality Index [21], divided into 4 categories [22]. Using these features in a factor graph model, an accuracy of 78% was achieved. Other pioneering research on mobile sensing and sleep was conducted by comparing the quality of a smartphone accelerometer with an actigraph accelerometer for sleep monitoring [23]. Both devices showed reasonable agreement with all features except sleep onset latency. However, on a more critical note, 1 study [24] found no significant correlation between sleep measured by PSG and a smartphone app, although the mobile app did have high sleep-wake detection performance (85.9%) in relation to PSG. Thus, although mobile sensing for sleep detection has attained modest success, it is unclear how robust these methods are to changes in features and how well they describe sleep in comparison to PSG.

Despite PSG being considered the gold standard for sleep research, it is being recently rivaled by numerous wearable devices that feature an integrated accelerometer (among other sensors). Moreover, a mobile app was developed that achieved better user experience and lower perceived intrusiveness than wearables [11]. Using light, phone usage (including screen state), physical activity, and sound features in a completely "hands-off" approach, the app had an estimated sleep duration error of approximately 42 minutes, a slightly worse result than the other sleep detection methods, with 23 minutes when the smartphone is on the bed and 10 minutes for wearables. Subsequently, an app called StudentLife was developed with which a significant negative correlation among sleep, depression, and stress was found [19]. By using the same features as those in an earlier study [11], 95% of bedtimes were predicted with an error of 25 minutes from the ground truth as measured with an actigraph (Jawbone UP). Bringing the sensing accuracy of smartphones on par with that of wearables is significant because wearables are still not pervasive, thus making smartphones the least obtrusive solution for now.

A more indirect way of assessing sleep is by dividing a night into small epochs and predicting whether a participant is asleep or awake through self-reported bed and wake-up times or actigraphy. Of course, these sleep-wake states can then be used to derive other features that may subsequently be used for predicting sleep proxy measures. For example, 10-minute segments of sleep-wake states were predicted with 93% accuracy, but daily sleep quality was predicted with 84% accuracy [12]. Similarly, 15-minute bins were predicted with 89% accuracy using only screen on/off events [25]. Furthermore, 88.8% accuracy was reported when determining whether a 10-minute segment was a sleep state, whereas using the time of day alone achieved 86.9% accuracy [26]. Moreover, the accuracy per participant ranged from 65.1% to 97.3% although

lower accuracies could mostly be attributed to missing data reports and misreports. After adjustments, the accuracy was increased to 91.8%, corresponding to a median absolute deviation (MAD) of 38 minutes for the sleep start time and 36 minutes for the sleep end time.

This Study

We analyzed data from a 2-week study involving various smartphone sensors and the experience sampling method (ESM, also known as ecological momentary assessment) to collect SSQ in the morning and daily moods in terms of NA, as well as a 1-time assessment of person-level depression using a validated depression screening instrument. As mentioned above, several theoretically and empirically based predictions can be made regarding what sensors are the most significant for predicting SSQ and the associated variables of daily moods and depressive symptom severity. In addition, there are multiple ways to process the data based on different thresholds and data combinations, and there are different options to model the relationship between mobile sensing and the predicted variables. To examine this variability, we perform a multiverse analysis [27] in which we compare prediction results across multiple sensors, extracted features, thresholds, outlier methods, and prediction models. In other words, essentially all sensible combinations of these aspects, choices referred to as multiverse parameters, are evaluated in terms of how they are capable of predicting the outcome measures. Using this approach, this study not only aims to predict sleep with mobile sensing but also to investigate (1) which model, (2) which feature, and (3) which sensor works best within the context of the study. Consequently, this method is an analysis of robustness and transparency because it shows how different choices affect the outcome.

Methods

Overview of Data Preprocessing

As already mentioned earlier, we focused on the many seemingly arbitrary choices to be made during data preprocessing. Consequently, we performed a multiverse study showing the robustness of these choices. Following this approach, this section describes each aspect of the multiverse approach separately. First, various preprocessing steps were conducted for minimizing the number of participants with faulty data, namely removing participants with fewer than 10 data points for a sensor, sensors where all values were 0 (broken sensor), and 1 participant who had 40,000 times more data points than the participant with the second highest number of data points. In this regard, we present preprocessing of the different sensors in this study and describe when they are considered to indicate that a participant is sleeping, often having more than 1 threshold. Next, we discuss how features were built. These features are used in various statistical models. In the context of a multiverse approach, we experimented with several models to see which one worked best. Finally, we tried different outlier

removal methods to catch faulty data entry and unlikely data instances.

Data Collection

Data were collected during a 2-week study in 2018 [28]. Participants installed 2 separate apps on their smartphones, 1 for collecting sensor data and 1 for tracking their moods and SSQ using ESM. Mobile sensing data were gathered from specific (software) sensors to account for behavioral and contextual factors. These sensors are described in Table 1. Participants were instructed to charge their smartphones at night and connect to Wi-Fi whenever possible. On the other hand, data on the participants' SSQ and NA were collected using ESM, where they were prompted 10 times per day with a 16-item questionnaire measuring, among other parameters, their momentary (positive or negative) affect and how they slept if it was their first survey of the day. Depression levels were recorded only after the study using the Depression, Anxiety and Stress Scale questionnaire [29,30]. Katholieke Universiteit Leuven's Social and Societal Ethics Committee, whose directives are based on the Helsinki Declaration, approved the study (reference no. G-2018 01 1095). Written electronic consent from all subjects included in this study was obtained.

In total, 230 people responded to the participant selection questionnaire posted on social networking sites and other places frequented by students at the University of Leuven. Participants were excluded if they (1) did not understand Dutch, (2) did not have sufficient activity on their devices, (3) did not own an Android smartphone (except Huawei, Wiko, Medion, or Xiaomi), and (4) did not grow up with smartphones (ie, below 32 years of age). Among the 114 individuals who participated in an information session, 69 decided to join; 2 refused to sign the informed consent, and app installation failed for another 2 individuals. After excluding 5 participants who completed fewer than 30 ESM surveys, 60 participants remained. Furthermore, all data were preprocessed such that participants with fewer than 10 observations in total or only 0s (indicating a broken sensor) were left out. Single observations were left out if they were far away in time from any other observations (ie, if there was a gap in time in the data) using boxplot outliers. Next, values for each sensor were visually inspected to exclude participants who had very poor data quality. Participants were only retained if they had sufficient data for all sensors (ie, more than 10 observations), resulting in a final data set of 50 participants. Because participants were mainly university students and advertising was mainly done on social media and the campus of the faculty of psychology, the majority of the sample was young and female (14 male and 36 female aged 17-32 years, mean 21.90, SD 2.38 years).

Sensor Data Preprocessing

In this study, we used the following sensors: accelerometer, charging status, light sensor, Android activity recognition (AAR), screen activity, and Wi-Fi status. Table 1 gives an overview of the sensors and how their data were handled to obtain information on participants' sleep quality.

Table 1. Description of sensors used in this study^a.

Sensor	Description	Considerations	Indication of sleeping when...
Accelerometer	Acceleration in m/s ² along the x-axis	Other axes (y and z) not measured owing to programming error	Absolute value is less than (0.25, 0.5, 1) m/s ² .
Charging	Indication of whether the smartphone is charging As participants were instructed to leave their smartphone charging at night, a charging smartphone can mean that the participant is sleeping.	Momentary sleep interruptions are unlikely to be picked up by this sensor.	Battery is charging.
Light	Illuminance in lux ^b captured by the light sensor (usually at the front-top side of the smartphone)	Room with translucent curtains may simulate a wake-up state. Smartphone may be upside down.	Value is less than (8, 12, 16) lux.
Physical activity	Category of physical activity as measured by AAR ^c (ActivityRecognitionApi app)	Proprietary algorithm obfuscates how AAR is transformed into discrete activities.	AAR returns “Still.”
Screen activity	Logs whether the screen has been changed to on or off.	Duplicate entries (screen off multiple times without screen on) are frequent. There is no distinction regarding whether the app turned the screen on (eg, notifications) or the participants.	Screen is off.
Wi-Fi	Information about whether the smartphone is connected to Wi-Fi	Unlikely to pick up temporary wake-up states	Connected to Wi-Fi.

^a The considerations column discusses issues that are (likely) associated with the sensors or their implementation. The sleeping when... column indicates when a sensor decides that a participant is sleeping in a window. Multiple values in parentheses indicate that the same data have been used but with a different cutoff value.

^b lux is the SI unit for intensity.

^c AAR: Android activity recognition.

One of the core elements in this multiverse study is inspecting each sensor and applying suitable preprocessing. The accelerometer was thought to be highly indicative of the sleep state [14,20]. However, as this sensor was sampled only every 2.9 minutes on average (SD 6.72 minutes with the longest interval being 15 minutes), only movement at that specific moment leads to the detection of a nonsleeping state. Additional problems with this sensor were that owing to a programming error, only the x-axis data were collected and the sensor in the participants' smartphones was uncalibrated. The latter issue led to some accelerometers not showing 0 acceleration at their lowest point. To offset this, accelerometer values were centered per participant, and the absolute values were calculated subsequently, such that a corresponding sleep or wake state could be derived from the threshold values specified in Table 1. As the accelerometers were not calibrated beforehand, we attempted to align them by centering. Moreover, for every acceleration, there must be an opposite deceleration. Physical activity is the product of on-the-fly processing by Google's AAR [31]. In brief, AAR runs an algorithm that combines multiple sensors to form discrete activities. In this research, only the activity “Still” was used because this indicates that the smartphone is not moving (whereas the other activities indicate some type of movement).

The screen state software sensor was preprocessed in such a way that interactions of less than 12 seconds were ignored. This is necessary because some of the smartphone screens light up whenever there is a new notification and thus pollute the actual

stream of the screen state. On the other hand, if people use their smartphone in the middle of the night for, say, checking the time, this will most likely also be thrown out. For the charging, light, and Wi-Fi sensors, no further preprocessing was applied.

After cleaning the data, the participant's nights were divided into windows of 5 minutes. To avoid a high number of false positives, only data from 10 PM to 10 AM on the next day were considered. For each window and sensor, a majority vote determined whether a participant was sleeping. For example, if the app sensed that the smartphone was charging twice and that it was not charging once (within the same window), a majority vote set the window to sleeping. If there were no data in the window, the last observations (ie, of the previous window) were carried forward.

Feature Creation

Several features were extracted from the data that were deemed indicative of sleep quality. Figure 1 displays a visual example of all the features explained in this section. The basic building blocks for most features are the BedTime and WakeUpTime features that are found by examining 3 to 5 adjacent windows where a participant is sleeping (BedTime) or not sleeping (WakeUpTime) according to a sensor. Concretely, for the first 3 to 5 adjacent windows where a participant is sleeping, the first window of that sequence is the BedTime window. The opposite is true for WakeUpTime, namely the first window of the first 3 to 5 adjacent windows where a participant is not sleeping.

Figure 1. A fictional example of the features used in this study. This figure only depicts the first and last hours of the windows for illustration purposes, where the ... obscures the rest of the night. Gray bars indicate sleep states, and white ones indicate nonsleeping states. The night starts at 10:20 PM (ie, before the first sleeping window) because BedTime requires 3 to 5 adjacent windows (4 windows in this example). Similarly, WakeUpTime starts at 9:20 AM because this denotes the start of 3 to 5 adjacent windows, depending on the chosen parameters. Notice how SleepTime is the time between BedTime and WakeUpTime, whereas TotalSleep is simply the sum of all the sleeping windows. Finally, the number of interruptions is given as the number of nonsleeping sequences minus the number of sleeping sequences; the interruptions duration feature includes all the nonsleeping windows within SleepTime.

From the initial features of BedTime and WakeUpTime, several others could be calculated as well. First, SleepTime was calculated as the time between BedTime and WakeUpTime. Second, sleep quality may be impacted when a participant sleeps unusually longer or shorter than usual. To capture this, we computed the deviation from each participant's average BedTime and WakeUpTime (in hours) for each night (abbreviated as devAvgBedTime and devAvgWakeUpTime, respectively). Hours have been recentred such that 10 PM=0, 11=1..., 10=12. Third, the number and duration of nightly interruptions (abbreviated as nInterruptions and InterruptionsDuration, respectively) are calculated as follows: Every pattern of neighboring wake-up minus the sleeping windows counts as one interruption, and the total number of nonsleeping windows forms the total duration (multiplied by the window size of 5 minutes). Both features are only calculated within the interval of BedTime – WakeUpTime, also known as the SleepTime.

As we did not know the validity of BedTime and WakeUpTime—based on which all features discussed so far—we added a feature called TotalSleep that is simply the number of sleeping windows at night (10 PM–10 AM) multiplied by the window size (ie, 5 minutes). Another feature not based on sleep or wake-up times but can be useful is the physical activity of the previous day, as measured by AAR. Concretely, UserActive is the sum of the time spent walking or cycling during the previous day.

Modeling Approach

As the purpose of this research was to predict SSQ, which cannot be measured directly, we used proxy measures to validate our approach. In particular, we trained models to predict the SSQ reported each morning, average NA of the next day, and the participants' general level of depressive symptoms. All these

variables are on a scale of 0 to 100. The input features used were those described in the previous section (ie, SleepTime, devAvgBedTime, devAvgWakeUpTime, nInterruptions, InterruptionsDuration, UserActive, and TotalSleep). For better understanding the effect of independent variables on dependent variables, only 1 input feature (eg, SleepTime) per dependent variable was used. Therefore, 21 combinations of independent and dependent variables had to be tested. We also attempted using several models to see which one worked best. We applied multilevel models (MLMs) [32], k-nearest neighbors (kNN) [33], support vector machines (SVMs) with a radial kernel [34], extreme gradient boosting (XGB) [35], and generalized additive models (GAMs) with smoothing splines [36]. For predicting depression, linear models (LMs) were used instead of MLMs because these data do not have a nested structure (ie, every participant has only 1 data instance). All these models were trained and tuned using the caret package in the R statistical software package [37]. Because there were several missing sleep values (see the Results section), we decided to apply only generalized and not personalized models because these would be left with too few observations.

Outlier Analysis

Because of the noisy nature of this type of data, outlier analysis may be needed to remove unlikely observations. Several strategies are available to detect outliers, including a strategy where no outliers are removed. A simplistic method for doing this is by subtracting a multiple of the SD from the median. First, the median was chosen because some variable distributions may be significantly skewed, and secondly, we chose to multiply the SD by 3 because we only wanted to throw out those observations that were truly outliers. A slightly adjusted version of this method is one that does not use the SD but uses the MAD because this is often a more robust measure of dispersion.

Finally, a multivariate outlier method was also applied, namely isolation forests that work by building a decision tree to isolate anomalies [38,39]. Outlier observational strategies were also parameters evaluated in this multiverse analysis and are given in Table 2.

Multiverse

As mentioned earlier, an important aim of this study is to evaluate the effect of several data preprocessing, sensor, and modeling choices on the prediction of sleep quality, mood, and depression via a multiverse study. Table 2 gives an overview of all the multiverse variables.

Table 2. Multiverse parameters and values considered in this study^a.

Parameter	Number of values (N)
Sensors	10
Sensor thresholds for sensors listed in Table 1	
Features	7
devAvgBedTime	
devAvgWakeUpTime	
InterruptionsDuration	
nInterruptions	
SleepTime	
TotalSleep	
UserActive	
Outcome variables	3
Subjective sleep quality	
Negative affect	
Depression	
Models	5
Generalized additive models with smoothing splines	
k-nearest neighbors	
Mixed effects models	
Support vector machines	
Extreme gradient boosting	
Outlier removal	4
None	
median(x) \pm 3 σ_x per participant	
median(x) \pm 3 \times mad ^b (x) per participant	
Isolation forests; Liu et al [38]; Cortes [39]	
Feature thresholds	3
3 to 5 adjacent windows	
Total number of combinations	12,600

^aFor each parameter, N indicates how many values are there so that the total number of combinations is the product of N.

^bmad: median absolute deviation.

Because there are 12,600 combinations in this multiverse setup, overfitting plays an even larger role than usual; that is, simply splitting the data set into a training and test set would lead us to choose the model that overfits the training and test sets the most. Therefore, our workflow to minimize overfitting followed a hold-out set approach given below [40]:

1. Split the data into training, validation, and test sets.
2. Train all models on the training set.

3. Validate these models on the validation set based on R^2 .
4. For each outcome variable, choose models (maximum of 5) within 1 SE from the best model (known as the 1-SE rule) [41,42].
5. Test these best models on the test set using R^2 .

In this procedure, the training set contains the data of the first week whereas the validation and test sets contain data of days

1 to 4 and days 5 to 7 of the second week, respectively. Alternatively, as we used only 1 data instance per participant when predicting depression, the data set was split such that 60%, 20%, and 20% of the participant data used for the training, validation, and test sets, respectively, were stratified by gender. By doing this, we extracted only the best models based on the validation set and then used them on the test set to confirm if they overfitted the test set. Results were measured by their predicted R^2 [43], a performance metric that is calculated as follows:

where n represents the number of data points, Y is the vector of the observed values, and \hat{Y} is the vector of the predicted values. In essence, this representation of R^2 is a scaled version of the commonly used mean squared error when applying machine learning models or cross-validation.

Results

Missing Data

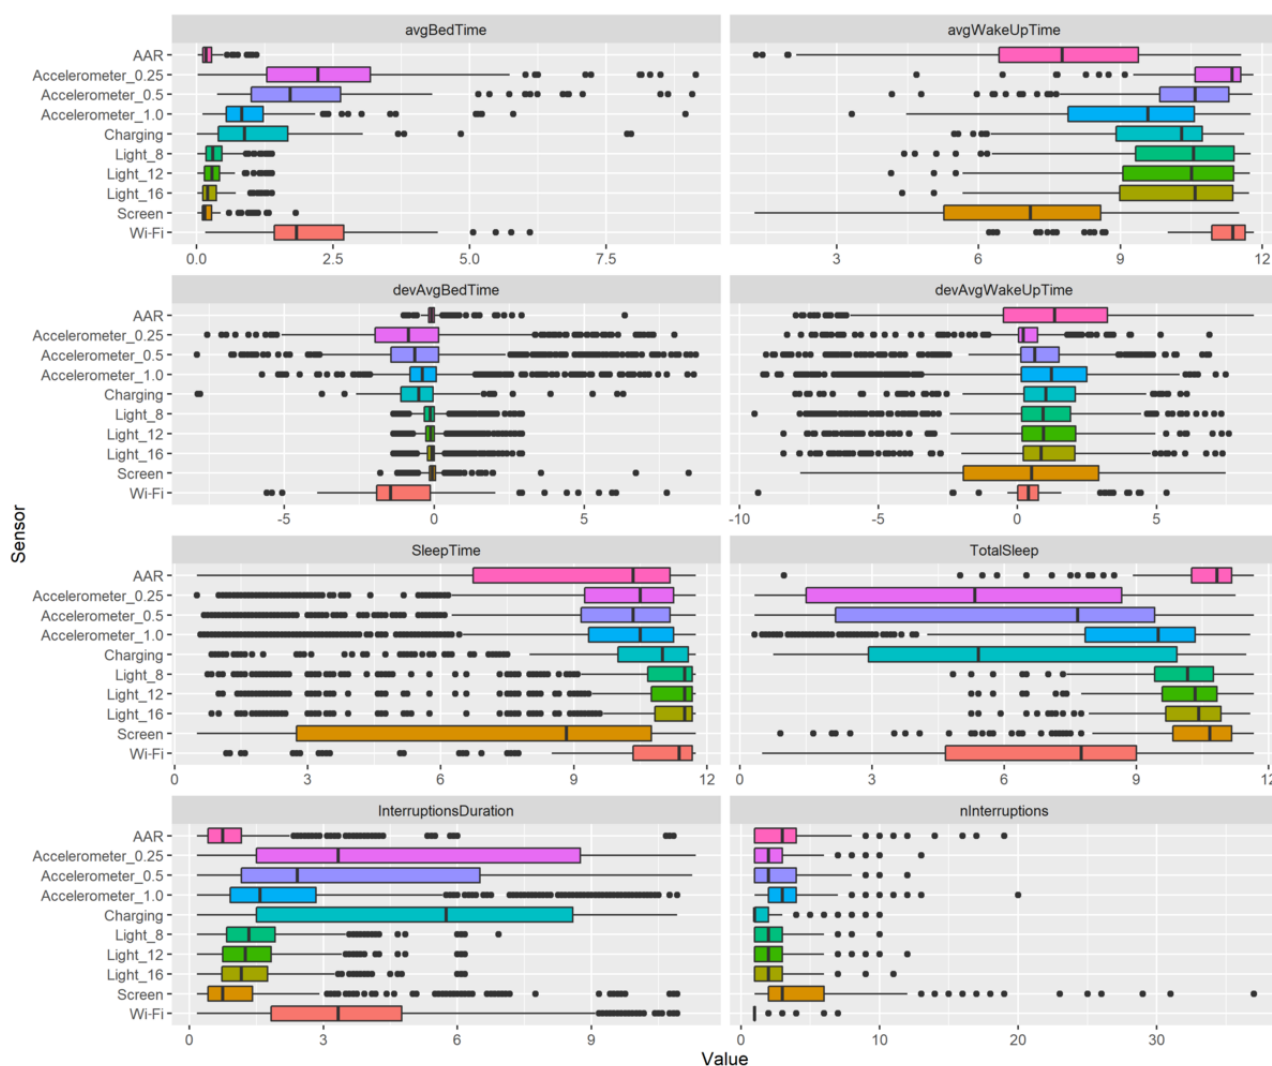

An important consideration in this type of data is missingness. There are multiple reasons for this. First, participants were

prompted with only 14 beeps asking about SSQ in total, so missing 1 beep could have led to the loss of valuable data. Second, preprocessing and outlier removal techniques are responsible for deleting even more data. This coincides with a third major reason for missing data; the wake-up time was often not found for several sensors. This is especially true for the light sensor possibly because it could not detect enough instances where the illuminance was higher than the threshold because the threshold was too high, the phone was upside down, or the phone disappeared inside the participant's pocket quickly after waking up; there could be other reasons as well. In our analyses, missing data were not imputed but considered as missing at random.

Descriptive Statistics

To obtain a better understanding of what the features encompass, Figure 2 presents boxplots for each feature per sensor. The displayed variation can be interpreted as how the values of the features change based on what settings (excluding the prediction model choices) are chosen for the multiverse parameters. Therefore, this variability is not related to the variability of features over participants; it purely highlights the robustness of the features with regard to the multiverse choices.

Figure 2. Boxplots showing how different settings in this multiverse study (for parameters see Table 2) affect each feature per sensor. The smaller the range of the boxplot, the more robust a feature is to multiverse choices. The feature for physical activity performed the previous day (UserActive) is not shown because this value does not vary with any multiverse parameter except in outlier analysis. Observe that the x-axis shows hours except in the case of nInterruptions, which shows a count. Moreover, avgBedTime and avgWakeUpTime are influenced by the criterion for defining a night, namely from 10 PM to 10 AM.

In general, the values within the features in Figure 2 vary considerably, depending on the sensors and other multiverse parameters. There are many outliers that can either represent true patterns or that occur because of data anomalies. Because of the explorative nature of this study and the many combinations we attempted, we assumed the actual patterns to be restricted to the boxes and whiskers, with outliers representing rare behavior or, more likely, data errors. We will now describe some of the key observations and patterns regarding specific features.

First, notice that devAvgBedTime and devAvgWakeUpTime are skewed toward 0. This occurs because these features are the deviations from the mean bedtime or wake-up time. Deviations for bedtime are usually not too high, but for the wake-up time, they seem more problematic. For bedtime, the range for some sensors is very small and skewed toward 0 (ie, at 10 PM), indicating that on average, participants went to bed as soon as the night started or possibly even earlier, no matter what values the multiverse parameters have. On the other hand, the spread for wake-up time is rather large, indicating that changing

multiverse parameters substantially impacts this feature. A second observation is that SleepTime appears to be more stable than TotalSleep, although this is not true for every sensor (eg, screen state).

One of the aims of conducting this multiverse experiment was to consider different thresholds for the light sensor and accelerometer. The light sensor provides consistent results for most features (ie, less spread), but this is mostly because almost all participants' bedtime is immediately at 10 PM. In other words, the highest variability appears to stem from a fluctuating wake-up time. For the accelerometer, a lower threshold corresponds to a later bedtime, a later wake-up time, and longer nightly interruptions. Furthermore, SleepTime is similar between different light and accelerometer thresholds, whereas TotalSleep is vastly different for the accelerometer but not for light.

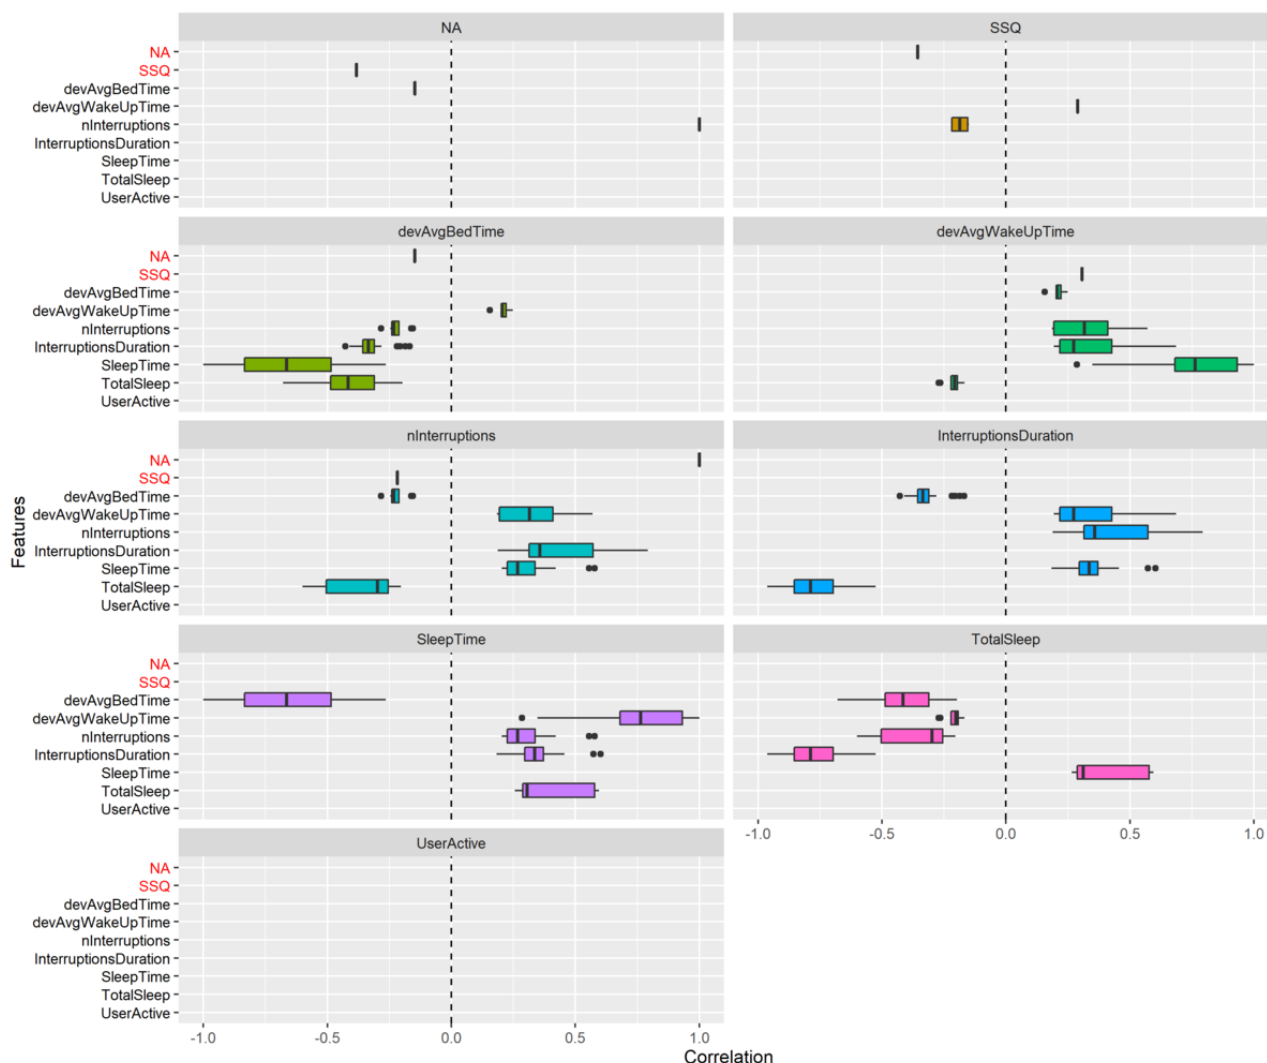

Correlations

To better understand how different features relate to each other, Figure 3 shows significant correlations between features, between outcome variables, and between features and outcome

variables. Correlations were extracted from mixed effects models as the coefficients of fixed effects using standardized inputs. The *P* values were calculated using analysis of variance. All correlations have been corrected for multiple tests [44]. Figure 3 shows that significant correlations between variables are scarce; for instance, UserActive is not related to any other

variable and the outcome variables NA and SSQ are also sparingly related to other variables. In fact, NA is only related to SSQ and the number of interruptions (nInterruptions) whereas SSQ is also only related to NA, nInterruptions, and the deviation from the average wake-up time (devAvgWakeUpTime).

Figure 3. Distribution of significant correlations between variables on the y-axis and in the facets. Note that in contrast to Figure 2, this plot does not show AvgBedTime and AvgWakeUpTime because there is only a single value per participant. SSQ and NA (highlighted in red) are outcome variables denoting the subjective sleep quality and negative affect, respectively. The variance in the boxplots represents how the correlation changes with different values for the multiverse parameters (including different sensors). Without the boxplot, there was no significant correlation. This plot is symmetrical, meaning that every relationship is also shown oppositely. Note that when the boxplot is reduced to a single bar, this likely means there is only a single value (or less likely that there are multiple values very close together).

For depression, correlations were not extracted from an MLM (and hence not shown in Figure 3) but rather as Pearson correlations because there is only a single observation per participant. For all variables, the mean was used to generate correlations with depression scores, and multiple testing correction was subsequently applied [44]. There was 1 significant negative correlation with depression and the feature SleepTime ($r=-0.46$) using the accelerometer (1 m/s^2), and 7 negative correlations with the outcome variable SSQ ($r=-0.46$ to -0.51) (0.25 to 1 m/s^2). Furthermore, there was 1 significant positive correlation between depression and NA ($r=0.51$) using AAR.

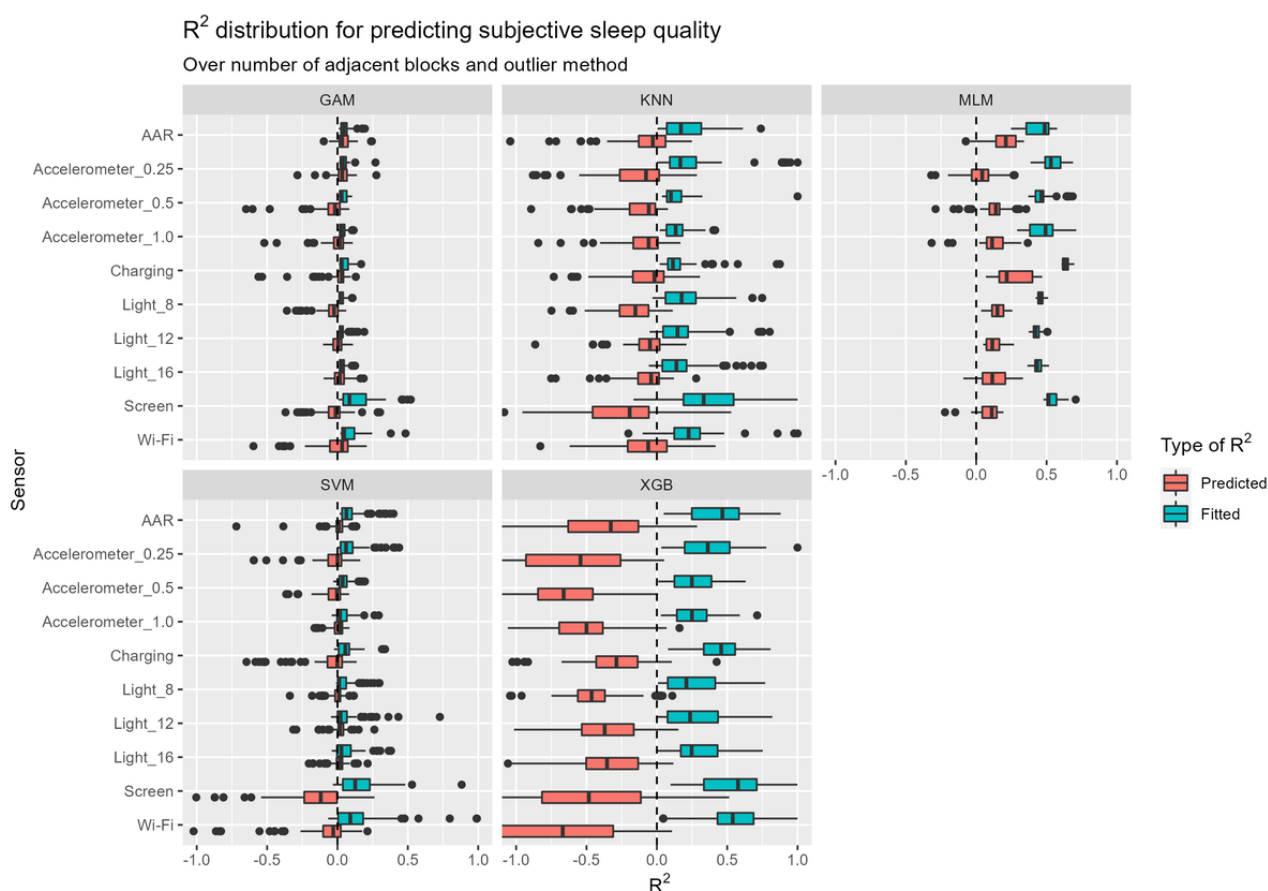

Evaluation

As described previously, the data set was divided into training, validation, and test sets. To gain a better understanding of how each sensor and sleep feature relates to the output variables, we trained separate models for each feature, sensor, and model combination. By doing so, we could inspect their performance (measured in terms of R^2) on the validation set in relation to the other multiverse parameters. After doing so, we selected the best (maximum 5) models within 1 SE from the best model (ie, the model with the highest R^2 on the validation set) and tested them on the test set to draw definitive conclusions.

First, we present the results of our predictions of SSQ on the validation set in Figure 4, where we can see the predictive performance of different models and the impact of selecting a specific sensor varying with other multiverse parameters (as specified in Table 2). In this plot, it is clear that the MLMs perform the best and the XGB models perform the worst in terms of the predicted R^2 on the validation set. Moreover, the GAMs and SVMs perform similarly, having an R^2 of approximately 0 with extreme values on either side. The kNN models show a slightly poorer performance, usually with an R^2 below 0. In terms of more general patterns, we can see that the models have generally overfitted the data; that is, the models have achieved a higher R^2 on the training set than on the validation set. However, the boxes and whiskers of the boxplots represent only the majority of the results, and even a single

outlier may represent a model that does not overfit and performs well. After all, the best models that we selected to be tested on the test set are probably “outliers” in these figures. As far as sensors are concerned, the charging sensor seems to perform slightly better, at least when using MLMs or XGB models but not for others. The other sensors appear to be approximately equivalent in performance. As observed in Multimedia Appendix 1, we replaced the sensors on the y-axis with features so that we could obtain an idea of how different features affect the outcome. As these boxplots are also separated based on the models used, they have approximately the same R^2 distribution, as shown in Figure 4. The performances of features are relatively similar. One might argue that nInterruptions generally performs slightly better in combination with XGB models and MLMs, but this effect is small.

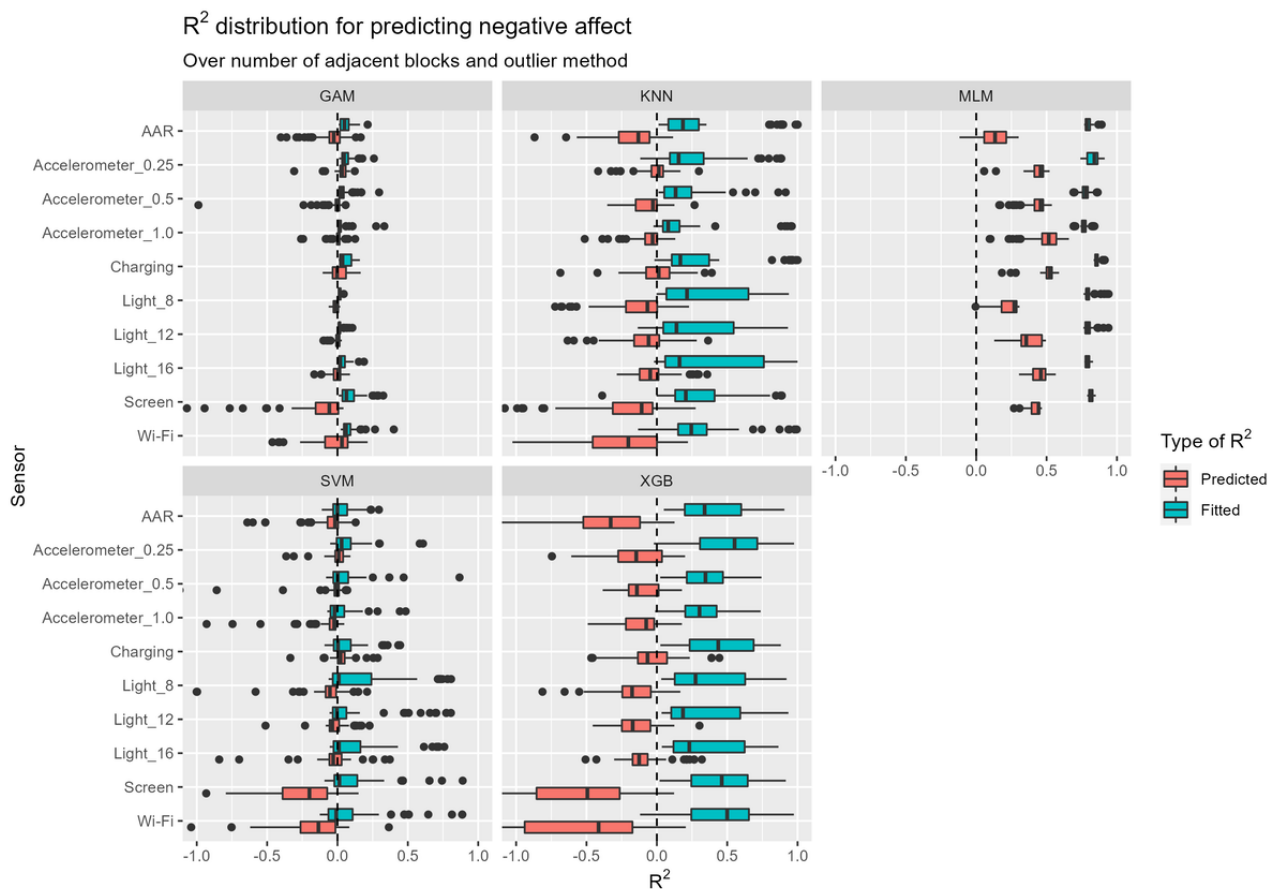

Figure 4. “ R^2 ” distribution for predicting subjective sleep quality. The spread of the boxplots represents how the “ R^2 ” of predictions of subjective sleep quality change with varying multiverse parameters, namely different sensors, features, models, number of adjacent windows, and outlier methods. GAM: generalized additive model; kNN: k-nearest neighbors; MLM: multilevel model; SVM: support vector machine; XGB: extreme gradient boosting.

Second, the predictive performance regarding NA on the validation set is represented visually in Figure 5. Again, for most models, the MLMs appear to perform best as they show the highest R^2 on the validation set. Nevertheless, as indicated by the high discrepancy in R^2 values between the training and validation set, models are once again overfitting. Similar to that

observed in the prediction of SSQ, the XGB models perform the worst followed by the kNN models, and finally GAMs and SVMs, showing a predictive R^2 value of approximately 0. A notable difference among these models is that there is little variation among the MLMs, GAMs, and SVMs, meaning that multiverse parameter choices have less impact than that observed for the kNN and XGB models.

Figure 5. "R²" distribution for predicting negative affect. The spread of the boxplots represents how the "R²" of predictions of negative affect change with varying multiverse parameters, namely different sensors, features, models, number of adjacent windows, and outlier methods. GAM: generalized additive model; kNN: k-nearest neighbors; MLM: multilevel model; SVM: support vector machine; XGB: extreme gradient boosting.

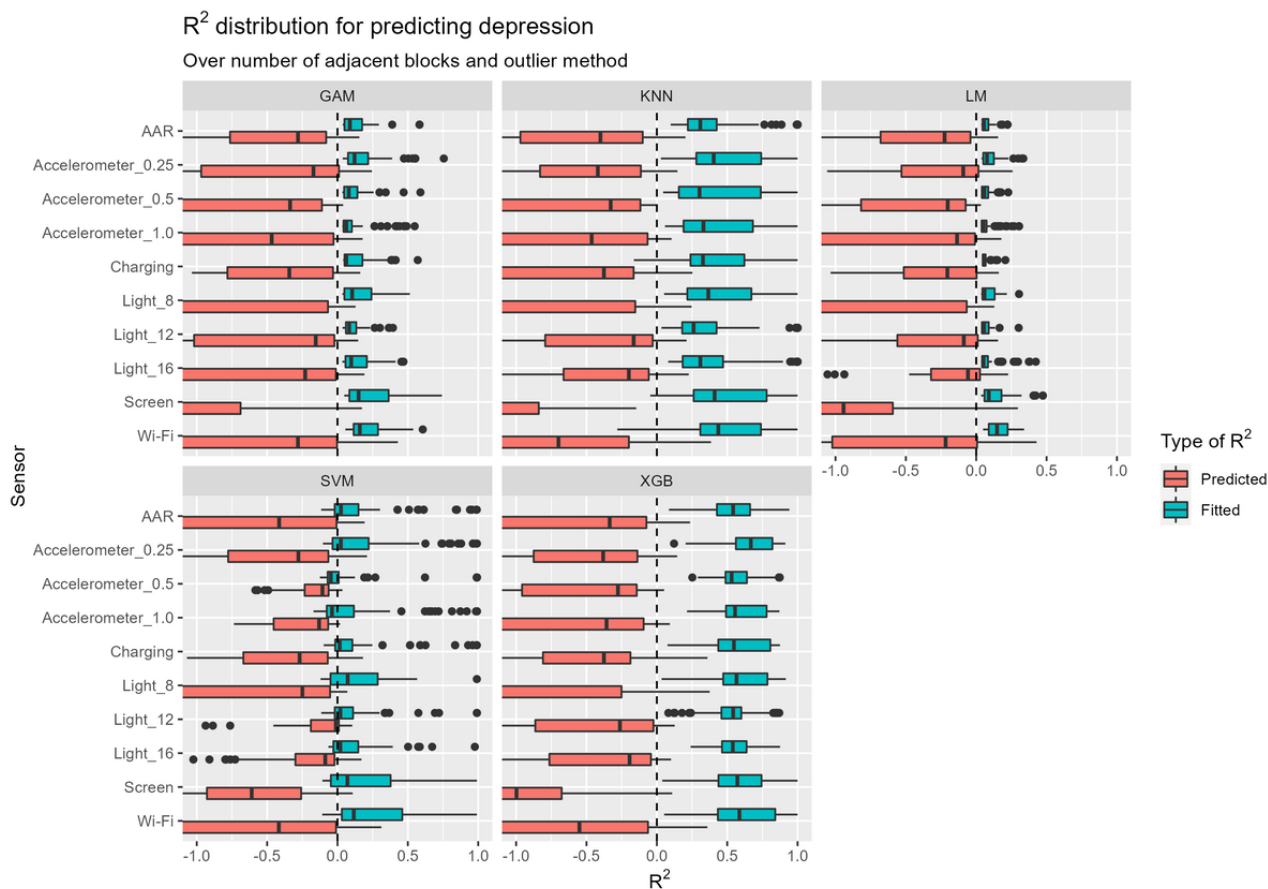

When predicting NA, choosing a specific sensor does not seem to matter, except for screen activity and Wi-Fi because these performed much worse. Indeed, all MLMs using the Wi-Fi sensor were found to be inoperable, indicating a serious problem with these models (eg, not enough data, no convergence). Compared to the rest of the sensors, screen activity and Wi-Fi also performed much worse when using XGB models. When finding the best performing feature, [Multimedia Appendix 2](#) shows a trend similar to that of the sensors, meaning that there is no single feature that is better than all the rest.

Finally, [Figure 6](#) shows the performance distribution when predicting depression in relation to other multiverse parameters.

Contrary to SSQ and NA, the model performance spread in terms of R^2 for depression is much greater, implying that the selection of the multiverse parameters influences model performance. There are considerable differences among sensors too. For example, charging and AAR appear to perform better across all models than the other sensors; that is, because their spread is smaller, models using the charging or AAR sensor are likely to perform better. On the other hand, the 1 m/s² accelerometer has a much larger spread and a lower mean R^2 than the other sensors.

Figure 6. "R²" distribution for predicting depression. The spread of the boxplots represents how "R²" values when predicting depression change with varying multiverse parameters, namely different sensors, features, models, number of adjacent windows, and outlier methods. GAM: generalized additive model; kNN: k-nearest neighbors; MLM: multilevel model; SVM: support vector machine; XGB: extreme gradient boosting.

Multimedia Appendix 3 presents similar findings about the features when predicting depression. That is, the predictions are much worse than those for other outcome variables. The nInterruptions feature appears to perform slightly better than the others although this applies only to the spread, implying that with this feature, models perform better on average but that there may be models from other features performing much better.

Although it is important to describe how different sensors and features impact the outcome variables on average, our ultimate objective is to find how we can best predict the outcome variables from the available data. To this end, Figure 7 presents the results of the best models per outcome variable.

Unsurprisingly, the sensors and features of these best models are generally also the ones that performed the best on average for those outcome variables. However, there is a remarkably large gap between the R^2 values on the test set and those on the training and validation sets. For example, a kNN ($k=7$) model for predicting SSQ using the screen state sensor, 5 adjacent windows, isolation forests, and the feature devAvgWakeUpTime achieved R^2 values of 0.558 and 0.528 on the training and validation sets, respectively. As this does not show much overfitting, one would expect the test R^2 to be similar. However, the R^2 on the test set is only -0.531 , revealing the model to be less than informative.

Figure 7. "R²" distribution for predicting depression. The spread of the boxplots represents how "R²" values when predicting depression change with varying multiverse parameters, namely different sensors, features, models, number of adjacent windows, and outlier methods. GAM: generalized additive model; kNN: k-nearest neighbors; MAD: median absolute deviation; MLM: multilevel model; SVM: support vector machine; XGB: extreme gradient boosting.

	Sensor	Model	# of Windows	Outlier Method	Feature	Training R^2	Validation R^2	Validation SE	Test R^2
Subjective Sleep Quality	Charging	MLM	3	Isolation forests	nInterruptions	0.658	0.469	0.102	0.348
	Charging	MLM	3	Isolation forests	devAvgWakeUpTime	0.619	0.461	0.106	0.334
	Charging	MLM	3	Isolation forests	SleepTime	0.624	0.450	0.107	0.303
	Screen state	XGB	5	MAD	devAvgWakeUpTime	0.501	0.514	0.238	-0.003
	Screen state	KNN	5	Isolation forests	devAvgWakeUpTime	0.558	0.528	0.167	-0.531
Negative Affect	Accelerometer_1.0	MLM	5	MAD	InterruptionsDuration	0.779	0.62	0.101	0.103
	Accelerometer_1.0	MLM	4	Isolation forests	UserActive	0.767	0.624	0.098	0.081
	Accelerometer_1.0	MLM	5	MAD	devAvgBedTime	0.828	0.623	0.107	0.074
	Accelerometer_1.0	MLM	4	Isolation forests	InterruptionsDuration	0.759	0.622	0.099	0.066
	Accelerometer_1.0	MLM	5	MAD	UserActive	0.831	0.659	0.073	0.005
Depression	Wi-Fi	GAM	4	MAD	SleepTime	0.074	0.429	0.126	0.025
	Wi-Fi	LM	4	MAD	SleepTime	0.074	0.429	0.126	0.025
	Wi-Fi	KNN	3	None	UserActive	0.477	0.385	0.230	-0.639
	Wi-Fi	KNN	3	SD	UserActive	0.477	0.385	0.230	-0.639
	Light_8	XGB	5	MAD	devAvgWakeUpTime	0.760	0.375	0.296	-0.688

Figure 7 shows that SSQ can be predicted reasonably well; MLMs using the charging sensor, 3 adjacent windows, and isolation forests for detecting outliers achieved a test R^2 of 0.303 to 0.348 with nInterruptions, devAvgWakeUpTime, or SleepTime. All these features were positively related to SSQ, having a slope of approximately 0.442–0.643 with a high 95% CI –3.06 to 4.35. However, predicting NA proved to be more challenging because we obtained a highest R^2 of only 0.103 on the test set, a value that is considerably lower than that obtained on the training and validation sets. Nevertheless, it is worth noting that all the best models for predicting NA are MLMs using the accelerometer with a threshold of 1 m/s². Of these models, the ones using InterruptionsDuration and devAvgBedTime were positively related to NA (slopes of 0.0449–0.279 and 0.427, respectively) whereas userActive was negatively related (slope of 0.199–1.37). Finally, predicting depression was the most difficult task because only 1 best model yielded a barely informative result, namely the LM with an R^2 of 0.025. The predictions for SSQ appear better because it is more closely associated with objective sleep than the other outcome variables, namely NA and depression.

Discussion

Principal Findings

Although various studies have used different methods and sensors to successfully track sleep with mobile sensing [14,25,26], it is not yet clear how these various approaches impact the results. To this end, this study was designed to provide a transparent and robust method for tracking sleep with mobile sensing. By accounting for many choices in a multiverse study design, we were able to separate and elucidate the various effects of sensors, features, and models on sleep proxy measures, thereby providing an important step forward for future researchers. Principally—and in accordance with previous research—we showed that it is possible to explain a reasonable and an interesting proportion of the variance observed in SSQ (or the related variable of daily negative mood) using mobile sensing. Moreover, our multiverse analysis indicates which combinations of multiverse parameters (shown in Table 2) can do this best, at least in this sample. Although the results in this

study are slightly more pessimistic than those in other studies concerning mobile sensing and sleep (ie, some studies showing very high accuracies) [12,25,26], they cannot be compared directly given that we applied a strict cross-validation plan.

From the outlined results, we can conclude that for predicting SSQ, the charging sensor is overall the best performing and the most robust sensor although this sensor has a significant advantage because participants were instructed to leave their smartphone charging at night. However, for predicting NA, we found the accelerometer to be the best sensor despite its previously noted limitations (ie, low sample rate and measurements only along the x-axis). Based on previous research [11,14], this finding suggests that the accelerometer is a feasible option for sleep detection. Nevertheless, when predicting person-level depression, we found that the results varied considerably and were often less than informative. Even the best performing sensor achieved an R^2 of only 0.025 on the test set, and hence we could not draw any conclusions from this.

Another aspect we accounted for in this study is using multiple ways of constructing models (ie, we attempted multiple models to see which one worked best). The results point out that MLMs are clearly the best performing models for any outcome variable. However, it should be noted that the analysis is between participants whereas MLMs also use within-person information (although large amounts of within-participant data were missing). Likewise, LMs seem to be the primary choice for predicting depression as well, suggesting that robustness must be an important characteristic. Furthermore, GAMs and SVMs showed reasonably similar performances but much worse than that of MLMs. Finally, kNN and XGB models seemingly performed the worst, with XGBs displaying excessive overfitting.

Although not described in detail, Multimedia Appendix 1 presents the R^2 distributions of the results split by feature. We have already mentioned that no feature appears to be more important than any other. Another inference supported by Figure 2 is that some features are more robust than others in this multiverse analysis. Concretely, nInterruptions has less spread than the other features, indicating that it is a relatively robust

feature. This could be interesting for future studies in which researchers have to manually select features.

Limitations

There are a number of limitations that should be considered when interpreting the results of this study. The results of this study are generally limited by the relatively small size of the data set. This limitation poses a drawback because it makes the models more prone to overfitting, although this risk was mitigated by an elaborate hold-out set approach. Next, we list 3 distinct limitations that may have impacted the results.

First, we relied on self-reports from ESM as an estimate of sleep. This, combined with the fact that participants did not always answer the SSQ item in the morning, may have led to odd or spotty patterns. Despite trying to minimize the impact of this factor by predicting several outcome variables known to be associated with sleep (ie, not only SSQ but also NA and depression), we cannot be certain about the impact of this factor on the research results.

The second limitation resulted from several sensor issues during the trial. The most pressing issue is the low sample rate for the accelerometer, charging, light, and Wi-Fi, averaging approximately 1 measurement instance every 2.9 minutes. Especially for the accelerometer, this is not enough data because it only allows the sensors to record momentary changes instead of tracking participants' contextual surrounds for longer periods, as mentioned earlier. The accelerometer also did not collect the y- and z-axes data, which further limits its use. Furthermore, the way in which sensors collected data was directly influenced by participants' behavior in that they were instructed to keep the smartphone charged at night and be connected to Wi-Fi. This may mean the charging and Wi-Fi sensors are less ecologically valid.

Finally, we assumed that a normal night of sleep is somewhere between 10 PM and 10 AM the next day. Although this assumption is probably true for most people, students may not always follow a regular sleep schedule. Moreover, because some sensors are prone to produce many false positives (eg, the light sensor detecting the smartphone being in a participant's pocket as sleep), we felt it was necessary to reduce this at the cost of cutting off a small portion of the participants' sleep.

Contributions to Previous Work

Our work complements previous work described in various ways. First and foremost, this study developed and implemented a method to unravel the effects of distinct variables as well as sensors and their thresholds for the prediction of SSQ, NA, and depression. Such a method can guide future researchers intending to conduct similar studies to further examine these effects or help them choose which sensors to select for estimating sleep. It also provides a tool for researchers when they have to make choices based on the many different results that exist when predicting sleep with mobile sensing, such as the widely varying results in earlier studies [22-26]. Moreover,

it stresses the importance of making considerations and makes researchers aware that such choices may have a significant impact on their study, as suggested by the multiverse theory [27] and previous studies [26]. In addition, this study can help verify theories that link smartphone-recordable behaviors to sleep and mood, such as the purported links among sleep, depression, and stress [19].

Second, we showed that continuous SSQ and NA can be reasonably predicted from sleep features whereas depression cannot be predicted. Most studies reduce these features to a discrete variable with only 1 or 2 categories [12,22], whereas we took on the challenge to expand this to a continuous variable between 0 and 100. Naturally, a continuously scaled variable brings about more variation, but this variation can be approximated.

Future Directions

When performing such an explorative study where it is not yet clear how different variables relate to each other, it is important to at least have enough data to work with. Future studies should focus on obtaining a sufficiently large sample size to minimize the necessity of a potential multiverse study or at least minimize the risk of selecting a nonrepresentative sample. Additionally, missing data posed a big challenge in this study because participants did not respond to the first beep of the day.

Although this study has solely relied on SSQ and proxy measures such as NA and depression, in future studies, it could be useful to also collect self-reported bed- and wake-up times to validate these features. After all, several other features were based on these times; therefore, obtaining a better understanding of their accuracy also helps in further improving these features. Moreover, wearable devices are not as reliable as PSG, but they are considerably less obtrusive and have already been adopted by a sizable portion of the mainstream population to record sleep. As such, they can be added in future studies to achieve an additional high-quality estimate of sleep. Finally, if an approach could be developed to use mobile sensing data to estimate sleep (eg, through a multiverse approach), it should be compared to PSG as a final measure of validation.

Conclusions

Sleep plays an important part in moods and mood disorders but is difficult to track unobtrusively. Therefore, this study has shown that it is feasible to track sleep with mobile sensing although this depends strongly on which sensors, features, and models are chosen. In fact, our approach demonstrated that most combinations of multiverse parameters often form noninformative models. This can be partly attributed to issues with data collection and not having enough data for developing personalized models, but further research is needed to validate these problems. Moreover, SSQ predictions were better than the other proxy measures (ie, NA and depression severity). Nevertheless, the findings of this study are promising and warrant further investigation into the use of mobile sensing for tracking sleep.

Abstract

Background: Many prostate cancer (PC) survivors experience disease and treatment-related symptomatology in both the physical and psychosocial domains. Although the benefits and barriers to using web-based resources for cancer patients are well-documented, less research has focused on the personal characteristics important for efficient tailoring and targeting of information that are associated with usage.

Objective: We used the Cognitive-Social Health Information Processing (C-SHIP) framework to guide our exploration of personal characteristics associated with use of PROGRESS, an informational PC survivorship website that addresses physical, emotional, interpersonal, and practical concerns relevant for PC survivors.

Methods: PC survivors (N=217) were randomized to the intervention arm (PROGRESS) of a randomized controlled trial. Of those randomized to the intervention arm, 84 used PROGRESS, and 133 did not use PROGRESS. Multivariable analyses evaluated demographic and psychosocial characteristics (eg, style of coping, health literacy, self-efficacy, affective states of depression, anxiety, and fatigue) associated with website use.

Results: A larger proportion of non-Hispanic White (68/160, 42.5%), compared with non-Hispanic Black (9/40, 23%), participants used PROGRESS ($P<.001$). Further, PROGRESS users were older in age ($P<.001$), had a monitoring style of coping ($P=.01$), and were less depressed ($P=.004$), anxious ($P=.02$), and fatigued ($P<.001$) than nonusers. Education, income, health literacy, blunting style of coping, self-efficacy, and treatment type (radiation therapy or surgery) were not significantly related to use. On multivariable analyses, race (OR 0.28, $P<.001$), age (OR 1.05, $P<.001$), monitoring style of coping (OR 1.27, $P=.02$), and overall mood (OR 0.98, $P<.001$) remained significant.

Conclusions: A combination of monitoring and low levels of negative affect were associated with website use. Additionally, users were older, non-Hispanic White survivors. To ensure that important survivorship-relevant information reaches users, future efforts need to focus on enhancing patient engagement.

Trial Registration: ClinicalTrials.gov NCT02224482; <https://clinicaltrials.gov/ct2/show/NCT02224482>

prostate cancer; cancer survivorship; web-based resource; monitoring style of coping; cancer; survivorship; eHealth; emotions; interpersonal

Introduction

Prostate cancer (PC) is the second most common cancer diagnosed in men in the United States, with about 1 in 9 men diagnosed during their lifetime. The American Cancer Society estimates that, in 2021, there will be 248,530 new cases of PC in the United States [1]. The 5-year relative survival rate for localized PC is near 100% [1]. Consequently, the population of PC survivors is growing, exhibiting specific disease and treatment-related symptomatology in both the physical (eg, urinary, bowel, or sexual dysfunction [2,3]) and psychosocial (eg, high rates of distress, anxiety, reduced quality of life, depression, adjustment difficulties, fear of cancer recurrence [4-7]) domains. Further, studies have shown there is a significant interpersonal impact of PC on patients' relationships with their spouses and loved ones, as they struggle with intimacy, sexual confidence, sense of masculinity, familial cancer risk, and communicating about their diagnosis, treatment, and symptoms with friends [8,9].

The rapid development of modern technology has facilitated the use of web-based resources for individuals dealing with illness and treatment-related side effects, as is the case for PC survivors. Web-based resources have been developed and evaluated for many groups including breast cancer survivors [10,11], patients with melanoma [12], and families with parental cancer, as well as to educate nurses on reproductive issues in cancer patients [13]. Existing web-based resources specifically for patients with or survivors of PC include education or decision aids, interventions to reduce distress after treatment, and physical activity interventions [13-21].

Benefits to using web-based resources include ease of access at the patient's own schedule in a private place; ability to access the intervention through multiple channels (ie, personal computer, tablet, smartphone); augmented content through interactive videos, graphics, and testimonials; tailored content for treatment approaches or specific time points in the recovery trajectory; access transcending geographical barriers; and tracking patient recovery in real time [22-28]. Yet, there are also unique barriers, including lack of internet access, participants' privacy concerns, and program costs associated with developing and maintaining web-based resources [29-32]. In addition, studies have reported challenges engaging patients for initial access and staying engaged in recommended programs. A systematic review of adherence to web-based interventions showed that, on average, only about 50% of participants engage in software-based interventions, with variations from 10% to 90% across studies [33].

To increase engagement and persistent use of health-related software programs, it is therefore important to identify psychosocial characteristics that go beyond the commonly known access and demographic variables (eg, younger age, higher education) [28,29]. Thus, the current study aimed to identify patient demographic and psychosocial characteristics associated with use of PROGRESS, a web-based intervention for PC survivors.

Methods

Conceptual Framework

Our study is guided by the Cognitive-Social Health Information Processing (C-SHIP) model, a theoretical framework that identifies 5 cognitive-affective constructs that are associated with engagement in health protective behaviors [34,35]. These constructs consist of (1) cancer-relevant interpretations, (2) beliefs and expectations about cancer treatment and disease outcomes, (3) cancer-relevant goals and values, (4) cancer-relevant affective states, and (5) self-regulatory competencies and skills for generating and maintaining goal-oriented health-related behaviors. For the purpose of our analyses, these theoretical C-SHIP constructs were operationalized with the following patient-level variables: monitoring styles of coping (ie, the disposition to stand for and attend to health-relevant cues that entail C-SHIP's cancer-relevant interpretations, beliefs, and expectations about health risks); health literacy (C-SHIP's skills for generating and maintaining goal-oriented health behaviors); self-efficacy (C-SHIP's self-regulatory competencies); depression, anxiety, and fatigue (C-SHIP's cancer-relevant affective states). We hypothesized that these constructs are significantly and positively related to patient engagement and usage of the PROGRESS program.

Patient Recruitment

For the parent randomized controlled trial (RCT), PC patients were recruited during routine posttreatment follow-up appointments at 4 mid-Atlantic cancer centers. Recruitment occurred over the course of 3 years (2013-2016). Patients were eligible if they were diagnosed with localized PC (T1-T3c N0M0), were within 1 year of treatment completion, had regular access to a computer or a tablet with internet either at home or at another public place, were aged 18 years or older, were able to give consent, and were able to communicate in English. Exclusion criteria were presence of another primary cancer or a cancer recurrence.

Eligible patients who agreed to participate in the study were enrolled after signing the consent form and completing the baseline survey. Using block randomization by site, participants were randomized to either the control group (print materials: NCI's *Facing Forward: Life after Cancer Treatment* and *What You Need to Know about Prostate Cancer*) or the intervention group (PROGRESS + print materials). This manuscript focuses only on the subgroup of participants that were randomized to the intervention group, PROGRESS. This study was approved by the Institutional Review Boards at Fox Chase Cancer Center (#11 - 825), Rutgers University (#0220110092), Northwell Health (#14 - 672), and Mt. Sinai (#11 - 01136).

Intervention Condition

PROGRESS Content

PROGRESS is a self-paced, web-based educational program to address PC survivors' information needs in 6 specific domains suggested by prior work of the investigators [15,16,21,36-37], literature on this population, and formative work to develop the intervention content. These domains are (1) treatment type and

expected prostate specific antigen (PSA) changes, which indicate PC status and progression; (2) physical side effects (eg, urinary and sexual dysfunction); (3) emotional concerns (eg, fear of cancer recurrence); (4) interpersonal concerns (eg, communications with providers and family); (5) practical concerns (eg, follow-up care, financial needs); and (6) healthy lifestyle (eg, nutrition, physical activities) [15,38]. Information is culturally targeted and tailored to different survivorship stages (eg, short-term vs long-term survivorship needs). PROGRESS was developed through a 2-phase, qualitative formative research study. Phase 1 included individual interviews with 5 and group interviews with 12 early-stage prostate cancer patients to determine intervention content and interface. Phase 1 employed iterative user and usability testing (n=12) to finalize the intervention. Participants expressed interest in action-oriented content on managing treatment side effects, handling body image and comorbidities related to overweight or obesity, coping with emotional and communication issues, tips to reduce disruption of daily living activities, and health skills training tools. An extensive readability evaluation was conducted in order to ensure that the PROGRESS intervention met plain language standards. To conduct this evaluation, members of the Office of Health Communications and Health Disparities at Fox Chase Cancer Center used the software program, Health Literacy Advisor, to calculate reading grade levels and offer replacement text for complex terms and long sentences. All text was revised as needed to conform to an 8th or 9th grade target level reading range. For more information on the development, preliminary testing, and efficacy of PROGRESS, see Miller et al [38] and Tagai et al [39,40].

PROGRESS features include a topics tab (addressing financial or legal issues; interpersonal communication, emotional and practical concerns; negative feelings; and side effects); videos from physicians, patients, and content experts; fields for personal tracking (of PSA level, health status, weight, sleep, urinary or erectile dysfunction, medication, living habits, and questions for upcoming physician appointments); information on the latest PC findings (in prevention, screening, treatment, and survivorship); a virtual health center and navigator; theoretically guided normalizing messages; testimonials from a group of diverse PC survivors; and technology support (a tutorial program and a help desk). The software program underwent extensive usability testing before it was released for study purposes [38].

Translating Theory-Driven Constructs to Practical Content

The 5 key theoretical constructs were operationalized within PROGRESS through the program's components of (1) providing accurate information, (2) creating realistic expectations and promoting self-efficacy, (3) exploring the patient's goals and values and encouraging behavior consistent with them, (4) validating feelings and facilitating emotional support, and (5) providing information and training to maximize self-regulatory competencies and skills.

Data Collection

Assessments were conducted at baseline and at 1-month, 3-month, and 6-month follow-ups. Data for these analyses were drawn from the baseline assessment and indication of website

use during the study. Patients completed the assessments via paper-and-pencil survey, online via REDCap, or telephone interview. Follow-up telephone calls or emails (based on participant's preferred survey completion method) were used for noncompleted surveys. Participants received a US \$20 gift card for each completed assessment.

Study Measures

Demographics assessed at baseline included race/ethnicity, age, and education. Comorbidities were captured using the Charlson Comorbidity Index, a 16-item weighted measure evaluating the presence or absence, or severity, of illnesses [41]. The Charlson is scored as a weighted sum of the illnesses, such that a positive response for certain illnesses (ie, myocardial infarction, congestive heart failure, dementia) adds 1 point each, a positive response for other illnesses (ie, leukemia) adds 2 points each, and a positive response for AIDS adds 6 points. The remaining illnesses, which are scored on a severity scale, are multiplied by 2, 3, 2, and 6 for diabetes mellitus, liver disease, renal disease, and malignant solid tumor, respectively. Style of coping was assessed using the Monitor/Blunter Style Scale (MBSS) [42]. Health Literacy was assessed using a 3-item screen for health literacy [43,44]. The 3 items are: "How often do you have someone help you read hospital materials?", "How confident are you filling out medical forms by yourself?", and "How often do you have problems learning about your medical condition because of difficulty understanding written information?" Response options are on a 5-point Likert scale ranging from "always to never" or "extremely to not at all." Self-efficacy for symptom control was measured using an author-constructed 12-item scale that asked participants how confident they were to "manage any treatment-related fatigue," "recover your emotional well-being," and "does your family know how to support you?" [45]. Depression, anxiety, and fatigue were assessed with the Profile of Mood States Short Form (POMS-SF), using the respective depression, anxiety, and fatigue subscales [46]. Depression was also assessed with the Center for Epidemiological Studies-Depression subscale (CES-D) [47]. Undergoing surgery or radiation therapy was assessed via self-report and confirmed with medical chart abstraction.

The outcome variable, PROGRESS use, was a binary variable coded as "use" or "nonuse" and was obtained via Google Analytics after completion of the participants' last follow-up assessments. Participants randomized to PROGRESS were considered to have used PROGRESS if they clicked beyond the home page at least once during the study period. Participants were categorized as nonusers if they did not log in or logged in but did not click through to any other page beyond the home page. We were unable to track amount of website use with the available tracking metrics.

Statistical Analyses

Data were analyzed with SPSS version 19.0 and R version 3.6. Descriptive statistics were used to characterize the sample [48,49]. We then used a series of univariable logistic regression models to test the association between website use and each variable of interest, using generalized estimating equations with robust standard errors to account for within-site correlation. We

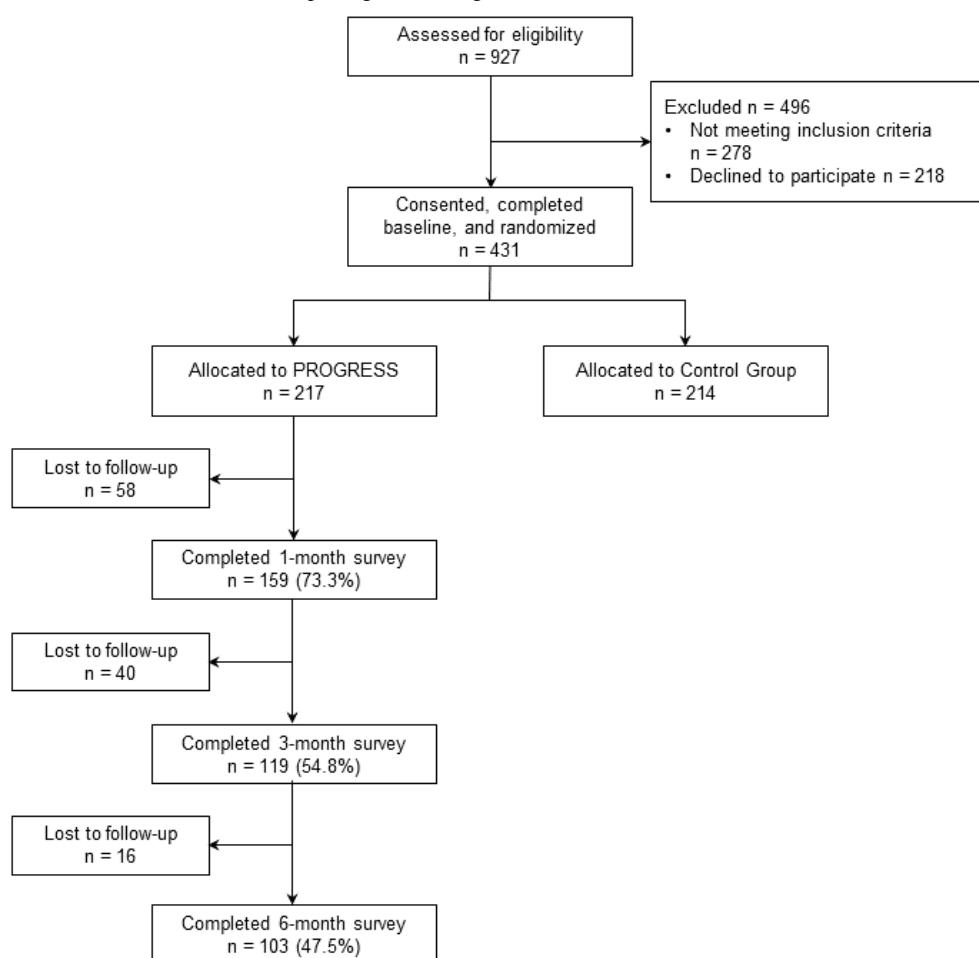

also used a multivariable logistic regression model to simultaneously evaluate the variables' associations with website use. Significant variables from the univariate logistic regression analyses, a priori variables of interest, and surgery or radiation treatment (hormone therapy was excluded due to low number of patients receiving this treatment) were included in the multivariable logistic regression model. To avoid collinearity, the POMS-SF total score was included rather than the individual subscales. A 2-sided P value $<.05$ was considered statistically significant.

Results

Recruitment

A total of 927 participants were assessed for eligibility; 278 did not meet inclusion criteria, leaving 649 eligible. A total of 431 participants (66.4% of those eligible) consented and were enrolled and randomized (217 PC survivors were randomized to PROGRESS, and 214 were randomized to the control condition), and 218 declined to participate. Of those randomized to PROGRESS, 73.3% (159/217) completed the 1-month time point, 54.8% (119/217) completed the 3-month time point, and 47.5% (103/217) completed the 6-month time point. See [Figure 1](#) for a detailed CONSORT (Consolidated Standards of Reporting Trials) diagram, adapted for this study focusing on the PROGRESS intervention arm.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram for the PROGRESS intervention arm.

Sample Demographics

Overall, the sample was mostly non-Hispanic White (160/217, 73.7%), married (175/217, 80.6%), and with no comorbidities (167/214, 78.0%). About half (103/215, 47.9%) had a college degree or higher, and about half (115/217, 53.0%) endorsed that they were in the highest income bracket (US \$75,001 and greater). In terms of treatment, about half (112/217, 51.6%) had surgery. The average age of the sample was 63.79 (SD 6.67) years. See [Table 1](#) for details.

Participants' mean scores were 2.46 (SD 2.20) and 1.44 (SD 1.41) on the monitoring and blunting subscales, respectively; 13.12 (SD 2.24) on the measure of health literacy; 8.75 (SD 1.11) on the self-efficacy for re-entry scale; 4.76 (SD 4.32) on the anxiety measure; and 6.27 (SD 5.05) on the measure of fatigue. Further, the average scores on the POMS-SF depression measure and CES-D measure were 3.30 (SD 3.94) and 5.99 (SD 5.27), respectively. See [Table 1](#) for details.

Table 1. Demographic characteristics of website users and nonusers (controlling for study site).

Variable	Website users (n=84)	Nonusers (n=133)	Total sample (N=217)	P value

Main Analyses

Of the 217 patients, 84 (38.7%) reported using the website versus the 133 (61.3%) who reported that they did not use the website. When controlling for study site, there were significant differences between those who used PROGRESS and those who did not use PROGRESS in the following variables: race/ethnicity, age, style of coping, depression, anxiety, and fatigue. Specifically, a larger proportion of non-Hispanic White (68/160, 42.5%), compared with non-Hispanic Black (9/40, 23%), participants used PROGRESS ($P<.001$; Table 1). Users of PROGRESS were older in age (mean 65.37, SD 7.03 years vs mean 62.79, SD 6.27 years; $P<.001$), higher on monitoring (mean 3.01, SD 1.93 vs mean 2.11, SD 2.29; $P=.01$), and less depressed (mean 5.29, SD 4.17 vs mean 6.43, SD 5.84; $P<.001$), anxious (mean 4.36, SD 3.74 vs mean 5.01, SD 4.65; $P=.02$),

and fatigued (mean 5.72, SD 4.64 vs mean 6.61, SD 5.28; $P<.001$). There were no other significant differences between those who used PROGRESS and those who did not use PROGRESS.

In the multivariable model, non-Hispanic Black participants were significantly less likely to use the website than non-Hispanic White participants (OR 0.28, 95% CI 0.25-0.32; Table 2). There was no significant difference between non-Hispanic White participants and those of all other race/ethnicities (OR 0.77, 95% CI 0.43-1.36). Additionally, older participants were more likely to use the website (OR 1.05, 95% CI 1.04-1.07), as well as those reporting greater monitoring style of coping (OR 1.27, 95% CI 1.04-1.56). Finally, those with a more negative mood state were significantly less likely to use the website (OR 0.98, 95% CI 0.97-0.98).

Table 2. Multivariable logistic regression analysis (controlling for study site).

Variable	OR ^a	SE	LCL ^b	UCL ^c
Non-Hispanic Black ^d	0.28	.07	0.25	0.32
All other races/ethnicities ^d	0.77	.29	0.43	1.36
Age	1.05	.01	1.04	1.07
Monitoring	1.27	.10	1.04	1.56
Self-efficacy for re-entry	0.89	.07	0.78	1.01
Mood total	0.98	.004	0.97	0.98

^eReference group: did not receive treatment.

Discussion

Principal Findings

PROGRESS was more likely to be used by PC survivors who were high on monitoring style of coping, a coping style to deal with threat that involves scanning for and magnifying disease-related cues [42]. Monitors are often more concerned about their illness, experience more treatment-related side effects, are more knowledgeable about their medical situation, feel themselves to be at greater personal risk, and are less satisfied with and more demanding about the psychosocial aspects of their care [50]. Notably, they are more often adherent to medical recommendations and place greater value on health-related information [50]. The PROGRESS website offered patients characterized as monitors authoritative information about PC from providers and testimonials by a diverse group of survivors who are addressing psychosocial aspects of the disease. Thus, PROGRESS offers monitors health-related information that they typically value and that translated into higher use.

Results also showed that PROGRESS was more likely to be used by non-Hispanic, White PC survivors, confirming prior established patterns of internet use. A study conducted by the Pew Research Center indicated that internet usage is more common in White compared with non-Hispanic Black populations [51,52]. Racial disparities in education are well-documented and favor non-minority populations [53,54]. Patients with higher levels of education are more likely to have used a computer in the past and would be more apt to use offered resources, such as PROGRESS.

PROGRESS users' relatively positive mood (less depressed, less anxious, and less fatigued) allows them to mobilize in support of their health, which includes taking advantage of the information PROGRESS has to offer. Using PROGRESS and other related health resources may be blunted in patients who are highly depressed, as depressed patients often cannot empower themselves to take care of their health. Similarly, high anxiety may hinder the use of PROGRESS, as these patients may have anxiety about the information that PROGRESS will provide. Patients with high levels of fatigue may not feel energized to a degree necessary to use a web-based resource such as PROGRESS. Our results also showed that older patients

were more likely to use PROGRESS. Though this finding was statistically significant, it was not clinically significant, with an average age of 65.37 years compared with 62.79 years. It is encouraging that older men are using this web-based resource, as PC survivors more generally are an older demographic given the average age of diagnosis is 66 years old [1]. Analyzing age as a categorical variable produces the same results. It is possible that the older participants were more motivated to use the site or that this finding is due to chance, as the numbers for each individual group are not that large.

The study findings highlight the need for strategies to increase patient engagement with web-based tools, as less than 40% of the intervention group reported that they used PROGRESS. Engagement needs to go beyond the commonly accepted development and access strategies, such as ensuring access to a computer and the internet (eg, providing tablets in clinic during down time), ensuring comfort with using a computer and the internet, using language and terminology appropriate for a low health-literate population, incorporating culturally targeted material into the program, and prompting use through text message or email reminders. The value of the recommended services needs to be clearly communicated, and if possible, gamification elements, such as badges or virtual competition with other users, can be incorporated.

Indeed, our study team did engage in a thoughtful, iterative process to design the PROGRESS website that included stakeholder feedback. Based on the initial design phase and the usability testing, the PROGRESS site was very positively evaluated. We think that this highlights the need for ongoing usability and acceptability testing, rather than collecting these data at one time point prior to intervention launch. This experience has suggested that, for future studies, researchers should build in a regular review of usage, usability, and acceptability and devise a plan for how to handle the responses if certain intervention components are not well-received. Collecting these data longitudinally during the RCT phase may not be able to inform the intervention being tested, but it would be useful to inform future interventions.

Low patient engagement is a threat to efforts to evaluate the efficacy of web-based tools. Before beginning a research study, power calculations are needed to ascertain sample size requirements necessary to detect clinically meaningful differences. Understanding that all of those enrolled in the intervention arm may not actually engage with the intervention may alter researchers' plans for how many patients to enroll. On a related note, researchers may, a priori, plan to conduct their analyses in 2 ways: first, comparing intervention and control, and second, comparing within the intervention arm, users with nonusers. In addition, rather than "using website" as a simple binary variable, future research should employ more sophisticated website use tracking features that allow investigators to capture detailed website use, such as time spent with each page, pages with most views, and number of downloads.

Limitations

This study is not without its limitations. First, the sample was highly homogenous and was mostly non-Hispanic White and high income, and thus, the results may not be generalizable to other, more diverse patient groups. Second, our "website use" variable was binary and therefore did not allow us to evaluate the full continuum of website usage from those who never logged in to the super-users who used PROGRESS over and over again. These limitations aside, we believe our study substantially contributes to the literature characterizing the patient profile of a web-based resource user.

Conclusions

Our study showed that, compared with nonusers, users of PROGRESS, a website for PC survivors, were more likely to be non-Hispanic White (compared with non-Hispanic Black participants), be older in age, have a higher monitoring style of coping, and have experienced higher levels of positive mood. Improved engagement features need to be developed and evaluated to increase the perceived value to patients. Additionally, the existence of a user patient profile indicates the potential to tailor web-based resources accordingly.

Abstract

Background: Digital technologies have changed how we manage our health, and eHealth literacy is needed to engage with health technologies. Any eHealth strategy would be ineffective if users' eHealth literacy needs are not addressed. A robust measure of eHealth literacy is essential for understanding these needs. On the basis of the eHealth Literacy Framework, which identified 7 dimensions of eHealth literacy, the eHealth Literacy Questionnaire (eHLQ) was developed. The tool has demonstrated robust psychometric properties in the Danish setting, but validity testing should be an ongoing and accumulative process.

Objective: This study aims to evaluate validity evidence based on test content, response process, and internal structure of the eHLQ in the Australian community health setting.

Methods: A mixed methods approach was used with cognitive interviewing conducted to examine evidence on test content and response process, whereas a cross-sectional survey was undertaken for evidence on internal structure. Data were collected at 3 diverse community health sites in Victoria, Australia. Psychometric testing included both the classical test theory and item response theory approaches. Methods included Bayesian structural equation modeling for confirmatory factor analysis, internal consistency and test-retest for reliability, and the Bayesian multiple-indicators, multiple-causes model for testing of differential item functioning.

Results: Cognitive interviewing identified only 1 confusing term, which was clarified. All items were easy to read and understood as intended. A total of 525 questionnaires were included for psychometric analysis. All scales were homogenous with composite scale reliability ranging from 0.73 to 0.90. The intraclass correlation coefficient for test-retest reliability for the 7 scales ranged from 0.72 to 0.95. A 7-factor Bayesian structural equation modeling using small variance priors for cross-loadings and residual covariances was fitted to the data, and the model of interest produced a satisfactory fit (posterior productive $P=.49$, 95% CI for the difference between observed and replicated chi-square values -101.40 to 108.83 , prior-posterior productive $P=.92$). All items loaded on the relevant factor, with loadings ranging from 0.36 to 0.94. No significant cross-loading was found. There was no evidence of differential item functioning for administration format, site area, and health setting. However, discriminant validity was not well established for scales 1, 3, 5, 6, and 7. Item response theory analysis found that all items provided precise information at different trait levels, except for 1 item. All items demonstrated different sensitivity to different trait levels and represented a range of difficulty levels.

Conclusions: The evidence suggests that the eHLQ is a tool with robust psychometric properties and further investigation of discriminant validity is recommended. It is ready to be used to identify eHealth literacy strengths and challenges and assist the development of digital health interventions to ensure that people with limited digital access and skills are not left behind.

Introduction

Background

Digital technologies have brought fundamental changes to modern-day life including how we manage our health. We can quickly search for health information at our fingertips but are also facing an avalanche of misinformation, as evident during the COVID-19 pandemic [1]. We can have instant access to our electronic personal health record, but these digital systems can be difficult to use or do not meet our expectation [2-5]. In addition, some people simply do not have or only have limited access or skills to use technologies for health, leading to the potential widening of health inequity when people with limited access or skills are being left behind in the digital age.

To characterize the challenges of accessing and using digital technologies for health, the concept of eHealth literacy was coined in 2006 [6]. At that time, it was defined as “the ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to addressing or solving a health problem” [6]. It is further recognized that any digital or eHealth strategy or intervention would be ineffective if the eHealth literacy needs of users are not addressed [6-8]. For example, in the postevaluation phase of the now defunct web-based personal health record in the United Kingdom, the HealthSpace, it was concluded that there was a mismatch of the system and users’ expectations, and some users seemed to lack the health literacy and digital literacy required to use the system [2,3].

The eHealth Literacy Questionnaire

To describe and address eHealth literacy needs, Norgaard et al [9] developed the eHealth Literacy Framework using a grounded validity-driven approach based on the results of a series of concept mapping workshops with a diverse range of stakeholders. Therefore, 7 dimensions of eHealth literacy were identified, depicting an overarching vision of how people access, understand, and use technology for health involving skills, health systems, and interaction between the individual and the systems [9]. This grounded framework provides a more comprehensive and contemporary view of eHealth literacy than the original definition, as it also taps into the role of digital systems and the interaction between users and systems. The framework was subsequently used to develop the eHealth Literacy Questionnaire (eHLQ) as a tool to measure eHealth literacy based on the seven dimensions:

1. Using technology to process health information
2. Understanding of health concepts and language
3. Ability to actively engage with digital services
4. Feel safe and in control

5. Motivated to engage with digital services
6. Access to digital services that work
7. Digital services that suit individual needs [10]

With the inclusion of eHealth literacy dimensions relating to user interaction and experiences in using digital health systems, the eHLQ embraces the real-world experiences of users while capturing the interactivity and increasing capabilities of digital technologies. It can provide rich information about the competencies of individuals as well as the maturity of digital health systems, as mature systems are likely to be more responsive to the individual needs of users [10]. As such, the eHLQ is a useful tool for digital health developers and implementers to promote equity-driven digital health systems and eventually contribute to health equity.

The eHLQ was simultaneously developed in Danish and English to avoid idiom and improve item wording to enhance future translation of the questionnaire into other languages [10]. The tool consists of 35 items with 7 scales, each with 4 to 6 items, and the response option is a 4-point ordinal scale of *strongly disagree* to *strongly agree*. The results are 7 equally weighted composite scale scores [10]. Initial validity testing of the Danish version of the eHLQ, based on data collected from 475 people from community and health care settings in Denmark, demonstrated the psychometric robustness of the tool. A 7-factor confirmatory factor analysis (CFA) model using the Bayesian structural equation modeling (BSEM) approach resulted in a satisfactory fit. All the 35 items of the tool loaded strongly on their relevant factors (range 0.36-0.94) with no significant cross-loadings. Good internal consistency was also demonstrated with satisfactory composite scale reliability for each of the 7 scales (range 0.75-0.87). In addition to taking the classical test theory (CTT) approach to the testing of psychometric properties, the item response theory (IRT) approach was also used. The results confirmed that the 35 items represented a range of difficulties and had good discrimination for testing people with different levels of eHealth literacy ability. Measurement invariance for age and sex was also demonstrated [10]. Although the study provided satisfactory validity evidence of the eHLQ in the Danish setting, evidence for the English version needs to be established. Described as a pioneer of eHealth in the world, Denmark has a national, publicly owned eHealth portal that is used by at least 2.3 million unique users out of their 5.8 million citizens per month as of 2019 [11,12]. Digital health is part of the routine for many Danish citizens. Although Australia also has a national digital health record system, information from an Australian Senate estimates hearing in 2019 revealed that only 4% of Australians had logged in to the Australian system [13]. Therefore, how the eHLQ will perform in settings with less prominent public use of digital health services is not known.

Validity Evidence

Validity testing is an ongoing process that involves the accumulation of 5 sources of evidence based on test content, response process, internal structure, relations to other variables, and consequences of testing, according to the authoritative reference of developing and using of educational and psychological measurements, the *Standards for Educational and Psychological Testing* (the *Standards*) [14].

Evidence based on test content is used to determine whether the items represent the content domain and may also include whether the wordings are easy to read and formats of administration are easy to use. Response process refers to the cognitive process of survey participants, that is, whether the interpretation of the items by participants aligns with the intended interpretation of items by test developers. It may also include whether interpretation remains the same across subgroups or across different formats of administration. Internal structure is the extent to which items conform to the constructs and relates to aspects such as factor analysis, reliability, and measurement invariance. Relations to other variables is the analysis of the relationship between the scores on another instrument relevant in the theoretical network of the construct being measured or other external variables that the scores can predict, whereas consequences of testing relates to the robustness of the proposed use of the test scores, including intended benefits, indirect effects, and unintended consequences such as construct underrepresentation or construct irrelevance [14-19]. This study focuses on the evidence collected in the Australian community health setting. Evidence on relations to other variables in this setting has been described by Cheng et al [20]. The aim of this study is to report and evaluate the evidence on test content, response process, and internal structure of the English eHLQ in Australia.

Methods

Data Collection

Methods to collect and evaluate the validity evidence were guided by the discussion in the *Standards* and related literature. A mixed methods approach was used with cognitive interviewing conducted to examine evidence on test content and response process, whereas a cross-sectional survey was undertaken for evidence on internal structure. Cognitive interviews were conducted in 2017 at a not-for-profit community health organization in the metropolitan area of Victoria, Australia. The clients of this site, together with clients from 2 private primary care medical clinics in the metropolitan and regional areas, were invited to participate in the cross-sectional survey in 2018.

Eligibility criteria for participation in both activities were clients aged ≥ 18 years, with or without any health conditions, and able to complete the questionnaire in paper-based format, web-based format, or face-to-face interview. Clients experiencing significant cognitive or mental health issues, who were too clinically unwell, and with insufficient English to complete the questionnaire and who did not have a carer to assist them were excluded.

Ethics Approval

Ethical approval of the study was obtained from the Deakin University Human Research Ethics Committee (HEAG-H 146_2017).

Cognitive Interviewing

Cognitive interviewing is commonly used to explore the cognitive process of how people answer survey items [21-23]. It may shed light on how people construct their answers to determine if their thinking matches the item as intended by the test developers, if people experience difficulties when answering the questions, or if the layouts are suitable. The results can also be used to identify response differences across sociocultural groups [17,22,24,25].

Given the qualitative nature of cognitive interviewing, a large sample size is not required but needs to be representative and diverse [14,24]. The process took an iterative approach that involved rounds of testing should issues be identified and the questions needed to be revised [21], with all items tested at least five times or until data saturation [26,27].

Participants were recruited with assistance from the health site, and a plain language information sheet was provided, with written consent requested. Interviews were conducted after participants completed the paper-based format. Participant behavior was observed when they answered the questionnaire. Upon completion, two questions were asked to gain insights into the cognitive process: (1) What were you thinking when you answered this question? (2) Why did you choose this answer? Participants were encouraged to make any further comments about the items or the format. They could be interviewed for all 35 items or part of the questionnaire, mainly for older participants to avoid fatigue and cognitive overload.

Data analysis was conducted using text summary [24]. Content analysis was first reviewed against the item intents of the eHLQ by one of the authors (CC), and further review was undertaken by another author (RHO). Any issues identified for revisions were discussed among all the authors until agreement was reached.

Cross-sectional Survey for Psychometric Testing

For the cross-sectional survey, clients were recruited at the waiting area and provided with an information sheet. A signed consent form was not requested with the return of the completed questionnaire as implied consent as a strategy to facilitate participation. Apart from self-administration using paper-based or web-based formats, interviews were included to ensure that older people or people with low literacy could participate. Demographic questions including age, sex, postcode, language spoken at home, education, health status, perceived health status, and use of digital services were also collected. Further description of recruitment is described in the study by Cheng et al [20].

Similar to the Danish eHLQ validity testing [10], this study also adopted both the CTT and IRT approaches for psychometric analysis. CTT is the traditional approach based on the assertion that an observed score comprises a true score and an error score [28,29]. This approach usually involves the evaluation of

dimensionality, discrimination, and reliability. However, CTT has been criticized for being sample dependent and does not take into account the characteristics of test items and how people at different levels of the construct of interest perform on those items, which is the focus of IRT, the modern approach [28,29]. Hence, both approaches were used in this study to strengthen the collection of evidence.

Statistical Analysis

Overview

Analyses were conducted using three statistical software programs, namely, SPSS (version 25.0; IBM Corp) [30], Mplus (version 8.3; Muthén & Muthén) [31], and IRTPRO (Item Response Theory for Patient-Reported Outcomes; version 4.20; Vector Psychometric Group) [32]. Descriptive statistics were generated for the demographic data, eHLQ scores, and floor and ceiling effects. The presence of floor and ceiling effects may indicate poor discrimination at the minimum or maximum values [33], with effects considered significant if over 15% of participants score in the top (ceiling) or bottom (floor) of a score range [34,35].

Missing Values

To deal with missing data for the eHLQ scores, the data set was first examined. If no clear pattern of missingness was found, that is, the missingness could be regarded as completely at random, a 2-step approach would be taken. The first step was to delete cases with more than 50% of missing values to reduce potential bias. The second step was to replace all missing values using the expectation-maximization algorithm imputation in SPSS [30,36,37]. This final data set was used for all psychometric analyses.

CTT Analysis

Item difficulty is an item property and is usually conducted as a first step in item analysis in the CTT approach [28,38]. This parameter was calculated as the proportion of survey participants who endorsed disagree and strongly disagree against the proportion of agree and strongly agree [39]. Hence, the higher the proportion responding to disagree and strongly disagree indicated a higher level of difficulty.

To measure reliability, internal consistency and test-retest reliability were evaluated. In addition to the commonly used Cronbach α for internal consistency, which has been criticized for producing biased estimates when items do not have equal factor loadings or in case of correlated item errors [39], composite scale reliability calculated through structural equation modeling using Mplus recommended by Raykov [40] was also evaluated. These 2 estimates are expected to be fairly comparable when the set of items is unidimensional, has uncorrelated errors, and has high loadings on the true score [29,40]. The acceptable range of both estimates is from 0.70 to 0.95, with 0.80 generally regarded as good reliability [41]. For test-retest, there is no consensus on the optimal length between time points, and invitations were sent 1 week after the first completion of the questionnaire. Test-retest reliability was evaluated using the intraclass correlation coefficient (ICC) [42]. A minimum of 10 participants is considered adequate for

detecting an acceptable ICC of 0.70 with 80% power at a significance level of .05 [43], and a sample size of 30 was estimated.

Following the classical item analysis, CFA was conducted, given that the hypothesized constructs were specified a priori. Similar to the Danish validity testing, the BSEM approach was adopted [10] using Mplus. There is no agreement on the sample size for CFA, which can range from 100 to 400 [33,44], and a sample size of 500 was estimated. Contrary to the traditional frequentist approach using the maximum likelihood estimation procedure, which assumes that measures not related to a latent factor will have zero loadings on that factor, which can easily lead to poor model fit and rejection [29,45], the parameters in BSEM are treated as variables, and this more flexible approach is described as a better reflection of substantive theories [45].

The different parameter specifications in BSEM at the start of an analysis are described as priors, which can be diffuse (noninformative) or informative [45]. Diffuse priors are hypothesized parameters that are fully estimated from the data, whereas informative priors are likely parameter values derived from previous studies, researchers' theories, or prior beliefs [45]. Informative priors can be applied to cross-loadings and residual covariances. For cross-loading priors, a variance prior of 0.01 means that 95% of the loading variation is within the range of -0.20 to $+0.20$, which is considered a small loading. Inverse-Wishart priors were used for the covariances among item residuals. The application is to start with a large enough df of the inverse-Wishart distribution and gradually lowers the df parameter to produce a more flexible model such that the residual covariances are not strictly constrained to zero [46].

A sequence of 1-factor models followed by a 7-factor model (Multimedia Appendix 1) were fitted to the data. Several models with different parameter specifications, using the Danish study as a reference [10], were tested and compared to identify the model of interest, which is a model that is not rejected by the data and is "closest to the CFA model that fits well enough" [46]. To evaluate model fit, Mplus produces a posterior predictive P (PPP) value and 95% CI for the difference between the observed and replicated chi-square values. A low PPP value and positive 95% CI indicate poor fit, whereas a PPP value of around .5 and a value of 0 falling close to the middle of the 95% CI indicates excellent fit [45]. Furthermore, a nonsignificant prior-posterior predictive P (PPPP) value, that is, $>.05$, indicates that the estimates of the cross-loadings can be considered approximate zero and are thus negligible [47]. Apart from the aforementioned estimates, a model comparison can be conducted by examining the model convergence and information criterion. The model of interest is the model with quicker convergence, that is, when the potential scale reduction is consistently less than 1.05 by the smallest number of iterations, and has a lower discrepancy information criterion [46].

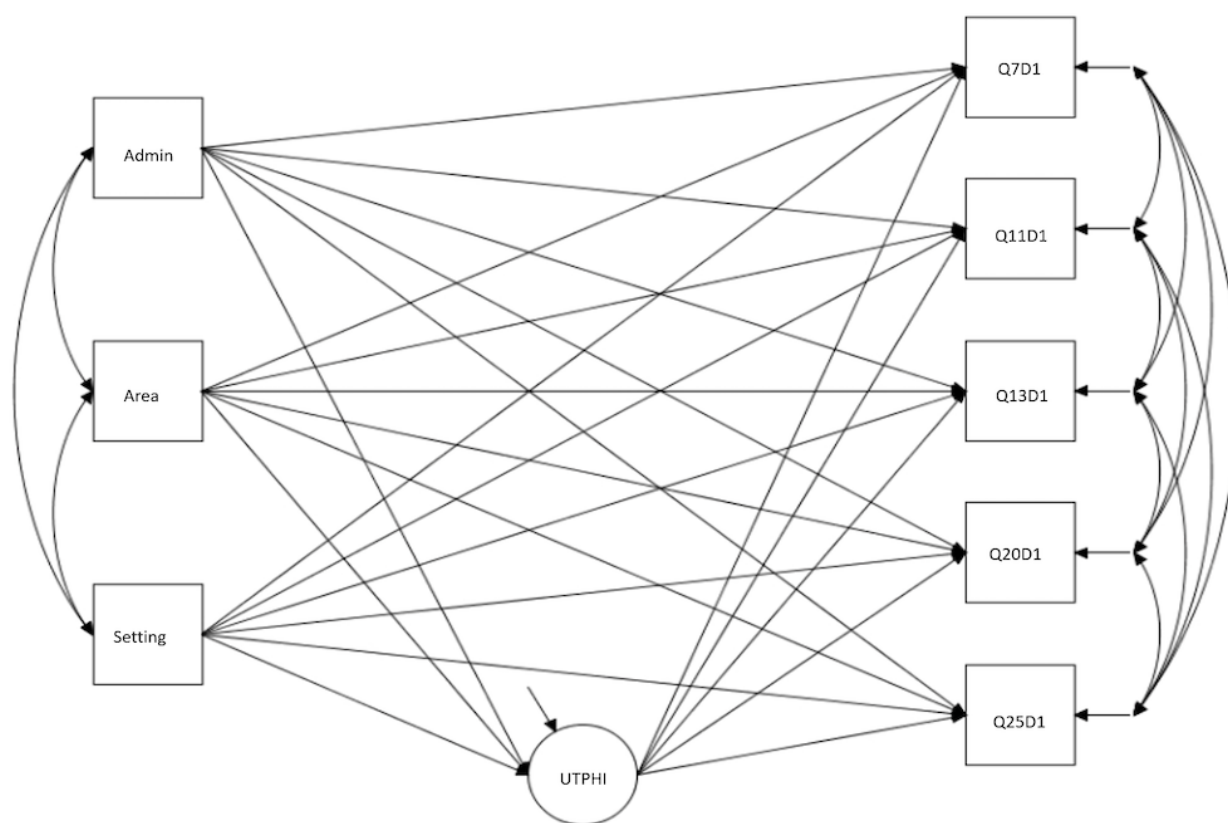

On the basis of the results of the selected 7-factor model, discriminant validity was evaluated using the Fornell-Larcker criteria [48] based on shared variance and average variance extracted (AVE). Shared variance is calculated by squaring the interfactor correlation between 2 factors, and the AVE is generated by the average of the sum of the squared factor

loadings of the related items [49]. If the AVE is >0.5 , the first Fornell-Larcker criterion that “a factor accounts for more variance in the observed variables associated with it than measurement error or similar external, unmeasured influences” [49] is met. To meet the second criterion about the factor’s association with other factors in the conceptual framework, the AVE of any 2 factors both “have to be greater than the shared variance estimate” between the 2 factors [48,49].

The BSEM approach is further used to test for differential item functioning (DIF), that is, the stability of measurement across different groups or grouping variables [50,51]. By using the multiple-indicators, multiple-causes (MIMIC) model approach, both DIF and group differences can be detected simultaneously [52]. This method has been used to test for group differences among different demographic groups in the same setting and is described with details in the study by Cheng et al [20]. For this analysis, administration format (paper-based vs face-to-face

interviews), site area (metropolitan vs regional area), and health setting (private clinic vs not-for-profit community health) were included as covariates. The web-based format was not included for analysis owing to the limited number of participants (13/525, 2.5%) using this format. See Figure 1 for the Bayesian model for testing DIF with scale 1 as an example. Procedures for model testing and selection are similar to BSEM described earlier, except priors were applied to DIF paths instead of cross-loadings. For the evaluation of DIF, a significant direct effect indicated the presence of DIF, and a 1-tailed P value of $<.025$ was considered significant as no directional hypotheses were set up. If DIF was identified, the estimates were further evaluated based on the model selected. For example, if the model with variance prior of 0.01 was selected and the $PPPP$ value was nonsignificant, then estimates within the range of -0.2 to $+0.2$ could be considered negligible [53]. Group differences were also examined as supplementary results.

Figure 1. Bayesian multiple-indicators, multiple-causes model for differential item functioning testing with scale 1 of eHealth Literacy Questionnaire as the example. Output from Mplus: Admin: administration format (0=face-to-face interview, 1=paper format); Area: site area, that is, location of participating organization (0=metropolitan, 1=regional); Setting: health setting (0=private clinic, 1=community health); UTPHI: eHealth Literacy Questionnaire scale 1 (using technology to process health information); Q7D1, Q11D1, Q13D1, Q20D1, and Q25D1: eHealth Literacy Questionnaire items.

IRT Analysis

To perform an IRT analysis, 4 assumptions need to be met. The assumptions of unidimensionality (items are measuring the same construct), local independence (each item should not be related except they are measuring the same construct), and item invariance (item parameters are the same across subgroups) can be examined through the CTT methods described in the CTT Analysis section. The assumption of monotonicity (the probability of endorsing an item increases as the trait level

increases) is evaluated by examining the test characteristic curves [54]. The sample size requirement for IRT analysis may range from 200 to 500 [54]. For this analysis, the generalized partial credit model, similar to the Danish study, was applied using IRTPRO. Apart from the test characteristic curves, item thresholds, item location, item discrimination, and information functions from the 7 unidimensional IRT models were evaluated. Item response thresholds were evaluated by inspecting the item characteristic curves, where the peak of each response category curve from the lowest (strongly disagree) to the highest (strongly

agree) should correspond to the lowest to the highest trait level to demonstrate that an item has an ordered set of response thresholds. For item discrimination, a steeper curve or slope of the item characteristic curves indicates better discrimination between people with different levels of the trait. A higher item discrimination estimate indicates higher discrimination between people with differences in ability [55,56]. For item location estimates, lower estimates represent easier items, as these items are expected to be endorsed by people with lower ability and are expected to be similar to the item difficulty estimates in the CTT analysis [54,57,58]. Finally, an inspection of the information function curve provided information on where an item could precisely measure the underlying trait. This measurement precision is analogous to the reliability in CTT [14]. It also helps to determine if the items of a scale measure the full spectrum of the underlying trait.

Results

Cognitive Interviewing

A total of 12 participants were recruited for 2 rounds of cognitive interviews. Of these 12 participants, 8 (67%) were women and 4 (33%) were men, with 58% (7/12) of the participants aged >65 years and 17% (2/12) speaking a language other than English at home. The sample provided a good representation of people from a range of different age groups and cultural backgrounds. The first round with 7 participants identified the term *health technology services* used in the 4 items of scale 7 (*Digital services that suit individual needs*) was confusing. Most participants could not immediately relate the term to digital systems as intended. Following the discussion within the research team, the term was changed to *eHealth systems*. The changed term was tested in a second round with

5 participants, and no further issue was identified. Participants' understanding of the other items was generally similar to the item intents. For example, for items about using *technology* to find, understand, share, or organize health information, participants could easily link it to the internet, Dr Google, or anything web based. In the item "I use measurements about my body...", participants thought about how they used results of blood test, body weight, or blood pressure, which was aligned with the item intent.

Despite the diverse backgrounds of participants, no major differences in understanding the items were identified, and all participants found the items easy to read. Recommendations from participants also led to changes in the introductory page to provide examples of technology, health technology, eHealth systems, and health care providers or health professionals. The completion time of the questionnaire ranged from 3 to <7 minutes.

Psychometric Testing

Participant Characteristics

A total of 530 completed questionnaires were collected. On the basis of the treatment of missing values described in the Statistical Analysis section, 5 cases were deleted, leading to a final sample size of 525 for psychometric analyses. The age of participants of the cross-sectional survey ranged from 18 to 94 years, and 61% (320/525) of the participants were women. A total of 33.3% (175/525) of the participants had a university education, and 30.9% (162/525) spoke a language other than English at home. Of the 525 participants, 300 (57.1%) reported having some form of chronic illness. Regarding technology use, of the 525 participants, 151 (28.8%) did not have a computer or laptop, and 131 (25%) did not use email or SMS text messaging (Table 1).

Table 1. Characteristics of cross-sectional survey participants (N=525).

Characteristics	Value
Age (years), mean (SD; range)	56.8 (18.6; 18-94)
Setting, n (%)	
Site 1: metropolitan private clinic	204 (38.9)
Site 2: metropolitan community health	204 (38.9)
Site 3: regional private clinic	117 (22.3)

Blogging	15 (2.9)
Forum/chat room	26 (5)
Number of platforms used, mean (SD; range)	2.7 (1.8; 0-10)
Looked for web-based information in the last 3 months, n (%)	392 (74.4)
Monitored health digitally, n (%)	183 (34.9)

^aSocioeconomic status is classified by IRSD10. This index is based on information provided by the Australian Bureau of Statistics [59]. Postcodes are divided into 10 ranks with the higher number indicating more advantaged suburbs.

^bIRSD: Index of Relative Socio-economic Disadvantage Decile 2016 of Australia.

Descriptive Statistics

The mean scale scores ranged from 2.43 (SD 0.57) for scale 7 (*Digital services that suit individual needs*) to 2.95 (SD 0.41) for scale 2 (*Understanding of health concepts and language*; Table 2). Missing values for individual items were <5%, another indication that the items were generally well understood. No floor effect was found, whereas ceiling effects were found for 8 items (range 16.2%-20.8%). These items were related to the use of technology and understanding of health knowledge, suggesting that a substantial proportion of participants were

comfortable in using technology and had good knowledge of health (Multimedia Appendix 2).

Observation during cognitive interviewing and the main survey did not identify any issue when people responded to the items for either the paper-based or web-based format. An inspection of the comments marked on the 530 completed questionnaires from the main survey found that 0.03% (15/530) of the participants put a question mark next to some items, indicating that they did not understand those items, while 0.10% (55/530) of the participants provided unclear answers. These results suggested that the items were generally understood, and the 4-point ordinal scale was acceptable.

Table 2. eHealth Literacy Questionnaire scale scores (N=525; score range 1-4).

Scale	Value, mean (SD)	Missing data
1. Using technology to process health information	2.59 (0.61)	0
2. Understanding of health concepts and language	2.95 (0.41)	0
3. Ability to actively engage with digital services	2.65 (0.68)	1
4. Feel safe and in control	2.83 (0.49)	5
5. Motivated to engage with digital services	2.63 (0.55)	0
6. Access to digital services that work	2.64 (0.45)	1
7. Digital services that suit individual needs	2.43 (0.57)	11

CTT Analysis

A range of item difficulty was found for all scales, reflecting a spectrum of difficulty levels across the relevant constructs. The scale with the smallest range of item difficulty was 7 (*Digital services that suit individual needs*; range 45%-60%). The widest range of item difficulty was observed for scale 4 (*Feel safe and in control*), ranging from 14% to 52%. Scale 7 was also the most *difficult* scale, as the difficulty level of all items was at least 45%, whereas scale 2 (*Understanding of health concepts and language*) was the *easiest* scale with 4 items <20% and the hardest item was 37% (Multimedia Appendix 3).

The chosen 1-factor Bayesian models (with informative priors for residual covariances of $df=60$) had *PPP* values that ranged from 0.19 to 0.24 for the 7 scales with all target loadings statistically significant, establishing evidence of scale homogeneity. Factor loadings were all >0.50, except for item 3 of scale 6 (*Access to digital services that work*) with a loading of 0.45. Residual variances were <0.50, except for 6 items, with item 3 recording the highest estimate of 0.80 (Multimedia Appendix 3).

A subsequent 7-factor model was fitted to the data set with 6 models tested. All models fitted the data well. The model with priors for the variance of cross-loadings set to 0.01 and inverse-Wishart df for residual covariances of 150 was chosen as the model of interest (*PPP*=.49, 95% CI for the difference between observed and replicated χ^2 values -101.40 to 108.83, *PPPP*=.92). No statistically significant cross-loadings were found for the chosen model, indicating that all items loaded only on 1 factor (Multimedia Appendix 4). Except for 4 items, all factor loadings of the chosen 7-factor model were >0.50, with item 26 of scale 2 (*Understanding of health concepts and language*) recording the lowest loading of 0.36. In addition, all cross-loadings were less than -0.20 to +0.20; that is, they could be considered approximate zero and negligible (Table 3).

Inspection of the AVE showed that the estimates of 4 scales met the first Fornell-Larcker criterion, whereas 3 scales were <0.50 (scales 2, 4, and 6). Given that these AVE estimates were based on the 7-factor model that allowed for cross-loadings and residual covariances, AVE estimates from the 1-factor models were also calculated, and the AVE estimates for the 7 scales were 0.66, 0.49, 0.72, 0.61, 0.65, 0.47, and 0.74. Hence, the AVE estimates of scales 2 and 6 were still <0.50. The second criterion of the factor's association with other factors was also not satisfied. On the basis of this criterion, only scale 2 demonstrated good discrimination with scales 4, 6, and 7, and scale 4 had good discrimination with all scales except scale 6.

Hence, there might not be sufficient discriminant validity among the scales (Table 4).

For internal consistency, the Cronbach α (range .74-.90) and composite scale reliability (range 0.73-0.90) estimates were very similar as expected. All were within the acceptable range, whereas scales 1, 3, 4, 5, and 7 had estimates >0.80, indicating good internal consistency. For test-retest, 42 participants completed the retest and ICC ranged from 0.72 to 0.95, suggesting good test-retest reliability (Multimedia Appendix 3).

The Bayesian MIMIC models for testing DIF for administration format, site area, and health setting achieved a good model fit. The model with a DIF path of 0.01 was chosen as the model of interest for the 7 scales with *PPP* ranging from .19 (scale 6) to .35 (scale 7), and all *PPPPs* were nonsignificant. No statistically significant effects of site area and health setting on the items were found. The administration format was found to have a statistically direct effect on 5 items, indicating possible DIF. However, all estimates were within the acceptable range of -0.2 to +0.2 and therefore considered negligible (Multimedia Appendix 5).

For group differences, no significant differences were found for site area and health setting, but group differences were identified for the administration format with the self-administered paper-based format scoring higher than face-to-face interviews for scales 1 (*Using technology to process health information*), 3 (*Ability to actively engage with digital services*), 5 (*Motivated to engage with digital services*), and 7 (*Digital services that suit individual needs*; Table 5). Further analysis using nonparametric tests was undertaken to explore if the 2 groups had significant differences in terms of age, education, and technology use, with a significance level set at <.05. A Mann-Whitney *U* test indicated significant difference in age for interview (median 75; $n=109$) and paper format (median 51; $n=387$; $U=7881.50$; $z=-10.00$; $P<.001$), with participants interviewed being older than those completing the self-administered paper format. A chi-square test for independence indicated a significant association between education and administration format, $\chi^2_1=0.4$ ($n=503$), $P<.001$. Among the participants being interviewed, 36.7% (40/109) did not complete secondary school, whereas only 13.2% (51/387) of participants completing the paper format did not complete secondary school. A significant difference in the number of devices was also found for interview (median 2; $n=111$) and paper format (median 2; $n=390$; $U=20,328.50$; $z=6.86$; $P<.001$), with more devices for participants using the self-administered paper format than for participants being interviewed.

IRT Analysis

The results of the 1-factor Bayesian models with all significant targeted factor loadings provided evidence of unidimensionality and local independence. Item invariance was supported by the testing of DIF for administration format, site area, and health setting. Measurement invariance across subgroups, including age, sex, education, language spoken at home, and information and communication technology use, was also established and reported by Cheng et al [20]. Hence, the results of the CTT analysis confirmed 3 of the 4 assumptions for IRT analysis. For

the final assumption of monotonicity, the test characteristic curves were examined, confirming that the probability of endorsing an item increased as the trait level increased.

Visual inspection of the item characteristic curves showed distinct peaks for the response categories along the continuum of the latent trait for the most likely responses, indicating ordered thresholds for all items ([Multimedia Appendix 6](#)). The item discrimination parameters demonstrated that items within each scale had different sensitivities to different levels of ability. All slopes of the item characteristic curves were steep, with the

steepest slope observed for item 33 of scale 7 (*Digital services that suit individual needs*), which also had the highest item discrimination parameter of 5.56. The items with lower discrimination parameters among all items were item 3 of scale 6 (*Access to digital services that work*; 0.86) and item 26 of scale 2 (*Understanding health concepts and language*; 0.88). However, the item characteristic curves of both items were still considered steep. The item location parameters also showed that items had different levels of difficulty within each scale but were not evenly distributed for scales 2 and 4. Items 15 and 21 of scale 2 (*Understanding of health concepts and language*) had very similar item location parameters of -1.19 and -1.18 , respectively. Scale 4 (*Feel safe and in control*) also had item location parameters of -0.58 for item 10 and -0.54 for item 22. The results were generally in line with the item difficulty indexes from the CTT analysis (Multimedia Appendix 3). Furthermore, the information function curves were evaluated for reliability. All items provided precise information at different levels of the latent trait, except item 14 of scale 4 (*Feel safe and in control*), which provided very low information across all levels of the trait (Multimedia Appendix 6).

Discussion

Principal Findings

This study collected and examined validity evidence based on test content, response process, and internal structure of the eHLQ in the Australian community health setting. Items and formats were easy to read and use, and items were understood as intended. The Bayesian CFA and IRT analyses confirmed the robustness of the internal structure. However, discriminant validity based on estimates of the 7-factor BSEM was not well established and will require further investigation.

The cognitive interviews were successful in identifying 1 confusing term, which was revised, and the introductory page of the questionnaire was also improved. The results combined with observation during interviews and the survey as well as the limited number of missing values provided a wealth of information in support of the validity evidence on test content and response process of the eHLQ.

The final sample size of 525 of the cross-sectional survey provided an adequate sample size for both the CTT and IRT analyses. Although the sample had more women and university-educated participants than the Australian national averages, the sociodemographic characteristics of the participants still reflected a generally diverse sample. Nevertheless, a quarter of the sample did not use email or look for web-based information, showing that people with limited use of technology or eHealth were represented in the survey. This would ensure that the validity testing results of the eHLQ were also applicable to people with potentially lower eHealth literacy. In addition, the group differences in the 4 scales identified in the administration format for paper-based and interviews further pointed to the results that these 2 groups were significantly different in terms of age, education, and technology use. As such, the purpose of an interview option as a recruitment strategy to include older people or people with lower literacy was fulfilled. By contrast, evidence of measurement invariance

across the 2 formats confirmed that responses were not influenced by interviewing bias or social desirability. Given a separate analysis of this sample found that older people also scored lower on the same 4 scales [20], the findings of the group differences between the 2 administration formats are not surprising. However, future studies may consider examining if such group differences continue to persist when the interview option is provided at random. The identified group differences also imply that the interview option should always be available such that older people or people with lower literacy are included in future eHealth literacy research to ensure that they are not being left behind in the age of digital health.

A rigorous assessment of the internal structure was undertaken using both the CTT and IRT approaches to ensure that different aspects of validity and reliability of the eHLQ data were investigated. For the CTT analysis, the Bayesian approach of applying informative priors was used. Although this modern approach may involve more steps in testing model fit, it allows for the hypothesis of approximate zeros for model parameters. Instead of being constrained to exact zeros, as in the traditional structural equation modeling approach, the approach provides a better approximation of the real world. As such, the seven 1-factor models were found to fit the data well, confirming scale homogeneity, while factor loadings and residual variances were acceptable. Estimates of internal consistency reliability were good for all scales, although scale 2 (*Understanding of health concepts and language*) and scale 6 (*Access to digital services that work*) were low but still fell within the acceptable range. Test-retest reliability was also good for all scales, indicating that the eHLQ produces stable and consistent results.

The characteristics of the test and items in accurately measuring eHealth literacy were further supported by the IRT analysis. The test and item characteristic curves demonstrated that participants with higher eHealth literacy were more likely to endorse items with agree and strongly agree. The information function curves indicated that the items could gather reliable and precise information across different levels of the underlying trait. Estimates further showed that the items had generally high sensitivity in discriminating participants with different levels of eHealth literacy. The item locations also supported the fact that the items represented different levels of difficulty. This is further verified with the item difficulty indexes from the CTT analysis, which showed the 2 estimates displaying very similar pattern, further strengthening the evidence that the items generally represented a range of difficulty levels of the latent factor. The use of MIMIC models also found no or negligible DIF for administration format, site area, and health setting, confirming measurement equivalence of the items across formats and settings.

Although it is noted that the Australian results are generally similar to the Danish validity testing results reported by Kayser et al [10], a comparison of the item location results found otherwise. The 2 results are in contradiction such that the easiest item in the Australian main sample is the hardest item in the Danish context for most of the scales. For example, in scale 1 (*Using technology to process health information*), item 7 is the easiest item for the Australian sample, but it is the hardest item for the Danish data set. As the Danish study does not report on

CTT item difficulty estimates, it cannot be used to calibrate with the Australian results. This may be due to people's different practices in using and accessing digital health between the 2 countries, as Denmark has much more regular users of web-based health systems than Australia. The real reason behind the differences is difficult to speculate and future investigation (eg, using cognitive interviewing specifically focused on the levels of response to items with contrasting difficulties in the 2 countries) may shed more light on the discrepancy.

Following the 1-factor models, a subsequent 7-factor model using informative priors for cross-loadings and residual covariances demonstrated excellent model fit of the factor structure, as hypothesized by the questionnaire developers. All target loadings were significant with acceptable factor loadings, and there was also no significant cross-loading for the chosen model of interest. Although the chosen model of interest has informative priors different from the chosen model of the Danish validity testing, the Australian data analyses generally replicate the Danish results, strengthening the evidence of the internal structure of the eHLQ.

A possible weakness in the psychometric properties of the eHLQ may be its discriminant validity. The AVE estimates suggested a lack of clear discrimination among all the scales except for scale 2 (*Understanding of health concepts and language*) and scale 4 (*Feel safe and in control*). Although AVE estimates were not investigated in the Danish validity testing, the high interfactor correlations between scales 1 and 5 and scales 6 and 7 in the Danish validity testing also suggested possible insufficient discrimination among those factors, and it was speculated that there might be some causal relationships among these scales [10]. However, the test developers argued that content analysis of the views of patients and professionals during development confirmed that these factors were indeed different constructs and decided to keep the 7 dimensions in the final model. Further investigation of discriminant validity is warranted in future validity testing of the tool.

This study provided robust validity evidence of inferences drawn from the eHLQ when used in the diverse Australian community

health settings. As this study was undertaken before the COVID-19 pandemic, which sees an increased acceptance and use of telehealth [60] as well as the widespread of misinformation and disinformation on social media [1], the eHLQ will be a useful tool for health care providers, researchers, digital health developers, and policy makers to better understand the eHealth literacy needs of individual patients and different population groups. The insights gained will help develop, implement, and evaluate digital health interventions that suit the needs of users to promote health and equity.

Limitations

A possible limitation to the validity evidence is that the sample involved only participants who spoke and understood English well. Although the eHLQ is one of the first questionnaires developed simultaneously in 2 languages to minimize cultural references, both languages are from Western culture with generally well-developed national health care systems. How the psychometric properties perform in other cultural groups and countries is not clear. Future research on the eHLQ should include validity testing in cross-cultural settings including in different contexts and use. The Danish validity testing study was undertaken in the community setting involving the general population. However, this study only included people attending community health services. Future testing of the eHLQ in other Australian settings may strengthen the validity evidence of the tool for the general population.

Conclusions

The evidence presented in this study suggests that the eHLQ is a tool with robust psychometric properties. There is support for test content, and the items are understood as intended. Although there are potential weaknesses in discriminant validity, it is reasonable to suggest that the items can provide valid and reliable assessment of the 7 constructs of eHealth literacy in the diverse Australian health settings. The eHLQ is ready to be used to identify eHealth literacy strengths and challenges and assist the development of digital health interventions to ensure that people with limited digital access and skills are not being left behind.

Abstract

Background: The 36-Item Short Form Health Survey (SF-36) is a popular questionnaire for measuring the self-perception of quality of life in a given population of interest. Processing the answers of a participant comprises the calculation of 10 scores corresponding to 8 scales measuring several aspects of perceived health and 2 summary components (physical and mental). Surprisingly, no study has compared score values issued from a telephone interview versus those from an internet-based questionnaire self-completion.

Objective: This study aims to compare the SF-36 score values issued from a telephone interview versus those from an internet-based questionnaire self-completion.

Methods: Patients with an internet connection and returning home after hospital discharge were enrolled in the SENTIPAT multicenter randomized trial on the day of discharge. They were randomized to either self-completing a set of questionnaires using a dedicated website (internet group) or providing answers to the same questionnaires administered during a telephone interview (telephone group). This ancillary study of the trial compared SF-36 data related to the posthospitalization period in these 2 groups. To anticipate the potential unbalanced characteristics of the responders in the 2 groups, the impact of the mode of administration of the questionnaire on score differences was investigated using a matched sample of individuals originating from the internet and telephone groups (1:1 ratio), in which the matching procedure was based on a propensity score approach. SF-36 scores observed in the internet and telephone groups were compared using the Wilcoxon-Mann-Whitney test, and the score differences between the 2 groups were also examined according to Cohen effect size.

Results: Overall, 29.2% (245/840) and 75% (630/840) of SF-36 questionnaires were completed in the internet and telephone groups, respectively ($P<.001$). Globally, the score differences between groups before matching were similar to those observed in the matched sample. Mean scores observed in the telephone group were all above the corresponding values observed in the internet group. After matching, score differences in 6 out of the 8 SF-36 scales were statistically significant, with a mean difference greater than 5 for 4 scales and an associated mild effect size ranging from 0.22 to 0.29, and with a mean difference near this threshold for 2 other scales (4.57 and 4.56) and a low corresponding effect size (0.18 and 0.16, respectively).

Conclusions: The telephone mode of administration of SF-36 involved an interviewer effect, increasing SF-36 scores. Questionnaire self-completion via the internet should be preferred, and surveys combining various administration methods should be avoided.

Trial Registration: ClinicalTrials.gov NCT01769261; <https://www.clinicaltrials.gov/ct2/show/record/NCT01769261>

Introduction

The 36-Item Short Form Health Survey (SF-36) is a popular questionnaire for measuring the self-perception of quality of life (QoL) in a given population of interest [1-3]: a query exploring the presence of the term *SF-36* in the title or the abstract of PubMed records retrieved 22,184 documents on September 28, 2021. SF-36 has been made available in 50 different languages, including French [4]. Although the SF-36 was initially developed as a paper-pencil format auto-questionnaire, the use of telephone interviews has also been reported for collecting SF-36 data [5-8]. Self-completion via the internet has been reported as a validated administration mode by Bell and Kahn [9] in 1996, and since then, with the spread of the internet and computers, several other computerized or internet-based formats have been applied in different studies [10-12].

Several randomized trials compared the SF-36 scores issued from different administration modes, such as paper versus the internet [13-17] or telephone versus paper [18-26]. Telephone interview is a common mode of questionnaire administration for several reasons, including the potential to increase response rate [24-26], practical convenience if other data of the study are already being collected via telephone, and exploring QoL in some special populations such as older patients. On the other hand, self-completion via the internet has advantages such as avoiding any potential response bias related to the interviewer effect [18], being potentially a simpler organization for collecting SF-36 data, and being associated with lower costs. However, and surprisingly, to our knowledge, no study has compared telephone interview and internet-based auto-questionnaire methods for collecting SF-36 data to investigate whether they can be used as alternative methods in mixed mode data collection procedures according to participant preferences and minimize the possible selection bias. This study investigated such questions in detail, owing to the availability of SF-36 data that had been collected in a multicenter randomized trial.

The SENTIPAT trial [27] explored the concept of sentinel patients who would voluntarily report their health evolution on a dedicated website. Participants enrolled in this trial were randomized to either the internet or the telephone group; patients in the internet group were invited to self-complete questionnaires on their health evolution after their hospital discharge via a dedicated website, whereas patients in the telephone group were invited to complete the same questionnaires through telephone interviews. However, 2 previous studies issued from the SENTIPAT trial have been reported: the first introduced an original questionnaire developed in the SENTIPAT study to investigate the opinion of patients about the organization of their hospital discharge [28], and the second introduced the I-Satis questionnaire, a questionnaire that was distributed in

hospitals at a national level in France to investigate patient satisfaction at the time of the SENTIPAT trial [29]. As the SF-36 questionnaire was also included in the SENTIPAT trial, the corresponding collected data were a perfect opportunity to precisely investigate the influence of the mode of administration of the questionnaire on SF-36 scores. This investigation is the aim of the ancillary study of the SENTIPAT trial reported here.

Methods

This research was an ancillary study of the multicenter, randomized SENTIPAT trial [27]. We took advantage of the trial to investigate the impact of the mode of administration of the SF-36 questionnaire on SF-36 scores.

Population

Briefly, as previously reported [28,29], participants recruited consecutively from 5 different volunteer units (hepatogastroenterology, gastrointestinal enterology and nutrition, general and digestive surgery, infectious and tropical diseases, and internal medicine) of the Hôpital Saint-Antoine were enrolled in the SENTIPAT trial. Patients with internet access at home, aged ≥ 18 years, not cognitively impaired and without a behavioral disorder, speaking French, returning home after hospitalization, and not opposed to participating in the trial were eligible for inclusion.

Inpatients were enrolled on the day of hospital discharge by a clinical research technician of the trial. At that time, the patients were informed about the study. Eligible patients not opposed to participating in the study were randomized into two parallel groups—internet or telephone follow-up (inherently resulting in an open-label trial)—in a ratio of 1:1. On the basis of centralized randomization that allocated the eligible patient either to the internet or to the telephone group through a website and using an underlying permutation block randomization stratified by hospital unit, a computer-generated list of permutations was established by a statistician independent of the study. At the time of patient inclusion, the technician also collected baseline variables (length of stay, sex, age, relationship status, level of education, activity, and type of insurance). The patient was then informed and discharged with documents explaining the corresponding questionnaire administration. A total of 1680 eligible patients (840 randomized in the internet group and telephone group each) were enrolled in the SENTIPAT trial between February 25, 2013, and September 8, 2014.

Ethics Approval

The SENTIPAT study was approved by the Comité de Protection des Personnes Île de France IX (decision CPP-IDF IX 12-014; June 12, 2012), the Comité Consultatif sur le Traitement de l'Information en matière de Recherche dans le domaine de la Santé (decision 12.365; June 20, 2012), and the

Commission Nationale de l'Informatique et des Libertés (decision DR-2012-582; December 12, 2012). According to the French law in force at the time of the study, the formal consent of participants was waived and replaced by the following: patients received full information on their participation in the study, and the nonopposition of each participant in the study was notified (including date of nonopposition declaration) in the SENTIPAT study register.

Survey Administration

Patients in the internet group had access to the French version of the SF-36 questionnaire 40 days after discharge on a website dedicated to SENTIPAT. Oral and written instructions had been delivered to these patients for a personal connection to the SENTIPAT website, and they received 1 reminder email per week for 3 weeks in case of nonresponse. Patients in the telephone group were interviewed by telephone approximately 42 days after discharge, and the data were simultaneously entered into the system by the interviewer using a website interface identical to that used in the internet group. The appointments for the telephone interviews of the patients in the telephone group were scheduled at the moment of patient inclusion, and up to 3 calls were tried whenever the first call did not reach the patient.

SF-36 Questionnaire and Score Calculations

The 8 scale scores and the 2 summary scores of SF-36 were calculated according to the Medical Outcomes Study SF-36 French scoring manual [30]. The main lines of the corresponding process can be summarized as follows. The SF-36 questionnaire is composed of 36 items. Completion of the SF-36 questionnaire consists in choosing one of the proposed precoded answers for each of the 36 items in the questionnaire. The analysis of 35 items (an item that relates to the evolution of perceived health is not involved in any score calculation) comprises a structured calculation of 10 scores corresponding to 8 scales measuring several aspects of perceived health and 2 summary components. The eight scales and the corresponding number of questionnaire items involved are as follows: physical functioning (10 items), role-physical (RP; corresponding to role limitations because of physical problems; 4 items), bodily pain (3 items), general health (5 items), vitality (4 items), social functioning (2 items), role-emotional (corresponding to role limitations because of emotional problems; 3 items), and mental health (5 items). The raw score of each scale was computed by the algebraic sum of the corresponding item values (the values assigned to each precoded answer were calibrated) and then normalized to a score value ranging from 0 (lowest possible) to 100 (highest possible). According to the recommendations, scale score calculations were performed only if at least half of the items involved were answered, and in such a case, missing item data were treated with a person-specific approach that uses the average score of the completed items on the same scale. Finally, the two remaining scores, the physical and mental component summary scores, were obtained by assigning predefined specific weights to each of the 8 scale scores.

Statistical Analyses

Bivariate analyses were performed using Fisher exact test or chi-square test of independence for categorical variables and the Wilcoxon-Mann-Whitney test for quantitative variables. The latter test was notably used to compare the SF-36 score differences between the internet and telephone groups. Several authors have discussed the task of interpreting observed differences in terms of *clinically meaningful* differences [31-33]. In this study, in addition to the abovementioned statistical test, the differences in SF-36 scores between the internet and telephone groups were also examined using two popular approaches: on the one hand, the effect size of the difference was considered according to Cohen's effect size index with corresponding small, medium, and large values at 0.2, 0.5, and 0.8, respectively [34]; on the other hand, we considered a threshold difference of 5 points, as proposed by Ware et al [33] for defining a clinically and socially relevant difference between 2 compared scores. The internal reliability of the SF-36 was evaluated by Cronbach's α coefficient calculation for the 8 scales and was considered acceptable if the α value was $>.7$. All statistical analyses of the study were performed using R freeware (version 3.3.3; R Foundation for Statistical Computing).

The difference between the observed SF-36 score estimates in responders of the internet group and responders of the telephone group may be mainly due to two features: (1) the difference in the mode of administration of the questionnaire, strictly speaking (self-completion of the patient via the internet vs completion of a research technician via a telephone interview with the patient), and (2) unbalanced characteristics of the individuals in the 2 groups issued from a selection bias of the responders (an unavoidable situation inherent to the modes of administration of the questionnaire). Assessing the respective impact of these 2 features on the observed differences between the SF-36 scores observed in internet and telephone responders is of primary importance, and to get more insight into this issue, we developed a procedure in which responders of the internet group were matched to similar responders of the telephone group according to their baseline characteristics, and we further examined how the score differences between the 2 groups changed in this matched sample, as compared with the score differences observed in the initial unmatched populations.

Internet responders were matched to telephone responders according to a propensity score-based procedure, and the R package MatchIt [35] was used to match each internet responder to the nearest telephone responder in a 1:1 ratio. The following baseline variables were included in the logistic regression model of the propensity score (propensity for being an internet responder vs being a telephone responder) as independent variables: age, length of stay, education, employment (unemployed because of health, retired or unemployed, job seeker, employed, and student), income, relationship status, and type of health insurance. We also forced each pair to be strictly identical according to three additional qualitative variables also included in the logistic regression model as independent variables: sex (male or female), type of hospitalization (conventional, weekly, or day-care hospitalization), and hospital ward (general and digestive surgery, gastroenterology and

nutrition, hepatogastroenterology, infectious and tropical diseases, or internal medicine).

Results

Enrollment of the Participants in the SENTIPAT Study

Figure 1 presents the flowchart of the study. The randomization of the participants in either the internet or telephone group

yielded the enrollment of 840 participants to the SENTIPAT study in each arm. Table 1 shows the baseline characteristics of the patients who constituted the population investigated in this study in each group and according to the responder or nonresponder status of the participants.

Response Rate, Delay of Questionnaire Completion, and Internal Validity of Questionnaire Completion

The response rate observed in the intervention group (245/840, 29.2%) was significantly lower ($P<.001$) than that observed in the telephone group (630/840, 75%). The median (IQR) delay between hospital discharge and questionnaire completion was 42 (40-46) and 42 (42-46) days in responders of the internet and telephone groups, respectively.

In terms of internal validity of questionnaire completion, Cronbach's α values calculated for each of the 8 scales comprising the SF-36 form in the internet and telephone groups (Multimedia Appendix 1) were all $>.7$, which is the threshold value considered as acceptable.

Assessment of the Procedure Matching the Responders of the Internet Group With Responders of the Telephone Group

The matching procedure matched the 245 responders in the internet group (no individual was dropped) with 245 individuals in the telephone group. The standardized mean difference of the global distance between internet and telephone groups was 0.4167 and 0.0215 before and after matching, respectively, with a corresponding balance improvement of 95%. Figure 2 details the standardized mean differences between the internet and telephone groups observed on baseline variables before and after the matching procedure. The differences between the internet and telephone groups before matching were globally dramatically decreased after matching, indicating that the matching procedure successfully yielded two populations, internet and telephone, which were highly comparable in terms of the baseline variables.

Figure 2. Differences in baseline variables between the internet and telephone responders before and after the matching procedure.

SF-36 Score Differences According to the Mode of Administration of the Questionnaire

Figure 3 shows the differences between the internet and telephone groups, before and after matching, for the 8 scales and the 2 summary measures composing SF-36. Figure 3 indicates that the matching procedure had a limited impact on

the differences observed between the internet and telephone groups in each of the components of SF-36; regardless of the value of the difference before matching, the corresponding difference after matching appeared similar. Importantly, the means observed in the telephone group were all above the corresponding values observed in the internet group.

Figure 3. Observed mean score differences (telephone–internet) of SF-36 scales and summary components before and after matching. SF-36: 36-Item Short Form Health Survey.

Table 2 details the results observed after matching. The mean difference between the internet and telephone groups was >5

(threshold recommended for declaring that the difference corresponds to a significant clinical status) for four scales (RP,

social functioning, role-emotional, and mental health) with an associated effect size ranging from 0.22 to 0.29, close to the value of 0.2, which is defined as a small effect size by Cohen. Moreover, the difference approached this threshold for 2 other scales (4.57 and 4.56 for physical functioning and bodily pain, respectively), with small corresponding effect size, 0.18 and 0.16, respectively. The abovementioned 6 differences were all

statistically significant (Table 2). In contrast, the observed mean difference between telephone and internet was low for the remaining 2 scales (0.04 and 0.82 for general health and vitality, respectively) and not significant. When examining the physical and the mental component summary, the difference was 0.99 and 2.72, respectively, the latter difference being statistically significant and with an associated effect size at 0.25.

Table 2. The 36-Item Short Form Health Survey scores in the internet and telephone groups after matching (N=245 each).

Scale or component summary and group	Score, median (IQR)	Score, mean (SD)	Score, mean (95% CI)	Score difference (telephone–internet)		
				P value	Mean difference	Effect size
Physical functioning				.02	4.57	0.18

Telephone	50.86 (41.81-55.50)	47.40 (11.15)	47.40 (46.01-48.76)			

Discussion

The Opportunity to Investigate the Influence of the Mode of Administration of the Questionnaire on SF-36 Scores

To our knowledge, this study is the first reported to date to compare SF-36 questionnaire data collected either via telephone interviews or via self-completion on a dedicated internet website. More precisely, the availability of SF-36 data collected in the SENTIPAT trial provided a perfect opportunity to precisely investigate the influence of the mode of administration of the questionnaire on SF-36 scores. This investigation was the aim of the ancillary study of the SENTIPAT trial reported here and constitutes the major contribution of our report. This investigation has benefited from 3 main strengths. First, the study is based on a randomized trial with a substantial number of patients included in both arms. Second, the population under study had a large patient case mix variability because of the fact that patients originated from 5 very different hospital wards. The third strength of the study is the construction of a matched subsample of comparable responders in the 2 arms according to baseline variables to mitigate the impact of an unavoidable selection bias of responders as much as possible.

Principal Findings

Figure 2 shows that the matching procedure highly succeeded in composing a sample of similar match-paired patients; however, the very modest impact of this matching procedure on modifying the initial score differences between the scores in the internet and telephone groups (Figure 3) highly suggests that the score differences between internet and telephone groups are mainly attributable to the mode of administration, strictly speaking, with a minor impact of selection bias issues. In addition, and importantly, the scores in the telephone group were always higher than those in the internet group (Figure 3; Table 2), likely reflecting another type of bias associated with the telephone interview mode of administration: the interviewer effect.

For all but 2 out of 8 scales, the mean difference in scores between the groups was statistically significant and >4.5 points (Table 2), and several comments have to be made about this statement. It is worth recalling that misinterpretations of P values are very common [36,37]. A statistically significant score difference was not systematically considered as meaningful by the authors [38,39], and Ware et al [33] had initially proposed a 5-point difference between 2 SF-36 scores as a threshold value for a clinically and socially relevant difference. In our view, considering effect size is an appropriate approach for examining the relevance of score differences as such a perspective takes into account the variability of the measures and not only a rough mean difference threshold. Interestingly, as shown in Table 2, even if there were substantial mean score differences between the 2 different modes of administration in most of the scales, these differences were all related to a small effect size in 8 scales and in 2 component summaries of SF-36 according to the effect size index classification proposed by Cohen [34]. Cohen defined the small effect size as “noticeably smaller than medium which represents an effect visible to naked eye of a careful observer

but also not so small as to be trivial.” On the one hand, the effect size perspective considerably softens the observed differences between the internet and telephone groups and raises concerns about the relevance of considering a mean difference of 5 points as the main critical element of comparison between 2 scores. Moreover, our analyses also indicate that in studies involving a substantially variable population, only very large mean differences in scores would be considered meaningful when adopting the effect size perspective, highly limiting the usefulness of SF-36 in such studies. On the other hand, some mean differences in scores observed in our study and most likely attributable to the interviewer effect are not negligible. For example, in patients with chronic hepatitis C, Younossi et al [40] reported a mean value of the RP scale at 74.4 and 79.6 in patients with advanced and none to mild fibrosis, respectively ($P=.002$). Therefore, the differences for the RP scale, likely attributable to the SF-36 mode of administration observed in this study (51.5 and 60.9 in the internet and telephone groups, respectively; $P=.002$; Table 2), are at least comparable with those attributable to substantially different health states reported in other studies.

Limitations

The main limitation of the study concerns the selection bias related to responder status in both arms; however, such a bias is inherent to the 2 corresponding modes of administration, and this bias is likely different from one mode of administration to the other. In this study, selection biases were mitigated as much as possible by conducting a part of the analyses in a matched subpopulation of responders. A detailed analysis comparing the scores observed in the whole set of responders (before matching) and in a subpopulation enhancing the similarity of the compared individuals (after matching) constitutes an important strength of the study. Our results evidence an interviewer effect, which artificially increased SF-36 scores when the questionnaire was administered through a telephone interview. Therefore, the telephone interview as a mode of administration of SF-36 cumulates two types of bias: the unavoidable associated selection bias of responders and the interviewer effect, which is discussed in more detail in the following sections. In general, several methods can be used for mitigating the selection bias of responders as much as possible: one takes advantage of the distribution of baseline values observed in the responders and nonresponders to correct initial responder estimates to estimates more representative of the whole population under study [41]. In contrast, the interviewer effect raises many more concerns as the corresponding bias cannot be removed.

For the rest, some of the estimates reported here raise concerns in terms of generalizability and should only be viewed as minor side results that were required in the global process of the main goal of the study, which was to investigate the impact of the mode of administration of the SF-36 questionnaire on the collected scores. For example, the response rates reported here should not be considered emblematic of the corresponding modes of administration of the questionnaires. As detailed below in the *Response Rates According to the Mode of Administration* subsection, response rates reported in any study, including ours, are hardly generalizable as such rates likely depend on many characteristics of the survey design. Similarly, the reader should

keep in mind that the SF-36 scores collected here reflect the QoL of a particular population of patients admitted in 5 departments of a French university hospital, and these scores are not generalizable to other populations.

Comparison With Prior Works

Interviewer Effect

To our knowledge, this study is the only one to date that compared modes of administration of SF-36 on a matched sample of responders to mitigate—as much as possible—the inherent lack of initial comparability of responders according to the mode of administration of the questionnaire. Nevertheless, our results are in agreement with previous studies that reported higher SF-36 scores when administered by telephone than those issued from a mailed paper mode of administration [18,21,22,24–26]. Similarly, Lyons et al [42,43] reported higher scores issued from a face-to-face interview administration than those issued from a mailed paper self-completion of the SF-36 questionnaire. Altogether, our results and those of previous studies suggest that as compared with patients' self-completion, the introduction of an interviewer likely acts as a veil that somehow embellishes patients' QoL-reported perception. Internet self-completion avoids any potential bias of responses related to an interviewer effect [44], and patients are more likely to freely express their opinions [45] on websites covering anonymity than through telephone. Therefore, self-completion (internet or paper) should be preferred for collecting SF-36 data, as the involvement of a third party appears to artificially increase the scores. In any case, our study indicates that an accurate comparison of different scores requires at least avoiding modes of administration of SF-36 mixing self-completion and interview.

Response Rates According to the Mode of Administration

Despite the reminders sent to the patients, the internet group response rate (245/840, 29.2%) to the survey was dramatically lower than that of the telephone group (630/840, 75%). Blumenberg and Barros [46] explored the response rate differences between web and alternative data collection methods for public health research; considering the 9 papers comparing web self-completion with telephone and with a sample size >100, which were selected in their review, the median and range of the response rates reported for web and telephone were 23% and 2% to 68% and 40% and 8% to 71%, respectively. Similarly, a recent meta-analysis comparing response rates of web surveys with those obtained with other modes of administration [47] indicated that the results were stable when compared with a similar analysis conducted 10 years earlier: web surveys still yielded lower response rates than other modes, with a mean difference of 12% and large heterogeneity in the differences observed. No study compared telephone and internet administration modes for SF-36; however, the participation rates reported in studies that compared several modes of administration of SF-36 substantially varied from one study to another. For example, the response rate with the telephone was significantly higher than that with postal mail in the study by Wettergren et al [26] (77% and 63%, respectively; $P<.001$), as well as in the study by Perkins and Sanson-Fisher [24] (85%

and 68%, respectively; $P<.001$), whereas corresponding response rates were similar in the study by McHorney et al [23] (65.3% and 65.1%, respectively; $P=.68$) and in the study by Bursik et al [18] (71% and 68%, respectively; $P=.48$). In addition, the participation rate observed in our study in the internet group was close to that of Basnov et al [13], who reported a lower response rate in the internet group than that observed in the paper group (23% vs 76%, respectively).

In our view, the numeric value of the difference between the response rates observed in the 2 modes of administration of the present survey should be considered as a minor side result. Indeed, the heterogeneity of the comparisons reported in reviews [46,47] mostly reflects the fact that the differences between response rates collected via the internet versus other methods of administration reported in any survey are difficult to interpret and are not generalizable at all: the modes of administration include underlying elements of the whole survey process for which the impact on participation rate is hardly assessable or even describable, such as the internet website design in terms of its attractiveness or convenience or the detailed procedure for reaching participants by telephone. For example, the relatively high rate of participation in the telephone group observed in this study is likely related to the fact that the schedule of the telephone interview was arranged with each participant at the moment of his or her enrollment, and moreover, up to 3 calls were tried whenever the participant was not reached at the first phone call. In addition, many other features, such as the age distribution of the target population of the survey, might influence the observed response rates according to the mode or modes of administration of the questionnaire. In the end, internet use and use of telephones have evolved considerably since the completion of the SENTIPAT study. Such changes include not only technological aspects but also the growing importance of the abovementioned uses for many purposes throughout society. In particular, the COVID-19 crisis had a substantial impact on such matters [48,49]. Therefore, these changes are an additional element for limiting the interest in the intrinsic value of response rates, and it would be hazardous to consider that the participation rates in any web and telephone survey made before the COVID-19 period would be replicable whenever a similar survey would be conducted nowadays.

Conclusions

As compared with the mode of administration based on telephone interviews, the response rate of volunteer patients communicating their SF-36 data via the internet was much lower; however, our study indicates that a substantial proportion of hospitalized patients volunteered to actively document their health data via the internet. Most of all, the study indicates that the telephone interviewer might be viewed as an intermediate subjective pattern in the collection of patient data, resulting in a nonnegligible increase in SF-36 scores. Therefore, self-administration of SF-36 should be preferred, including via the internet, which is likely a low-cost method. Importantly, the results of this study also strongly advocate avoiding the conduction of surveys combining methods of SF-36 administration that mix self-reporting and interviews.

Acknowledgments

The Assistance Publique-Hôpitaux de Paris (Département de la Recherche Clinique et du Développement) was the trial sponsor. The SENTIPAT study was funded by grant AOM09213 K081204 from Programme Hospitalier de Recherche Clinique 2009 (Ministère de la Santé).

The sponsor and the funders had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

The authors would like to thank the SENTIPAT study group (scientific committee: Fabrice Carrat, Bérengère Couturier, Gilles Hejblum, Morgane Le Bail, Alain-Jacques Valleron, and the below-mentioned heads and physicians within the poles and units in which patients were recruited), personnel of the study group within the poles and units concerned (heads: Marc Beaussier, Jean-Paul Cabane, Olivier Chazouillères, Jacques Cosnes, Jean-Claude Dussaule, Pierre-Marie Girard, Emmanuel Tiret, and Dominique Pateron), additional corresponding physicians (Laurent Beaugier, Laurence Fardet, Laurent Fonquernie, François Paye, and Laure Surgers), and nursing supervisors (Françoise Cuiller, Catherine Esnouf, Hélène Haure, Valérie Garnier, Josselin Mehal-Birba, Nelly Sallée, and Sylvie Wagener).

The authors are indebted to the excellent technical team of the study—the clinical research technicians (Élodie Belladame, Azéline Chevance, Magali Girard, and Laurence Nicole, who included patients, collected baseline data, and interviewed the patients followed-up by telephone) and the software staff (especially Pauline Raballand but also Frédéric Chau and Frédéric Fotré, who created and maintained the trial's dedicated website).

The authors would like to thank all the medical and nursing and administrative staff of the General and Digestive Surgery (including Ambulatory Surgery), Gastroenterology, Hepatology, Infectious Diseases, and Internal Medicine departments of Hôpital Saint-Antoine.

The authors would like to thank all patients who participated in the study.

Authors' Contributions

GH had full access to all the raw data in the study and can take responsibility for the integrity of the data and the accuracy of the data analysis. GH was involved in the study conception and design and data acquisition. AA and GH were involved in the analysis and writing of the first draft of the manuscript. AA, FC, and GH were involved in the interpretation of data. All authors approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Accurate prediction of survival is crucial for both physicians and women with breast cancer to enable clinical decision making on appropriate treatments. The currently available survival prediction tools were developed based on demographic and clinical data obtained from specific populations and may underestimate or overestimate the survival of women with breast cancer in China.

Objective: This study aims to develop and validate a prognostic app to predict the overall survival of women with breast cancer in China.

Methods: Nine-year (January 2009-December 2017) clinical data of women with breast cancer who received surgery and adjuvant therapy from 2 hospitals in Xiamen were collected and matched against the death data from the Xiamen Center of Disease Control and Prevention. All samples were randomly divided (7:3 ratio) into a training set for model construction and a test set for model external validation. Multivariable Cox regression analysis was used to construct a survival prediction model. The model performance was evaluated by receiver operating characteristic (ROC) curve and Brier score. Finally, by running the survival prediction model in the app background thread, the prognostic app, called iCanPredict, was developed for women with breast cancer in China.

Results: A total of 1592 samples were included for data analysis. The training set comprised 1114 individuals and the test set comprised 478 individuals. Age at diagnosis, clinical stage, molecular classification, operative type, axillary lymph node dissection, chemotherapy, and endocrine therapy were incorporated into the model, where age at diagnosis (hazard ratio [HR] 1.031, 95% CI 1.011-1.051; $P=.002$), clinical stage (HR 3.044, 95% CI 2.347-3.928; $P<.001$), and endocrine therapy (HR 0.592, 95% CI 0.384-0.914; $P=.02$) significantly influenced the survival of women with breast cancer. The operative type ($P=.81$) and the other 4 variables (molecular classification [$P=.91$], breast reconstruction [$P=.36$], axillary lymph node dissection [$P=.32$], and chemotherapy [$P=.84$]) were not significant. The ROC curve of the training set showed that the model exhibited good discrimination for predicting 1- (area under the curve [AUC] 0.802, 95% CI 0.713-0.892), 5- (AUC 0.813, 95% CI 0.760-0.865), and 10-year (AUC 0.740, 95% CI 0.672-0.808) overall survival. The Brier scores at 1, 5, and 10 years after diagnosis were 0.005, 0.055, and 0.103 in the training set, respectively, and were less than 0.25, indicating good predictive ability. The test set externally validated

model discrimination and calibration. In the iCanPredict app, when physicians or women input women's clinical information and their choice of surgery and adjuvant therapy, the corresponding 10-year survival prediction will be presented.

Conclusions: This survival prediction model provided good model discrimination and calibration. iCanPredict is the first tool of its kind in China to provide survival predictions to women with breast cancer. iCanPredict will increase women's awareness of the similar survival rate of different surgeries and the importance of adherence to endocrine therapy, ultimately helping women to make informed decisions regarding treatment for breast cancer.

KEYWORDS

app; breast cancer; survival prediction model; iCanPredict

Introduction

Accurate prediction of survival will help both physicians and women with breast cancer to determine the type of surgery and the adjuvant therapy that are beneficial for these women [1]. Physicians usually make survival predictions and adjuvant therapy formulations according to the clinical characteristics of women with breast cancer, such as age, tumor size, clinical stage, hormone receptor status, and molecular characteristics, in addition to their own clinical experience [1-3]. The predicted adjuvant benefit is achieved by calculating the percentage improvement in the predicted survival rate after adjuvant treatment [1].

Currently, some survival prediction tools are widely used, such as PREDICT [1,4] and Adjuvant! Online [5-9]. PREDICT was developed based on clinical data of women with breast cancer collected from East Anglia (UK) between 1999 and 2003 [1,4], and Adjuvant! Online was developed based on data at the Netherlands Cancer Institute from 1987 to 1998 [5-9]. Studies have shown that such prediction tools underestimated or overestimated the survival rate of women with breast cancer, especially in Asia [10-12]. Differences in access to health care and the quality of existing health care among countries are possible reasons [13].

In China, the practice of surgery for breast cancer markedly differs from that in Western countries. A national survey reported that breast-conserving surgery accounted for 22% of surgeries in China [14], in contrast to 64.5% in the United States [15], despite the similar survival rates of breast-conserving surgery and mastectomy for women with early stage breast cancer [16,17]. Furthermore, some recent studies have shown that breast-conserving surgery has higher breast cancer-specific and overall survival rates than mastectomy [18]. The insufficient and unbalanced medical resources, information disparity between physicians and women with breast cancer, distrust of breast-conserving surgery by some physicians and women, and fear of recurrence are important reasons for the low rate of breast-conserving surgery in China [14]. In addition, for women with breast cancer in China who had received adjuvant endocrine therapy, the nonpersistence rates ranged from 5.9% to 22.6% in years 1-5, and the rate of low compliance ranged from 2.1% to 11.2% [19]. The low compliance with endocrine therapy may be partially explained by inadequate information and social support [19-23]. Therefore, demonstrating the similar survival rate of different surgeries and the efficacy of adherence to

endocrine therapy may help physicians and women with breast cancer make better clinical decisions.

In 2020, the popularity of mobile phones in China exceeded 1 per person [24], and 920 million people could surf the internet using mobile phones [25]. Further, WeChat, a popular mobile phone platform, has over 1 billion monthly active users in China [26]. The Mini app, one of the functionalities of WeChat, provides an easily accessible platform to present the Chinese survival prediction model for women with breast cancer.

To the best of our knowledge, no prognostic app has been designed and applied to women with breast cancer in China. Such survival prediction tools would be beneficial to help physicians and women with breast cancer obtain and understand the survival rate of different surgeries and adjuvant therapy, thereby enabling better clinical decision making. The aim of this study is to develop and validate a prognostic app to predict the overall survival of women with breast cancer in China.

Methods

Study Design

A retrospective design was applied. All samples were randomly divided (7:3 ratio) into a training set for model construction and internal validation, and a test set for model external validation [27].

Study Setting and Population

Clinical data collection was conducted at 2 hospitals in Xiamen, a tertiary hospital and a hospital for women and children health. Data on death were collected from the Xiamen Center of Disease Control and Prevention (CDC), which retains all death records for Xiamen residents.

The inclusion criteria were women with breast cancer (1) who received treatment including surgery and adjuvant therapy in these 2 hospitals from January 1, 2009, to December 31, 2017; and (2) who were Xiamen residents. Women who lacked surgical and treatment information were excluded from the analysis.

Sample Size Calculation

The pmsampsize package for Stata and R written by Riley et al [28] was used to calculate the sample size. The 10-year mortality rate in women with breast cancer was 0.214, and the median follow-up was 11.7 years [6]. To target a margin of error in the estimate of death risk of ≤ 0.05 , a total of 680 samples were

needed with Cox-Snell R^2 statistic of 0.1 [28], assumed outcome event rate of 0.214, follow-up of 11.7 years [6], timepoint of interest for 10 years' prediction, and 8 parameters (variables).

Procedure

The researchers collected clinical data of all patients with breast cancer who received treatment at 2 participating hospitals from January 2009 to December 2017. Further, the population information on death for Xiamen residents from January 2009 to December 2020 was obtained from the Xiamen Center CDC. The citizen ID number was used as the basis for matching. If the match was successful, the death dates of those women were recorded. If not successful, women with breast cancer were assumed to be alive. Finally, a data set was developed for model construction and validation.

Ethical Consideration

Ethical approvals were obtained from Research Ethics Committees at School of Medicine, Xiamen University (number XDYX2019008), First Hospital Affiliated to Xiamen University (number XMDY-2020-019), and Women and Children's Hospital affiliated to Xiamen University (number KY-2019-058). To protect the privacy of women with breast cancer, data collection, entry, and processing were carried out by 2 professional researchers. During the use of iCanPredict, the users' input information can only be accessed by authorized researchers, who needed to log-in to the iCanPredict website background thread with the protected account number and passport. Accordingly, unauthorized personnel was prohibited from viewing and using the clinical data and users' input information.

Data Collected

Outcomes data were obtained from the medical records (January 2009-December 2017) of the 2 participating hospitals including age at diagnosis, clinical stage (stage 0-IV), molecular classification (luminal A, luminal B, Her-2 overexpression, basal-like), operative type (breast conservative surgery, mastectomy), breast reconstruction, axillary lymph node dissection, chemotherapy, and endocrine therapy. These 2 participating hospitals used the TNM clinical stages from the American Joint Committee on Cancer, which are determined by tumor size (T), lymph node metastasis (N), and distant metastasis (M) [29].

Xiamen residents' death information from January 1, 2009, to December 15, 2020, was collected from the Xiamen Center CDC. Women's citizen ID number was retrieved from the hospital to link women's medical records to Xiamen residents' death information at the Xiamen Center CDC.

Outcomes

The 5-year (or 10-year) mortality was defined as the number of deaths divided by the total number of breast cancer cases from the diagnosis to 5-year (or 10-year) follow-up. The outcome event was the death of women with breast cancer from January 1, 2009, to December 15, 2020. The survival of women with breast cancer at the end of follow-up was considered as a truncated event [30].

Data Analysis

Data analysis was performed using SPSS version 25.0 (IBM) [31] and R version 4.0.4 (R Foundation). Demographic data were summarized using descriptive statistics. Because all variables satisfied the proportional hazards (PH) assumption, multivariate Cox regression analysis was used to develop a PH regression model for time-to-event data (eg, happening of death) and produce an equation to predict an individual's outcome risk on the condition of her values of multiple predictors [28].

Model Construction

The training set was used for model construction. On the basis of the hazard ratio (HR) of each prognosis factor estimated by multivariable Cox regression, the survival prediction model was expressed as

$$S(t) = S_0(t) \exp(-\beta X)$$

where $S(t)$ indicates the predicted survival rate of women with breast cancer after treatment, $S_0(t)$ represents the baseline survival rate of women with breast cancer, β is the coefficient for each prognostic factor in the multivariable Cox regression, X is the value of the prognosis factor, and \bar{X} is the mean of the prognosis factor.

Validation

The training set was analyzed for model internal validation and the test set was analyzed for model external validation. Model discrimination was evaluated using the receiver operating characteristic (ROC) curve. In general, the larger the area under the curve (AUC), the higher the model discrimination. Further, an AUC greater than 0.7 indicates that the model has a certain distinctive ability. Model calibration was based on the Brier score; the lower the Brier score, the higher the calibration degree. When the Brier score was less than 0.25, the model could be predicted.

Design of a Prognostic App to Predict Survival

The research team comprised researchers, statisticians, breast cancer specialists, and app specialists at Xiamen University, the participating hospitals, and Tung Wah College of Hong Kong. The Xiamen Quanwu Information Service Company (Xiamen, People's Republic of China) undertook the technical development and maintenance of the iCanPredict app.

iCanPredict is mainly divided into a website background thread (back end) and the user side (front end). The website background thread was developed to approve the users' applications for registration, run the survival prediction model on the basis of the users' input information, and track the app usage frequency and duration. Only researchers are able to access the website background thread with protected account number and passport. The users' side was developed to interact with users and present the 10-year survival rate for women with breast cancer.

According to the Technology Acceptance Model proposed by Davis [32], perceived ease of use and perceived usefulness are 2 decisive variables of the user's reception of the information system. Perceived ease of use refers to the degree of difficulty a user perceives when using an information system [33].

Perceived usefulness refers to the fact that users can obtain certain values when using an information system [33]. Perceived ease of use affects perceived usefulness and further affects users' actual use behavior by affecting their attitudes and behaviors [33]. To promote ease of use, the iCanPredict app was incorporated into the functionality of WeChat, the most popular mobile phone platform in China. Prior to implementing the iCanPredict app, the perceived ease of use and perceived usefulness were tested by women with breast cancer and surgeons.

Results

Participants' Demographic and Clinic Characteristics

The clinical data of 1686 participants were collected, of which 97 lacked treatment information, leaving data on 1592 participants for model construction and validation. The training set comprised 1114 individuals and the test set comprised 478

individuals. By December 15, 2020, 147/1592 participants died (9.23%) and 1445/1592 (90.77%) were still alive. In this study, the mean follow-up was 6.38 years, ranging from 0.32 to 12.35 years. The mean age at diagnosis was 49.92 (SD 11.59) years, and most participants were diagnosed with stage II breast cancer (733/1592, 46.04%). Luminal B-type (1059/1592, 66.52%) was the most common molecular classification. Only 95/1592 participants (5.97%) underwent breast-conserving surgery, while 1497/1592 (94.03%) underwent mastectomy. A total of 453/1497 participants underwent breast reconstruction, accounting for 30.26% of the participants who underwent mastectomy and 28.45% (453/1592) of all participants. Most participants underwent axillary lymph node dissection (1143/1592, 71.80%), received adjuvant chemotherapy (1305/1592, 81.97%), and received adjuvant endocrine therapy (1007/1592, 63.25%). The demographic and clinical characteristics of the participants in the training and test sets are presented in [Table 1](#).

Table 1. Demographic and clinical characteristics of participants in the training set and the test set.^a

Characteristics	Total (n=1592)	Training set (n=1114)	Test set (n=478)
Deaths, n (%)	147 (9.23)	103 (9.25)	44 (9.21)

^aPercentage=number/group total number.

Initial Model Fit

The training set was used to fit the initial model. The graph based on the standardized Schoenfeld residual method and the $-\ln(-\ln[\text{survival}])$ test indicated that all 8 variables met the PH assumption. A survival prediction model was constructed for women with breast cancer (Table 2). Age at diagnosis ($P=.002$), clinical stage ($P<.001$), and endocrine therapy ($P=.02$) were identified as significant prognostic factors. The risk of death increased by 0.031 times per year with an increase in age at

diagnosis for women with breast cancer (HR 1.031, 95% CI 1.011-1.051). When the clinical stage increased, the risk of death in women increased by 2.044 times per stage (HR 3.044, 95% CI 2.347-3.928). Women with breast cancer receiving endocrine therapy had a 0.407 (1–0.592) times lower risk of death than those that did not receive endocrine therapy (HR 0.592, 95% CI 0.384-0.914). The other 5 variables, including molecular classification ($P=.91$), operative type ($P=.81$), breast reconstruction ($P=.36$), axillary lymph node dissection ($P=.32$), and chemotherapy ($P=.84$), were not significant.

Table 2. Hazard ratios and model coefficients for prognostic factors included in the models (n=1114).

Prognostic factors	β	Standard error	Hazard ratio (95% CI)	P value
Age at diagnosis	0.031	0.01	1.031 (1.011-1.051)	.002
Clinical stage	1.113	0.133	3.044 (2.347-3.928)	<.001
Molecular classification	0.016	0.145	1.017 (0.765-1.351)	.91
Operative type	0.127	0.52	1.136 (0.410-3.145)	.81
Breast reconstruction	-0.318	0.343	0.728 (0.372-1.426)	.36
Axillary lymph node dissection	0.42	0.422	1.521 (0.665-3.478)	.32
Chemotherapy	-0.067	0.34	0.935 (0.480-1.821)	.84
Endocrine therapy	-0.524	0.222	0.592 (0.384-0.914)	.02

Validation Results

All statistically significant and nonsignificant factors are included in the prediction model because all factors are clinically significant. Further, the prediction model including nonsignificant factors presented model discrimination and calibration similar to those presented by the prediction model excluding nonsignificant factors. The AUC and Brier score of the training and test sets are presented in [Tables 3](#) and [4](#), respectively. For internal validation with the training set, the ROC curve of the training set indicated that the model exhibited good discrimination for predicting 1- (AUC 0.802, 95% CI

0.713-0.892), 5- (AUC 0.813, 95% CI 0.760-0.865), and 10-year (AUC 0.740, 95% CI 0.672-0.808) overall survival ([Figure 1A,C,E](#)). The Brier scores at 1, 5, and 10 years after diagnosis were 0.005, 0.055, and 0.103, respectively. For external validation with the test set, except that the AUC at 10 years after diagnosis was 0.685, the AUC values 1 and 5 years after diagnosis were greater than 0.7, indicating that the model has a certain distinctive ability ([Figure 1B,D,F](#)). The Brier scores 1, 5, and 10 years after diagnosis were less than 0.25, indicating that the model calibration was also good. Therefore, the prediction model could be used to predict survival.

Table 3. Internal validation and external validation: model discrimination (AUC^a) at 1, 5, and 10 years after diagnosis.

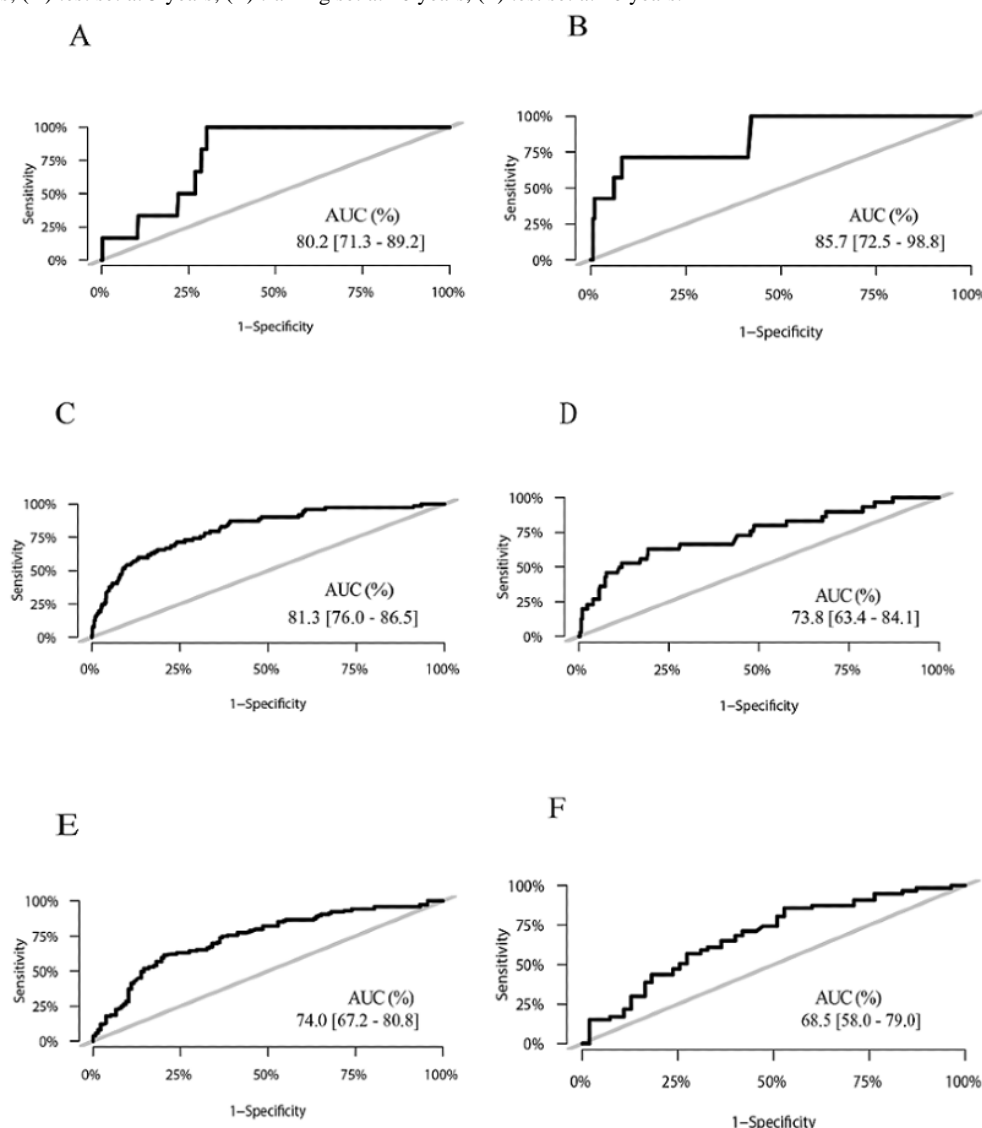

Year	Internal validation		External validation	
	AUC	95% CI	AUC	95% CI
1	0.802	0.713-0.892	0.857	0.725-0.988
5	0.813	0.760-0.865	0.738	0.634-0.841
10	0.740	0.672-0.808	0.685	0.580-0.790

^aAUC: area under the curve.

Table 4. Internal validation and external validation: calibration (Brier) at 1, 5, and 10 years after diagnosis.

Year	Internal validation		External validation	
	Brier score	95% CI	Brier score	95% CI
1	0.005	0.001-0.010	0.014	0.004-0.025

Development of Preliminary Survival Prediction for Breast Cancer Survivors

The development of iCanPredict was based on a uniAPP open-source free framework with separation technology for the back end and the front end. The back end was developed using the Java language 8 environment, IntelliJ IDEA for code development, and Maven for service dependency management. The front end utilized an Ant-design-VUE component for page interaction construction under the VUE framework. Each function in the iCanPredict app was tested multiple times to ensure usability and stability.

A QR code was generated for the users to scan with their own WeChat account. After downloading the iCanPredict app into their WeChat platform, the users need apply for registration. The researcher will approve the users' application from the

website background thread. Each user's mobile phone number is set up as the unique username and an automated passport is sent to the user's mobile phone (changeable later). The users do not need to pay for the access to the iCanPredict app.

iCanPredict includes 2 function modules: survival prediction and a personal home page for women with breast cancer. The purpose and data sources are displayed on the home page with a statement as follows: "iCanPredict aims to be used for scientific research and provide the survival probability of different treatment options. Neither the model author nor the relevant hospitals can guarantee the calculation accuracy for any specific patient. Any decision related to cancer treatment should consult your physician". Women need to click the button "I agree" under the statement before using iCanPredict (Figure 2A).

Figure 2. Screenshots of the iCanPredict app.

In the survival prediction model module, there are interactive page and report page. In the interactive page, users need to input personal information, including the year of birth, the year of diagnosis, breast cancer clinical stage, and molecular classification. In addition, users need to choose surgery type (breast-conserving surgery or mastectomy), whether they will undergo reconstruction if they choose mastectomy, whether they will undergo axillary lymph node dissection, and whether they will receive chemotherapy or endocrine therapy (Figure 2B). In addition, to make it easier and faster for users to learn how to input information, there are tutorials and concept explanations beside each concept in the input information interface. Tutorials and concept explanations can resolve doubts in the use process. After the completion of information input, users need to click the button “generate report” at the bottom of the interactive page.

In the report page, iCanPredict will present the 10-year survival rates after surgery only, surgery plus chemotherapy, and surgery plus chemotherapy plus endocrine therapy based on the user’s input information. The survival rates are presented as tables and diagrams for women with breast cancer. The tables present 5- and 10-year survival rates, while the diagrams describe the continuous survival rates within 10 years after primary treatment. The predicted benefits of adjuvant chemotherapy and endocrine therapy are represented by the percentage increase in the predicted survival rate with differently colored curves in the diagram for women with breast cancer who received adjuvant therapy, compared with those who did not receive adjuvant therapy [1] (Figure 2C).

Users can make different choices on different surgeries and adjuvant therapies, and the corresponding survival prediction data will be saved on their personal home page. The personal home page module includes personal centers, problems

feedback, and history. Personal center refers to the account-related information (nickname, avatar, basic information, etc.), which is set up by the users themselves. Problems feedback is an interactive platform for communication between users and the iCanPredict developer group. Users can provide feedback on the problems encountered in the use of iCanPredict or provide suggestions for app improvement. History summarizes user input information and survival prediction data are expressed in tables and diagrams and arranged in chronological order for users to compare the survival rates of different surgeries and adjuvant treatments. The flowchart of the use of iCanPredict is presented in Figure 3.

A total of 6 women with breast cancer and 2 surgeons were invited to assess the perceived ease of use and perceived usefulness. Of these, 2 women were aged over 60 years and were reluctant to use the iCanPredict app. One woman got confused about her own value of molecular classification and needed to refer to the laboratory test report to input information. With help from the researchers to download the iCanPredict app and explain the laboratory test, all 6 women showed great interest in the prediction model. They appraised the iCanPredict app’s convenience, ease of use, and ability to provide valuable information they wanted. The 2 surgeons indicated that it was easy to use the iCanPredict app. The surgeons expressed surprise that mastectomy and breast conservative surgery resulted in similar survival rates. They also suggested to add more information to predict survivals following other treatment options, such as immunotherapy or gene therapies. Such therapies have been emphasized to treat women with breast cancer in the recent years, but were not commonly applied before. Both women with breast cancer and surgeons indicated that it was feasible and acceptable to use the iCanPredict app in the clinics.

Figure 3. Flowchart of the use of the iCanPredict app.

Discussion

Principal Findings

In this study, we constructed a well-calibrated prediction model on the basis of 9 years of clinical and death information for women with breast cancer in Xiamen. The survival prediction model was run in the app background thread, and the iCanPredict prognostic app was designed and developed for women with breast cancer in China.

iCanPredict was developed on the popular mobile phone platform in China (WeChat), which is easily accessible and user-friendly for both physicians and women with breast cancer [34]. iCanPredict provides individual survival predictions and calculates the benefits of the corresponding treatments. The tables display the percentage of predicted survival rates for physicians and women to compare the predicted results among different surgeries and adjuvant therapies. The use of colored diagrams to display the improvement in the predicted survival rate will facilitate sophisticated and difficult discussions on corresponding adjuvant therapies for patients [1].

Comparison With Prior Work

In our prediction model, the type of surgery was not an independent prognostic factor for breast cancer overall survival, which is consistent with some previous studies [16,17]. When physicians discuss the choices of breast surgeries with women, they may input women's clinical data and attempt different types of surgery in the iCanPredict app, which presents the survival prediction rate for different surgeries in an easy-to-understand manner. In combination with value preferences, women may thus make better informed decisions on surgeries [35,36].

In our prediction model, endocrine therapy was a significant prognostic factor for overall survival, which was also supported by the literature [37]. iCanPredict will present the benefit of endocrine therapy based on the percentage of improvement in the predicted survival rate if physicians or women choose endocrine therapy. iCanPredict will provide a quick, visual presentation, such as tables and diagrams, to inform women about the beneficial effects of endocrine therapy.

For clinical implementation, it is recommended that women with breast cancer use the iCanPredict together with surgeons when making decisions on treatments. Further, cautions should be exercised when using this iCanPredict app to guide the decision making, considering new therapies that are constantly emerging in recent years such as immunotherapy [38-41] or gene-based therapies [42,43], which may affect the survival rate of women with breast cancer.

Strengths and Limitations

iCanPredict is the first tool of its kind in China to provide survival predictions to women scheduled to undergo breast surgeries and corresponding adjuvant therapies. iCanPredict was proved to have good model discrimination and calibration. This study had several limitations. First, the sample size was relatively small to build a prediction model, as there were only limited number of eligible cases in the 2 participating hospitals, which may limit the generalization of the iCanPredict app. Second, death data from the Xiamen Center CDC did not include specific causes of death; therefore, this study did not have specific breast cancer survival rates, and only contained overall survival rates. Therefore, the iCanPredict app may overestimate the mortality of breast cancer. Third, due to the incomplete clinical records of adjuvant endocrine therapy and adjuvant chemotherapy treatment, we can only predict the benefits of

adjuvant therapy by determining whether adjuvant therapy was administered (yes vs no). In future studies, the adherence to adjuvant endocrine therapy should be emphasized to help clinicians and patients make accurate and individual medical decisions.

Future Directions

Future studies need to combine the results of this study with the financial burden of different treatments [44] and patients' own preferences [35,36] to provide better clinical decision support. Studies with large sample size and more comprehensive clinical data, in combination with the medical costs related to

medical treatments and patients' value preference, are warranted to be conducted in different countries and cultures.

Conclusions

The prediction model had good model discrimination and model calibration to predict the overall survival of women with breast cancer in China. iCanPredict will increase women's awareness of the similar survival rate of different surgeries and the importance of adherence to endocrine therapy, ultimately helping them make informed decisions about treatment for breast cancer. In the long run, better choice of surgery and increased adherence to prescribed endocrine therapy may be attained.

Acknowledgments

The authors thank physicians and nurses, and other individuals that assisted with data collection and processing. This research was funded by the National Natural Science Foundation of China (grant number 71974162). The funding body had no role in the study design, data collection and interpretation, and manuscript preparation.

Authors' Contributions

JZ and XZ designed the study. JZ and SWCC obtained the funding for this study. SH, XW, YL, YH, and XZ collected the data. ZM analyzed and interpreted the data. ZM, JZ, and XZ interpreted the results and wrote the manuscript. All authors read the manuscript.

Abstract

Background: Gestational diabetes mellitus (GDM) is a common endocrine metabolic disease, involving a carbohydrate intolerance of variable severity during pregnancy. The incidence of GDM-related complications and adverse pregnancy outcomes has declined, in part, due to early screening. Machine learning (ML) models are increasingly used to identify risk factors and enable the early prediction of GDM.

Objective: The aim of this study was to perform a meta-analysis and comparison of published prognostic models for predicting the risk of GDM and identify predictors applicable to the models.

Methods: Four reliable electronic databases were searched for studies that developed ML prediction models for GDM in the general population instead of among high-risk groups only. The novel Prediction Model Risk of Bias Assessment Tool (PROBAST) was used to assess the risk of bias of the ML models. The Meta-DiSc software program (version 1.4) was used to perform the meta-analysis and determination of heterogeneity. To limit the influence of heterogeneity, we also performed sensitivity analyses, a meta-regression, and subgroup analysis.

Results: A total of 25 studies that included women older than 18 years without a history of vital disease were analyzed. The pooled area under the receiver operating characteristic curve (AUROC) for ML models predicting GDM was 0.8492; the pooled sensitivity was 0.69 (95% CI 0.68-0.69; $P<.001$; $I^2=99.6\%$) and the pooled specificity was 0.75 (95% CI 0.75-0.75; $P<.001$; $I^2=100\%$). As one of the most commonly employed ML methods, logistic regression achieved an overall pooled AUROC of 0.8151, while non-logistic regression models performed better, with an overall pooled AUROC of 0.8891. Additionally, maternal age, family history of diabetes, BMI, and fasting blood glucose were the four most commonly used features of models established by the various feature selection methods.

Conclusions: Compared to current screening strategies, ML methods are attractive for predicting GDM. To expand their use, the importance of quality assessments and unified diagnostic criteria should be further emphasized.

digital health; gestational diabetes mellitus; machine learning; prediction model; prognostic model

Introduction

According to the latest Global Diabetes Map (9th edition) released by the International Diabetes Federation, the number of patients with diabetes during pregnancy is increasing globally, with about 20.4 million (15.8%) women suffering from hyperglycemia; among them, 83.6% of cases were due to gestational diabetes mellitus (GDM) [1]. GDM, a common metabolic disease, is usually a transient disorder during pregnancy that resolves at delivery. Pregnant women with GDM are at greater risk of adverse pregnancy outcomes that threaten a normal birth. An oral glucose tolerance test (OGTT) is typically recommended to screen for GDM between the 24th and 28th weeks of gestation. Physicians usually measure the fasting plasma glucose concentration 1 to 2 hours after the patient ingests glucose [2]. The American Diabetes Association recommends that women be screened at the first prenatal examination to aid with the early identification of hyperglycemia risk. Nonetheless, GDM screening recommendations are controversial among international organizations regarding four aspects: (1) universal versus selective screening, (2) early pregnancy screening (ie, before pregnancy or at the first prenatal visit versus screening at 24-28 gestational weeks), (3) a one-step versus two-step approach, and (4) inconsistent diagnostic criteria (Table S1 in Multimedia Appendix 1) [3].

Machine learning (ML) methods have become favorable tools for disease prevention and management. For instance, the multivariate logistic regression (LR) model is a recognized ML algorithm for predicting diabetes and its complications. Furthermore, other methods, such as random forest (RF), extreme gradient boosting (XGBoost), and light gradient boosting machine (LightGBM), are also applied to diabetes-related problems. A growing number of studies have used such methods to identify risk factors of GDM and construct early prediction models for the disease [4,5]. ML presents a powerful tool for analyzing large amounts of diverse health care data and augmenting doctors' capabilities. However, ML has limitations that can lead to inaccurate predictions in some clinical scenarios, and the significance of its assessment was highlighted in a real-world study [6]. The US Food and Drug Administration (FDA) has issued guidance on software as a medical device that explains risk stratification and the analytical and clinical validation required of artificial intelligence (AI) tools in health care. IDx-DR, the first FDA-approved ML application to help make screening decisions, achieved high sensitivity (87%) and specificity (91%) for diabetic retinopathy in primary care clinics [7]. Most of the published prognostic models for GDM also showed acceptable discrimination and calibration [8], but they vary in quality and perform inconsistently.

Few systematic analyses of ML models for GDM are currently available. Here, we conducted a thorough meta-analysis of the predictive value of ML in GDM using a quality evaluation by the Prediction Model Risk of Bias Assessment Tool (PROBAST) and compared ML models with universal and selective screening methods. Essentially, we wondered if ML could be a new GDM screening option.

Methods

Research Design

This study was conducted according to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Table S2 in Multimedia Appendix 1) [9].

Search Methods

The PubMed, Web of Science, IEEE Xplore, and China National Knowledge Infrastructure databases were searched for articles published in English or Chinese between August 2019 and October 2020. We built up the search strategy according to the PICO (population, intervention, control, and outcomes) principle; for our study, "P" represents GDM populations, "I" represents ML methods as interventions, "C" represents gold standards as controls, and "O" represents the outcomes of prediction and diagnosis, such as sensitivity, specificity, and accuracy (Table S3 in Multimedia Appendix 1). The details of the search keywords are listed in Textbox S1 in Multimedia Appendix 1. Additionally, the reference list of each identified study was manually searched to identify any additional studies. NoteExpress 3.2 (Aegean) [10] and EndNote X7 (Clarivate) [11] were employed to manage the studies and remove duplicate items.

Inclusion and Exclusion Criteria

All studies included had to meet the following criteria: (1) published in English or Chinese; (2) included pregnant women from the general population, with a clear definition for GDM diagnosis; (3) included ML models for GDM prediction, with a clear description of the ML models; and (4) showed the performance of ML models, including sufficient data to enable the inference of sensitivity and specificity.

Articles in other languages, other types of articles (eg, reports and reviews), or those that used other measures for GDM detection were excluded. Four investigators (LY, WH, YW, and CG) participated in the literature screening to review all the studies that met the inclusion criteria. Each chosen article was screened at least twice, and disagreements were resolved by the reviewer (ZZ). Studies providing the most detailed information of variables and outcome indicators were kept for reference.

Data Extraction

Data extraction was performed independently by two investigators (LY and LZ) according to the existing literature and the Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis (TRIPOD) standardized protocol [12]. A total of 25 studies were ultimately selected for the analysis. The following data were extracted from each study: (1) demographic information (ie, the country in which the data were gathered, the setting, the data source, the study design, the prediction temporality, and the outcome definition); (2) the data division method, the feature selection algorithms, the features of the model training, the ML prediction model type, and the model validation and application; (3) prediction outcomes, including accuracy, sensitivity, specificity,

and area under the receiver operating characteristic curve (AUROC); and (4) funding and ethics approval.

Quality and Bias Assessments

The PROBAST [13], which includes a total of 20 signaling questions in four domains (ie, participants, predictors, outcome, and analysis), was used as a tool for assessing the risk of bias and applicability of each included study.

Statistical Analysis

The performance of each ML model was described using the primary outcome measures of discrimination and calibration. Model discrimination or concordance index (C-index) is similar to the AUROC [14] and indicates its diagnostic or prognostic discrimination ability as none (AUROC ≤ 0.6), poor (AUROC > 0.6 to 0.7), fair (AUROC > 0.7 to 0.8), good (AUROC > 0.8 to 0.9), or optimum (AUROC > 0.9 to 1). Model calibration is a metric of goodness of fit that assesses the agreement between observed and predicted outcomes and reflects the stability of the model via calibration plots. The diagnostic odds ratio (DOR) was also calculated via the following equation:

$$\text{DOR} = \text{PLR} / \text{NLR} \quad (1)$$

where PLR is the positive likelihood ratio and NLR is the negative likelihood ratio. The PLR and NLR were calculated to express how frequently the model predicted GDM among the individuals with GDM versus among those without GDM using the following equations:

$$\text{PLR} = \text{Sensitivity} / (1 - \text{Specificity}) \quad (2)$$

$$\text{NLR} = (1 - \text{Sensitivity}) / \text{Specificity} \quad (3)$$

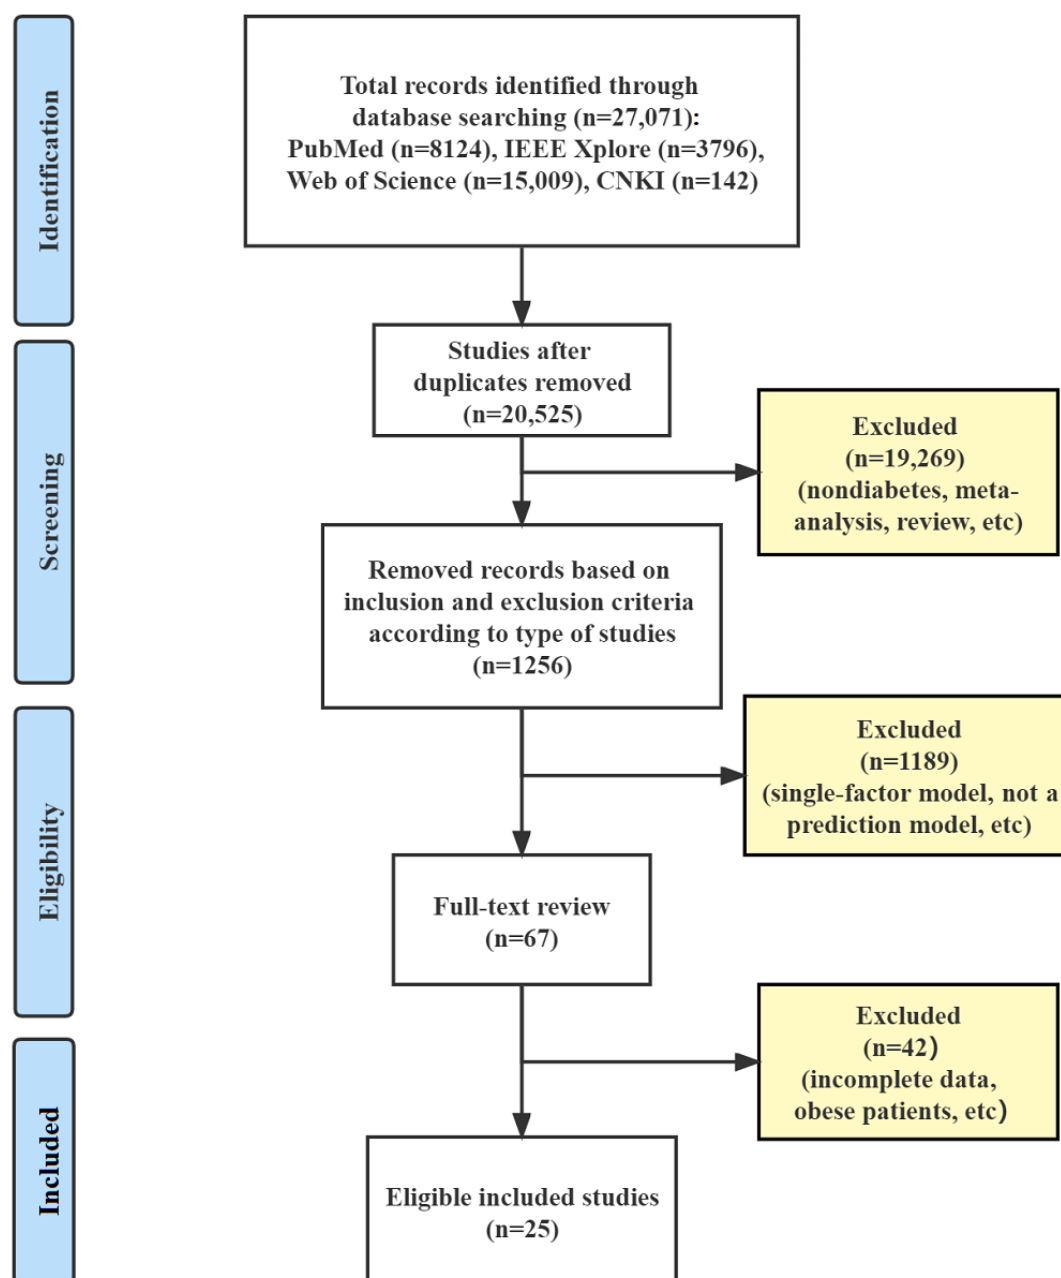

In this meta-analysis, the Meta-DiSc software program (version 1.4) [15] was used to calculate the pooled estimates of AUROC, sensitivity, specificity, PLR, NLR, and DOR. It was used to summarize the data from the included studies and graphically investigate the homogeneity among the studies. The I^2 test was used to assess the statistical heterogeneity among the included studies. An I^2 value of more than 75% indicated high heterogeneity among the studies [16]. The analysis of the included studies was divided into primary and subgroup analyses to judge the performances of the ML methods in predicting GDM in different clinical scenarios. Sensitivity analysis, subgroup analyses, and a meta-regression were also conducted to gain insight into potential sources of interstudy heterogeneity due to selector or inclusion criteria bias. The abilities of the different ML algorithms (eg, LR, Bayesian model, TreeNet, and GA-CatBoost [genetic algorithm category boosting]) for predicting GDM are discussed in the Subgroup Analysis section. The four predictive models with the highest and the lowest values were excluded from the sensitivity analysis to assess the impact of outliers on pooled sensitivity and specificity.

Results

Study Selection

A total of 27,071 studies were initially identified; of those, 1256 (4.6%) that discussed GDM were subjected to abstract screening. A total of 67 studies were subjected to full-text review; of those, 25 (37%) were included in the meta-analysis [17-33]. Figure 1 shows the PRISMA flow diagram of the study selection process.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for study selection. CNKI: China National Knowledge Infrastructure.

Study Characteristics

The articles' years of publication ranged from 2004 to 2020; 10 out of 25 (40%) were published in 2020 (Figure S1 in [Multimedia Appendix 1](#)). All studies included women older than 18 years without a history of heart or cerebrovascular disease or vital organ dysfunction. Out of 25 studies, 9 (36%) included patients with a history of GDM, while other studies excluded those cases with a history of GDM (Tables S4-S6 in [Multimedia Appendix 1](#)). The source data for ML training were mostly obtained from medical centers and maternity hospitals; some also included self-administered questionnaires. Out of 25 studies, 9 (36%) were conducted using data from a population-based prospective cohort or multicenter study. The sample size of the included studies varied from 134 to 66,687 participants.

Feature selection is an important step for ML training. Xiong et al [19] developed a prediction model for GDM risk in the first 19 weeks of gestation with several hepatic, renal, and coagulation function measures; they observed that a cutoff of prothrombin time and activated partial thromboplastin time could reliably predict GDM with a sensitivity of 88.3%, a specificity of 99.47%, and an AUROC of 94.2%. Maternal age, family history of diabetes, BMI, and fasting blood glucose were the four most commonly used features of the established models, whereas pregnancy-associated plasma protein A, leptin, lipocalin-2, adiponectin, weight gain, and soft drink intake during pregnancy were used in only one or two models each. [Table 1](#) [17-41] summarizes the most frequent features included in the prognostic models.

The LR model was the most universally used model in the 25 studies (n=17, 68%) for predicting GDM risk, while 5 (20%) studies assessed the performance of other ML methods (ie, GA-CatBoost, XGBoost, Bayesian model, TreeNet, gradient-boosting decision tree [GBDT], adaptive boosting [AdaBoost], LightGBM, Vote, and RF). For measuring deep

learning performance, AUROC and the Youden index were most commonly used. AUROC was used in studies that did not provide the C-index. Out of 25 studies, 2 (8%) did not report metrics of model discrimination. Of the 25 studies, only 7 (28%) presented calibration measures. Internal validation was performed in 13 studies (52%) using random split or k-fold

cross-validation and bootstrapping. Only 4 studies out of 25 (16%) performed external validation.

Quality Assessment

Items from the PROBAST checklists ([Multimedia Appendix 2](#)) were used to assess the risk of bias and applicability of the prognostic prediction model studies. According to the criteria, the biases of participants in 4 out of 25 (16%) studies [30,31,33,36] were moderate, mainly due to debatable criteria, while biases in the other studies were low. Out of 25 studies, 24 (96%) study groups had a low bias of predictors, while 1 (4%) [32] had a moderate risk of bias because the prediction assessment was created with knowledge of the outcome data. The bias of outcome in 6 (24%) studies [22,30,33,35-37] was moderate due to the diagnostic criteria, while the others were low. A total of 8 (32%) groups had a moderate bias of analysis [21,23,27,31-33,36,37] and 1 (4%) [30] showed a high risk of bias due to an unreasonable number of participants with

outcomes. The overall bias rating of 10 (40%) groups [21-23,27,30,32,33,35-37] was moderate. Overall concerns regarding the applicability rating of 7 (28%) studies [21-23,27,29,32,33] were moderate because of excessive features in models making it difficult to collect data in actual use, whereas others were low (Table S7 in [Multimedia Appendix 1](#)).

Performance of ML Models for GDM Prediction

The overall pooled AUROC for ML models for predicting GDM was 0.8492 ([Figure 2](#)). Additional values were as follows: sensitivity 0.69 (95% CI 0.68-0.69; $P<.001$; $I^2=99.6\%$; [Figure 3](#)); specificity 0.75 (95% CI 0.75-0.75; $P<.001$; $I^2=100\%$; [Figure 4](#)); DOR 13.78 (95% CI 9.53-19.94; $P<.001$; $I^2=99.1\%$); PLR 4.02 (95% CI 3.13-5.17; $P<.001$; $I^2=99.6\%$); and NLR 0.31 (95% CI 0.26-0.38; $P<.001$; $I^2=98.7\%$).

Figure 2. The overall pooled area under the receiver operating characteristic curve (AUROC) of machine learning models for gestational diabetes mellitus prediction. Q*: the sensitivity at the intersection of the SROC curve and the straight line (sensitivity=specificity); SROC: summary receiver operating characteristic.

Figure 3. The overall pooled sensitivity of machine learning models for gestational diabetes mellitus prediction. First authors for each study are listed along the y-axis. The vertical red dotted lines are the 95% CIs of the pooled sensitivity. BYS: Bayesian; DNN: deep neural network; GA-CB: GA-CatBoost (genetic algorithm category boosting); GBDT: gradient-boosting decision tree; KNN: k-nearest neighbors; LGB: LightGBM (light gradient boosting machine); LR: logistic regression; SVM: support vector machine; Tnet: TreeNet; XGB: XGBoost (extreme gradient boosting).

Figure 4. The overall pooled specificity of machine learning for gestational diabetes mellitus prediction. First authors for each study are listed along the y-axis. The vertical red dotted line is the 95% CI of the pooled specificity. BYS: Bayesian; DNN: deep neural network; GA-CB: GA-CatBoost (genetic algorithm category boosting); GBDT: gradient-boosting decision tree; KNN: k-nearest neighbors; LGB: LightGBM (light gradient boosting machine); LR: logistic regression; SVM: support vector machine; Tnet: TreeNet; XGB: XGBoost (extreme gradient boosting).

Sensitivity Analysis

After the exclusion of the 4 (16%) models with the lowest and highest sensitivity and specificity, the random effects meta-analysis produced estimated pooled sensitivity of 0.73 (95% CI 0.72-0.74; $P < .001$; $I^2 = 98.3\%$) and pooled specificity of 0.73 (95% CI 0.72-0.73; $P < .001$; $I^2 = 99.8\%$). Therefore, the pooled estimates were deemed insensitive to the exclusion of outliers (Figure S2 in Multimedia Appendix 1).

Subgroup Analysis

The comparison of the GDM prediction performance results is shown in Table 2; forest plots are shown in Figures S3-S8 in Multimedia Appendix 1.

In this study, 19 prediction models were established using the LR models [17,18,20-23,26-33,35-39], and the overall pooled AUROC for the LR models for predicting GDM was 0.8151 (Figure 5). The overall pooled AUROC for non-LR models to predict GDM was 0.8891 (Figure 6), the highest value among

these subgroups. Further analysis of these non-LR methods showed that two support vector machine (SVM) models [19,20] achieved AUROC values of 0.82 and 0.98, respectively (Figure S9 in [Multimedia Appendix 1](#)), while two Bayesian models [24,34] achieved AUROC values of 0.766 and 0.71, respectively (Figure S10 in [Multimedia Appendix 1](#)). Interestingly, Ye et al [20] developed eight common ML methods—GBDT, AdaBoost, LightGBM, LR, Vote, XGBoost, decision tree (DT), and RF—and two common regression models to predict the occurrence of GDM with a data set of 822,242 patients. GBDT,

AdaBoost, and LightGBM (AUROC 0.70-0.75) were the top three models, while DT and RF were the worst models (AUROC 0.5-0.68) in that study. The capabilities of three ML methods were compared using data from 490 people [21]. The deep neural network model achieved the highest AUROC of 0.92, while the SVM and k-nearest neighbors (KNN) models achieved AUROC values of 0.82 and 0.68, respectively. XGBoost, LightGBM, GA-CatBoost, and TreeNet were used in 4 out of 25 (16%) studies and achieved AUROC values of 0.742, 0.942, 0.872, and 0.676, respectively [17,19,21,25] (Table 2).

Table 2. The comparison of performance of machine learning models in gestational diabetes mellitus (GDM) prediction applied to different subgroups.

Subgroup	Models (N=30), n (%)	AUROC ^a	Sensitivity (95% CI)	Specificity (95% CI)	PLR ^b (95% CI)	NLR ^c (95% CI)	DOR ^d (95% CI)
Overall	30 (100)	0.8492	0.69 (0.68-0.69)	0.75 (0.75-0.75)	4.02 (3.13-5.17)	0.31 (0.26-0.38)	13.78 (9.53-19.94)
0-13 weeks before diagnosis	16 (53)	0.8667	0.74 (0.73-0.75)	0.64 (0.64-0.64)	3.89 (2.92-5.19)	0.28 (0.22-0.36)	16.55 (9.52-28.77)
14-28 weeks before diagnosis	14 (47)	0.8365	0.64 (0.63-0.65)	0.85 (0.84-0.85)	3.90 (2.76-5.53)	0.35 (0.25-0.48)	11.67 (7.59-18.02)
With GDM history	11 (37)	0.8759	0.67 (0.66-0.68)	0.85 (0.85-0.86)	5.29 (3.39-8.25)	0.28 (0.18-0.44)	19.82 (11.49-34.13)
Without GDM history	19 (63)	0.8330	0.70 (0.66-0.68)	0.65 (0.64-0.65)	3.12 (2.52-3.86)	0.35 (0.30-0.41)	8.27 (5.14-13.29)
Logistic regression	19 (63)	0.8151	0.71 (0.70-0.72)	0.67 (0.67-0.67)	3.04 (2.37-3.89)	0.37 (0.32-0.43)	8.73 (5.99-12.73)
Non-logistic regression	11 (37)	0.8891	0.66 (0.65-0.67)	0.85 (0.85-0.86)	6.80 (4.45-10.37)	0.24 (0.15-0.38)	31.85 (15.93-63.69)

Meta-regression

The meta-regression analysis was conducted due to the high level of interstudy heterogeneity [42]. Sample size, country where the data were collected, publication year, ML methods used, and model quality did not affect diagnostic accuracy ($P=.13$). The antilogarithm transformations of the resulting estimated parameters could be interpreted as a relative DOR of the corresponding covariate, indicating the change in diagnostic performance of the test under study per unit increase in the covariate (Table S8 in [Multimedia Appendix 1](#)).

Discussion

Principal Findings

This study was a pilot meta-analysis evaluating the performance of ML models for predicting GDM. Its overall pooled estimation of 25 studies showed that ML models achieved high accuracy in early recognition of GDM patients. ML models could forecast based on data from 8 to 24 weeks' gestation. There was even a model that used prepregnancy features to predict the outcome up to 28 weeks in advance, suggesting the significance of ML models for GDM prediction. Compared to the census or existing screening methods, ML methods have certain advantages. Universal screening leads to 100% detection for physicians who usually make decisions based on an OGTT test, which may place an unnecessary burden on individual women and health care resources. Current selective screening strategies are based on a list of risk factors and have fixed sensitivity ($\pm 65\%$) and specificity ($\pm 80\%$). Although the ML methods do not provide greater benefit than current available screening strategies, an

advantage is that a preferred trade-off between sensitivity and specificity can be selected [43]. The choice of statistical method is more to compute a quantitative measure of existing data than to predict unknown data in a general and feasible way [44].

According to the subgroup analysis, models created using non-LR methods achieved the highest AUROC, suggesting that researchers should test more candidate models. One study aimed to review and compare the predictive performances of LR and other ML algorithms for developing or validating a multivariable prognostic prediction model for pregnancy care; that study also recommended a reanalysis of existing LR models for several pregnancy outcomes by comparing them with those algorithms that apply standard guidelines [45]. Among those non-LR models, ensemble methods, like LightGBM and GA-CatBoost, that are composed of multiple weaker models and are independently trained had a satisfactory result. Variables in the GBDT model underscored the advantage of identifying nonlinear relationships. The SVM model also achieved superior outcomes; that method builds a model that assigns new examples to one category or the other, making it a nonprobabilistic binary linear classifier. Methods like KNN, DT, and RF did not perform as well as the LightGBM and GA-CatBoost methods, which may be due to the fact that DT classifications are based on a single condition at the bottom, so small changes can lead to mistakes. For RF, the high dimension of medical data complicates the classification and prediction. Similarly, KNN cannot be used in high-dimensional feature spaces. Some researchers [23] found that the difference between two methods had no statistical significance, since LR models are suitable for simple data with linear relationships between variables and outcomes. Our study also found that LR models were conducive to achieving more

stable performance according to the summary receiver operating characteristic curve. The subgroup of 0 to 13 weeks before diagnosis achieved the highest pooled sensitivity, while the subgroup of 14 to 28 weeks before diagnosis achieved the highest specificity, meaning that ML may assist clinicians identify more patients in early screening and avoid excessive misdiagnosis in the second trimester.

The feature selection was also crucial for model performance and interpretation. Among the 25 studies, maternal age was used as a feature in 19 studies, as was previously reported and validated in our study. One of the included studies reported that the incidence of GDM increases after 25 years of age, the main reason being that the function of islet β -cells decreases with age, so the insulin antagonism of older adult pregnant women is aggravated [46]. Eight models considered GDM history to be a vital factor for predicting GDM. A DOR value of 21.09 appeared when a GDM history was included as a risk factor for predicting future GDM. Previous research discovered that women with GDM were more likely to have a family history of type 2 diabetes mellitus and a history of GDM, partially due to overlapping genetic bases between the diseases [18]. The nonsignificant association of GDM with a GDM history in other studies was a result of the overwhelming proportion of nulliparous women in their studies who had no risk of developing GDM. The association between GDM and blood lipid indexes, including triglyceride (TG), high-density lipoprotein, and low-density lipoprotein (LDL), has been studied, and TG level had the closest relationship with GDM [47]. Our research also found that although the levels of TG, total cholesterol, and LDL in the GDM group were higher than those in normal pregnant women in most included studies, only TG level was a high-risk factor of GDM after the feature selection. A novel model that included ultrasound data of maternal fat distribution and serum inflammatory factors observed that pregnant women with GDM had greater visceral fat thickness and subcutaneous fat thickness; the model also demonstrated that increased subcutaneous and visceral fat may lead to increased insulin resistance in muscle and adipose tissue [36]. Sweeting et al [27] observed higher leptin and lipocalin-2 levels and lower adiponectin levels in women who developed GDM and proposed adipokines as GDM features.

Strengths and Limitations

The main strength of the study is that its methodology was logical and described in sufficient detail to be reproducible. Almost all published prognostic models for GDM were included in this meta-analysis, which enabled their comparison. The data collection table was based on the characteristics of the GDM prediction models. Additionally, the novel PROBAST was used to assess the risk of bias and applicability of prognostic prediction model studies. The Quality Assessment of Diagnostic Accuracy Studies (QUADAS) tool is a widely used tool for estimating the bias and applicability of primary diagnostic accuracy studies, but is not perfectly suited for predictive models [48]. An increasing number of researchers prefer the PROBAST to the QUADAS tool for assessing the bias of AI-based models in systematic reviews as well as meta-analyses; this is the case because more details of the model, such as data source, processing, number of events per variable, feature selection,

model development, and model validation, were checked intensively [49–52]. We found that 14 development studies had a risk of bias in methodological quality or applicability, which may lead to overfitted prediction models. It is noteworthy that the quality of recent models is higher than that of those published earlier according to the PROBAST. Some bias could be prevented if the studies reported their research according to the TRIPOD initiative [12].

Despite our study's confirmation that ML models have promising prediction ability for GDM, there are some limitations to our research. The main limitations arose from the interstudy heterogeneity. First, the sample sizes and distributions differed among studies, affecting each model's performance and applicability. There were also a heterogeneous variety of feature selection methods. Some researchers preferred the features that have a statistically significant association with GDM, while others included the factors based on existing knowledge from previously established models in combination with predictor reliability, consistency, applicability, availability, and cost. Second, the performance of a low-quality model might be overestimated when the analysis of the internal bias of the model is ignored. As some studies have bias to various degrees, the results of the studies in this analysis must be applied with caution. It should be noticed that the PROBAST is more likely to identify bias in prediction models than other tools designed for conventional diagnostic methods. The other limitation is that few models underwent external validation to test their extensibility. However, a previous study [8] performed an external validation of 12 published GDM prediction models and suggested that most of the published models showed acceptable discrimination and calibration, but the author pointed out possible heterogeneity in these models due to variations in GDM incidence in different populations.

Clinical Implications

Although several GDM scoring systems have been developed, none are widely recommended by current guidelines. Based on the discussion above, several items must be considered in order to maximize the advantages of ML models for predicting GDM in clinical practice for model researchers or for decision makers. For the former, we recommend that the decision concerning which feature selection methods and ML algorithms to use should be based on clinical need rather than accuracy. A model with excess features that are difficult to obtain in routine medicine is unlikely to be applied broadly. Researchers should also provide the process of data preprocessing and outcomes of validation, discrimination, calibration, and classification to elaborate the performance of models from multiple perspectives. For decision makers, we recommend that data sources, such as a population-based cohort designed for GDM research with a unified international diagnostic criterion, promote the ML methods in this target. Studies revealed that although electronic health records provide various data, including time series and images for novel ML methods, they have inherent biases that are influenced by the interaction of the patient with the health care system. In contrast, community-based predictions may robustly capture more asymptomatic high-risk cases [53]. The incidence of GDM based on the International Association of the Diabetes and Pregnancy Study Groups (IADPSG) (22.94%)

and the National Institute for Health and Care Excellence (21.72%) is over 3-fold higher than that based on the criteria from the 7th edition of the Chinese obstetrics and gynecology textbook (6.08%) published by the People's Medical Publishing House [54]. Some experts in China have advocated implementation of the IADPSG criteria because they believe that it will guide researchers to better understand the prevalence of GDM in different regions and ensure that the country's standards will be aligned with international ones. Nevertheless, researchers doubt that the IADPSG findings will apply to all populations, since those criteria were applied to mainly Caucasian women. All in all, it would indeed be helpful to unify the GDM diagnostic criteria as soon as possible. This

meta-analysis reported the advantages of ML models and the factors requiring attention. A similar meta-analysis of ML models and deep learning algorithms used to detect patients at risk of developing diabetes reported that AI-based automated tools provide substantial benefits for reducing screening costs and can replace earlier treatments [55].

Conclusions

In conclusion, ML methods demonstrate high performance and will be a more selective and cost-effective screening method for GDM. The importance of quality assessment and unified diagnostic criteria should be further emphasized.

Abstract

Background: In the physician-patient relationship, patients' uncertainty about diseases and the lack of trust in physicians not only hinder patients' rehabilitation but also disrupt the harmony in this relationship. With the development of the web-based health industry, patients can easily access web-based information about health care and physicians, thus reducing patients' uncertainty to some extent. However, it is not clear how patients' web-based health information-seeking behaviors reduce their uncertainty.

Objective: On the basis of the principal-agent theory and the perspective of uncertainty reduction, this study aims to investigate the mechanism of how web-based disease-related information and web-based physician-related information reduce patients' uncertainty.

Methods: A web-based survey involving 337 participants was conducted. In this study, we constructed a structural equation model and used SmartPLS (version 3.3.3; SmartPLS GmbH) software to test the reliability and validity of the measurement model. The path coefficients of the structural model were also calculated to test our hypotheses.

Results: By classifying patients' uncertainties into those concerning diseases and those concerning physicians, this study identified the different roles of the two types of patients' uncertainty and revealed that web-based disease-related information quality and web-based physician-related information can act as uncertainty mitigators. The quality of disease-related information reduces patients' perceived information scarcity about the disease ($\beta = -.588$; $P < .001$), and the higher the information scarcity perceived by patients, the higher their uncertainty toward the disease ($\beta = .111$; $P = .02$). As for physician-related information, web-based word-of-mouth information about physicians reduces patients' perceived information scarcity about the physician ($\beta = -.511$; $P < .001$), mitigates patients' fears about physician opportunism ($\beta = -.268$; $P < .001$), and facilitates patients' trust ($\beta = .318$; $P < .001$). These factors further influence patients' uncertainty about the physician. In addition, from the test of mediating effect, patients' trust in the physician fully mediates the relationship between their perceived information scarcity about the physician's medical service and their uncertainty about the physician. Patients' trust also partially mediates the relationship between their fear of the physician's opportunism and their uncertainty about the physician. As for the two different types of uncertainty, patients' uncertainty about the physician also increases their uncertainty about the diseases ($\beta = .587$; $P < .001$).

Conclusions: This study affirms the role of disease-related web-based information quality and physician-related web-based word-of-mouth information in reducing patients' uncertainties. With regard to the traits of principal-agent relationships, this study describes the influence mechanism based on patients' perceived information scarcity, fears of physicians' opportunism, and patients' trust. Moreover, information about physicians is effective in reducing patients' uncertainties, but only if the information

enhances patients' trust in their physicians. This research generates new insights into understanding the impact of web-based health information on patients' uncertainties.

KEYWORDS

patient trust; online health information quality; online word-of-mouth; patient uncertainty; principal-agent theory; physician-patient relationship

Introduction

Background

In a physician-patient relationship, it is always difficult for patients to evaluate medical services and their physicians because medical services are typical credence products [1,2]. Patients also lack the specialized knowledge to judge whether a physician's treatments would be helpful before the treatments begin. Therefore, as principals, in this typical principal-agent relationship, patients face many uncertainties.

Previous research has explored how to achieve better treatment outcomes by reducing patients' uncertainty [3-6]. The uncertainty in this principal-agent relationship is caused by information problems [7], such as hiding information and hiding behaviors; therefore, to reduce patients' uncertainties, it is important to provide patients with more information. With the rapid development of patient-centered care [8], the physician-patient relationship is gradually changing from the traditional physician-led model to a new type of patient-centered diagnosis and treatment, with increasing emphasis on the role of patients [9]. The role of patients is changing from passive information recipients to active participants in medical decision-making [10]. The development of the eHealth industry has led to an increase in the number of patients who become electronic patients, namely, e-patients [9]. The channels for e-patients to obtain information about diseases and physicians have expanded, and this information can enhance patient-centered care [8]. For example, in a survey by Wong and Cheung [11], 97.32% (1162/1194) of the respondents used the internet, of which 87.44% (1016/1162) had used the internet to find health information. In a survey by Hedges and Couey [12], 90% of patients used web-based reviews to evaluate their physicians. By actively acquiring information about diseases and physicians through electronic information technology, e-patients can enhance their understanding of their medical condition and have a sense of control over their health, while reducing their uncertainties about the consultation processes and the physicians.

Although web-based information can reduce patients' uncertainty to some extent, information overload can pose a major challenge [13], leading to confusion in e-patients. Incorrect information does not effectively reduce patients' uncertainty. Moreover, this information may undermine patients' trust and have a counterproductive effect [14]. Therefore, it is important to understand how patients' web-based information consumption reduces their uncertainty, so that information providers can improve the design of information to better help patients. With this as the objective, this study intends to answer the following research questions: how do patients' web-based

information-seeking behaviors reduce their uncertainties about diseases and physicians? In addition, how does web-based information, such as information related to diseases and physicians, alleviate problems in this principal-agent relationship and then reduce patients' uncertainty?

To address these research questions, based on the framework of *uncertainty mitigator-uncertainty antecedent-uncertainty*, this study explores how web-based health information mitigates patients' uncertainty. The contributions of this study are as follows. First, based on the principal-agent theory and the uncertainty reduction theory (URT), this study explores the mechanism of how patients' web-based health behaviors can reduce their uncertainty. Second, following the classification of consumers' uncertainty about products and sellers by Dimoka et al [15], this study also distinguishes between patients' uncertainty about diseases and physicians; the influence chain is also investigated. Finally, this study emphasizes the significant role of trust. Additional information can help reduce patients' uncertainty, but only if it can enhance patients' trust in their physicians.

Principal-Agent Theory

Originating from the field of enterprise management, the principal-agent theory describes the relationship in which one entity (the principal) delegates work to another entity (the agent) who performs the work under a mutually agreed contract [16]. The relationship between enterprise owners and professional managers is a typical principal-agent relationship. This relationship applies to all transactional relationships in socioeconomic systems where opportunism, information asymmetry, and limited rationality exist. Owing to the separation of ownership and management rights of enterprises, the goals of principals and agents are inconsistent, which will lead to adverse selection before the contract [17] and the moral hazard of hidden behaviors after the contract [18].

The physician-patient relationship is also a typical principal-agent relationship in which the physician acts as an agent to provide medical services to the patient (the client) under a contract [19,20]. Patients, as principals, receive diagnoses of the disease, treatment plans, and medical care services from the agents (ie, physicians). Physicians and patients have inconsistent goals and asymmetrical information. Compared with physicians, patients are always at a disadvantage in information about diseases and physicians' medical services. Patients want to receive superior medical services at a low cost to improve their health, whereas physicians want to provide medical services at a higher fee and lower cost (to themselves) to increase their income and reputation.

Perceived Information Scarcity

Owing to the principal-agent relationship and the specialization of medical services, there is natural information asymmetry between physicians and patients [21]. Compared with physicians, patients have limited information about diseases and physicians, leading to patients' perception of information scarcity. Previous literature defined scarcity as the limitation or unavailability of objects (eg, commodity) [22]. In the research of Wells et al [23], an individual's degree of prepurchase information scarcity related to the product of interest is operationalized as whether a consumer had any prior information or experience with products offered on web-based shopping websites. Compared with physicians, patients lack professional medical education process and clinical experience; therefore, patients will be aware of the information scarcity regarding diseases and the physician's medical service. In this study, patients' perceived scarcity of information about diseases is defined as patients' perception of their limited information related to diseases, whereas perceived scarcity of information about the physician's medical service information is defined as patients' perception of their limited information related to the physician's medical service.

In the web-based environment, the emergence of information systems can help alleviate the principal-agent problem to some extent. For example, the website and product information can reduce customers' information scarcity about products, thereby reducing customers' worries about the platform's opportunism and their purchase uncertainty [24]; the implementation of information systems within organizations, such as hospitals, was also found to be an effective means of improving information transparency [25]. Similarly, the disease-related and physician-related information obtained by patients through web-based searches can respectively help patients understand diseases and their physicians better. Web-based disease-related and physician-related information can reduce patients' perceived scarcity of information about diseases and their physicians.

However, the information quality is unevenly distributed in the problem of information asymmetry [24], but existing studies failed to take into account the impact of the information quality of search behavior, especially because web-based health information lacks accuracy and credibility [26]. Information quality is always measured by the perceived information quality, which represents information receivers' subjective perception about four dimensions of information quality, namely, relevance, adequacy, usefulness, and understandability of the information [27]. Higher-quality information can lead to better descriptions about the targets, and it is more useful than lower-quality information [28]. With a higher quality of diseases information in the web-based environment, patients will perceive the information as more relevant, adequate, and useful, thereby increasing their information about the diseases. As a result, the higher the quality of disease-related information sought by patients, the lower the perceived scarcity of information about the disease, leading to the following hypothesis: web-based health information quality reduces patients' perceived scarcity of information regarding diseases (H1).

In addition to disease-related information, web-based health information provides patients with physician-related information, such as web-based word-of-mouth information about physicians, which represents other patients' visiting experiences. In traditional offline hospitals, patients had very limited access to physicians' medical service information, which was often confined to the small reach of word-of-mouth communication, making it difficult to obtain a large amount of word-of-mouth physician information. Web-based word-of-mouth information can effectively reduce asymmetries of products information [29,30]. Web-based word-of-mouth information can inform later customers about the details of the products or the service [28,31]. Similarly, physicians' web-based ratings are also found to reflect their quality perceived by offline patients [32]. Web-based word-of-mouth information about physicians obtained by patients before their visit helps patients to know the physicians better, such as the physicians' manner, treatments, and knowledge. Therefore, web-based word-of-mouth information can reduce patients' perceived scarcity of information about their physician's medical services, leading to our second hypothesis: patients' perceived web-based word-of-mouth information about physicians reduces patients' perceived scarcity of information regarding the physicians' medical services (H2).

Fear of Physicians' Opportunistic Behaviors

In the principal-agent relationship, both parties expect to maximize their own interests [16]. The agents will work to increase their benefits, but some of their behaviors may even increase principals' costs, leading to agents' opportunistic behaviors [33]. As principals, patients are concerned about whether the physicians have opportunistic behaviors because patients cannot accurately evaluate physicians' behaviors, especially in China. Owing to the imperfections of the medical systems in China, opportunistic behaviors of medical service providers have caused widespread concerns [34,35], such as whether physicians receive kickbacks, prescribe high-priced drugs [36], or ask patients to do excessive or unnecessary examinations or treatments [36], all of which are beneficial to physicians' own interests but harm patients' interests [37]. Opportunistic behaviors are also harmful to the physician-patient relationship because these behaviors reduce patients' trust in physicians [38].

Patients can not only obtain health information such as diagnoses and treatments through eHealth data but also browse web-based reviews about physicians. Compared with offline word-of-mouth information, web-based word-of-mouth information has a greater impact on consumers' behaviors because of its extensive sources, large coverage, and convenient dissemination [39]. Positive web-based word-of-mouth information can effectively reduce principals' concerns about agents' opportunistic behaviors [24,40]. Web-based word-of-mouth information about physicians helps improve the transparency of medical services and enhance patients' confidence in medical decisions [41]. It also reflects the experiences of other patients with similar diseases [42]. With more web-based word-of-mouth information about the physicians, patients can evaluate the likelihood of the physicians' opportunistic behaviors, and then they can choose physicians who are less likely to engage in those opportunistic

behaviors. Therefore, positive web-based word-of-mouth information helps reduce patients' concerns about physicians' opportunism. Physicians' opportunism, in this study, is defined as the behaviors of physicians who do not provide good services but charge high prices, conduct excessive and unnecessary examinations, and receive rebates to prescribe high-priced drugs [36]. With better web-based word-of-mouth information about physicians, patients will be less apprehensive of the physicians' opportunistic behaviors, leading to the following hypothesis: patients' perceived web-based word-of-mouth information about a physician reduces patients' fear of the physician's opportunism (H3).

Trust

In the principal-agent relationship, trust is the most valuable aspect [43], because if the relationship occurs under ideal conditions, there is no need for trust [44,45]. Trust is the expectation that an individual or a group will make an effort of good faith to behave following commitments (both explicit and implicit), to be honest, and not to take excessive advantage of others, even when the opportunity exists [46]. Owing to the scarcity of patients' information about clinical diagnoses and treatments, the asymmetry of physicians' medical service information between patients and physicians makes it difficult for patients to determine whether the physicians are trustworthy [24]; therefore, in the physician-patient relationship, the information scarcity of physicians' medical services impedes patients' trust in the physicians, leading to hypothesis 4: patients' perceived information scarcity about physicians' medical service information reduces patients' trust in physicians (H4).

In the principal-agent relationship, as agents, patients' fear of physicians' opportunistic behaviors also influences patients' trust in physicians. Existing research has confirmed that opportunistic behavior in web-based banking leads to low levels of trust of users in internet banking [47]. In the e-commerce environment, fear of sellers' opportunism also harms buyers' trust [33]. In the physician-patient relationship, opportunistic behaviors are also harmful because these behaviors reduce patients' trust in physicians [38]. Although physicians' behaviors are not always immoral, patients still worry about the possibility of physicians' opportunistic behaviors because the principal-agent relationship is favorable for physicians to act immoral behaviors. This worry will be enhanced if the possibility of the physicians' opportunism is high. Physicians' opportunistic behavior benefits their own interests but harms the interests of patients, which also impedes patients' trust in them. Patients cannot monitor physicians' behaviors, and they worry that their physicians will act opportunistic behaviors; thus, the fear of physicians' opportunism reduces patients' trust, leading to hypothesis 5: the fear of physicians' opportunism reduces patients' trust in physicians (H5).

Web-based word-of-mouth information is an important factor affecting potential customers' purchase intentions and behaviors [48,49], because web-based word-of-mouth information reflects previous consumers' evaluation of the products. In medical situations, some studies have also explored the impact of web-based physician reviews on patients' decision-making

behavior. For example, higher web-based ratings of physicians increase patients' intention to consult them [50]. Web-based word-of-mouth information about physicians also increases physicians' offline visits [51]. Acting as the previous patients' evaluation cue, physicians' web-based word-of-mouth information serves as an important reference for the selection of physicians by patients. The better the patients perceive web-based word-of-mouth information about the physicians, the more favorable it is for the patients to trust in the physicians, leading to the following hypothesis: patients' perceived web-based word-of-mouth information about physicians increases patients' trust in the physicians (H6).

URT Overview

In the principal-agent relationship, uncertainty arises because the principal cannot fully monitor the agent's behavior, resulting in adverse selection [17] and the moral hazard of hidden behaviors [18]. It is important to understand how to reduce uncertainty in this relationship. For example, reducing uncertainty can increase consumers' purchase intention and lead to an actual purchase [24]; reducing uncertainty can also increase users' trust in the web-based world so that they can effectively use a tool [52]. Originating from the field of interpersonal communication, the URT posits that uncertainty occurs when people cannot predict the future behavior of others or when they do not meet their own expectations [52,53]. URT is widely used in fields such as organizational behavior and information systems, among others [52]. For example, Srivastava and Chandra [52] considered 3 ways to reduce users' uncertainty to enhance their trust and use intention in the web-based world. The three ways include acquiring information passively through observation, acquiring information actively through third-party search, digital signatures, and third-party authentication, and acquiring information from interactions, such as direct interaction with the target object [52].

In the medical scenario, patients' uncertainties, that is, their inability to accurately predict the state of their disease because of a lack of information, exist in every aspect of their diagnoses and treatments. Uncertainties in the principal-agent relationship are caused by specific information problems (eg, hiding information and hiding behavior), and these problems can be alleviated by the use of information systems [24]. In the physician-patient relationship discussed previously, the disclosure of information comes from the agent (eg, medical information provided by the physician), and it reduces only a few uncertainties of patients, but with the development of technology, medical and health information is no longer only in the hands of the medical providers (agents). The client can actively acquire medical and health information from a third party [20], enabling patients to overcome the restrictions of time and space and actively obtain information about the causes of diseases, treatments, and reputations of physicians and hospitals through the internet. With the active information acquisition method [52] to reduce uncertainty, patients' web-based search behavior can help actively reduce uncertainty, but the influence mechanism of how web-based information acquired by patients reduces uncertainty is not yet clear.

Patients' Uncertainty

Uncertainty in the medical context refers to a cognitive state in which the meaning of medical events cannot be determined [3,4]. Uncertainty, as a medical experience characterized by unpredictability, unfamiliarity, and ambiguity, is associated with poor medical outcomes and psychological states (eg, fear, stress, and loss of control) [43]. Existing research on uncertainties in the medical field has mainly focused on information uncertainty related to diseases, diagnoses, and treatments [5]. Uncertainties regarding illness can be divided into the medical providers' uncertainty about diseases and the patients' uncertainty about diseases. Previous research has mainly focused on the physician's uncertainty of expressing disease-related information during patients' visits and its impact [54]. The latter, that is, patients' uncertainty about diseases, is the focus of this study.

Patients' uncertainty means that the patients are unable to determine the meaning of disease-related events or accurately predict the outcomes of such events [5,6]. In the uncertainty in illness theory presented by Mishel [3], the antecedents (eg, symptom stimulus, patients' cognitive abilities, and physicians' information authorities), the appraisal process, the coping mechanism, and the adaptation outcomes of patients' uncertainty in diseases are concluded, and the scale of patient uncertainty about illness is developed. This theory is effective in guiding interventions to manage patients' uncertainty [55].

In web-based markets, as sellers cannot fully describe the product or predict the products' future performances, consumers' uncertainty about products and sellers should be distinguished, between which the former uncertainty is related to the description and performance of products, and the latter uncertainty is related to sellers' adverse selection and moral hazard [15]. The uncertainty about sellers also increases uncertainty about products, and the two types of uncertainties reduce price premiums [15]. Similarly, in the physician-patient relationship, as physicians cannot fully describe the diseases or predict the effectiveness of treatments, patients' uncertainty in the process may be not only about the diseases but also about the physicians. Owing to the traits of principal-agent relationship, patients, who are the inferior party because of the scarcity of information, tend to question the rationality of physicians' advised medical treatments. However, in the medical context, few researchers have focused on patients' uncertainty about physicians. Given this, considering the principal-agent relationship between physicians and patients, we follow the classification of customers' uncertainties about sellers and products by Dimoka et al [15] to distinguish between patients' uncertainty about diseases and patients' uncertainty about physicians. In this way, this study can contribute to research on patients' uncertainty.

In the principal-agent relationship, how much information principals have played a key role in their uncertainty [23,24]. The lower the availability of product information, the greater the consumers' uncertainty about the product quality [23]; therefore, in our context, patients' perception of scarcity of disease information can increase patients' uncertainties about the diseases, and we hypothesize the following: patients'

perceived information scarcity about diseases increases patients' uncertainty about the diseases (H7).

Owing to information scarcity, it is difficult for patients to judge the quality of physicians' medical services. Less information about physicians' medical services leads to patients' stronger sense of uncertainty about physicians. According to research on the uncertainty of patients regarding disease [3], the causative factors include event familiarity. When patients have more knowledge about the physicians' medical services, it helps to reduce their uncertainty about the physicians' medical services, leading to the following hypothesis: patients' perceived information scarcity about physicians' medical services increases patients' uncertainty about the physicians (H8).

Trust can overcome uncertainty, and trust is necessary only when the environment is uncertain [45]. When patients trust their physicians, they can predict their physicians' behaviors based on their belief in the physicians' integrity, benevolence, and competence under uncertain circumstances. They believe that their physicians are honest and have great capabilities. Therefore, this study believes that a patient's trust in a physician will help reduce the patient's uncertainty about the physician, leading to hypothesis 9: a patient's trust in a physician can mitigate the patient's uncertainty in that physician (H9).

Because of the internally inconsistent goals between physicians and patients, physicians' opportunistic behaviors are inevitable, such as physicians taking kickbacks to prescribe expensive drugs, unnecessary tests, and overtreatment. Patients often lack professional information to judge the rationality of physicians' treatment plans and examination procedures, which leads to a sense of uncertainty about the rationality of physicians' treatment behaviors. In China, concern about physicians' opportunistic behavior is an important factor that leads to patients' sense of uncertainty [37,56]. Possible opportunistic behavior of vendors' drug prescription also leads to more uncertainty for buyers [45], and thus we hypothesize the following: patients' fear of the physician's opportunism increases patients' uncertainty in the physician (H10).

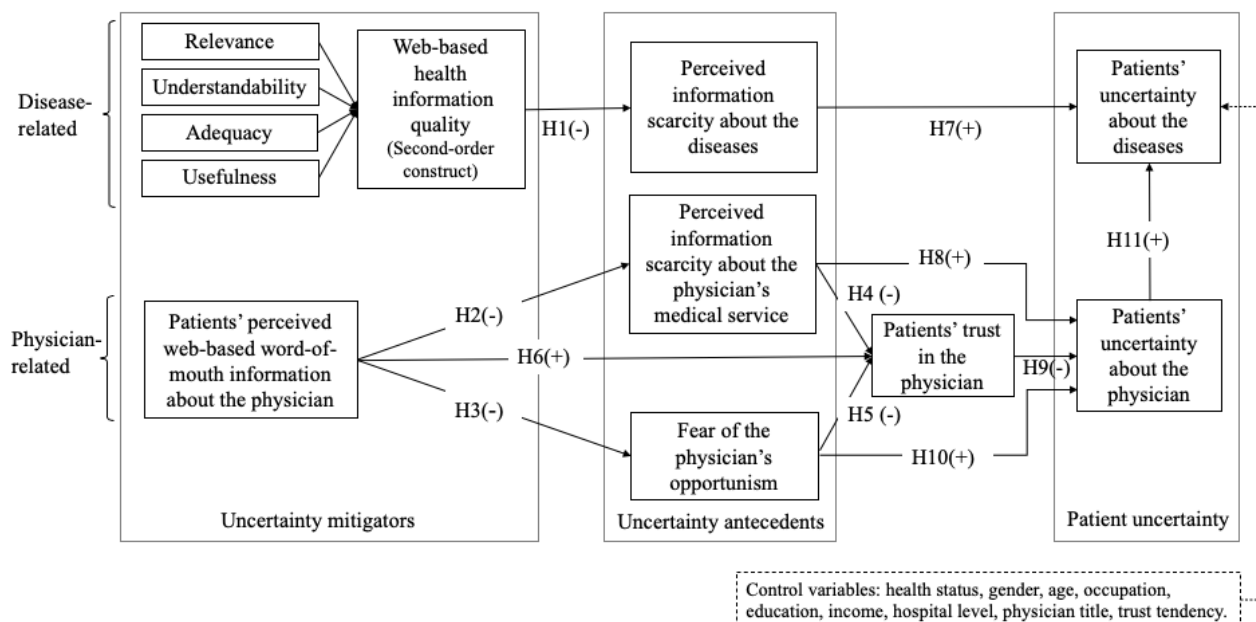

Consumers' uncertainty about sellers is distinct from the uncertainty about products, between which the former uncertainty can increase the latter uncertainty [15]. The process of patient consultation entails providing a series of examinations, diagnoses, and other services by the physician to identify the disease and determine other relevant treatments for the patient. If patients are uncertain about the rationality of the medical services provided by physicians and doubt the rationality of the physician's examination and treatment plans, it will be detrimental to patients' certainty about the disease; therefore, we hypothesize the following: patients' uncertainty about the physician increases patients' uncertainty about their diseases (H11).

In summary, based on existing literature, this study uses the principal-agent theory and the URT to develop a research model to explain the mechanism of how web-based information search by patients can reduce their uncertainties, as shown in Figure 1. In the context of patients' active information acquisition, we hypothesize that two types of web-based health information (ie,

web-based disease-related information quality and web-based physician-related information) as uncertainty mitigators to reduce patients' uncertainty. When identifying the antecedents of uncertainty and its consequences, we followed the descriptions by Pavlou et al [24] and Srivastava and Chandra [52] on the use of unique and specific variables related to customers' uncertainty. Principals' perception of information scarcity and principals' concern about agents' opportunistic

behaviors are the causes of the principals' uncertainty. Principals' trust in the agents acts as a mediator when the uncertainty antecedents reduce principals' uncertainty. Following the classification of customers' uncertainty about sellers and products by Dimoka et al [15], we classified patients' uncertainties into uncertainty about diseases and uncertainty about physicians. Our research model is depicted in Figure 1.

Figure 1. Research conceptual model. H: hypothesis.

Methods

Ethical Considerations

An ethics review was not applicable for this study because the online survey measured the subjects' perceptions and did not influence their perceptions or attitudes.

Data Collection

This study adopted the survey method to collect data. A total of 108 questionnaires were collected for the pilot test before the formal survey. The wording of some items and typesetting in the questionnaire were modified according to the feedback of the participants. A professional survey company (Wenjuanxing) was responsible for collecting the formal data. The survey started in May 2020 and lasted for a month. Each questionnaire corresponding to a separate IP address provided a reward of RMB 14 (US \$2.20). The questionnaire was also set to ensure that valid respondents should answer all the questions before submitting. At the beginning of the questionnaire, the background of the survey was introduced, and screening questions were set to meet the 3 requirements for the survey. Only those who might have a certain disease and have seen a physician offline within 3 months, who had engaged in web-based disease information search behavior, and who had read the web-based word-of-mouth information of the visited physicians were eligible.

Specifically, our questionnaire first used 3 questions to exclude invalid respondents. The first question was "Did you suffer a

certain disease and have any experience of offline medical treatments in the past three months?" The respondents who answered "Yes" proceeded to the next question, and the respondents who answered "No" were regarded as invalid respondents, and their questionnaires were terminated. Then, at the top of each page, there was a statement "Please recall the most recent experience of seeing a physician within the past three months, and based on this experience, answer the following questions." The second question to screen out the invalid respondents was "Before the consultation, have you searched for disease-related information on the internet for this consultation?" Similarly, respondents who answered "No" were prompted to end answering the questionnaire, and those who answered "Yes" continued to the next question. The third screening item was "Do you know the evaluation of the physician (based on the most recent visit within three months) on the Internet?" Only respondents who answered "Yes" continued to answer the questions about the perception of web-based word-of-mouth information, and respondents who answered "No" were prompted to end answering the questionnaire.

To ensure that the respondents responded seriously, the question regarding the evaluation of physicians' medical services appeared twice in different places in the questionnaire. Questionnaires with completely inconsistent answers (eg, strongly disagree and very agree) were excluded. A total of 40 invalid respondents were screened out, and the final sample size was 337. This sample size meets the requirement that the sample

size should be 5-10 observations for each estimated parameter [57,58].

Measurements

All items in this study are from mature scales, as shown in Table 1. Web-based information quality is a formative construct and the measurements were from Zahedi and Song [59]. The modified scale for perceived web-based word-of-mouth information about physicians was derived from Collins and Stevens [60]. As mentioned previously, there is a filter item—"Do you know the evaluation of the physician (based on the most recent visit within three months) on the Internet?"—which asked the respondent whether he or she had browsed through the web-based word-of-mouth information about the physician from those who had previously consulted that physician. With this filter item, we could ensure that the respondent's answers to web-based word-of-mouth information and other items were for the same physician. The measurement of perceived information scarcity about disease and physicians' medical service was derived from Wells et al [23], who developed reflective measures to assess individuals' degree of prepurchase information scarcity about products. The measurement of fear of physicians' opportunism was from the measurement of fear of sellers' opportunism [24,40], which referred to patients' concerns about the rationality of the visited

physicians' treatment behaviors (eg, excessive examination and high-priced drugs). Patients' trust measurement was modified from that suggested by McKnight et al [61] and Zhou et al [62]. Patients' uncertainty about diseases was measured using the community scale of uncertainty in illness (Mishel Uncertainty in Illness Scale–Community form) [3]. Patients' uncertainty about physicians was modified from the perceived uncertainty scale [63], which referred to patients' uncertainty about the rationality of medical services provided by physicians. Respondents in this study are native Chinese speakers; therefore, all items were translated into Chinese. We conducted translation–back-translation procedure to ensure the validity of our questionnaire. Specifically, the translated questionnaire was evaluated by 2 doctoral students with relevant research backgrounds. Some adjustments were made to the wording and expression of the questionnaire based on their feedback. Items of constructs (ie, perceived web-based word-of-mouth information about physicians, perceived information scarcity, fear of the physician's opportunism, perceived uncertainty, and trust) were measured by a 5-point Likert scale ranging from complete disagreement (1) to complete agreement (5). Items of the 4 dimensions of information quality were measured by the extent to which the internet health information conforms to the description in the item (eg, 1 point for a very low level and 5 points for a very high level).

Adequacy2	For your health information needs, to what degree do you believe internet health information provided by the website was complete?
Adequacy3	For your health information needs, to what degree do you believe internet health information provided by the website was adequate?
Adequacy4	For your health information needs, to what degree do you believe internet health information provided by the website contained the necessary topics or categories?
Usefulness1	For your health information needs, to what degree do you believe internet health information provided by the website was informative?
Usefulness2	For your health information needs, to what degree do you believe internet health information provided by the website was valuable?
Usefulness3	For your health information needs, to what degree do you believe internet health information provided by the website was helpful?
Usefulness4	For your health information needs, to what degree do you believe internet health information provided by the website was useful?
PWOM^b [60]	
PWOM1	In online reviews, the physician is very popular and many patients come to see the physician.
PWOM2	In online reviews, patients who visited the physician had a good experience.
PWOM3	According to online reviews, the physician is a good physician.
PWOM4	According to online reviews, the physician has a good relationship with patients.
PSD^c [23]	
PSD1	I have a good idea of the disease-related information (eg, symptoms, causes of disease, treatment methods, etc).
PSD2	I have sufficient information about the disease (eg, symptoms, cause of disease, treatment, etc).
PSD3	I possess adequate knowledge about the disease-related information (eg, symptoms, causes of disease, treatment methods, etc).
PSPMS^d [23]	
PSPMS1	I have a good idea of the medical services of the physician whom I visited this time.
PSPMS2	I have sufficient information about the medical services of the physician for this visit.
PSPMS3	I possess adequate knowledge about the medical service information of the physician whom I visited this time.

Construct, label, and source	Item
FPO^e [24]	
FPO1	In this visit, the physician might not have provided good service but charged a high price.
FPO2	In this visit, the physician might have overexamined, unnecessarily examined, or overtreated me.
FPO3	In this visit, the physician might have received a rebate for prescribing an overpriced drug (eg, imported drug).
FPO4	In this visit, the physician might have breached formal or informal agreements to his or her benefit.
T^f [61,62]	
T1	The physician is sincerely concerned about my medical issues
T2	The physician is honest in his or her medical practices
T3	I believe that the physician does a very good job
T4	I feel that I can count on the physician to help me with my medical problems
MUIS^g [3]	
MUIS1	I don't know what is wrong with me
MUIS2	I have a lot of questions without answers.
MUIS3	It is difficult to know if the treatments or medications I am getting are helping.
MUIS4	Because of the unpredictability of my illness, I cannot plan for the future.
MUIS5	The effectiveness of the treatment is undetermined.
PU^h [63]	
PU1	I think the rationality of the medical services provided by the physician involves a high degree of uncertainty.
PU2	I think the rationality of the medicine prescribed by the physician is uncertain.
PU3	I think the rationality of the disease examination and treatment plan is uncertain.
PU4	The rationality of the services provided by the physician is uncertain (ie, the service I received may not be exactly what I wanted).
PU5	I feel the uncertainty associated with the rationality of the medical services provided by the physician is high.
TDⁱ [64]	
TD1	I generally trust other people.
TD2	I generally have faith in humanity.
TD3	I feel that people are generally reliable.
TD4	I generally trust other people unless they give me reasons not to.

^aIQ: web-based health information quality.

^bPWOM: perceived web-based word-of-mouth information about physicians.

^cPSD: perceived information scarcity about the diseases.

^dPSPMS: perceived information scarcity about the physicians' medical services.

^eFPO: fears of physician's opportunism.

^fT: patients' trust in the physician.

^gMUIS: patients' uncertainty about diseases.

^hPU: patients' uncertainty about the physician.

ⁱTD: trust tendency.

To reduce other possible influences on our model, we considered control variables in 3 ways, although these variables are not our interest in this study. To reduce the possible influence of individual differences, demographic information, such as gender, age, education level, income per month, and occupation, is controlled. To reduce the possible influence of the impact of medical treatment, health-related and medical experience-related factors are also controlled, such as the respondent's health status,

the physician's title (an official certification of a physician's quality by the government) [65], and the hospital's level (an official certification of a hospital's quality by the government) [65]. To reduce the possible influence of the respondent's characteristic of trust, the respondents' trust tendency was also controlled. For example, with the same word-of-mouth information about a physician, some patients may easily trust the physician, whereas others may still doubt the physician.

Trust tendency [64] was also measured by a 5-point Likert scale ranging from complete disagreement (1) to complete agreement (5).

Results

Overview

As the model measured in this study has a formative construct, partial least squares (PLS) structural equation modeling is suitable for data analysis. SmartPLS (version 3.3.3, SmartPLS GmbH) software was used in this study. In addition, PLS is also widely used in information systems research owing to its relaxed requirements for the normal distribution of samples, its ability to process data with small sample size, and its applicability to development theory rather than test theory [66]. We first used SmartPLS (version 3.3.3, SmartPLS GmbH) software to test

the reliability and validity of the measurement model and then tested the path coefficients of the structural model.

Descriptive Statistics

The respondents' demographic information, health-related information, and medical experience-related information are shown in Table 2. More respondents were female (231/337, 68.5%). In terms of age distribution, age groups 21-30 years (165/337, 49%) and 31-40 years (117/337, 34.7%) were the most represented. Education level was relatively high, with high school and below accounting for only 4.5% (15/337). The monthly income distribution was relatively even. The surveyed samples were mainly working people, with enterprise employees accounting for 68.2% (230/337). The physicians' titles and hospitals' levels are also relatively high.

Table 3 lists the descriptive statistics of the constructs involved in the model.

Table 2. Demographic profile, health-related information, and medical experience–related information (N=337).

^aThe web-based health information quality is a formative construct; therefore, the details of this construct are described in the *Measurement Model* section.

^bPWOM: perceived web-based word-of-mouth information about physicians.

^cPSD: perceived information scarcity about the diseases.

^dPSPMS: perceived information scarcity about the physicians' medical services.

^eFPO: fears of physician's opportunism.

^fT: patients' trust in the physician.

^gMUIS: patients' uncertainty about diseases.

^hPU: patients' uncertainty about physicians.

ⁱTD: trust tendency.

Common Method Variance

As with all self-reported data, we should examine the potential common method variance. We follow the suggestions of Podsakoff et al [67] to minimize potential common method biases. First, we tried procedural remedies of Podsakoff et al [67]. To reduce respondents' evaluation apprehension and avoid their answers being socially desirable, at the beginning of the questionnaire, we reminded them that their answers are anonymous and there are no right or wrong answers to our questions. All items in the questionnaire were designed in a random order to ensure that the measurement of predictor and criterion variables are psychologically separated for respondents. To ensure that the scale items are specific, concise, and clear, we also conducted the pilot test before the formal survey. We modify the wording according to the feedback of the participants to reduce ambiguity.

Second, the Harman single-factor test was conducted to diagnose whether the common method bias is a problem [68]. We ran an exploratory factor with all variables included [23]. The results showed that more than one factor can be extracted from the unrotated solution, and the variance contribution rate of the first factor was not more than 50% (23.7%), so there was no one single major factor that can reflect the majority covariance of all items, indicating that common method bias was not serious [57].

Moreover, based on our survey context and the suggestions of Podsakoff et al [67], we conducted a single-common-method-factor approach by controlling for the effects of a single unmeasured latent method factor to control the common method variance. Following Liang et al [69], we included in the PLS model a common method factor whose indicators included all the indicators of the constructs in this study. We calculated each indicator's factor loadings and variances substantively explained by the construct and by the method factor. [Multimedia Appendix 1](#) provides the detailed procedure and results [67,69,70]. As shown in Table S1 in [Multimedia Appendix 1](#), most factor loadings of the method factor are insignificant. The average substantively explained variance of the indicators is 0.594, whereas the average method-based variance is 0.002. The ratio of substantive variance to method variance was 297:1, indicating the variance of each observed indicator explained by its substantive construct

is substantially greater than the variance explained by the method factor. Therefore, based on the studies by Liang et al [69] and Williams et al [70], we further conclude that common method bias is not a serious problem in this study.

Measurement Model

First, we tested the reliability and validity of the formative indicators (ie, web-based information quality). As web-based health information quality is a second-order formative construct, this study follows the method suggested by Wetzels et al [71]. In the structural equation model, four first-order reflective constructs (ie, information relevance, understandability, adequacy, and usefulness) point to the second-order constructive variable (information quality). A total of 16 items in the first order are taken as the measurement items of second-order constructs. PLS and Bootstrap were used to test the reliability and validity of the model and the outer weight of second-order formative constructs. First, the results of reliability and validity test of first-order reflective constructs showed information relevance (Cronbach α =.641; composite reliability [CR]=0.786; average variance extracted [AVE]=0.480), information understandability (Cronbach α =.726; CR=0.830; AVE=0.551), information usefulness (Cronbach α =.699; CR=0.816; AVE=0.526), and information adequacy (Cronbach α =.868; CR=0.910; AVE=0.717) all have good reliability and validity. Then, we tested the reliability and validity of the information quality of the second-order formative index, and the weight of the information quality (0.263, 0.314, 0.293, and 0.463) was >0.2 and significant at the level of $P<.001$, which passed the reliability and validity test of the formative construct. The variance inflation factors among all items were <2, satisfying the multicollinearity test, and the outer weight was significant and >0.2 [72].

Second, reflective indicators of this model were tested. We followed the methods suggested by Lewis et al [58] and Straub et al [73] to test the reliability and validity of the measurement model. The results are listed in [Table 4](#). First of all, we tested the reliability of the constructs. The results show that the component reliability of each construct is >0.7 with good internal consistency [74,75]. The average variance extraction is also >0.5, which has good convergent validity [76]. In most cases, Cronbach α is >.7, and in all cases, the values are >0.6, which are within the acceptable range [66].

^aCR: composite reliability.

^bAVE: average variance extracted.

^cPWOM: perceived web-based word-of-mouth information about physicians.

^dPSD: perceived information scarcity about the diseases.

^ePSPMS: perceived information scarcity about the physicians' medical services.

^fFPO: fears of physician's opportunism.

^gPU: patients' uncertainty about physicians.

^hMUIS: patients' uncertainty about diseases.

ⁱT: patients' trust.

^jTD: trust tendency.

As shown in Table 5, we also tested the discriminant validity of the measurement model. The square root of the AVE (ie, italicized number on the diagonal line) for each factor in the table is larger than the correlation coefficient between the factor

and other factors, so this measurement model has good discriminant validity [76]. Therefore, all the reflective constructs of this measurement model have good reliability and validity.

Construct Model and Results

We used PLS to test the hypotheses of this model and the Bootstrap method to test the significance of path coefficients [77]. The results are shown in Figure 2, and the path coefficients and T values are shown in Table 6. The control variables were also included in the model as predictors of the finally dependent variable (ie, patients' uncertainty about the diseases). From Figure 2, the R^2 of this model for patients' uncertainty in diseases is 0.515. Both the disease- and physician-related uncertainty mitigators have significant effects on the uncertainty

antecedents. Specifically, web-based health information quality can reduce patients' perceived information scarcity about diseases ($\beta = -.588$; $P < .001$), supporting H1. Patients' perceived web-based word-of-mouth information about physicians can reduce patients' perceived information scarcity about the physician's medical service ($\beta = -.511$; $P < .001$) and fears of physicians' opportunism ($\beta = -.268$; $P < .001$), thus supporting H2 and H3. Patients' perceived web-based word-of-mouth of physicians also increases patients' trust in the visited physician ($\beta = .318$; $P < .001$), supporting H6.

Figure 2. Structural equation model results. H: hypothesis.**Table 6.** Hypotheses test results.

Hypothesis	Path	Path coefficient (SD)	P value	Result
H1	IQ ^a →PSD	-.588 (0.035)	<.001	Supported
H2	PWOM ^b →PSPMS ^c	-.511 (0.045)	<.001	Supported
H3	PWOM→FPO ^d	-.268 (0.048)	<.001	Supported
H4	PSPMS→T ^e	-.279 (0.062)	<.001	Supported
H5	FPO→T	-.262 (0.050)	<.001	Supported
H6	PWOM→T	.318 (0.068)	<.001	Supported
H7	PSD ^f →MUIS ^g	.111 (0.045)	.02	Supported
H8	PSPMS→PU ^h	.051 (0.045)	.22	Rejected but fully mediated by patients' trust in the physician
H9	T→PU	-.288 (0.043)	<.001	Supported
H10	FPO→PU	.596 (0.047)	<.001	Supported and partially mediated by patients' trust in the physician
H11	PU→MUIS	.587 (0.043)	<.001	Supported

^aIQ: web-based health information quality.^bPWOM: perceived web-based word-of-mouth information of the physician.^cPSPMS: perceived information scarcity about the physicians' medical services.^dFPO: fears of physician's opportunism.^eT: patients' trust in the physician.^fPSD: perceived information scarcity about the diseases.^gMUIS: patients' uncertainty about diseases.^hPU: patients' uncertainty about the physician.

Patients' perceived information scarcity about the physician's medical service reduces their trust in the visited physician ($\beta = -.279; P < .001$), supporting H4. Fear of physicians' opportunism reduces patients' trust in the visited physician ($\beta = -.262; P < .001$), supporting H5. Patients' perceived information scarcity about the diseases increases patients' uncertainty in diseases ($\beta = .111; P = .02$), supporting H7.

However, patients' perceived information scarcity about physicians' medical services has no significant influence on patients' uncertainty in the visited physician ($\beta = .051; P = .22$), thus rejecting H8. Patients' trust in the visited physician can reduce patients' uncertainty in the visited physician ($\beta = -.288; P < .001$), supporting H9. Fear of physicians' opportunism has the most significant positive effect to increase patients'

uncertainty about the physician ($\beta=.596$; $P<.001$), supporting H10. Finally, uncertainty about the visited physician can increase patients' uncertainty in diseases ($\beta=.587$; $P<.001$), supporting H11.

Besides respondents' perception about their health status, other control variables have no significant influence on the model. Health status has a significantly negative impact on the model, which means that compared with patients who feel their health status is poor, patients who feel they are healthy perceive a higher level of uncertainty about the diseases.

To further explore the possible explanation of the rejection of H8, we conducted the Sobel test [78,79] to investigate the mediation role of trust in the relationship between the uncertainty antecedents and patients' uncertainty about the physician. From the results in Table 7, after introducing patients'

trust in their physicians, the relationship between patients' perceived information scarcity about physicians and their uncertainty about the physicians becomes nonsignificant, indicating that patients' trust in their physicians fully mediates the relationship of H8; therefore, the direct relationship of H8 is rejected, and only when more information can increase patients' trust, their uncertainty about physicians can be reduced. Moreover, increasing physicians' medical service information can be effective in reducing patients' uncertainty about their physicians. The relationship between patients' fear of the physician's opportunism and their uncertainty about the physician is still significant, indicating patients' trust in their physicians partially mediates the relationship of H10. The Sobel test statistics [80] are also significant, which further confirms that patients' trust in their physicians plays the role of mediation.

Table 7. The Sobel test of the mediating effect of patients' trust in the physician.

^eT: patients' trust in the physician.

^fPartially mediated.

^gFPO: fears of physician's opportunism.

Discussion

Principal Findings

This study investigated the mechanism of how web-based health information search behavior reduces patients' uncertainty. Our empirical test results supported most of our hypotheses, except H8. Patients' perceived web-based word-of-mouth information about physicians and the quality of web-based health information can effectively reduce patients' uncertainty about diseases and physicians. The uncertainty reduction effect is achieved by affecting the antecedent factors of patients' uncertainty, including patients' fears of physicians' opportunism,

patients' perceived information scarcity, and patients' trust, which are all the traits of principal-agent relationship.

Specifically, the higher the possibility of the physician's opportunism and information scarcity perceived by patients, the greater their uncertainty. Among the antecedents of patient uncertainty, patients' fear of physicians' opportunism has the most significant impact on patients' uncertainty about physicians. By segmenting patients' uncertainty, this research discussed the relationship between patients' uncertainty about the diseases and patients' uncertainty about physicians. The results show that patients' uncertainty about physicians has a significant positive impact on patients' uncertainty about diseases.

In addition, this study also demonstrated the significant role of patients' trust in physicians. Patients' perceived web-based word-of-mouth information about physicians can enhance patients' trust in physicians. Patients' having more information and less fear of physicians' opportunistic behaviors also increases patients' trust. However, from the result of the mediation test, only when the information can increase patients' trust in their physicians, patients' uncertainty about physicians can be reduced; thus, increasing physicians' medical service information can be effective in reducing patients' uncertainty about their physicians. Patients' trust in their physicians fully mediates the relationship between their perception of information scarcity about the physicians' medical service and their uncertainty about their physicians.

Theoretical Contributions

First, on the basis the principal-agent theory and from the perspective of reducing patient uncertainty, this study is the first to explore the influence mechanism of web-based disease-related information quality and web-based word-of-mouth information received by patients on patients' uncertainty. It is to be noted that information can reduce uncertainty, but the mechanism of how information reduces uncertainty is not clear. Therefore, we propose our *uncertainty mitigators–uncertainty antecedents–uncertainty* framework to explore the mechanism. On the basis of the URT, web-based information quality and web-based word-of-mouth information of physicians effectively reduce the antecedents of patients' uncertainty, including perceived information scarcity, fears of physicians' opportunism, and trust. Thus, patients' uncertainty about the disease and the physician are reduced.

Second, this study enriches the literature on patients' uncertainty by classifying patients' uncertainties into patients' uncertainty about the diseases and patients' uncertainty about their physicians. Following the classification of consumers' uncertainty about sellers and products by Dimoka et al [15], we also found that patients' uncertainty about diseases and physicians should be distinguished. In particular, we explored the role of patients' uncertainty about physicians, which has been rarely studied in the existing literature. Reducing patients' uncertainty about their physicians can further reduce their uncertainty about diseases.

Third, this study emphasizes the significant role of patients' trust. As an important factor in principal-agent relationships, trust is the most valuable aspect [43]. We also found that without trust, just increasing patients' information does not help reduce their uncertainty about their physicians. This result further supports the fact that building trust is crucial to address the principal-agent problem.

Practical Contributions

First, this study found that the better the web-based word-of-mouth information of a physician and information quality obtained by patients, the better the reduction in patients'

uncertainty. Therefore, for physicians in the internet era, attention should be paid to the role of web-based health information. More authoritative, more reliable, and higher-quality web-based platforms should be provided to meet patients' demands for health information. In addition, physicians should encourage offline patients to participate in web-based word-of-mouth evaluations, maintain their own web-based word-of-mouth information, and provide more information about their services to potential patients [81]. Web-based word-of-mouth information can reach a wider audience and has a greater impact than offline word-of-mouth information. Web-based word-of-mouth information can effectively nudge physicians to improve their service quality and help patients acquire relevant information about physicians, thereby reducing patients' uncertainty [39].

Second, from the full mediator role of trust, web-based information is effective only when this information can help build patients' trust in their physicians. This suggests that web-based platforms that provide information (ie, web-based word-of-mouth information about physicians) should strictly check the quality of the information. More importantly, platforms can provide some cues to inform patients that the information is trustworthy, such as third-party certifications and guarantees. Only when patients can trust their physicians through this information can it help reduce their uncertainties.

Limitations and Future Directions

First, as for the sample composition, there are 3 prerequisites for this study. Only those who might have a certain disease and had seen the physicians offline within the past 3 months, read the web-based word-of-mouth information about physicians, and engaged in web-based disease information search behaviors were eligible, which resulted in a large overrepresentation of younger people in our sample. More than 90.5% (305/337) of our respondents were aged <40 years, so the sample had possible self-selection bias and a bias of young age. Second, regarding the collection time of data, the research data were collected in May 2020 after the COVID-19 epidemic in China. The external validity of the results may be jeopardized. Then, this study only considered the influence mechanism of web-based word-of-mouth information about physicians on offline patients' trust. Future studies can further consider the situation of web-based health consultation and investigate the possible differences in web-based health information on the physician-patient relationship in different channels. Moreover, because the focus of this study is the information about diseases and physicians, the respondents' health status is controlled, and the result shows that respondents' perception of their health status influences their uncertainty. Future studies can further discuss and explain the effect of health status. Finally, the study data were cross-sectional subjective data, which were provided by the same subjects at the same time, and future studies can use longitudinal analysis or experiments to better test the causal relationships in the model.

Abstract

Background: Innovative surveillance methods are needed to assess adherence to COVID-19 recommendations, especially methods that can provide near real-time or highly geographically targeted data. Use of location-based social media image data (eg, Instagram images) is one possible approach that could be explored to address this problem.

Objective: We seek to evaluate whether publicly available near real-time social media images might be used to monitor COVID-19 health policy adherence.

Methods: We collected a sample of 43,487 Instagram images in New York from February 7 to April 11, 2020, from the following location hashtags: #Centralpark (n=20,937), #Brooklyn Bridge (n=14,875), and #Timesquare (n=7675). After manually reviewing images for accuracy, we counted and recorded the frequency of valid daily posts at each of these hashtag locations over time, as well as rated and counted whether the individuals in the pictures at these location hashtags were social distancing (ie, whether the individuals in the images appeared to be distanced from others vs next to or touching each other). We analyzed the number of images posted over time and the correlation between trends among hashtag locations.

Results: We found a statistically significant decline in the number of posts over time across all regions, with an approximate decline of 17% across each site ($P<.001$). We found a positive correlation between hashtags (#Centralpark and #Brooklynbridge: $r=0.40$; #BrooklynBridge and #Timesquare: $r=0.41$; and #Timesquare and #Centralpark: $r=0.33$; $P<.001$ for all correlations). The logistic regression analysis showed a mild statistically significant increase in the proportion of posts over time with people appearing to be social distancing at Central Park ($P=.004$) and Brooklyn Bridge ($P=.02$) but not for Times Square ($P=.16$).

Conclusions: Results suggest the potential of using location-based social media image data as a method for surveillance of COVID-19 health policy adherence. Future studies should further explore the implementation and ethical issues associated with this approach.

Introduction

Innovative surveillance methods are needed to assess adherence to COVID-19 recommendations [1], especially methods that can provide near real-time or highly geographically targeted data [2,3]. Social media, phone mobility data, and digital tracing apps have been discussed as potential data sources to use to better understand and track COVID-19-related behaviors and policy adherence [4-8]. However, no known COVID-19 or other research has examined whether social media images posted on a location hashtag (eg, #Centralpark) might inform regional surveillance and intervention efforts. Understanding these trends in local adherence to emergency public health orders could help inform public health and clinical needs. Accordingly, in a pilot study, we evaluated whether publicly available images might be used as a low-cost, near real-time method to monitor adherence to COVID-19 health policies.

Methods

Instagram is the most popular photo-sharing application in the United States. It allows users to take pictures of their current activities and environment, and share them with others in real time. Pictures can have location tags where users can post pictures to a specific topic thread (eg, pictures taken in Central Park, New York). Approximately 37% of US adults use Instagram, with 75% of use among those 18-24 years of age, 57% among those 25-29 years of age, 47% among those 30-49 years of age, 23% among those 50-64 years of age, and 8% among people 65 years and older [9].

We built a Python web crawler to collect Instagram images and corresponding user information and metadata. Specifically, the BeautifulSoup package was used to parse the original HTML files. The keywords, with hashtags such as #brooklynbridge, were used to identify relevant data. The images were only collected from public accounts, which led to a sample of 43,487 Instagram images in New York from February 7 to April 11, 2020, during a timeline throughout which New York COVID-19-related public health recommendations shifted from no recommendations (March 1, 2020, the first confirmed case within New York; March 5, 2020, Mayor de Blasio reports that fears should not keep New Yorkers off the subway), to heightened awareness (March 7, 2020, Governor Cuomo declares a state of emergency), to statewide stay-at-home orders for all nonessential activities, including limiting all outdoor activities with a possibility of coming into close contact with others (March 22, 2020). For example, as part of the stay-at-home order, New Yorkers were instructed that all nonessential gatherings of individuals of any size for any reason should be canceled or postponed. They were also informed that individuals should limit outdoor recreational activities to noncontact and avoid activities where they come in close contact with other people [10].

Images were only collected from location hashtags known for nonessential activities or crowded spaces where it would likely be difficult for people to socially distance (#Centralpark; n=20,937), #Brooklyn Bridge (n=14,875), and #Timesquare (n=7675). These data were collected to attempt to describe the

changing response to stay-at-home orders within these locations. We excluded images that might have been posted by the same person by only retaining up to 1 image per day per username. We also excluded images if we were unable to verify location. The final sample of images were manually reviewed by 23 graduate students to attempt to visually verify that the individuals in the pictures were at the hashtag locations (eg, images posted to #Brooklynbridge were excluded if they appeared to be indoors). Intercode reliability was assessed by having students each label a subset of the sample of pictures to determine consistency. These students then reviewed the labels to resolve inconsistencies. This process occurred on the final sample.

We counted and recorded the frequency of valid daily posts at each of these hashtag locations over time (trend in frequency of posts at each hashtag location), as well as rated and counted whether the individuals in the pictures at these location hashtags were social distancing (ie, whether the individuals in the images appeared to be distanced from others vs next to or touching each other). As an additional metric for assessing the reliability/consistency of findings, we also measured the correlation between the location hashtags in their frequency of posts over time using data from the entire sample of individuals associated with these locations. The graduate students rating the pictures were provided with guidance on how to conduct the rating and reviewed for agreement, including instructing them to estimate social distancing based on individuals in the photos not touching or being directly next to other individuals (ie, not posing with, standing, or sitting next to each other).

We used R software (R Foundation for Statistical Computing) to conduct regressions analyzing the number of images posted over time and to calculate the correlation between trends among hashtag locations (eg, the correlation between frequency of daily images posted to #Centralpark and #Brooklyn Bridge). For illustration purposes, we calculated the average number of images posted before versus after the first New York case (March 1, 2020). Logistic regression was used to estimate changes in the proportion of posts exhibiting social distancing over time. City University of Hong Kong research ethics committee (#2-25-202001-01) and the University of California, Irvine Institutional Review Board approved this study.

Results

The final sample included 37,447 manually verified images: #Centralpark (n=17,761), #Brooklynbridge (n=13,459), and #Timesquare (n=6227). A total of 100 randomly selected images were reviewed by 4 of the 23 labelers to assess intercode reliability that individuals in the pictures were at the reported hashtag locations ($\kappa=0.64$). We found a statistically significant decline in the number of posts over time across all regions, with an approximate decline of 17% across each site ($P<.001$; Figure 1 and Table 1). We found a positive correlation between hashtags (#Centralpark and #Brooklynbridge: $r=0.40$; #BrooklynBridge and #TimesSquare: $r=0.41$; and #Timesquare and #Centralpark: $r=0.33$; $P<.001$ for all correlations). The logistic regression analysis showed a mild statistically significant increase in the proportion of posts over time with people

appearing to be social distancing at Central Park ($P=.004$) and Brooklyn Bridge ($P=.02$) but not for Times Square ($P=.16$).

Figure 1. Number of images posted to the location hashtags over time, New York, 2020. Trendlines are estimated by a third-order polynomial function.

Table 1. Change in mean number of daily Instagram images for each location, New York, 2020.

Location	Number of daily posts before March 1, 2020, mean	Number of daily posts after March 1, 2020, mean (% change)	Slope	95% CI	P value
Central Park	342.8	282.2 (–13.7)	–1.76	–2.89 to –0.62	<.001
Brooklyn Bridge	252.9	218.3 (–17.7)	–1.66	–2.61 to –0.71	<.001
Times Square	119.8	99.2 (–17.2)	–1.03	–1.45 to –0.62	<.001

Discussion

Results suggest that publicly available image data might be incorporated into public health surveillance methodologies as an additional tool for monitoring people's adherence to public health guidelines, such as for the COVID-19 pandemic. We collected more than 40,000 images throughout a 10-week study period, which provided potential information about people's locations and adherence to stay-at-home orders. Sample data were a small subset of available images, and for only 1 city, suggesting that this approach could be scaled and automated with artificial intelligence to assist with near real-time regional health surveillance. Although this is a pilot study to explore this new approach for surveillance, it provides an opportunity for future researchers to explore expanding these methods using artificial intelligence and to assess the potential cost-effectiveness of this approach.

There are a number of potential public health and emergency clinical applications of this research. First, health officials might

use social media image data to better understand trends in adherence to COVID-19 prevention and other health policies. Second, using similar methods as other areas of health informatics, social media image data could be analyzed in health prediction models alongside other data sources, including case diagnoses, health services use, and demographic information, to learn how social media images might predict future COVID-19 cases within a specific region or county [11,12]. Finally, by providing data on where, when, how, and who are adhering or not adhering to health recommendations within a specific region, these data might help inform both the need for and ability to craft education and behavior change campaigns that are tailored to specific demographic or regional audiences [13,14], as well as trends in potential future local emergency department visits related to COVID-19 [15].

Although the number of posts decreased by approximately 17% throughout the study period, on average, 600 posts continued per day after issuance of stay-at-home orders, supporting the continued need for behavior change interventions. Although

we found a correlation between locations, the percentage reduction in images posted was greatest for #Timesquare and least for #Centralpark. This may be because Times Square is primarily a tourist location (and tourist activity substantially diminished), while people may have continued to use Central Park to exercise.

This study was limited by a New York focus and inability to verify the exact location, time of photo, or demographic information (eg, race, sex, or home city) about the users and a biased sample of Instagram users. Future research may help to address these questions by incorporating survey data into the current types of methods. Instagram's younger demographic [9] might help to explain the relatively small reduction in images posted after issuance of stay-at-home orders due to the common desire for independence and reduced risk perception among this age group. In addition, there are limitations with the social distancing measure (eg, it would code household members sitting together in the park having a picnic as not adhering to social distancing, when household members sitting together is appropriate, and we were unable to verify the specific number of feet individuals were from each other). We are also unable to identify why people were in these locations. As restrictions lessened over time to allow certain recreational activities, it would be helpful in future research to develop tools (eg, through

artificial intelligence) that could help to identify the specific types of activities participants are doing to better understand if they were adhering to policy recommendations. Despite being publicly accessible data and social media-based public health surveillance research being supported by government agencies (eg, Centers for Disease Control and Prevention) [12,16-18], privacy and ethics-related concerns need to be further explored before implementation [19]. Relatedly, in the future, it is possible that people would intentionally choose to alter their behavior due to demand characteristics or surveillance efforts [20], including deciding to not post to certain location hashtags if they thought this method might be used for surveillance efforts. However, we believe it is unlikely that people would alter their behavior in this way as people continue to publicly share large amounts of personal health information (eg, sexual risk behaviors and drug use) on social media despite ongoing monitoring of social media and digital data [21].

As states and local health departments continue to issue public health orders, a large number of surveillance tools and approaches are needed to control the growing COVID-19 pandemic. Results from this pilot study suggest that image data might be explored and integrated with traditional epidemiology approaches to help address and better inform local health and emergency department efforts.

Acknowledgments

We wish to thank Dr Lifang Li and Mr Jiannan Ye for cleaning the data and doing preliminary analysis. SDY reports grant funding to University of California, Irvine from the National Institute of Allergy and Infectious Diseases (NIAID) and National Institute on Drug Abuse (NIDA). The funders played no role in the study planning, analysis, or outcomes.

Authors' Contributions

QZ and DDZ had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. YZ collected the data. SDY conceived of the initial idea, advised on analysis, and wrote the first draft of the manuscript. WC advised on analysis and edited the manuscript.

Conflicts of Interest

SDY has received equity in MotiSpark, a company that uses images/videos for health behavior change. SDY has been a previous recipient of gift funding from Facebook (funding was made to the University of California with SDY as PI).

Abstract

Background: The treatment of many chronic illnesses involves long-term pharmaceutical therapy, but it is an ongoing challenge to find effective ways to improve medication adherence to promote good health outcomes. Cardioprotective medications can prevent the enlargement of harmful clots, cardiovascular symptoms, and poor therapeutic outcomes, such as uncontrolled high blood pressure and hyperlipidemia, for patients with coronary heart disease. Poor adherence to cardioprotective medications, however, has been reported as a global health concern among patients with coronary heart disease, and it is particularly a concern in China.

Objective: This study aimed to evaluate the efficacy of a mobile health (mHealth) intervention using 2 mobile apps to improve medication adherence and health outcomes.

Methods: A randomized, placebo-controlled, 2-arm parallel study was conducted in a major university-affiliated medical center located in Chengdu, China. Participants were recruited by flyers and health care provider referrals. Each participant was observed for 90 days, including a 60-day period of mHealth intervention and a 30-day period of nonintervention follow-up. The study coordinator used WeChat and Message Express to send educational materials and reminders to take medication, respectively. Participants used WeChat to receive both the educational materials and reminders. Participants in the control group only received educational materials. This study received ethics approval from the Duke Health Institutional Review Board (Pro00073395) on May 5, 2018, and was approved by West China Hospital (20170331180037). Recruitment began on May 20, 2018. The pilot phase of this study was registered on June 8, 2016, and the current, larger-scale study was retrospectively registered on January 11, 2021 (ClinicalTrials.gov).

Results: We recruited 230 patients with coronary heart disease. Of these patients, 196 completed the baseline survey and received the intervention. The majority of participants were married (181/196, 92.4%), male (157/196, 80.1%), and lived in urban China (161/196, 82.1%). Participants' average age was 61 years, and half were retired (103/191, 53.9%). More than half the participants (121/196, 61.7%) were prescribed at least 5 medications. The mean decrease in medication nonadherence score was statistically significant at both 60 days ($t_{179}=2.04$, $P=.04$) and 90 days ($t_{155}=3.48$, $P<.001$). Systolic blood pressure and diastolic blood pressure decreased in the experimental group but increased in the control group. The mean decrease in diastolic blood pressure was statistically significant at both 60 days ($t_{160}=2.07$, $P=.04$) and 90 days ($t_{164}=2.21$, $P=.03$). The mean decrease in systolic blood pressure was significantly different in the groups at 90 days ($t_{165}=3.12$, $P=.002$).

Conclusions: The proposed mHealth intervention can improve medication adherence and health outcomes, including systolic blood pressure and diastolic blood pressure.

Trial Registration: ClinicalTrials.gov NCT02793830; <https://clinicaltrials.gov/ct2/show/NCT02793830> and ClinicalTrials.gov NCT04703439; <https://clinicaltrials.gov/ct2/show/NCT04703439>

KEYWORDS

mHealth; medication adherence; coronary disease; blood pressure; China; randomized controlled trial

Introduction

Coronary heart disease (CHD) is a heart and blood vessel disease related to atherosclerosis in which plaque builds up in the walls of the coronary arteries, narrowing the arteries and restricting the flow of blood [1]. CHD is the world's leading cause of death [2], accounting for over one-third of all deaths in individuals over the age of 35 [3]. Approximately 4 out of 5 global deaths caused by CHD occur in low- and middle-income countries [4], and the burden of CHD is anticipated to increase in these countries [5]. By the year 2030, CHD is projected to cause more than 9 million deaths yearly [6]. China is the world's largest low- or middle-income country [7,8], and in China, CHD is the second leading cause of death, accounting for over 1.5 million deaths per year [9,10]. CHD has been an enormous economic burden on Chinese society in terms of health care costs and loss of productivity, and the mortality rate of CHD is increasing [11,12]. The administration of cardioprotective medications is a key treatment modality for CHD and a preventive measure against cardiovascular events [13,14]. Cardioprotective medications, including antiplatelet drugs, beta-blockers, calcium channel blockers, statins, and angiotensin-converting enzyme inhibitors can reduce the mortality rate of CHD [15-17].

In China, however, poor adherence to cardioprotective medications has been reported as a public health concern [18], contributing to increased health care costs and a high mortality rate for cardiovascular diseases [14,19-21]. For example, studies in China have shown that 18.2% to 38% of patients with CHD did not adhere to their statin medications [22,23], and only 49% consistently used beta-blockers after hospital discharge [16,21]. The vast majority of highly qualified health care providers in China practice in large urban hospitals; for serious illness, such as CHD, patients prefer to utilize large hospitals rather than local primary health care clinics [24,25]. Under this treatment-focused health care utilization model, many patients with CHD in China receive prescriptions and medication-related education without a primary care clinician to monitor their medication-taking behavior [20]. Consequently, after being discharged from the hospital, patients often do not receive proper follow-up care or information regarding medication-taking behavior [19,23]; therefore, it is important to develop innovative interventions to address this issue. Mobile health (mHealth) is defined as the use of portable electronic devices with software applications to provide health care services and manage patient information [26-28]. China has 1.3 billion mobile phone users [29]; mobile technology is booming, with 97% of netizens using mobile phones to access the internet [30]. Pilot studies conducted in China have shown that it is feasible and acceptable

to implement an mHealth intervention to improve medication adherence among patients with CHD [19].

After these pilot studies, mobile phone-based mHealth interventions have been conducted in the field of cardiovascular medicine in China [31-34], but none of them has been specifically aimed at improving medication adherence among patients with CHD, nor has any of them tested mHealth interventions that integrate 2 mobile apps. For example, in Shanghai, Dorje et al [31] conducted an mHealth intervention using social media to send participants educational materials to promote cardiac rehabilitation and secondary prevention, but the educational materials were not specifically about medication adherence. Also, reminders to take medication were not a primary intervention in this study; only participants whose blood pressure was outside the target level received reminders. In Guangzhou, Li et al [34] evaluated an mHealth intervention that aimed to improve blood pressure and self-management behavior in people with hypertension, but this intervention was neither specifically designed to improve medication adherence nor focused on patients with CHD. These studies indicate that although using mHealth interventions to improve medication adherence is a promising approach, more evidence is needed to examine the effect of mHealth intervention on improving medication adherence and clinical outcomes among patients with CHD [35]. The aim of this paper was to assess if our mobile phone-based mHealth intervention could improve medication adherence and relevant health outcomes (ie, systolic blood pressure, diastolic blood pressure, and heart rate) among patients with CHD in comparison to a control group that received general educational materials over a period of 60 days. The pilot phase of this study was registered in ClinicalTrials.gov (NCT02793830) on June 8, 2016, and the current, larger-scale study was retrospectively registered (NCT04703439) on January 11, 2021. This was because we wanted to make the study more accessible to the public and also because we believed that this would better reflect the continuousness of our mHealth intervention, from the initial evaluation of its feasibility and acceptability (ie, the pilot phase) to the later evaluation of its efficacy (ie, the larger-scale phase).

Methods

mHealth Technologies

This study used 2 mobile apps: WeChat (Tencent Inc) and Message Express (Bluemobile.zt). WeChat is the most widely used messaging app in China [36]. Message Express (also known as “Xiao Xi Su Di” in Chinese) is a message saving and delivery app that can send personalized messages to a WeChat

account. It can be integrated with WeChat to deliver reminders to take medication from a message library. After saving a library of reminders to Message Express, a clinician can easily choose personalized reminders in Message Express and send them to a participant's WeChat. BB Reminder is a third-party app with similar functions to Message Express that we used in the pilot study, but it became unavailable after April 2018. Thus, in this study, our study coordinator used WeChat and Message Express to send educational materials and reminders to take medication, respectively. Participants used WeChat to receive both educational materials and reminders. At baseline, we assessed the mobile phone literacy of participants by recording the length of time they had been using WeChat, their frequency of WeChat use, and their educational level. To protect participants' data and privacy, we followed the patient privacy policies of West China Hospital and Duke University and used an encrypted cellphone to send messages. Participants' data were stored in a secure database (REDCap, Vanderbilt University). No data were stored in WeChat or Message Express.

Study Design and Participants

This unblinded, 2-arm, parallel randomized controlled trial was conducted between May and December 2018 at the Cardiology Department of West China Hospital, located in Chengdu. West China Hospital is a major university-affiliated hospital that serves more than 10,000 outpatients a day [37]. A total of 230 participants were recruited for this study using flyers and health care provider referrals [19]. The sample size was determined by a statistical power analysis (Gpower 3.1), with an α of 0.05, power of 0.80, and effect size of 0.35. The effect size was calculated using Cohen's criteria based on data from phase II of the pilot study [38,39]. Written consent was obtained from participants, and they were randomly assigned to the experimental group using stratified randomization by gender with a permuted block size of 4. The random allocation sequence was generated using SAS software version 9.4 by the first author (ZN), who also enrolled participants and assigned participants to interventions. Each participant was observed for 90 days, including a 60-day period of mHealth intervention and a 30-day period of nonintervention follow-up. The mHealth intervention was developed and tested in a pilot study with 2 phases, in 2016 and 2017 [19]. In the pilot study, we found it was feasible to conduct an mHealth intervention by integrating 2 apps to remind patients with CHD to take medications. The apps that we chose to use in this study were based on the results of the pilot study. Participants were included in this study if they satisfied the following criteria [19]: (1) they had a medical diagnosis of CHD; (2) they were aged 18 years or older; (3) they had an antihypertensive medication regimen that would last for 90 days

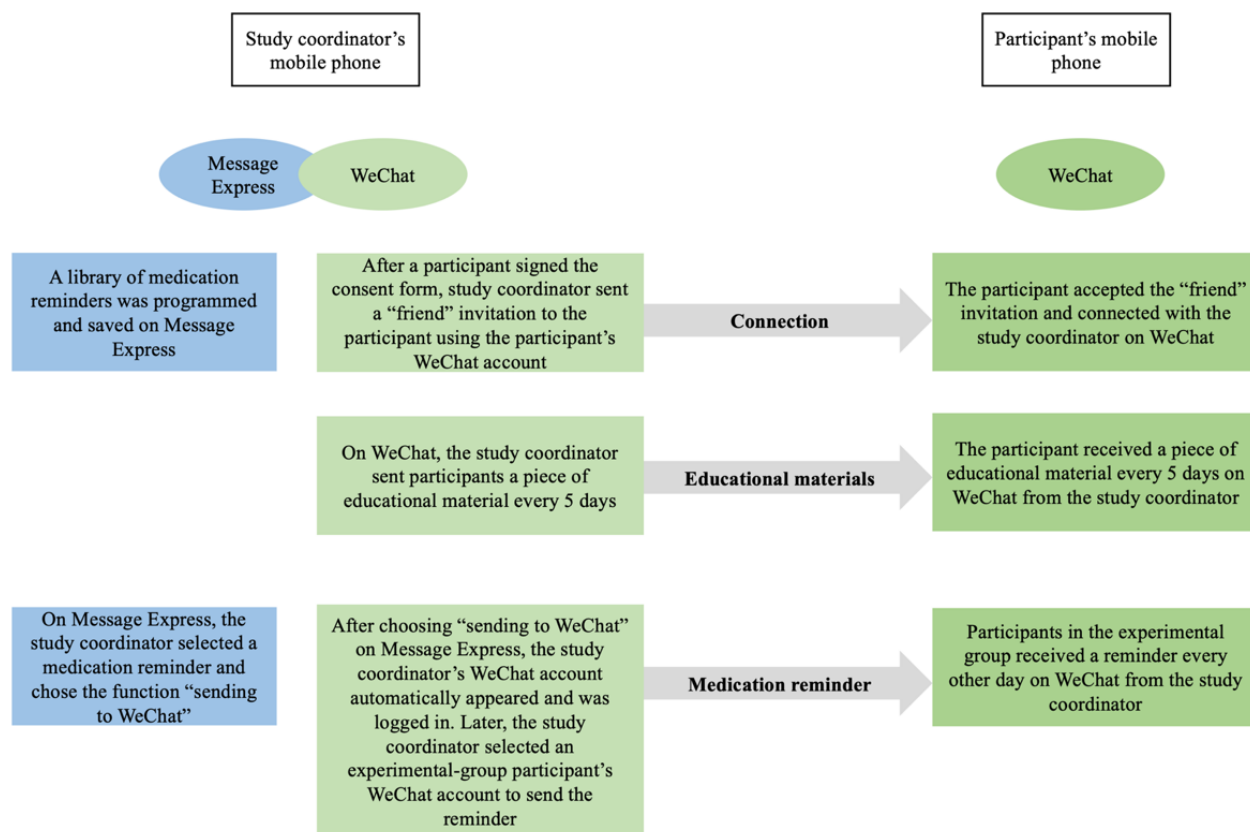

or more after enrollment; (4) they were able to read messages through a mobile phone; (5) they had a mobile phone that could receive messages from WeChat and reminders from Message Express; (6) they were capable of giving consent; and (7) they had an electronic blood pressure cuff to check blood pressure and heart rate.

Ethics Approval

This study received ethical approval from the Duke Health Institutional Review Board (Pro00073395) and West China Hospital (20170331180037).

Interventions

The interventions were refined based on the pilot study [19]. Once a participant completed the baseline questionnaire, they received the allocated intervention. Participants in the experimental group received reminders to take medication and educational materials from Message Express and WeChat, respectively (Figure 1). Participants in the control group only received educational materials from WeChat. The educational materials were sent every 5 days at a random time between 8 AM and 9 AM. The educational materials sent to the 2 groups were different. Materials sent to the experimental group were specifically related to CHD and medication adherence and included information on the function of cardioprotective medications, potential negative consequences of not taking these medications daily, and some common reasons why people with CHD fail to take them. Materials sent to the control group contained general medical information that was not specifically related to CHD or medication adherence. For example, some of the materials were related to population aging in China and age-related health problems, such as hearing loss. All educational materials were retrieved from the website of the World Health Organization [40,41] and were screened by a cardiologist and a nurse to ensure their accuracy before being sent to participants. In addition to educational materials, participants in the experimental group received reminders to take medication every morning at a random time between 7 AM and 8 AM. (The reminders included phrases such as "Please remember to take today's medications" and "It is time to take today's medications. Do not stop taking your medications without consulting a cardiologist.") The time participants received the reminders was selected based on feedback that we collected in the pilot study. The educational materials and reminders were sent through Message Express on an encrypted external device (an iPhone 5 borrowed from Duke University that was used specifically for this study). The intervention lasted for 60 days for each participant. After the intervention, participants were observed for 30 days.

Figure 1. Brief description of the 2 apps.

Data Collection and Variables

Participants' demographic characteristics were recorded, including age, gender, ethnicity, weight, height, marital status, job status, education, medical insurance status, living area, number of prescribed medications, and family income. A REDCap survey hyperlink was sent to each participant to collect their demographic characteristics and track their health outcome variables at 7 time points: enrollment (ie, baseline); 15, 30, 45, and 60 days after enrollment (ie, at the end of the intervention); and 75 and 90 days after enrollment (ie, at the end of follow-up). Health outcome variables included medication nonadherence score, heart rate (HR), systolic blood pressure (SBP), and diastolic blood pressure (DBP). The primary outcome (ie, medication nonadherence score) was measured using a validated 3-item, 5-point Likert scale, the Voils Extent Scale [42]. To calculate the total nonadherence score, the responses to the relevant 3 items of the survey were added up. A lower score indicated better medication adherence. If a participant did not complete a survey, the study coordinator sent them a WeChat message as a reminder. If there was no reply after 2 such attempts, the study coordinator called the participant. If there was still no answer, the participant was treated as lost to follow-up. Participants who deleted the study coordinator's WeChat account were treated as having withdrawn from the study.

Data Analysis

All analyses were performed using SAS 9.4. Categorical variables such as gender, ethnicity, marital status, job status, medical insurance, and living area were reported as frequency

(n) and percentage (%). Numerical variables including age, weight, height, and number of prescribed medications were reported as mean (SD). The chi-square test and independent *t* tests were used to determine between-group differences at baseline. The Fisher exact test and Wilcoxon 2-sample test were used as alternatives when a chi-square test was not applicable due to small expected values in some cells or when a 2-sample *t* test assumption was not met. All statistical tests were nondirectional (2-tailed) and the significance level was set at $P=.05$. If a difference in a baseline characteristic was significant, the baseline variable was included as a covariate in the modeling stage.

The mean (SD) for all outcome variables (ie, medication nonadherence, HR, SBP, and DBP) in each group was computed and graphed to show trends at the 7 time points described above. Differences in outcomes between the experimental and control groups at the critical time points (ie, baseline, 60 days, and 90 days) were determined using the *t* test. Both the control and experimental groups contained individuals with extremely low or high blood pressure and HR, and calculating the mean of these abnormal values was likely to produce values that were misleadingly normal. Therefore, we dichotomized SBP, DBP, and HR values into binary variables: normal and abnormal. We defined normal blood pressure according to the 2010 Chinese Hypertension Guidelines [43], which define normal SBP and DBP as less than 140 mmHg and less than 90 mmHg, respectively, and define normal HR as between 60 bpm and 100 bpm. The proportional rates of normal HR, SBP, and DBP in the subjects were graphed to show trends. To test between-group differences in the trajectory of change in all outcomes after

adjusting for relevant covariates, a mixed-effects model was used for continuous outcomes and a generalized mixed-effects model with a logit link was used for the dichotomized binary outcomes. Considering the correlations between repeated longitudinal measurements of the same patient, a random intercept, a random slope, and an unstructured covariate matrix were used. The fixed effects included in the 2 models were the intervention group (ie, experimental versus control), time, the group-by-time interaction, and baseline variables that were significantly different in the experimental and control groups or covariates that could clinically impact HR and blood pressure. We also accommodated a quadratic time trend by including a time-by-time fixed effect and testing for it. If the quadratic effect was not significant, we removed it from the mixed-effects model.

Results

Baseline Characteristics

In this study, we recruited 230 participants and randomly assigned 116 to the experimental group and 114 to the control group (see Figure 2 for the CONSORT [Consolidated Standards of Reporting Trials] diagram [44]). Of the 230 participants, 34

participants did not complete the baseline questionnaire and thus did not receive the intervention. We collected baseline data from the 196 participants who received the intervention; of these, 6 participants later dropped out of the study and 9 were lost during the follow-up period. There was no statistically significant difference ($P>.05$) in any baseline characteristic between the 2 groups (Table 1). The majority of the participants were married (181/196, 92.4%), male (157/196, 80.1%), Han Chinese (184/196, 93.9%), and living in urban China (161/196, 82.1%). Participants' average age was 61 years, and half were retired (103/191, 53.9%). More than half the participants (121/196, 61.7%) were prescribed at least 5 medications. Half the participants had an annual family income less than CNY ¥54,000 (US \$7950). The majority of participants (186/192, 96.9%) had medical insurance; nearly 28% (41/147) of participants had their medications fully covered, 60% (89/147) were partially covered, and 11.6% (17/147) of participants did not have insurance coverage for their medication. Most participants (109/196, 88%) had used WeChat for more than a year and were using WeChat every day (152/188, 80.9%) before participating in the study; only 5.8% (11/188) had never used WeChat before the study. There was no difference between the experimental and control groups in mobile phone literacy.

^aThe Fisher exact test was used due to small values in cells.

^bThe Mann-Whitney *U* test was used due to missing data: 25% of participants did not know whether their prescribed medications would be covered by their medical insurance at the time of discharge; and 21% of participants refused to disclose their family income.

Medication Nonadherence and Health Outcomes

The medication nonadherence score (Figure 3) consistently decreased in the experimental group. The nonadherence score decreased in the control group during the first 45 days, but then increased and approached the baseline level at 90 days (the score at 90 days was 0.08 less than baseline). The mean decrease in medication nonadherence score in the experimental group was greater than the mean decrease in the control group at 60 days ($t_{179}=2.04$, $P=.04$) and 90 days ($t_{155}=3.48$, $P<.001$) (Table 2).

HR decreased (Figure 4) at 60 days and 90 days in both groups compared to baseline, but the difference in the decrease between the 2 groups was not statistically significant at either 60 days ($t_{148}=-0.28$, $P=.78$) or 90 days ($t_{145}=0.32$, $P=.75$). SBP (Figure 5) and DBP (Figure 6) decreased at 60 days and 90 days in the experimental group but increased in the control group. The difference in the change in DBP between the intervention and control groups was statistically significant at both 60 days ($t_{160}=2.07$, $P=.04$) and 90 days ($t_{164}=2.21$, $P=.03$). The difference in the change in SBP between the 2 groups was statistically significant at 90 days ($t_{165}=3.12$, $P=.002$), but not significant at 60 days ($t_{161}=1.92$, $P=.06$).

The proportional rate of participants with normal SBP (Multimedia Appendix 1) and DBP (Multimedia Appendix 2) increased in both groups at 60 days and 90 days compared to baseline, but the difference between the 2 groups at these times was not statistically significant (Multimedia Appendix 3). Unlike

SBP and DBP, the proportional rate of participants with normal HR (Multimedia Appendix 4) decreased in both the experimental and control groups, but the difference between the 2 groups was not statistically significant at either 60 days ($P=.37$) or 90 days ($P=.41$).

Although no baseline characteristics were significantly different between the experimental group and the control group, HR and blood pressure can be influenced by body weight [45,46], gender [47,48], and age [49]; therefore, they were included as covariates in the modeling stage. After controlling for the effects of baseline body weight, gender, age, educational level, group, time, and the group-by-time interaction in the mixed-effects model, the difference in the rate of change of medication nonadherence between the 2 groups was statistically significant ($\beta=-.02$, $P<.001$) (Table 3).

The difference in the rate of change of SBP ($\beta=-.08$, $P<.001$) and DBP ($\beta=-.05$, $P=.004$) between the 2 groups was also statistically significant. However, the difference in the rate of change in HR between the 2 groups was not statistically significant ($\beta=-.01$, $P=.74$). In the generalized mixed effect model with a logit link for dichotomized binary outcomes, we found that the difference in the change of the proportional rate of participants with a normal SBP between the 2 groups was statistically significant ($\beta=.01$, $P=.02$), but that the difference between the 2 groups was not statistically significant for either the proportional rate of participants with normal DBP ($\beta=.006$, $P=.32$) or normal HR ($\beta=.003$, $P=.60$) (Multimedia Appendix 5).

Discussion

Principal Findings

The aim of this study was to assess if a mobile phone-based mHealth intervention could improve medication adherence and relevant health outcomes (eg, blood pressure and HR) among patients with CHD in comparison to a control group that received general educational materials over a period of 2 months. We found that our mHealth intervention increased medication adherence and had a lasting effect in improving

medication adherence among patients with CHD, even though no intervention was given after 60 days. We also found that our mHealth intervention improved health outcomes by lowering SBP and DBP, and that this effect continued for 30 days after the intervention. Unlike SBP and DBP, our mHealth intervention did not significantly lower HR, although mean HR consistently remained within the normal range. After dichotomizing SBP, DBP, and HR into binary variables, we found that there was no significant difference between the proportional rate of

participants with normal SBP, DBP, and HR at baseline, 60 days, or 90 days between the intervention and control groups.

A mixed-effects model for continuous outcomes showed that differences in the rate of change of medication nonadherence, SBP, and DBP were statistically significant between the 2 groups after controlling for the effects of group, time, the group-by-time interaction, and some baseline variables that can influence HR and blood pressure, such as body weight, gender, age, and educational level. Similarly, the generalized mixed-effects model with a logit link used for dichotomized binary outcomes showed that after controlling for the effects of baseline body weight, gender, age, educational level, group, time, and the group-by-time interaction, our mHealth intervention could significantly increase the proportional rate of participants with normal SBP. In summary, these key findings demonstrate that our mHealth intervention could significantly increase medication adherence and the proportional rate of participants with normal SBP, as well as lower SBP and DBP, in patients with CHD.

In this study, participants were defined as dropping out if (1) they filled out the baseline survey but deleted the study coordinator's WeChat account at any time point before their completion of the study; or (2) they told the study coordinator that they wanted to withdraw from the study. Participants were defined as lost to follow-up if they filled out the baseline survey and kept the study coordinator's WeChat account, but did not fill out later surveys and did not respond to reminders and WeChat calls made by the study coordinator. This could happen at any time point during the study. In this study, 9 participants were lost to follow-up and 6 participants dropped out, which together accounts for 7% of the data. Due to the small amount of missing data, we did not perform missing data imputation. We compared the baseline variables between participants who dropped out or were lost to follow-up with those who completed the study, and found that none of the baseline variables were significantly different between these groups ([Multimedia Appendix 6](#)).

In this study, the ratio of male to female patients with CHD was 4:1, which is the same ratio as in our pilot study conducted in 2017. The higher proportion of male participants reflects the higher prevalence of CHD in men in China; Chinese men are more likely to engage in risky behaviors, such as smoking and drinking [12]. This result is consistent with findings that US men had a higher prevalence of CHD than women in all age strata from 45 to 94 years, according to the American Heart Association's report *Heart Disease and Stroke Statistics* [50,51].

Limitations

This study contributes important knowledge about mHealth as a tool to improve medication adherence, but it has several limitations. First, all participants were recruited at a major university-affiliated hospital; many of them were middle-aged male urban residents and were thus not representative of the general Chinese population. Second, health outcomes such as SBP, DBP, and HR were self-reported by participants. There may therefore have been discrepancies regarding these measurements. Third, during this study, some participants did not provide their health outcome data in a timely manner. To

collect these data, some participants had to be reminded by WeChat messages and phone calls. These messages and phone calls might have been covariates that could influence the participants' medication-taking behaviors, but we did not consider their influence. Finally, the mHealth intervention was not automated and lasted for only 60 days, a comparatively short period of time. To adopt this intervention in real clinical settings, which have thousands of patients, and to create long-term effects, it will be necessary to use automated methods. Finally, this study was unblinded. All participants, data collectors, and data analysts were aware of which treatment arms participants had been assigned to. To increase rigor and reduce bias, future large multisite studies should consider a double-blind design.

Future Directions

The treatment of many chronic illnesses involves long-term pharmaceutical therapy. Nevertheless, it is an ongoing challenge to find effective ways to improve medication adherence and other health behaviors to improve health outcomes. For patients with CHD, cardioprotective medications can prevent the enlargement of harmful clots [52], cardiovascular symptoms, and poor therapeutic outcomes. Poor adherence to cardioprotective medications, however, is considered to be a public health concern [18,52]. It has been linked to increases in health care costs due to poor therapeutic outcomes that typically require major medical interventions, such as coronary angioplasty and coronary artery bypass grafting [20]. Mobile phones are widely used in China; 97% of Chinese netizens access the internet through a mobile phone [30]. This makes mobile phones an ideal platform for implementing an mHealth intervention to improve medication adherence. If this mHealth intervention could be scaled up for use in real-world clinical settings, it would have 3 useful aspects. First, it is able to overcome geographic barriers. This is particularly useful in China, considering the fact that the majority of its highly qualified health care providers reside in cities, and most of its tertiary hospitals are located in urban areas [53,54]. Hospitals in China are categorized into a 3-tier system: primary, secondary, and tertiary [55], with tertiary being the highest level of quality. To seek quality medical care, many rural residents have to travel to urban areas to find qualified health care providers. This geographic barrier limits the access of rural patients with CHD to quality medical care and may impact their health outcomes across their lifespans. Our mHealth intervention has the potential to increase the access of patients with CHD to quality medical care through mobile phones without requiring them to travel to hospitals. Second, the core technology of this mHealth intervention is app-based mobile messaging, which is widely used in China. Therefore, this intervention could be a cost-effective method to remind people across socioeconomic strata and across geographic areas to take their medications. If this intervention were automated, and if it resulted in even modest improvements in medication adherence and blood pressure, there could be population-level benefits. Given the economic burden and prevalence of CHD in China, even small clinical improvements could have a large impact. In other words, the cost-benefit ratio of this mHealth intervention is expected to be positive.

Although some studies have been conducted in China on using mobile apps (eg, WeChat) to improve blood pressure and self-management behavior [31-34], none have been designed specifically to address the problem of medication nonadherence in patients with CHD. Previous interventions have also not been individualized. For example, in an mHealth intervention study conducted in Guangzhou, educational materials were sent to a group of participants rather than to individuals [34]. Moreover, no previous study has used an mHealth intervention that integrated 2 mobile apps. Given that medication nonadherence is a complex issue involving multiple factors related to patients, health care providers, and health care systems [21], integrating mobile apps with different functionalities might be a promising approach. The mHealth intervention that we tested in this study could be harnessed and adapted to other fields, such as endocrinology, orthopedics, and mental health. Finally, adopting this intervention is integral to developing a platform for immediate medical consultation and emergency health care. Cardiovascular events such as heart attack, heart failure,

arrhythmia, and heart valve problems [1] are emergencies in which many patients need immediate medical treatment, consultation, and guidance. Adopting this mHealth intervention is an important step for hospitals to develop online tools for immediate health care service.

Conclusion

The treatment of many chronic illnesses involves long-term pharmaceutical therapy, but it is an ongoing challenge to find effective ways to improve medication adherence and promote good health outcomes. In this study, we examined an mHealth intervention to remind patients with CHD to take their cardioprotective medications. Our results demonstrate that it is feasible to conduct an mHealth intervention to improve medication adherence and health outcomes, represented by measures including SBP and DBP. In summary, mHealth interventions that are constructed using evidence-based content show promise to help increase medication adherence and improve health outcomes.

Abstract

Background: Evidence-based infectious disease and intensive care management is more relevant than ever. Medical expertise in the two disciplines is often geographically limited to university institutions. In addition, the interconnection between inpatient and outpatient care is often insufficient (eg, no shared electronic health record and no digital transfer of patient findings).

Objective: This study aims to establish and evaluate a telemedical inpatient-outpatient network based on expert teleconsultations to increase treatment quality in intensive care medicine and infectious diseases.

Methods: We performed a multicenter, stepped-wedge cluster randomized trial (February 2017 to January 2020) to establish a telemedicine inpatient-outpatient network among university hospitals, hospitals, and outpatient physicians in North Rhine-Westphalia, Germany. Patients aged ≥ 18 years in the intensive care unit or consulting with a physician in the outpatient setting were eligible. We provided expert knowledge from intensivists and infectious disease specialists through advanced training courses and expert teleconsultations with 24/7/365 availability on demand respectively once per week to enhance treatment quality. The primary outcome was adherence to the 10 *Choosing Wisely* recommendations for infectious disease management. Guideline adherence was analyzed using binary logistic regression models.

Results: Overall, 159,424 patients (10,585 inpatients and 148,839 outpatients) from 17 hospitals and 103 outpatient physicians were included. There was a significant increase in guideline adherence in the management of *Staphylococcus aureus* infections (odds ratio [OR] 4.00, 95% CI 1.83-9.20; $P < .001$) and in sepsis management in critically ill patients (OR 6.82, 95% CI 1.27-56.61;

$P=.04$). There was a statistically nonsignificant decrease in sepsis-related mortality from 29% (19/66) in the control group to 23.8% (50/210) in the intervention group. Furthermore, the extension of treatment with prophylactic antibiotics after surgery was significantly less likely (OR 9.37, 95% CI 1.52-111.47; $P=.04$). Patients treated by outpatient physicians, who were regularly participating in expert teleconsultations, were also more likely to be treated according to guideline recommendations regarding antibiotic therapy for uncomplicated upper respiratory tract infections (OR 1.34, 95% CI 1.16-1.56; $P<.001$) and asymptomatic bacteriuria (OR 9.31, 95% CI 3.79-25.94; $P<.001$). For the other recommendations, we found no significant effects, or we had too few observations to generate models. The key limitations of our study include selection effects due to the applied on-site triage of patients as well as the limited possibilities to control for secular effects.

Conclusions: Telemedicine facilitates a direct round-the-clock interaction over broad distances between intensivists or infectious disease experts and physicians who care for patients in hospitals without ready access to these experts. Expert teleconsultations increase guideline adherence and treatment quality in infectious disease and intensive care management, creating added value for critically ill patients.

Trial Registration: ClinicalTrials.gov NCT03137589; <https://clinicaltrials.gov/ct2/show/NCT03137589>

Introduction

Background

Worldwide, health workforce shortages are a pressing concern. By 2030, it is estimated that there will be a shortage of 9.9 million physicians and nurses worldwide [1,2]. In addition, the proportion of older people in Europe will exceed 30% by 2050 [3,4]. Hence, health care systems must become more flexible and efficient, for example, through accelerated digitization. Infectious disease management, especially the management of sepsis, is one area in which the potential for digitization to reduce the global burden of disease is particularly strong.

Increasing antimicrobial resistance (AMR) poses a growing threat to patients. Important underlying drivers are the overuse and misuse of antibiotics. Every year, approximately 700,000 patients worldwide die from infections that are treatable with antibiotics [5]. Global pandemics such as COVID-19 are likely to promote the overuse of antimicrobials, thereby facilitating the further development of AMR. AMR could cost US \$100 trillion between now and 2050, with the annual mortality rate reaching 10 million over this period [5].

In 2017, there were approximately 48.9 million cases of sepsis worldwide and 11 million sepsis-related deaths (19.7% of all deaths globally) [6]. Sepsis is the most common cause of morbidity and mortality in intensive care units (ICUs) around the world. Although the sepsis-related mortality rate is continuously decreasing, it is still remarkably high (30%-50%) [7-9]. The associated costs are US \$24 billion annually in the United States alone [6].

Numerous studies have shown that adherence to clinical practice guidelines for antibiotic therapy and sepsis management is associated with improved patient outcomes [10-15]. Alarming, compliance with these guidelines is low [10,16-18]. International educational health care campaigns, such as the *Choosing Wisely* initiative, have responded to this global challenge by increasing professional awareness of evidence-based medicine [19]. In general, the *Choosing Wisely* recommendations promote

essential practices and the avoidance of unnecessary diagnostic, preventive, and therapeutic procedures [15,19].

Telemedicine has the potential to support these efforts. It facilitates direct, round-the-clock interactions between physicians who care for patients in hospitals with limited subspecialist staff and intensivists or infectious disease specialists located far away. Observational studies have demonstrated that expert teleconsultations can reduce sepsis-related mortality by approximately 25%, with a simultaneous increase in guideline adherence [12,20]. Despite decades of intensive care research worldwide, no drug or other therapeutic measure has achieved a comparable reduction.

Objective

The aim of TELnet@NRW is to establish and evaluate a telemedical inpatient-outpatient network (24/7/365) to improve the application of evidence-based medicine in infectious disease management, especially the management of sepsis. We hypothesized that the establishment of a digital network based on expert teleconsultations increases treatment quality in inpatient and outpatient care for these 2 subspecialties.

Methods

Trial Design and Ethics Approval

TELnet@NRW was a multicenter, stepped-wedge cluster randomized trial conducted at 2 university hospitals (Aachen and Muenster), 17 hospitals and 103 outpatient physicians' offices associated with 2 physician networks. The protocol is publicly available [21], and the trial was prospectively registered at ClinicalTrials.gov (NCT03137589). The Ethics Committee of the Medical Faculty of the RWTH Aachen approved the study (EK 068/17). The study was funded by the Innovation Fund of the Federal Joint Committee (February 2017 to January 2020, funding code 01 NVF16010). Independent researchers from the Department of Health Economics and Health Care Management at Bielefeld University conceptualized and performed the analyses. The reporting of this trial is in line with the CONSORT-EHEALTH (Consolidated Standards of Reporting

Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist [22].

Inpatient and Outpatient Participants

Inpatients, aged ≥ 18 years, who had *Staphylococcus aureus* bacteremia or required intensive care treatment and who provided written informed consent were eligible for inclusion.

Outpatients, aged ≥ 18 years, with a possible infectious presentation based on the International Classification of Primary Care, who provided written informed consent were eligible for enrollment. Measles vaccination rates in children were also evaluated.

Because of the complexity and diversity of possible diagnoses and the extremely high total number of patients during the entire study period, triage for study enrollment was carried out by the attending physician on-site.

We excluded minors and patients who did not formally consent to participate in the study. In addition, patients who were in a dependent or employment relationship with the sponsor or one of the investigators or the principal investigator and patients who lived in an institution as mandated by a legal or administrative order were excluded from the study.

Technical Requirements

Initially, the standardized technical requirements at each participating site were established in line with the relevant guideline recommendations [23]. This also included setting up a wireless local area network in hospitals and medical practices. A secure, privacy-compliant infrastructure was used for communication, including 2 high-encryption audio-video conference systems and the certified data exchange platforms *FallAkte Plus* (Healthcare IT-Solutions) and *ELVI* (CompuGroup Medical), which complied with the General Data Protection Regulation (EU Regulation 2016/679). Overall, our data protection measures were externally reviewed by independent data protection experts and continuously monitored throughout the study. The video conferencing infrastructure met high requirements in terms of quality, data security and portability. This infrastructure operated in a high-security, closed network (hardware virtual private network) or on dedicated lines.

Interventions: Expert Teleconsultations Plus Advanced Training Courses

The innovative telemedical network TELnet@NRW involved outpatient-inpatient cooperation. Separate facilities (hospitals of different levels of care and outpatient physicians' offices) established a new digital health care structure for North Rhine-Westphalia, Germany. TELnet@NRW provided expert knowledge from 2 university hospitals to participating hospitals and outpatient physicians through expert teleconsultations (24/7/365 availability). Expert teleconsultations were provided on request after the initial triage was carried out by the attending physician on-site. Consultants for intensive care medicine participated in key care processes 24/7, whereas infectious disease specialists were available once weekly and on demand, including participation in rounds, additional expert teleconsultations, emergency consultations, and audits of clinical

patient data. Before implementation of the expert teleconsultations, participants received advanced training courses on guideline-compliant treatment.

Study Schedule and Data Collection

All clusters went through three different study phases: During the preintervention phase, pseudonymized patient data from routine care was documented (details are provided in [Multimedia Appendices 1](#) and [2](#), with the preintervention phase shown in red). During the subsequent transition phase (shown in white), the required hardware infrastructure was set up at the different study sites. Then, participants received on-site training according to their cluster schedule. To familiarize participants with the new processes, expert teleconsultations were already provided during the transition phase. Data on the effects of the intervention were collected during the following intervention phase (shown in blue). Primary data were generated using standardized case reporting forms. For the analyses of influenza and measles vaccination rates, we used routine outpatient claims data from the Association of Statutory Health Insurance Physicians (AHIP).

Outcomes

The primary outcome measure was adherence to the 10 *Choosing Wisely* recommendations for infectious diseases provided by the German Society for Infectious Diseases, which are applicable to both inpatient and outpatient care; these contain 5 *Dos* and *Don'ts* for infectious disease management (for each definition, please refer to [Multimedia Appendix 3](#)) [15]. Notably, the first 2 *Dos* address important quality indicators in intensive care medicine as they are associated with lower mortality [12,20,24,25]. For improved overview, [Textbox 1](#) shows the 10 *Choosing Wisely* recommendations sorted by their applicability to the inpatient and outpatient sector.

Secondary outcome measures for the inpatient sector were rate of sepsis therapy in compliance with guidelines (in compliance with the Surviving Sepsis Campaign guidelines for the management of severe sepsis and septic shock, defined as adherence to the 3- and 6-hour sepsis bundles [9]); rate of acute respiratory distress syndrome (ARDS) therapy in compliance with guidelines (measured against the evident ventilation targets, ventilation with low ventilation volumes, and low peak pressures; with controlled ventilation; breath volume of 6 mL/kg calculated ideal body weight; positive end-expiratory pressure setting in proportion with the necessary FiO₂; and plateau pressure <30 cm H₂O [26]); and ICU and sepsis-related mortality, hospital mortality, ICU length of stay (LOS) and hospital LOS, rate of patients with dialysis at discharge from the ICU, and rate of transfer transport (defined as rate of patients discharged to another hospital).

Secondary outcome measures for the inpatient sector were health-related quality of life (measured using the 36-Item Short Form Survey version 2.0 questionnaire).

In our protocol, the 3 process variables *rate of sepsis diagnosis*, *rate of ARDS diagnosis*, and *rate of undiagnosed sepsis* were listed as part of the secondary outcomes. We corrected this in the report. All process variables are now reported as such.

Textbox 1. Primary outcome sorted by sector.

<p>Primary outcome inpatient sector: adherence to the following <i>Choosing Wisely</i> recommendations</p> <ul style="list-style-type: none"> • “<i>Staphylococcus aureus</i> bloodstream infection imperatively needs efficacious antimicrobial treatment and identification and elimination of the source of infection” [P1] • “In critically ill patients with signs of infection, early appropriate antibiotic therapy is crucial after obtaining cultures, and treatment should be regularly re-evaluated” [P2] • “Prescribe oral forms of highly bioavailable antimicrobial agents to patients who can reliably receive and absorb medications via the enteral route” [P5] • “Do not treat asymptomatic bacteriuria with antibiotics” [N2] • “Do not treat <i>Candida</i> recovered from respiratory or gastrointestinal tract specimens” [N3] • “Do not extend the administration of prophylactic antibiotics after surgery (after the patient has left the operating room)” [N4] • “Do not treat elevated C - reactive protein or procalcitonin levels in serum with antibiotics in patients not presenting signs or symptoms of infection” [N5] <p>Primary outcome outpatient sector: adherence to the following <i>Choosing Wisely</i> recommendations</p> <ul style="list-style-type: none"> • “Annual influenza vaccination should be given to individuals aged >60 years, patients with specific comorbidities, and people (eg, health care workers) who may infect vulnerable persons” [P3] • “All children should receive the measles vaccine, and adults born after 1970 without prior documented vaccination against measles should get at least one dose of the vaccine” [P4] • “Avoid prescribing antibiotics for uncomplicated upper respiratory tract infections including bronchitis” [N1] • “Do not treat asymptomatic bacteriuria with antibiotics” [N2]
--

Randomization and Masking

Participating hospitals and outpatient physician offices were randomly assigned to 4 clusters of 4 to 5 hospitals and 4 clusters of 23 to 28 outpatient physicians’ offices ([Multimedia Appendices 1 and 2](#)). Participants were randomly assigned to one of the clusters with different start dates for the intervention phase by an independent statistician using a computer-generated random allocation sequence. It was not possible to mask the health care staff or patients, as they were involved in the delivery of the intervention.

Statistical Methods

Primary outcomes were evaluated using binary logistic regression models (primary data) and zero-or-one inflated beta regression models (AHIP data).

In the analyses of the inpatient data, we controlled for the treating hospital, patient age, and the Sequential Organ Failure Assessment (SOFA) score at enrollment in the study [27]. SOFA scores were calculated based on the data in routine clinical patient records. Missing baseline values for the different SOFA subscores were imputed, if available, by measurements within the first 3 days after enrollment (next observation carried backward) [28]. Only patients with complete SOFA scores (ie, measurements for all 6 subscores) at baseline were included in the analyses.

To differentiate the training effect and the external effect of expert teleconsultations from the direct counseling effect, the intervention group was separated into patients with and without expert teleconsultations, as not all patients who received interventions were treated with expert teleconsultations. Models for ICU and sepsis-related mortality and sepsis bundle

compliance were specified in the same manner. Effects on the LOS were estimated using linear, gamma, and log-linear regression models with the same control variables.

In the evaluation of the primary outpatient data, we controlled for the treating outpatient physician and patient age. Three different models were estimated for each outcome:

- Model 1 contained only the group variable (group) and the control variables.
- In addition, model 2 contained a count variable (n) that recorded the number of expert teleconsultations the outpatient physician had already used before the visit with the respective patient.
- Finally, model 3 contained a quadratic term of the count variable (n²) to map possible learning curves among outpatient physicians in the sense of a decreasing marginal utility of the expert teleconsultations.

In the AHIP data, influenza and measles vaccination rates were documented quarterly at the practitioner level. To isolate the effect of the intervention on the vaccination rates, we controlled for the treating practitioner, the number of patients during the quarter and seasonal or quarterly effects.

Baseline group differences were tested using odds ratios (ORs) for binary variables or 2-tailed *t* tests for metric variables. Data cleaning and statistical analyses were performed in *R* (R Foundation for Statistical Computing; version 3.6.3) using the functions *glm* for logistic models and *gamlss* for beta regression models. CIs for regression estimates were computed using the *confint* command from the *stats* package, which calculated the CIs based on profile likelihood estimation. All analyses were based on a significance level of $\alpha=.05$. The model structures are detailed in the [Multimedia Appendix 4](#).

Results

Overview

A total of 17 hospitals and 103 outpatient physicians underwent randomization. The participating hospitals had between 101 and 449 beds; participating ICUs had on average 10 ICU beds (range 5-14) and were mixed medical-surgical ICUs staffed with anesthesiologists and internists. Hospitals were in both urban and rural areas. Of the 17 hospitals, 8 (47%) served populations <50,000; 7 (41%) served populations from 50,000 to 100,000; and 2 (12%) served populations >250,000. Most

outpatient physicians were in urban areas with a high outpatient physician density per capita. Among the participating doctors, multiple specialties were represented, and the majority were general practitioners, internists, ophthalmologists, or gynecologists. Between May 3, 2017, and September 30, 2019, we enrolled patients (n=159,424) who required infectious disease or intensive care treatment in our study ([Figure 1](#)). Overall, we provided 8505 inpatient expert teleconsultations. For outpatients, the average teleconsultation rate was 1.33% (1980/148,839). In the following, we report first the results of the inpatient sector and then the results of the outpatient sector.

Figure 1. Study flow diagram.

Inpatient Study Enrollment

After initial triage by the attending physicians, we enrolled 10,585 inpatients ([Multimedia Appendix 5](#)). The baseline characteristics of the inpatients are detailed in [Table 1](#). A total of 0.57% (60/10,585) of the patients with incomplete data were excluded from the analysis, and we provide details on the distribution of missing values before and after imputation ([Multimedia Appendix 6](#)). For the recommendation *Staphylococcus aureus* bloodstream infection imperatively needs efficacious antimicrobial treatment and identification and elimination of the source of infection, the SOFA score was not

included in the statistical model, as we mainly observed non-ICU patients for this outcome, for whom the relevant parameters to calculate the score are not routinely recorded.

Compared with those in the control group, inpatients in the intervention group were older (mean age 69.25 years in the control group vs 72.14 years in the intervention group) and had higher SOFA scores at baseline (mean SOFA 3.58 in the control group vs 4.12 in the intervention group). The higher morbidity in the intervention group also manifested itself in a higher sepsis rate (5% vs 9%) and a higher ARDS rate (13% vs 17.9%). For the outcome-specific analysis samples, we found no fundamental deviations from the characteristics of the overall sample.

Table 1. Inpatient characteristics.

Inpatient Primary Outcomes

We found significant between-group differences in the management of *Staphylococcus aureus* bloodstream infections (*Staphylococcus aureus* bloodstream infection imperatively needs efficacious antimicrobial treatment and identification and elimination of the source of infection, P1). As expert teleconsultations were provided to all patients in this analysis, we did not divide the intervention group to estimate the effects of the intervention on this recommendation. Patients in the intervention group were significantly more likely to be treated in accordance with the recommendation (OR 4.004, 95% CI 1.828-9.202; $P=.001$; Table 2).

The direct effect of expert teleconsultations became also evident in the treatment of critically ill patients with severe sepsis and septic shock. We found significant between-group differences for the recommendation *In critically ill patients with signs of infection, early appropriate antibiotic therapy is crucial after obtaining cultures, and treatment should be regularly re-evaluated* (OR 6.822, 95% CI 1.271-56.607; $P=.04$; Table 2). However, patients in the intervention group who did not receive expert teleconsultations also received treatment that was more in line with the guideline recommendation than that received by the control group. Notably, across all included patients diagnosed with severe sepsis and septic shock, adherence to this recommendation was negatively associated with patient age (Table 2).

We found no significant intervention effects for the recommendation *Prescribe oral forms of highly bioavailable antimicrobial agents to patients who can reliably receive and absorb medications via the enteral route* (Table 2).

Regarding the recommendations *Do not treat asymptomatic bacteriuria with antibiotics* ($n=24$) and *Do not treat Candida recovered from respiratory or gastrointestinal tract specimens* ($n=32$), we had too few observations to generate logistic regression models (Table 2).

Regarding the extension of the period of treatment with prophylactic antibiotics after surgery once a patient has left the operating room, we observed a higher guideline adherence in patients in the intervention group who did not receive expert teleconsultations than in patients in the control group (OR 9.372, 95% CI 1.519-111.467; $P=.04$; Table 2). However, the estimated coefficient for the portion of the intervention group who directly received expert teleconsultations remained statistically nonsignificant.

Furthermore, no significant intervention effects could be found for the recommendation *Do not treat elevated C - reactive protein or procalcitonin levels in serum with antibiotics in patients not presenting signs or symptoms of infection* (Table 2). It should be noted that the latter was already fulfilled in 90% (531/590) of the control cases.

^bPrimary outcome P1: Imperatively start antimicrobial treatment and remove the focus on *Staphylococcus aureus* bloodstream infection.

^cPrimary outcome P2: Critically ill patients with signs of infection need early appropriate antibiotic therapy.

^dPrimary outcome P5: Prefer oral formulations of highly bioavailable antimicrobials whenever possible.

^ePrimary outcome N4: Do not prolong prophylactic administration of antibiotics in patients after they have left the operating room.

^fPrimary outcome N5: Do not treat an elevated C - reactive protein or procalcitonin level with antibiotics in patients without signs of infection.

^gOR: odds ratio.

^hSOFA: Sequential Organ Failure Assessment.

ⁱDue to differences model specifications, the respective variables were not included in all models.

^jN/A: not applicable.

^kRef: reference group.

Inpatient Secondary Outcomes

Significant between-group differences were also found in the adherence to the 3- and 6-hour sepsis bundles for patients with the diagnoses of severe sepsis and septic shock (Figure 2 and Multimedia Appendix 7). Overall (0-6 hours), patients in the intervention group with expert teleconsultations outperformed the controls with regard to sepsis bundle compliance (OR 7.739, 95% CI 2.379-28.026; $P=.001$). This was mainly driven by an

improvement in compliance with the 4 to 6-hour bundle. With expert teleconsultations, the odds of being treated in accordance with the guideline recommendations in the 4- to 6-hour therapy course after receiving a diagnosis of sepsis were 14.2 times higher (OR 14.245, 95% CI 3.121-85.424; $P=.001$) than in the control group. Overall and for the 3- and 6-hour sepsis bundles, we found significant improvements in compliance for patients in the intervention group who did not receive direct telemedical treatment support.

Figure 2. Sepsis bundle compliance over time.

Regarding treatment quality in patients with mild ARDS, the descriptive analysis showed an increase in compliance from 7.4% (16/217) in the control group to 18.4% (9/49) in the intervention group without expert teleconsultations and 11.8% (19/161) in the group with expert teleconsultations. In the logistic regression model, a significant OR of 3.621 (95% CI 1.256-10.319; $P=.02$) was obtained for patients without expert teleconsultations. Patients with expert teleconsultations also showed a significantly increased chance of correct treatment mild ARDS (OR 2.355, 95% CI 1.023-5.516; $P=.04$). For patients with moderate or severe ARDS, we could not demonstrate these effects. A detailed description of this outcome is presented in [Multimedia Appendix 8](#).

Regarding ICU mortality (OR 1.276, 95% CI 0.909-1.794; $P=.16$) and sepsis-related mortality (OR 0.680, 95% CI 0.230-10.874; $P=.37$), no statistically significant intervention effects were found in our model estimations; however, a reduction in the sepsis-related mortality rate of 5% was achieved (19/66, 28.8% in the control group vs 50/210, 23.8% in the intervention group). Also, no significant improvements with regard to hospital mortality were observed.

ICU LOS was significantly longer for intervention patients with (+1.971 days, 95% CI 1.858-27.708; $P=.004$) and without (+2.253 days, 95% CI 2.235-40.535; $P=.002$) expert teleconsultations than for the respective controls. Regarding hospital LOS, it is noticeable that patients in the control group were hospitalized longer (mean 16.3 days, 95% CI 15.65-16.97 days) than patients in the intervention group without expert teleconsultations (mean 14.15 days, 95% CI 12.96-15.35 days) but for shorter periods than patients with expert teleconsultations (mean 20.62 days, 95% CI 19.55-21.70 days). The linear regression model confirms this result for patients with expert

teleconsultations. These patients stayed on average 4.6 days ($\beta=4.610$ days, 95% CI 3.316-5.905 days; $P<.001$) longer in hospital than control patients. For the group of patients without expert teleconsultations, there was no significant difference to the control group.

A total of 0.3% (6/1983) of the patients in the control group and 1.1% (8/739) in the intervention group were discharged from hospital on dialysis. With this very low prevalence, effects of any intervention cannot be shown.

Overall, 4.38% (86/1965) of the patients in the control group were transferred to another hospital during our study. In the intervention group, this proportion was 11.34% (143/1261). Patients with expert teleconsultations were transferred more frequently (101/857, 11.8%) than patients in the intervention group without expert teleconsultations (42/404, 10.4%). The model calculation also shows a significant intervention effect. Patients who received an expert teleconsultation had a 2.9-fold higher chance of being transferred (OR 2.903, 95% CI 2.012-4.186; $P<.001$). In patients in the intervention group without expert teleconsultations, this chance was also significantly increased compared with that in the control group (OR 2.432, 95% CI 1.570-3.721). Overall, the analyses thus show an increase in the number of transfers owing to the intervention.

Outpatient Study Enrollment

In the outpatient sector, 148,839 patients were enrolled in our study. The intervention group differed significantly from the control group with regard to their distribution between the 2 physician networks. Baseline characteristics are detailed in [Table 3](#), and [Multimedia Appendix 9](#) provides details concerning study enrollment.

Table 3. Outpatient characteristics.

Outpatient characteristics	Control group	Transition group	Intervention group	Intervention group versus control group	
				Difference (95% CI)	P value
Patients, mean (SD)	47,250	67,650	33,939	N/A ^a	N/A
Age (years), mean (SD)	42.08	40.50	42.20	0.12 (–0.4538 to 0.2208)	.49

^aN/A: not applicable.^bMuM: Medizin und Mehr eG.^cGKS: Gesundheitsnetz Köln-Süd eV.

Outpatient Primary Outcomes

Use of expert teleconsultation was associated with a significantly higher degree of adherence to the guideline recommendations for antibiotic therapy. Overall, the treatment of patients in the intervention group was significantly more compliant than that in the control group with regard to the *Choosing Wisely* recommendation for the treatment of uncomplicated upper respiratory tract infections (N1; OR 1.343, 95% CI 1.155–1.562; $P=.001$; model 1). This effect was significantly influenced by the number of expert teleconsultations conducted, as indicated by the estimated coefficient of the count variable (OR 1.007, 95% CI 1.001–1.013; $P=.04$; model 2). In addition, the estimated coefficient for the quadratic term of the count variable showed a statistically significant negative effect, which illustrates the decreasing marginal utility of the expert teleconsultations (OR 0.9998, 95% CI 0.9996–0.9999; $P=.001$; model 3). Here, we also observed an accumulation of noncompliance in the treatment of older patients (Table 4).

Our telemedical inpatient-outpatient network also achieved significant results with regard to the management of asymptomatic bacteriuria (N2). Patients in the intervention group were more likely to be treated in line with the guideline

recommendations than were the controls (OR 9.312, 95% CI 3.794–25.936; $P<.001$; model 1). This effect was influenced more by the number of expert teleconsultations conducted than by the training of the treating physicians (OR 1.533, 95% CI 1.212–2.190; $P=.004$; model 2). Although not statistically significant, we also observed a trend toward a decreasing marginal utility of the expert teleconsultations with regard to this outcome (model 3). The *Choosing Wisely* recommendations also provide advice for increasing influenza (P3) and measles vaccinations (P4). For these analyses, we examined the quarterly vaccination rates at the physician level during the study period. In our basic model, we found no significant effect of expert teleconsultations on influenza vaccinations (rate ratio 1.089, 95% CI 0.911–1.302; $P=.34$). However, to better capture seasonal effects on the vaccination rates, we additionally constructed a model in which we extended the observation period and considered the transition phase as part of the intervention phase because the expert training occurred at the end of the control phase. In this model, intervention physicians had significantly higher influenza vaccination rates (rate ratio 1.204, 95% CI 1.079–1.344; $P=.001$). Regarding measles vaccination rates, we found no significant intervention effects in either model.

^aEach model also controlled for physician-specific effects, which are not reported individually in this table; CIs were calculated based on profile likelihood estimation.

^bOR: odds ratio.

^cPrimary outcome N1: Avoid prescribing antibiotics for uncomplicated upper respiratory tract infections.

^dN/A: not applicable.

^eRef reference group.

^fDue to the different model specification, the respective variables were not included in all models.

^gPrimary outcome N2: Do not treat asymptomatic bacteriuria with antibiotics.

Outpatient Secondary Outcome

We had planned to assess health-related quality of life in outpatients measured with the 36-Item Short Form Survey version 2.0 questionnaire. Completed questionnaires from a total of 540 patients were available for the initial survey time t0 (study enrollment). This corresponds to 0.4% (540/148,839) of the patients included in the outpatient study. Of the 540 patients, 72 (13.3%) were eligible for a further survey after 3 or 12 months, as the contact data required for a renewed contact were collected for them at t0. The response rates in the follow-ups for these 72 patients were 32% (n=23) for t1 and 28% (n=20) for t2. An analysis of changes over time did not appear to be appropriate based on the low response rates for t1 and t2, and no analysis was performed.

Discussion

Summary of Main Findings

To the best of our knowledge, TELnet@NRW is the largest telemedical cluster randomized controlled study in Europe, with

more than 150,000 patients. We established a telemedical inpatient-outpatient network as a novel digital structure in the health care system, and we found that it measurably improved the quality of patient care. The consistent introduction and implementation of standardized communication using a certified electronic patient record was a feature that was essential for increasing the effectiveness of the processes involving the new digital health network. The key findings of this study suggest that expert teleconsultation is an effective tool to provide inpatient and outpatient physicians with evidence-based expertise on a large scale, thus improving guideline compliance and the quality of infectious disease and intensive care management.

Concerning the inpatient primary outcomes, our telemedical intervention had significant quality-improving effects on the management of *Staphylococcus aureus* bloodstream infections (P1), severe sepsis and septic shock (P2), and prophylactic antibiotic therapy (N4). Quality improvements for several outcomes reached not only those patients who were treated with direct expert teleconsultations but also other patients treated by

the same physicians. This finding can be interpreted as a positive effect of the initial training courses and/or an indirect effect of the expert teleconsultations. It can therefore be assumed that the treating physicians also apply the knowledge acquired in teleconsultations to patients whose treatment is carried out without telemedical support.

In the outpatient sector, our telemedical intervention significantly increased guideline compliance in the management of uncomplicated upper respiratory tract infections (N1) and asymptomatic bacteriuria (N2). The chance of being treated according to the recommendations was positively associated with the number of teleconsultations already participated in by the outpatient physician before the respective patient visit. Furthermore, we found evidence for a decreasing marginal utility of these teleconsultations, which may reflect the physicians' learning curve. To obtain a better understanding of physicians' learning behavior and the associated practical implications, studies with longer observational periods are needed. Basic analyses of influenza and measles vaccination rates uncovered no significant intervention effects. However, when considering the initial transition phase as part of the intervention phase, influenza vaccination in the intervention group increased significantly. This could be explained either by the better statistical control of seasonal effects (as more observation quarters were included) or by the fact that the effects were larger immediately after the start of the intervention. The latter would indicate that the transition period was probably too long to capture the full potential of our intervention. Nevertheless, as this analysis deviates from the original study plan, it can only be interpreted as exploratory.

With regard to our secondary outcomes analyzed for the inpatient sector, we found that the provision of expert teleconsultations led to a higher overall sepsis bundle adherence, which was mainly driven by improvements in compliance with the 4- to 6-hour bundle. However, although the direct relationship between sepsis bundle compliance as a quality-of-care indicator and mortality is well documented in the scientific literature [10-15,20,29], we did not observe significant intervention effects on ICU mortality, sepsis-related mortality, or hospital mortality.

Although its cross-sectoral applicability was an argument for selecting compliance with the *Choosing Wisely* recommendations as the primary outcome of this study, parts of these recommendations are not applicable to both inpatient and outpatient care, especially the ICU setting. Because gastrointestinal function is very often impaired in patients in the ICU and therefore the absorption of oral medications cannot be guaranteed, most medication is administered intravenously. Likewise, obtaining tracheal secretions and microbiological tests is a rarity in the outpatient sector, as the therapeutic consequence outside of serious infections is very low. As most patients in the ICU have an indwelling urinary catheter and are sedated, the criterion *asymptomatic* cannot be evaluated in the context of bacteriuria. Notably, the compliance with abstaining from treating elevated C - reactive protein or procalcitonin levels in the serum with antibiotics in patients without signs or symptoms of infection was already 90% (531/590) in the control phase. In summary, 40% (4/10) of *Choosing Wisely*

recommendations for infectious disease management are not fully applicable to ICU care.

Within the real-world setting of our trial, it was at the discretion of the practitioners for which patients an expert teleconsultation was requested. Hence, attending physicians tended to include patients thought to be more ill during the intervention phase of the study, which is reflected by the higher SOFA scores, sepsis, and ARDS incidences for inpatients in the intervention phase compared with those in the control phase. We controlled for such selection effects by including relevant variables in our regression models, but we could not rule out the presence of unknown confounders for which there were no data available. Although our regression models were adjusted for the SOFA score, this may not have fully controlled for the differences in the baseline risks of morbidity and mortality between the study groups. It is unclear to what extent this problem has been aggravated by the frequent occurrence of missing values for the different SOFA subscores and the associated need for data imputation. It should be highlighted that TELnet@NRW was not designed or powered to detect differences in sepsis-related mortality because the primary outcome focused on quality indicators for infectious disease management ([Multimedia Appendix 3](#)). Nevertheless, in the treatment of patients with sepsis, the early detection of sepsis followed by the early initiation of therapy conforming to the recommendations in the guidelines significantly improves the clinical outcomes [8,10,20,24,30]. Hence, if expert teleconsultations continue to be part of routine health care, we expect that this will also have a positive effect on mortality in ICUs, as has been reported in similar trials in the past [12,20,24]. The equivalent is well documented in the literature regarding adherence to evidence-based management of *Staphylococcus aureus* bacteremia. Guideline adherence significantly improves clinical outcomes and reduces mortality [31-35].

As Hemming et al [36] note, control for secular effects plays a crucial role in stepped-wedge trials. However, especially the need for an appropriately long transition phase to implement the intervention at the participating sites impeded an adequate mapping of time in our statistical models. To address this shortcoming, we estimated secular effects on our inpatient primary outcomes under consideration of transition phase data in a secondary analysis. Our models incorporate time in two ways: (1) the days since the beginning of the study (ie, the beginning of the control phase) and (2) the days since the beginning of the transition phase. Results of the estimations are displayed in the [Multimedia Appendix 10](#). For most of the primary outcomes, we observed no significant time effects (P5, N4, and N5). The estimation for P2 shows (1) a significant negative overall time effect and (2) a significant positive effect since the beginning of the implementation of the intervention. Thus, we conclude that our intervention was a major driver of the observed improvements and that our primary model without time variables may rather tend to underestimate the intervention effects. For outcome P1, however, the estimation shows significant time effects pointing in the opposite direction. It can be assumed that the negative time effect observed since the beginning of the transition phase is largely due to implementation difficulties in the participating normal wards.

However, we cannot rule out that the intervention effects measured in the primary evaluations were overestimated owing to a possible time trend.

Limitations

Overall, the findings of this study should be interpreted in the context of its limitations. The participating hospitals, ICUs, and outpatient physicians were not chosen at random; instead, the 17 sites and 103 outpatient physicians were self-selected based on their willingness to participate in a study to improve patient care. However, we chose a randomized stepped-wedge design to control for clinical characteristics, demographics, and setting to protect our findings against bias. Nevertheless, our results should be interpreted with the consideration of the possibility for selection bias due to the on-site triage of patients. We controlled for such selection effects by including relevant variables in our regression models, but we could not rule out the presence of unknown confounders for which there were no data available. We also acknowledge potential bias related to secular trends in care given the fact that the control and intervention clusters did not overlap in time. Furthermore, for some outcomes, the real effect size remained uncertain, which is reflected by the large CI. This holds true especially for sepsis bundle compliance. Nevertheless, there is sufficient certainty that the associated ORs were >1 ; thus, intervention effects existed.

Conclusions

Despite the mentioned limitations, TELnet@NRW robustly demonstrated that a cross-sectoral health network, as a new digital structure in the health care system, can develop into a quality network that operates under the premise that cross-sectoral and interregional cooperation can significantly improve evidence-based care. On the basis of the technical equipment, the principles of TELnet@NRW are transferable from intensive care medicine and infectious disease management to other subspecialist medical fields that mostly rely on expert knowledge. Thus, the concept of TELnet@NRW can be adapted to other patient populations, other conditions, or other areas, in which expertise rather than equipment needs to be transported over large distances. Our results must also be interpreted in light of the most recent SARS-CoV-2 pandemic; a digital inpatient-outpatient health network is well suited to meeting pressing challenges faced by health care systems, which we will have to address in the future (eg, staff shortages in health care sectors, lack of experts in the geographic area, and aging societies). However, further research is needed with regard to the long-term patient-relevant effects of our telemedical solution and its cost-effectiveness especially in less complex cases in the outpatient setting.

Acknowledgments

The authors thank all the patients who participated in the study and the clinical and research staff at all the participating sites, without whose assistance the study would never have been completed. The authors wish to thank all members of the TELnet@NRW study group, who are listed in [Multimedia Appendix 11](#). The authors also thank Kassenärztliche Vereinigung Nordrhein and Kassenärztliche Vereinigung Westfalen Lippe for their support of TELnet@NRW.

The funder of the study had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Authors' Contributions

GM, KS, SWL, RD, SD, DB, CJ, and AP contributed to the study concept and design. GM, KS, RD, CJ, JE, AG, CL, SWL, MH, FJ-K, SD, DB, HS-S, SR, JK, and AP contributed to data acquisition. WG, DG, SE, and AP conceptualized and performed the statistical analysis. GM, KS, RD, WG, DG, SE, SD, AP, and CB contributed to data interpretation. GM, SD, CB, DG, SE, and WG wrote the report, with critical revision for important intellectual content by all other coauthors. All authors read and approved the final manuscript. GM supervised the study.

The corresponding author had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Conflicts of Interest

GM is the coordinator of the S1 Guideline Telemedicine in Intensive Care Medicine and chairman of the German Society for Telemedicine (DGTelemed). In the past, he has given lectures for Philips. GM is cofounder of Clinomic GmbH. WG, SE, and DG report grants from the Federal Joint Committee (Gemeinsamer Bundesausschuss), during the conduct of the study. AP is a cofounder of Clinomic GmbH. The authors declare no other competing interests.

Abstract

Background: Smoking cessation (SC) interventions may contribute to better treatment outcomes and the general well-being of cancer survivors.

Objective: This study aims to evaluate the effectiveness, cost-effectiveness, and cost-utility of a digital interactive SC intervention compared with a noninteractive web-based information brochure for cancer survivors.

Methods: A health economic evaluation alongside a pragmatic 2-arm parallel-group randomized controlled trial was conducted with follow-ups at 3, 6, and 12 months. The study was conducted in the Netherlands over the internet from November 2016 to September 2019. The participants were Dutch adult smoking cancer survivors with the intention to quit smoking. In total, 165 participants were included and analyzed: 83 (50.3%) in the MyCourse group and 82 (49.7%) in the control group. In the intervention group, participants had access to a newly developed, digital, minimally guided SC intervention (MyCourse-Quit Smoking). Control group participants received a noninteractive web-based information brochure on SC. Both groups received unrestricted access to usual care. The primary outcome was self-reported 7-day smoking abstinence at the 6-month follow-up. Secondary outcomes were quality-adjusted life years gained, number of cigarettes smoked, nicotine dependence, and treatment satisfaction. For the health economic evaluation, intervention costs, health care costs, and costs stemming from productivity losses were assessed over a 12-month horizon.

Results: At the 6-month follow-up, the quit rates were 28% (23/83) and 26% (21/82) in the MyCourse and control groups, respectively (odds ratio 0.47, 95% CI 0.03–7.86; $P=.60$). In both groups, nicotine dependence scores were reduced at 12 months, and the number of smoked cigarettes was reduced by approximately half. The number of cigarettes decreased more over time, and the MyCourse group demonstrated a significantly greater reduction at the 12-month follow-up (incidence rate ratio 0.87;

95% CI 0.76-1.00; $P=.04$). Intervention costs were estimated at US \$193 per participant for the MyCourse group and US \$74 for the control group. The mean per-participant societal costs were US \$25,329 (SD US \$29,137) and US \$21,836 (SD US \$25,792), respectively. In the cost-utility analysis, MyCourse was not preferred over the control group from a societal perspective. With smoking behavior as the outcome, the MyCourse group led to marginally better results per reduced pack-year against higher societal costs, with a mean incremental cost-effectiveness ratio of US \$52,067 (95% CI US \$32,515-US \$81,346).

Conclusions: At 6 months, there was no evidence of a differential effect on cessation rates; in both groups, approximately a quarter of the cancer survivors quit smoking and their number of cigarettes smoked was reduced by half. At 12 months, the MyCourse intervention led to a greater reduction in the number of smoked cigarettes, albeit at higher costs than for the control group. No evidence was found for a differential effect on quality-adjusted life years.

smoking cessation; cancer survivors; effectiveness; cost-effectiveness; eHealth

Introduction

Background

In cancer survivors, continued tobacco use is one of the most important risk factors for the development of secondary cancers, iatrogenic effects of cancer treatment, and cancer mortality [1]. The prevalence of smoking among cancer survivors is considerable, estimated at 11.8% for US cancer survivors in 2018 [2], with rates that tend to be higher among women and younger cancer survivors [3,4] and those with low health-related quality of life [5]. In the Netherlands, no difference in smoking prevalence was found between cancer survivors and noncancer survivors after adjusting for sociodemographic variables [6].

Many cancer centers in the United States have not implemented tobacco treatment services [7]; less than half of cancer care providers routinely discuss smoking cessation (SC) medication with cancer survivors [8]; and the delivery of effective SC support to cancer survivors is currently lacking [9,10]. In Europe, the general picture is comparable [11]. At the same time, cancer survivors are generally receptive toward discussions of SC with their health care professionals [3,12,13]. Among patients with head and neck cancer receiving SC counseling, 26% higher SC rates were observed than control groups in a meta-analysis of 3 randomized controlled trials (RCTs) and 3 cohort studies [14]. Distance-based SC support was also found to be more effective in reducing smoking than a range of control conditions [15]. Nayan et al [16] reported that SC interventions delivered in the perioperative period lead to higher quit rates in cancer survivors (odds ratio [OR] 2.31) but found no effect of SC interventions delivered in the cancer clinic. In addition, when considering biochemically validated smoking status, no significant effect of SC interventions was found in cancer survivors [17]. An integrated tobacco treatment program in a cancer setting showed that high abstinence rates of 45.8% at 6 months could be achieved, as demonstrated in a cohort study of 3245 patients (593 had no cancer history) [18], but this was

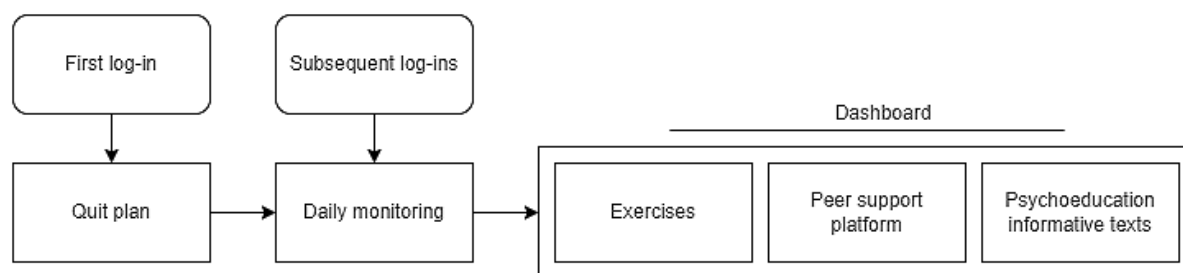

a highly intensive treatment program consisting of in person and telephone sessions spanning 8 to 12 weeks, which not only provided behavioral counseling for SC but also pharmacotherapy and treatment of related mental health conditions. Overall, there is a paucity of literature on SC interventions, specifically for cancer survivors, and the relevant literature shows conflicting outcomes.

Even fewer studies have evaluated the cost-effectiveness of digital SC interventions in the population of cancer survivors. Digital interventions may have the benefit of being scalable, easily accessible, and providing a cost-effective way to support the growing number of cancer survivors [19]. A pilot study demonstrated good acceptability of a digital SC intervention among cancer survivors [20]. A recent meta-analysis [15] indicated that few SC interventions for cancer survivors were digital interventions (2 out of 10), with most being delivered over the telephone. However, the effectiveness and cost-effectiveness of existing digital SC interventions over the internet when specifically tailored to cancer survivors is unclear.

Objectives

It was deemed timely and appropriate to launch a new study evaluating the effectiveness and cost-effectiveness of a recently developed digital intervention with minimal guidance aimed at supporting cancer survivors to quit smoking: MyCourse—Quit Smoking (in Dutch: MijnKoers—Stoppen met Roken; Figure 1 [21]). Details of how the intervention was developed are provided elsewhere [21]. In this study, we aim to answer the following research questions:

1. Is the digital interactive SC intervention *MyCourse—Quit Smoking* more effective than a web-based SC brochure to improve smoking cessation rates?
2. Is the digital interactive SC intervention *MyCourse—Quit Smoking* more cost-effective than a web-based SC brochure in terms of incremental costs per reduced pack-year and incremental costs per quality-adjusted life year (QALY) gained?

Figure 1. Intervention flowchart (adapted from Mujcic et al [21]).

Methods

Design

The effectiveness, cost-effectiveness, and cost-utility of a digital SC intervention for cancer survivors was evaluated in an individual RCT with 2 parallel arms. The trial was conducted in the Netherlands between 2016 and 2019. The first inclusion was on November 4, 2016, and the last inclusion was on September 15, 2018. The last follow-up data were collected on September 24, 2019. The study was prospectively registered in the Netherlands Trial Register (NTR6011) on September 1, 2016. For an extensive description of the study protocol, see the study by Mujcic et al [21]. This study was part of a set of 2 separate RCTs on interventions for SC and alcohol moderation, both targeting cancer survivors. The results of the RCT on the alcohol moderation intervention (MyCourse—Moderate Drinking) will be published separately.

Ethics Approval

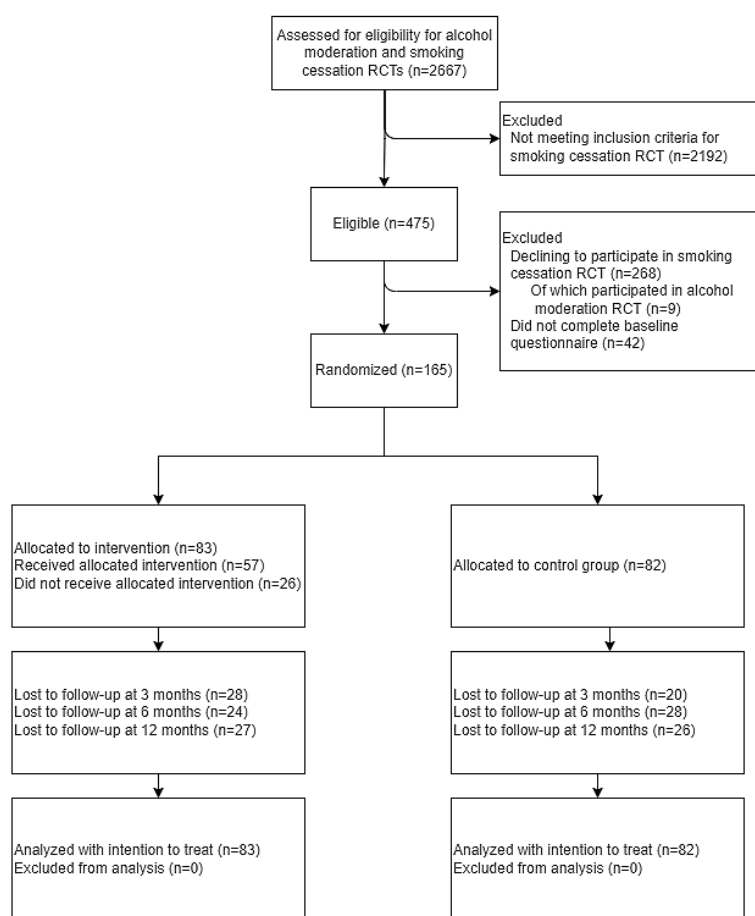

Ethical approval was obtained from an accredited medical research and ethics committee in the Netherlands (Toetsingscommissie Wetenschappelijk Onderzoek Rotterdam e.o. NL55921.101.16).

Participants and Recruitment

A dedicated website was created where participants could inform themselves about the study and apply for participation.

Applicants for the trial were eligible if they were aged ≥ 18 years, diagnosed with any form of cancer in the past 10 years, had a PC or laptop and internet connection at home, had the ability and intention to participate in the 12-month study, smoked ≥ 5 cigarettes per day in the past 7 days, and had the intention to quit smoking cigarettes. Those who had insufficient mastery of the Dutch language; those who were pregnant; or those who self-reported suicidal ideation, acute psychosis, severe alcohol dependence, dementia, or severe depression were excluded. These criteria were assessed using a web-based screening questionnaire on the website. The same screening questionnaire was used for both trials to evaluate the SC and alcohol moderation intervention [21]. Some people were eligible for both the current SC trial and the alcohol moderation trial; they were offered to participate in 1 trial of their choice (Figure 2). None of the participants were allowed to participate in both trials simultaneously.

Recruitment was conducted through web-based and offline strategies. Targeted web-based (social) media and search engine advertisements were pointed to the website and web-based screening questionnaire. SC clinics, oncology departments, and meeting centers for cancer survivors were contacted and offered promotional material (flyers and posters) to help refer cancer survivors to the website.

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) flowchart. RCT: randomized controlled trial.

Procedure

After completing the screening questionnaire on the study's website, applicants were informed by a computer-generated email about their eligibility for study participation. Those eligible were sent an invitation email containing patient information, an informed consent form, and a link to register. They then had 30 days to decide on their participation; during this time, they could contact the research team or an independent physician with questions. Once the informed consent form was digitally signed, the participants completed the baseline questionnaire. Immediately after completion of the baseline measurement, participants were allocated to either the intervention or the control group arm in a 1:1 ratio through adaptive randomization (minimization of baseline imbalance for age, sex, and education level) performed automatically by a server-side PHP script using a Mersenne twister random number generator. Participants received an email confirming their allocation and containing their username and instructions on how to log on. The participants were not blinded to the study group allocation. At 3, 6, and 12 months after randomization, participants received a link to the web-based questionnaire via email. Nonresponders received up to 3 reminder emails and, in case of continued nonresponse, were contacted by telephone. For each completed follow-up assessment, they were reimbursed approximately US \$30. As this was a pragmatic randomized controlled trial, in both groups, patients were allowed to use

additional support (eg, nicotine replacement therapy) if they felt they needed it.

Intervention

MyCourse—Quit Smoking is a newly developed, minimally guided, digital intervention aimed at supporting SC in cancer survivors, based on well-established therapeutic approaches: motivational interviewing, cognitive behavioral therapy, and acceptance and commitment therapy. These approaches have been incorporated into effective SC interventions in the general population [22–24]. Cancer survivors and professionals in eHealth, oncology, and SC were involved throughout the development process. The intervention was accessible through a PC, tablet, and smartphone. At first, log-in participants were guided in setting up a quit plan including a quit date, after which they gained access to 13 exercises, a web-based diary for self-monitoring of tobacco use and contextual cues, information on SC and cancer, and a peer support platform (Figure 1 [21] and Multimedia Appendix 1). Participants could choose to use the intervention whenever they wanted for the duration of the study but were encouraged to log in daily for at least 4 weeks. Elsewhere, we have provided a more extensive description of the intervention and its development [21].

Control Group

Participants in the control group received access to a noninteractive web-based information brochure on the risks of

smoking and tips on how to quit smoking, which they could access whenever they wanted by logging into the website. It contained both general SC information and information specifically relevant to cancer survivors. However, it did not contain any responsive elements of the MyCourse intervention.

Additional Support

Participants in both groups were free to seek additional help if needed and were referred to the National SC Information Line (in Dutch: *Rokeninfo-lijn*) for more information. The use of additional support was retrospectively assessed at follow-up. At the end of the study, at 12 months after randomization, the control group participants also received access to the digital intervention MyCourse—Quit Smoking.

Measures

Baseline

Sociodemographic characteristics and type of cancer were assessed. Tobacco use was assessed by using Timeline Followback (TLFB) self-reports [25] for the number of cigarettes smoked in the past 7 days. Nicotine dependence was assessed using the Fagerström Test for Nicotine Dependence (FTND) [26], a 6-item questionnaire. In participants reporting alcohol use, problematic alcohol use was assessed using the Alcohol Use Disorders Identification Test (AUDIT) [27], a 10-item questionnaire. The Marlowe-Crowne Social Desirability Scale (MCSDS) was used to assess the reliability of the self-reported questionnaire data [28]. QALYs were assessed using the 5-level EuroQol (EQ-5D-5L) [29]. In addition, the Medical Outcomes Study Short Form Survey-36 was administered to calculate the Short Form 6-dimension (SF-6D) quality of life measure [30] using the Brazier algorithm [31].

Follow-up Measurements

At all follow-up measurements, we assessed tobacco and alcohol use by using TLFB self-reports, nicotine dependence by using FTND, productivity and health care costs, QALYs using EQ-5D-5L and Medical Outcomes Study Short Form Survey-36, and the use of other SC support and e-cigarettes. Intervention use variables (eg, number of log-ins and use of major content elements) were collected throughout the study period. At 3-month follow-up treatment, satisfaction was assessed using the German adapted Client Satisfaction Questionnaire (Fragebogen zur Messung der Patientenzufriedenheit, ZUF-8), which was translated into Dutch [32].

Primary and Secondary Outcome Measures

The primary predefined endpoint was 7-day smoking abstinence at the 6-month follow-up, measured by using TLFB self-reports. Those who reported not smoking at all in the past 7 days were considered abstinent smokers (yes or o). Secondary measures included the number of smoked cigarettes in the past 7 days, nicotine dependence as measured by the FTND (range 0-10), treatment satisfaction as measured by ZUF-8 (range 8-32), health care costs, productivity loss, and QALYs.

Costs

Costs were calculated from a societal perspective for the year 2019. Intervention costs included depreciation costs (the

estimated loss of value of an interactive website, as it needs to be updated regularly to keep up with technological advancements and prevent safety issues), costs for hosting the website, and technical support and recruitment costs (which consisted of both advertising costs in web-based and offline media, as well as the costs of printing promotional material), and these were allocated evenly to all participants regardless of intervention use. Recruitment costs were included as they were considered an essential part of the intervention and control condition. Health care costs were calculated by multiplying all reported contacts with health services with the standard unit cost prices for the Netherlands [33]. Health service costs stemmed from contacts with specialized somatic and mental health care and patients' out-of-pocket costs for home care, but travel costs were not included because in both groups the interventions were delivered over the internet. Other health care costs included appointments for physiotherapy, alternative medicine, and social work. Medication costs were valued by multiplying the reported dose of that drug with unit cost price [34]. Productivity loss included costs from absenteeism and presenteeism, calculated according to the friction cost method, meaning productivity losses were limited to a maximum of 85 days after which production losses cease to exist because the sick employee would be replaced by another and using an elasticity factor of 0.8 because there is not a strict 1:1 relation between days not worked and productivity losses. Cost data related to health care use and productivity loss were assessed using the Trimbos and iMTA questionnaire for Costs associated with Psychiatric Illness [35]. Cumulative societal costs over the entire follow-up period of 12 months were calculated as the sum of health care costs and productivity losses. Costs were converted from euros to US dollars using purchasing power parities for the reference year 2019.

Sample Size

A study on an SC intervention among cancer survivors found a quit rate of 30% in the active SC intervention group versus 15% in the SC control group, translating to a relative risk (RR) of 2.14 [36]. A pilot trial of an acceptance and commitment theory web-based SC intervention found a 23% quit rate in the experimental arm versus a 10% quit rate in the control arm, translating to an RR of 2.20 [24]. On the basis of the average of these RRs, an RR of 2.1 was expected, translating into a 21% quit rate in the experimental arm, assuming a 10% quit rate in the control arm at the 6-month follow-up. On the basis of the conventional statistical significance level (Cronbach $\leq .05$), an RR of 2.1 at the 6-month follow-up, 204 participants would yield a power of 0.83 for 1-sided tests or a power of 0.74 for 2-sided tests.

Statistical Analyses

Imputation of Missing Data

All primary and secondary outcome measures were analyzed in accordance with the intention-to-treat principle, except for ZUF-8 (treatment satisfaction). To that end, missing data for primary and secondary outcome measures and costs were imputed using the predictive mean matching method from the mice package in R (R Foundation) [37]. The responses to ZUF-8 were not imputed. For the 2 deceased participants, the smoking

status and number of cigarettes smoked were left missing, and the quality of life (EQ-5D-5L) score and costs were set to 0.

Effect Evaluation

Tobacco abstinence (binary yes or no outcome) was analyzed using a Generalized Linear Mixed Model (GLMM) with a binomial distribution and log link function. Although imputation of missing values is not always deemed necessary when running a GLMM, imputation of missing values before running a GLMM allowed us to consider all variables that could have impacted dropout and not only the variables within a specific model. The number of cigarettes smoked (count data 0, 1, ..., N) was analyzed using a GLMM with a log link function and negative binomial distribution [38]. Included covariates were the minimized variables (gender, age, and education) and the MCSDS (social desirability of responses). Model estimates, ORs, incidence rate ratios (IRRs) or Cohen *d*, 95% CIs, and *P* values were reported. The effect of time on the number of cigarettes was analyzed using an *F* test. Differences between the intervention and control groups on FTND nicotine dependence and ZUF-8 patient satisfaction scores were analyzed using a Linear Mixed Model for the Gaussian distribution with identity as the link function; estimates, 95% CIs, and *P* values were also reported.

Cost-effectiveness Analyses

An economic evaluation was conducted alongside this RCT following the approach of Drummond et al [39] and in concordance with the Consolidated Health Economic Evaluation Reporting Standards statement [40]. QALYs over the entire follow-up period were computed using the Dutch tariff (utility weights) [41] through the area under the curve method; that is, linear interpolation for cumulating the cost over the 12-month follow-up period. The incremental cost-effectiveness ratio (ICER) was calculated as follows: $ICER = (C_1 - C_0) / (E_1 - E_0)$, where *C* refers to costs, *E* refers to effect, and the subscripts 1 and 0 refer to the MyCourse and control groups, respectively. We generated 2500 replicate samples by bootstrap and estimated the corresponding incremental costs and effects for each replicate sample, which were then plotted on a cost-effectiveness plane. In addition to the ICER per QALY gained, the ICER per reduced pack-year was calculated. Pack-years were calculated by multiplying cigarettes smoked in the past week by 52 (weeks

in a year) and dividing by 20 (cigarettes per pack) and 365 (days in a year). We calculated ICERs from the following four perspectives: societal, health care, productivity loss, and intervention cost-only. Cost-effectiveness acceptability curves (CEACs) were graphed to assess the likelihood that the intervention was deemed cost-effective, given a series of willingness-to-pay ceilings for gaining 1 QALY.

Sensitivity Analyses

The negative binomial and binomial analyses of the mice-imputed data constituted the main analyses. We conducted several sensitivity analyses for the effectiveness and incremental cost-effectiveness analyses using QALYs based on the SF-6D (instead of the EQ-5D-5L), using Winsorizing cost outliers, using the Amelia-2 package (R Foundation) instead of the mice-package for imputations, considering a gradual decline in pack-years, and using different statistical models (Multimedia Appendix 1).

Results

Sample Characteristics

The participant flow and retention rates are shown in Figure 2. Of the 2192 ineligible people, 1684 (76.82%) had no diagnosis of cancer in the past 10 years. Of the 475 eligible cancer survivors, 268 (56.4%) declined to participate, 9 (3.4%) of whom chose to participate in our parallel RCT on MyCourse for alcohol moderation, and another 42 (8.8%) cancer survivors did not complete the baseline questionnaire and were, therefore, not randomized. Sociodemographic and other characteristics are reported in Table 1. The participants' mean age was 54.2 (SD 11.2) years, 17.6% (29/165) were men, approximately half were married or living together (93/165, 56.4%), and 30.3% (50/165) had a lower education level. On average, participants had smoked for 34.5 (SD 12.0) years and smoked 100 (SD 51.2) cigarettes per week. Three participants quit smoking between screening and completing the baseline questionnaire (Table 2). Breast cancer (75/165, 45.5%), lung cancer (23/165, 13.9%), uterus cancer (19/165, 11.5%), and head and neck cancer (18/165, 10.9%) were the most frequently reported. There was no difference in the proportion of missing data between groups at any of the time points ($\chi^2_1=0.09$; $P=.77$; Multimedia Appendix 2).

Treatment Uptake and Satisfaction

Overall satisfaction with the SC intervention was highest in the MyCourse group (mean 21.4, SD 4.6) than in the control group (mean 17.3, SD 6.1; Cohen *d*=0.77; $t_{108.8}=4.13$; $P < .001$; [Multimedia Appendix 2](#)). Most participants in the MyCourse group logged in at least once (57/83, 69%). The number of times participants logged in was skewed, with an average of 20 (SD 61.2) and a median of 3 (range 0–384). The average time between the first and last log-in for those who logged in at least once was 105.2 (SD 157.5; median 24) days. Most reported SC support in addition to MyCourse at the 6-month follow-up was nicotine replacement therapy (control group: 25/82, 30%; MyCourse group: 14/83, 17%) and contact with a health care professional (control group: 7/82, 9%; MyCourse group: 3/83, 4%). The use of nicotine replacement therapy was reported more often (18.1% vs 30.5% at 12 months) in the control group than in the MyCourse group ($P = .02$).

Adverse Events

Two deaths occurred in the MyCourse group over the course of the study period, which was reported to the medical research and ethics committee. The cause of death was deemed to be unrelated to the study. No other adverse events were observed.

Incremental Effects

Primary Outcome

At the 6-month follow-up, 28% (23/83) of smokers had quit smoking in the MyCourse group versus 26% (21/82) in the control group ([Table 2](#)). No difference in 7-day abstinence was found between the 2 groups (adjusted OR 0.47, 95% CI 0.03–7.86; $P = .60$) when controlling for social desirability, baseline number of cigarettes used in the last week, gender, age, and education.

Secondary Outcomes

[Table 2](#) and [Figure 3](#) present the effect estimates on the secondary outcomes. In brief, the number of cigarettes smoked in the past week was significantly reduced at all follow-ups and

in both groups compared with baseline ($F_3=51.5$; $P<.001$; Table 2 and Figure 3). At 12-month follow-up, number of cigarettes was reduced by about half in both the MyCourse group, showing an average reduction of 57 cigarettes (57/101.8, 56%), and in the control group, showing an average reduction of 48 cigarettes (48/98.2, 49%; Table 2 and Figure 4). At 12-month follow-up, the reduction of number of cigarettes smoked was significantly greater in the MyCourse group than in the control group (adjusted IRR 0.87, 95% CI 0.76-1.00; $P=.04$). At 3- and 6-month follow-up, the difference in number of cigarettes between groups was not significant.

FTND scores were significantly lower at all follow-ups in both groups compared with baseline scores, whereas the time \times condition interaction was not significant (Cohen $d=0.03$; 95% CI -0.27 to 0.34 ; $P=.95$), indicating no significant difference between the groups over time.

The mean EQ-5D-5L QALYs gained in the intervention group was 0.75 (SD 0.18) and in the control group was 0.78 (SD 0.15). There was no significant effect of treatment on quality of life based on EQ-5D-5L scores ($B=-0.03$, SE 0.03; $P=.26$).

Figure 3. Percentage of quitters in both groups at baseline and during the course of the study. A total of 3 participants quit smoking between screening and completing the baseline questionnaire.

Figure 4. Mean number of cigarettes smoked in both groups at baseline and during the course of the study, including SEs. Error bars show SEs of the mean.

Incremental Costs

Table 3 presents the costs per group and the incremental costs (cost difference between the MyCourse and control groups) per cost item. The intervention costs were estimated at US \$193 per participant in the MyCourse group and US \$74 per participant in the control group. The average health care costs accumulated over the full 12 months follow-up time were US \$14,416 (SD US \$20,604) per participant in the MyCourse group and US \$12,950 (SD US \$17,704) per participant in the

control group, resulting in incremental health care costs of US \$1466 (SD US \$27,165). Cost owing to productivity losses was mainly driven by absenteeism at US \$10,444 (SD US \$17,277) in the MyCourse group and US \$8145 (SD US \$15,750) in the control group, with high within-group variance. Incremental productivity costs per participant were on average US \$1908 (SD US \$23,490). The average cumulative societal costs were US \$3493 (SD US \$38,913) higher in the MyCourse group than in the control group. See **Table 3** for a detailed breakdown of the main cost items and the corresponding SDs.

Table 3. Mean cumulative costs (in US \$) by group and incremental costs.

Cost item	MyCourse; (n=83), mean (SD)	Control; (n=82), mean (SD)	Incremental costs ^a ; mean (SD)
Health care costs	14,416 (20,604)	12,950 (17,704)	1466 (27,165)
Specialized somatic	8418 (11,792)	7180 (10,674)	1238 (15,906)
Specialized psychiatric	2151 (10,143)	1380 (5441)	771 (11,510)
Patient and family costs	1310 (10,034)	1954 (9252)	-644 (13,648)
Other	1533 (2671)	1411 (2518)	122 (3671)
Medication	1358 (3901)	1023 (3254)	335 (5080)
Productivity loss	10,720 (17,345)	8812 (15,841)	1908 (23,490)
Presenteeism	231 (733)	332 (864)	-101 (1133)
Absenteeism	10,444 (17,277)	8145 (15,750)	2299 (23,379)
Unpaid work	451 (1048)	474 (1007)	-23 (1453)
Intervention costs	193 (0)	74 (0)	119 (0)
Total societal costs	25,329 (29,137)	21,836 (25,792)	3493 (38,913)

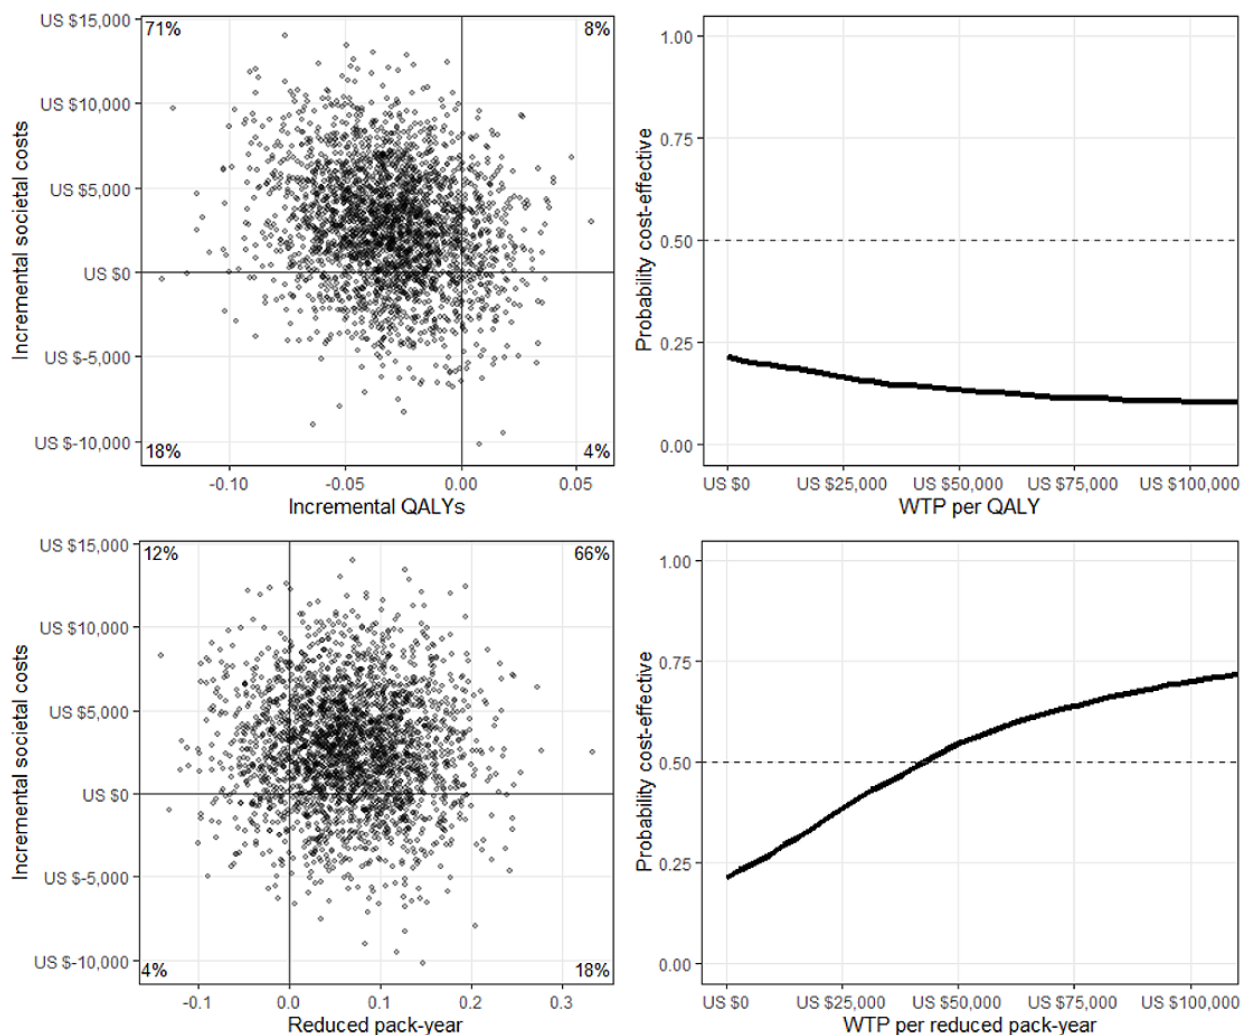

^aCosts in the MyCourse group minus costs in the control group.

Cost-Utility

Participants in the MyCourse group gained fewer QALYs than participants in the control group (0.75 vs 0.78). In addition, the societal costs in the MyCourse group were higher than those in the control group (US \$25,329 vs US \$21,836). In other words,

fewer QALYs were gained against higher costs, which rendered the control group the preferred option, as seen from a cost-effectiveness viewpoint. The cost-effectiveness plane in **Figure 5** shows that there is a 71% likelihood that MyCourse is dominated by the control group.

Figure 5. Cost-effectiveness planes and cost-effectiveness acceptability curves in US \$. Each quadrant in the cost-effectiveness planes represents a different association between the incremental costs (y-axis) and the incremental effects (x-axis) of the MyCourse group compared with the control group. When incremental cost-effectiveness ratios (ICERs) fall in the upper-right quadrant, this represents more effect at higher costs. When ICERs fall in the upper-left quadrant, this represents less effect at higher costs, meaning the MyCourse group is dominated by the control group. ICERs in the lower-right quadrant represent more effect at lower costs: the dominant quadrant. ICERs in the lower-left quadrant represent less effect at lower costs. QALY: quality-adjusted life year; WTP: willingness to pay.

Cost-effectiveness

Participants in the MyCourse group reduced pack-years more than the control group (0.41 vs 0.34) against higher societal costs (US \$25,329 vs US \$21,836). Comparing the difference in total societal costs to the difference in pack-years yielded an ICER of US \$52,067 per reduced pack-year (95% CI US \$32,515-US \$81,346). There is a 66% chance that the

intervention leads to more reduced pack-years at a higher cost (Figure 5). The CEAC based on the societal cost perspective presented in Figure 5 indicates that the intervention will be preferred over the control group when the willingness to pay per reduced pack-years is more than US \$50,000. From an intervention cost-only perspective, ICER per pack-year was calculated to be US \$1772 (95% CI US \$1384-US \$2502). See Table 4 for a breakdown by perspective.

Table 4. Incremental cost-effectiveness ratios between baseline and the 12-month follow-up.^a

Perspective	Incremental costs per reduced pack-year	
	Mean (US \$)	95% CI
Health care perspective	21,851	9179-38,920
Productivity loss perspective	28,444	16,832-44,749
Intervention cost-only perspective	1772	1384-2502
Societal perspective	52,067	32,515-81,346

^aThe incremental cost-effectiveness ratios were calculated as follows: $(C_1 - C_0) / (E_1 - E_0)$, where C refers to costs, E refers to effects, and the subscripts 0 and 1 refer to the experimental and control arms, respectively.

Sensitivity Analyses

Sensitivity analysis of the Amelia 2-imputed data (adjusted OR 3.16, 95% CI 0.17-57.80; $P=.44$) and completers only (ie, those who completed the questionnaires, without imputation; adjusted OR 2.89, 95% CI 0.16-53.18; $P=.47$) showed similar results on the effect of treatment group on tobacco abstinence rates. The Poisson model with correction for overdispersion showed similar results on the effect of treatment on cigarettes smoked at the 12-month follow-up (adjusted B=−0.055, 95% CI −1.05 to −0.04; $P=.03$). Sensitivity analyses of the Amelia-2 imputed data also showed a large effect of time but found no effect of treatment group at the 12-month follow-up (adjusted IRR 0.997, 95% CI 0.82-1.22; $P=.97$). The completers only sensitivity analysis showed a greater reduction in the number of cigarettes in the control group at 6 months (adjusted IRR 1.08, 95% CI 1.01-1.15; $P=.03$), but at 12 months, a greater reduction in the MyCourse group (adjusted IRR 0.88, 95% CI 0.82-0.94; $P<.001$). For the number of cigarettes smoked, the social desirability score was a significant predictor in the Poisson model, but not in the negative binomial model. When QALYs were based on SF-6D scores, results of the economic evaluation remained similar. When Winsorization of extreme costs was applied at the 95th percentile, the cost-effectiveness planes and CEACs remained similar, but ICER per pack-year was lower at US \$31,342 (95% CI US \$17,912-US \$50,007). When the gradual decline in the number of pack-years was accounted for, ICER per pack-year was higher (US \$68,267, 95% CI US \$42,293-US \$111,044) and the cost-effectiveness planes comparable (Multimedia Appendix 3). Overall, the sensitivity analyses attested to the robustness of the findings in the main analysis.

Discussion

Principal Findings

This study evaluated the effectiveness and cost-effectiveness of MyCourse, a digital SC intervention tailored to cancer survivors, versus a web-based noninteractive information brochure. In the MyCourse group, 27.7% of the participants quit smoking after 6 months. In the control group, 25.6% of the participants quit smoking. The number of cigarettes smoked in the past 7 days was reduced by more than half in both groups. At the 12-month follow-up, MyCourse participants showed significantly larger reductions in the number of smoked cigarettes than participants in the control group. However, no statistically significant difference was found in the SC rates

between the intervention and control groups. Nicotine dependence as measured by FTND was also significantly reduced at all time points in both groups, but no difference was found between the groups. Participants in the MyCourse group had significantly higher treatment satisfaction scores than those in the control group. From a societal perspective, the MyCourse intervention was dominated by the control group in the cost-utility analysis. In the cost-effectiveness analysis, MyCourse led to marginally better results against higher costs, with a mean ICER of US \$52,067 per reduced pack-year. Cessation rates were high in the MyCourse and control groups.

Findings in Context

We found no difference in SC rates between the MyCourse and control groups. In previous literature, digital SC interventions have shown superior effectiveness over nonactive control groups (including both usual care and printed self-help materials), among the general population as well as other target groups [42,43]. There is evidence that among cancer survivors, distance-based SC interventions (including digital interventions) also show greater effectiveness than control groups [15]. At the same time, cessation rates in the MyCourse group found in this study are comparable with cessation rates found in 2 previous studies on digital SC interventions for (childhood) cancer survivors [20,44], but cessation rates in our control group were higher than in these previous studies.

Our study did not find an effect on QALYs; a longer follow-up period may be necessary to detect improvements in quality of life among cancer survivors, as their quality of life may be more directly influenced by factors pertaining to cancer diagnosis [45]. There are also some differences in the ICERs that we found compared with previous studies. A systematic review in the Netherlands showed greater cost-utility (< US \$22,689 [€20,000] per QALY per year) of intensive SC counseling and pharmacotherapy over care as usual in another patient population: patients with chronic obstructive pulmonary disease [46], and a similar study on a digital SC intervention among the general population showed an ICER of about US \$3398 (€3000) per abstinent smoker [47]. The large ICER per reduced pack-year in this study can partly be explained by the relatively small difference in effect on the reduced number of cigarettes between the intervention and control groups, and the high health care and productivity costs in this population. Benefits or costs due to changes in tax revenue are not included in a cost-effectiveness analysis but could be a topic of interest in social cost-benefit analyses.

Cessation rates in our control group were higher than those in the studies referenced for power analysis. This might be due to differences in target groups between the studies: we studied cancer survivors, whereas the referenced studies either focused on the general population [24] or cancer survivors with a comorbid problem such as drinking or depression [36]. The similar effect on SC of the MyCourse and control groups might be due to several factors. Notably, twice as many participants in the control group reported the use of nicotine replacement therapy, suggesting that this might have influenced SC rates. The control group participants may have had an increased need for additional support. As this was a pragmatic trial, both groups were provided with the contact details of a free national telephone helpline (in Dutch: Rokeninfo-lijn), which could help find participants additional support if the current intervention was deemed insufficient. Furthermore, to recruit participants, a dedicated website and social media campaign was in place, aimed at informing cancer survivors of the short-term benefits of SC after a cancer diagnosis, emphasizing an accepting tone to reduce possible feelings of guilt, and ultimately guide them to participate in the study. Other contributing factors might have been related to the fact that over the course of the study period, participants received multiple reminder emails and telephone calls from the researchers to fill out the survey at the respective follow-up measurement waves. Although these calls were kept as short as possible, some participants might have experienced those as part of the intervention, feeling supported by them, which could have influenced SC rates. To summarize, the low-threshold provision of psychoeducation, offered in an accepting manner, encouragement to seek support provided in recruitment materials and the information brochure, repeated reminders, and increased use of nicotine replacement therapy may have been sufficient to support many participants in their SC efforts. This should be evaluated in future studies.

To considerably increase SC rates among cancer survivors compared with control groups, intensive and well-implemented programs are needed. It is possible that cancer survivors require digital interventions with more guidance, as suggested by a meta-analysis that found that only nurse-delivered SC interventions moderated effectiveness among cancer survivors [17]. Guidance might also help improve adherence, as the median number of log-ins (median 3) was lower than the recommended (almost) daily use of the intervention over the course of 4 weeks. The period between the first and last log-in came close to use as intended, with a median of 24 days.

Strengths and Limitations

The findings of this study should be interpreted in light of their strengths and limitations. A strength of this study is that the evaluation was conducted in a real-world setting: recruitment was done through both offline and web-based channels, which

will also be used for the intervention's future implementation. The difference in the number of people who completed the screening questionnaire and those who were eligible might seem to show a large selection, but this could be due to our web-based recruitment strategies, which attracted many interested people with no history of cancer on the website as well. This study recruited cancer survivors from a range of cancer types. Several sensitivity analyses were used to corroborate these findings. Missing data were dealt with using multiple imputations. We attempted to control for possible social desirability of reported smoking behavior by including MCSDS scores in our models. Limitations include the fact that participants were not blinded to their intervention allocation. Most of the participants were women (82.6%); therefore, these results might not be generalizable to men. Self-reported smoking status was not biochemically verified in this study, although self-reports in the general population generally showed good validity, 2 studies among cancer survivors found falsification rates of 48% [48] and 80% [49], whereas a third (substantially smaller study) among thoracic cancer survivors showed relatively good agreement between self-reported and biochemically validated smoking status [50]. Adherence was a limitation in this study and might have influenced the effects in the MyCourse group. The effects were limited in size, and our final sample size was somewhat lower than anticipated. As for any RCT, it remains possible that a true effect was not found in this study (type 2 error). Both the main outcome measure (SC during a single week) and the length of follow-up time (a single year) may have masked the possible long-term impact of sustained cessation on long-term health care use and productivity losses. Now it remains for future studies to evaluate whether sustained SC over several years would have contributed to a reduction in health care and societal costs in the long run.

Conclusions

There was no evidence that at 6 months, the digital MyCourse intervention had a differential effect on cessation rates among cancer survivors compared with a web-based noninteractive information brochure; both conditions led to approximately a quarter of the cancer survivors quitting smoking. The number of cigarettes smoked was reduced by 50% in both groups. At 12 months, assignment to the MyCourse group was associated with a greater reduction in the number of smoked cigarettes at higher costs and higher satisfaction scores compared with the control group. It should be further investigated how to achieve considerably higher quit rates, but this study provides an indication that it is possible to achieve somewhat higher cigarette reduction rates with the help of a digital SC intervention. Although both interventions were low-cost, the noninteractive information brochure was more likely to be economically sustainable.

Acknowledgments

This study was supported by grant TBOS2014–7169 from the Dutch Cancer Society (KWF Kankerbestrijding). The sponsor has no role in the design, data collection, analysis, and interpretation of the data, or in writing the paper or the decision to submit for publication. The authors would like to thank Diede Kesler for her assistance in recruitment and follow-up assessments of the participants and Yvonne Borghans for her assistance in the follow-up assessments of participants.

Conflicts of Interest

The intervention described in this study was developed by the Trimbos Institute (the Netherlands Institute for Mental Health and Addiction).

Abstract

Background: Health professions education has undergone major changes with the advent and adoption of digital technologies worldwide.

Objective: This study aims to map the existing evidence and identify gaps and research priorities to enable robust and relevant research in digital health professions education.

Methods: We searched for systematic reviews on the digital education of practicing and student health care professionals. We searched MEDLINE, Embase, Cochrane Library, Educational Research Information Center, CINAHL, and gray literature sources from January 2014 to July 2020. A total of 2 authors independently screened the studies, extracted the data, and synthesized the findings. We outlined the key characteristics of the included reviews, the quality of the evidence they synthesized, and recommendations for future research. We mapped the empirical findings and research recommendations against the newly developed conceptual framework.

Results: We identified 77 eligible systematic reviews. All of them included experimental studies and evaluated the effectiveness of digital education interventions in different health care disciplines or different digital education modalities. Most reviews included studies on various digital education modalities (22/77, 29%), virtual reality (19/77, 25%), and online education (10/77,

13%). Most reviews focused on health professions education in general (36/77, 47%), surgery (13/77, 17%), and nursing (11/77, 14%). The reviews mainly assessed participants' skills (51/77, 66%) and knowledge (49/77, 64%) and included data from high-income countries (53/77, 69%). Our novel conceptual framework of digital health professions education comprises 6 key domains (context, infrastructure, education, learners, research, and quality improvement) and 16 subdomains. Finally, we identified 61 unique questions for future research in these reviews; these mapped to framework domains of education (29/61, 47% recommendations), context (17/61, 28% recommendations), infrastructure (9/61, 15% recommendations), learners (3/61, 5% recommendations), and research (3/61, 5% recommendations).

Conclusions: We identified a large number of research questions regarding digital education, which collectively reflect a diverse and comprehensive research agenda. Our conceptual framework will help educators and researchers plan, develop, and study digital education. More evidence from low- and middle-income countries is needed.

Introduction

The world is faced with a shortage and an unequal distribution of health workforces across low-income, middle-income, and high-income countries [1]. The shortfalls and inequitable distributions affect the likelihood of reaching the United Nations' third Sustainable Development Goal—health and well-being for all by 2030 [1-5]. To enable an increase in and a more equitable distribution of competent health workforce, there is a need for more effective and accessible health professions education.

The use of digital technology in health professions education can help in overcoming some of the health workforce-related challenges by providing more accessible, standardized, relevant, timely, and affordable medical education and training [6,7]. Until recently, digital education was perceived as primarily supporting in-person health professions education [8]. The social distancing measures introduced to control the COVID-19 pandemic have dramatically changed the delivery of health professions education worldwide. Many medical schools and health professions education institutions had to pivot to digital education [9,10]. With this sudden shift, research and evidence in digital health professions education have become even more important.

The evidence on digital education has grown substantially in recent years and has been the subject of many systematic reviews. Existing reviews seem to mostly focus on the effectiveness of different digital education modalities [11-16]. However, the adoption of digital education is complex and includes other research questions, in addition to its effectiveness. It is important to identify evidence that already exists and evidence gaps across the full scope of relevant questions to inform and guide future research and reduce research waste. To address this need, we seek to (1) create a map of existing research, (2) develop a conceptual framework outlining key components of digital education, and (3) highlight specific research questions across a comprehensive research framework. We do this by systematically identifying and analyzing previous systematic reviews on digital health education.

Methods

We used an evidence map methodology to identify and summarize systematic reviews on digital health professions education [17]. We also developed a novel conceptual framework using an established methodological approach [18] and identified specific research questions in alignment with this conceptual framework.

Study Identification

To identify relevant systematic reviews on different types of digital health education for health professionals, we used a comprehensive search strategy mentioned in [Multimedia Appendix 1](#), including key terms for participants (eg, *health professionals*, *health personnel*, and *students*), intervention (eg, *e-learning*, *patient simulation*, and *serious games*), and article type (eg, *systematic reviews* and *evidence synthesis*). We searched the following major bibliographic databases for studies published between January 1, 2014, and July 21, 2020, without any restrictions on language or study design: MEDLINE (Ovid), Embase (Ovid), Cochrane Library, Educational Research Information Center (EBSCO), and CINAHL (EBSCO). We also manually checked the reference lists of the included systematic reviews for other potentially relevant systematic reviews on digital education for health professionals. In addition, we searched Google, Google Scholar, ResearchGate, and OpenGrey for any other studies that might be relevant for our topic, using keywords *systematic review*, *digital education*, *health professionals*, *health professions education*, *eLearning*, and *e-learning*, and reviewing either the first 10 pages or 500 results.

Eligibility Criteria

We included systematic reviews focusing on digital education for health care professionals in preservice (ie, student) and in-service (ie, postdegree, including postgraduate trainees and those in independent practice) positions [19]. This includes disciplines such as medicine, dentistry, nursing and midwifery, medical diagnostic and treatment technology, physiotherapy and rehabilitation, and pharmacy. Practitioners of traditional, alternative, and complementary medicine were excluded. Digital health professions education refers to health professions education that is conducted using digital technology [20] and

includes modalities ranging from the basic conversion of content into a digital format (eg, a book converted into a PDF or HTML format) to more complex applications such as mobile education, digital games, virtual patients, and virtual reality (VR). Systematic reviews were included if they focused on ≥ 1 modality of digital education (as defined in [Textbox 1](#)) delivered in a stand-alone or blended format [20]. We defined blended education as education that incorporates aspects of traditional

and digital education. Traditional education was defined as education that encompasses the use of nondigital educational materials (eg, textbooks or models) or in-person human interactions. We included systematic reviews of all the types of studies. We excluded older reviews because of the rapid evolution of the field, with the assumption that most of the active research questions from the reviews published >5 years ago would be collated in more recent reviews.

Textbox 1. Digital education technologies and modalities and working definitions and descriptions.

Offline digital education

- Education delivery requires no internet or local area network connection and can be delivered through external media, including CD-ROM, external hard disk, and USB stick [21].

Online digital education

- Computer-assisted instruction using the internet or a local intranet as the means of delivery, also referred to as online, internet-based, or networked [22,23], includes multiple media formats (eg, text, videos, and images and online discussion (eg, via email, chat, or videoconferencing) and is designed to be primarily delivered on PCs.

Massive open online course

- A (free) online course available over the internet to a large number of geographically dispersed participants [24]

Mobile education (m-Learning)

- Flexible and accessible learning delivered via personal mobile devices, such as smartphones and tablets [25]

Serious gaming and gamification

- Knowledge and training activities are set within a competitive activity. Games are intended to promote the development of knowledge, cognitive skills, or psychomotor skills in a virtual environment [26].

Virtual reality

- Interactive exploration of a digital (3D) multimedia environment can reflect a real-world environment (eg, clinic) or an artificial or surreal context (eg, positioning the learner within the human body) [16,27].

Virtual patient

- A computer program that simulates real-life clinical scenarios where students take on the role of a health professional and obtain a patient's history, conduct a physical examination, and make diagnostic and therapeutic decisions [28]

High-fidelity manikins

- Realistic, computerized mannequins that mimic elements of human physiology (eg, breathing and heart rhythm) and are used to simulate a real-life clinical scenario [29].

Blended education

- The use of digital education modalities in combination with traditional education methods

Traditional education

- Education that uses nondigital educational material (eg, textbook or model) or in-person human interaction

Study Selection

The search results from different databases were combined in a single EndNote library, and duplicate citations were removed. A total of 2 review authors (SP and BMK) screened all titles and abstracts for inclusion independently and in duplicate. Disagreements during the title and abstract screening were resolved by consensus. Full texts of articles considered eligible or uncertain based on the title and abstract screening were

retrieved and screened independently and in duplicate by the same 2 authors.

Data Extraction

From the included systematic reviews, 2 authors (SP and BMK) used a standardized form to independently extract information on the review aim; the study design, participants, interventions, comparators, and outcomes of the original research studies included; the method used to appraise the quality of the included studies (eg, risk of bias) or overall evidence (eg, the Grading

of Recommendations Assessment, Development and Evaluation assessment); and recommendations for future research. We classified the outcomes according to the definitions presented in [Multimedia Appendix 2](#). We also extracted information on all additional outcomes reported in the included reviews that did not correspond to our predefined outcome-related definitions. We classified the systematic review in terms of the single digital modality they most focused on, according to our framework ([Textbox 1](#)). In most instances, it was clear that a given review focused predominantly on 1 modality. Less often, a review encompassed multiple modalities equally, in which case we classified it as digital education; that is, the use of digital technology in health professions education in general. Finally, we identified recommendations for future research by extracting exact quotes from each review that articulated such recommendations. At every stage, disagreements between the review authors were resolved through discussion and input from the third author (LTC).

Analysis

Authors SP and BMK rephrased the quoted research recommendations into research questions and then refined these by applying consistent terminology, removing duplicates, and merging or subdividing themes. Questions that focused on specific digital modalities (eg, online modules) were rewritten to make them relevant to the broader research agenda for digital health education. The final list of research questions was refined by LTC.

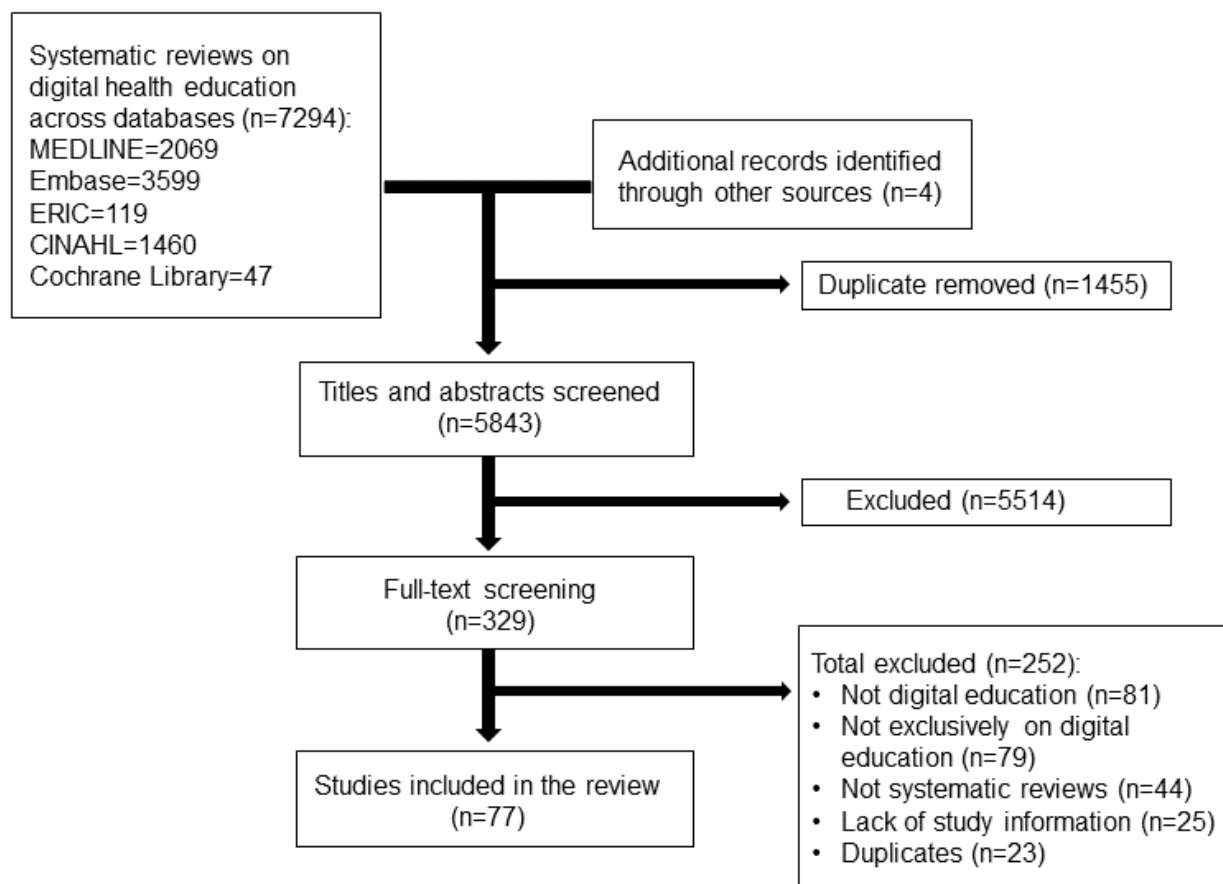

We developed a conceptual framework outlining various digital health professions' education components according to the methodology described by Jabareen [18]. We consulted and built on our previous conceptual work in this area and existing frameworks for the implementation or adoption of digital education generally [30-39]. We identified these frameworks through a focused literature search on PubMed, Google, and Google Scholar. On the basis of the discussions and consensus among the review authors, key domains and subdomains were finalized. The framework and its components were represented diagrammatically. Recommendations for future research were classified according to the proposed framework in parallel by 2 authors (SP and BMK). Discrepancies were resolved through consensus and with the guidance of the third author (LTC). On the basis of the analysis of the included reviews and the observed gaps in the literature, we outline a research agenda for digital health professions education and present it in the *Results* section.

Results

Search Results

Of 7294 systematic reviews from our initial search, we identified 73 (1%) eligible systematic reviews ([Figure 1](#)). Another 4 systematic reviews were identified through Google, Google Scholar, ResearchGate, and OpenGrey. In total, 77 systematic reviews were included for data extraction.

Figure 1. Study flow diagram. ERIC: Educational Research Information Center.

The number of published systematic reviews increased over time, from 6% (5/77) published in 2014 to 56% (43/77) published in 2019. The systematic reviews focused on digital education for health professions students (17/77, 22% studies), postgraduate or independently practicing (18/77, 23% studies) health professionals, or both (42/77, 55% studies). Most of the systematic reviews were on digital education in surgery (13/77, 17% studies) or health professions education in general (ie, those not focusing on a particular type of practitioner, health care area, or topic; 36/77, 47% studies), followed by nursing (11/77, 14% studies; [Table 1](#); [Multimedia Appendix 3](#) [11-16,32,34,40-109]).

A breakdown of the digital modalities being investigated in the included systematic reviews is shown in [Figure 2](#). Most systematic reviews focused on digital education in general (22/77, 29%), VR (19/77, 15%), and online education (10/77, 13%). Of the 19 reviews on VR, 17 (89%) were on VR complemented with physical objects or devices such as probes or handles and focused on psychomotor, procedural, or technical skill development. There were fewer reviews published on m-Learning (6/77, 8%), digital game-based learning (3/77, 4%), and virtual patients (2/77, 3%).

The most common outcomes in the included reviews were health professionals' knowledge (49/77, 64%), skills (51/77, 66%), attitudes about the clinical topic (13/77, 17%), and satisfaction with digital education (18/77, 23%). Most systematic reviews

compared the effectiveness of digital education to traditional education (ie, nondigital; 59/77, 77%) or other forms of digital education (35/77, 45%; [Table 1](#)). Most reviews reported only immediate, short-term outcomes; 22% (17/77) of reviews reported the impact of digital education on long-term delayed outcomes; that is, outcomes assessed with delay after the intervention [34,40-55]. Most reviews appraised methods using the Risk of Bias tool [110] only (24/77, 31%), followed by Grading of Recommendations, Assessment, Development, and Evaluation [111] (which also includes the risk of bias assessment; 22/77, 29%) and Medical Education Research Study Quality Instrument [112] (10/77, 13%). Of the 77 studies, 9 (12%) reviews did not report on the quality appraisal of the included evidence, whereas the remaining 14 (18%) reviews used different instruments to determine the evidence quality ([Table 1](#); [Multimedia Appendix 3](#) [11-16,32,34,40-107,109]). The included reviews mostly reported original research to be low or very low quality of evidence or reported unclear or high risk of bias in most studies ([Multimedia Appendix 3](#) [11-16,32,34,40-107,109]). Most systematic reviews reported data from high-income countries (14/77, 18% systematic reviews) or both middle- and high-income countries (42/77, 55% systematic reviews). Only 4% (3/77) of the systematic reviews included studies from low-income countries [11,56,57]. Approximately 29% (22/77) of the included reviews did not report the setting of the included studies.

Conceptual Framework of Digital Health Professions Education

To outline different aspects of digital health professions education and identify gaps in the literature, we developed a novel conceptual framework (Figure 3) grounded in key findings of these systematic reviews together with 7 existing frameworks for digital education general [35-39,113-117] and a framework we developed previously for health professions education [33].

Broadly, the fundamental domains include an enabling and supportive context, sound infrastructure, and the optimal use of education tools and processes. The context is a combination of institutional norms, sociocultural norms, and settings in which the learner resides, as well as the level of education the learner is at. Subdomains of the context have a direct impact on the

infrastructure components required and available for the delivery of digital education—digital and physical spaces, policies and regulatory standards, and human resources. Both context and infrastructure components are important in consideration of health professions education. Learners, individually and as part of a larger group, are at the core of digital health education, and their needs, preferences, prior expertise, and competencies should shape how education is delivered. The interaction among components within and across each layer is dynamic, with different parts being interconnected, as reflected using dotted lines to separate context, infrastructure, education, and learners. Studying and identifying optimal relationships between the components are handled by the research and quality assurance blocks, which are connected to the rest of the framework. Table 2 provides the detailed operational definitions for each domain of the framework.

Figure 3. Conceptual framework of digital health education for healthcare professionals. CME: continuing medical education; CPD: continuing professional development; IT: information technology.

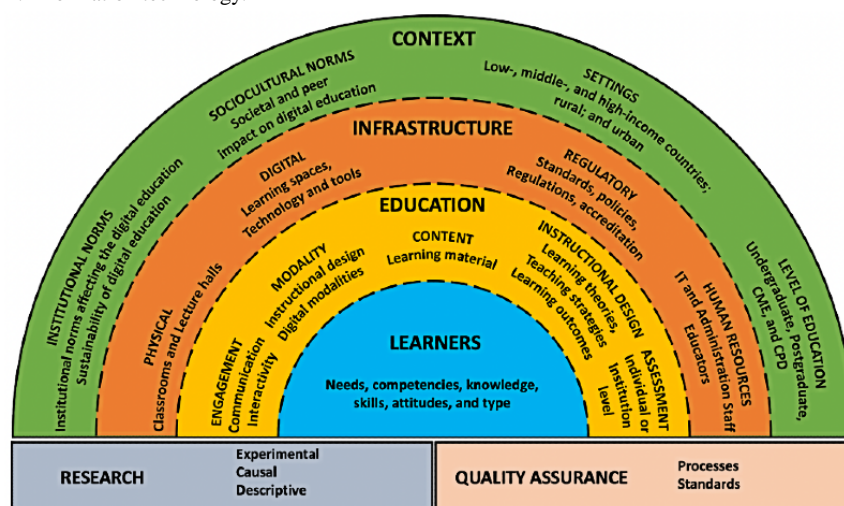

Table 2. Definitions of digital health professions education conceptual framework components.

Domain and subdomain	Definition
Context	
Sociocultural norms	The acceptability and adoption of digital education as a form and norm of education within the society
Institutional norms	The acceptability, impact, considerations, and processes concerning the adoption of digital education at the institutional level
Settings	The setting in which digital health education is conducted or implemented, including clinical or classroom environments; low-, middle-, and high-income countries; and rural or urban environments
Level of education	The impact and integration of digital education with other forms of education (eg, inter- and intraprofessional training opportunities) and clinical work in which participants are engaged
Infrastructure	
Physical	The physical learning space within which the in-person component of blended digital health education is taking place
Digital	The information and communication technology devices (both hardware and software) to support and create learning environments (virtual environments, digital networks, technological modifications) or media for digital health education, as well as the speed and capacity of internet access
Regulatory	Policies and regulatory standards for health professionals' licensing and accreditation, as well as those relating to the design and delivery of digital health professions education
Human resources	The human resources required for digital health education to be maintained and sustained, including educators, administrators, and information technology staff
Education	
Modality	The choice and configuration of digital education modality (eg, online learning and m-Learning) and its potential blending with in-person education
Instructional design	The method and practice of digital health professions education encompassing teaching strategies, learning principles, learning outcomes, and the assessment approach
Content	Health professions education area, discipline, theme, or topic delivered via digital education
Engagement	The level of communication, interactivity, or immersion of participants taking part in digital health professions education
Assessment	Measurement of digital health professions education conducted at the individual and institutional level to determine its impact on educational and clinical outcomes
Learners	Health professionals with distinctive needs, competencies, digital literacy, knowledge, skills, and attitudes toward working and learning, both individually or as a group
Research	Systematic study of digital health professions education to create and disseminate new knowledge and allow for more effective and efficient adoption, implementation, and transfer of interventions to various contexts—this encompasses experimental, observational, descriptive, and qualitative research
Quality assurance	A context-specific and systematic evaluation of practices and procedures to understand the current state and improve the performance of digital health education in a particular setting

Research Questions From the Included Systematic Reviews

We identified 318 discrete research questions posed in these 77 articles, from which we distilled a final list of 61 (19.2%) distinct questions covering 14 of the 16 subdomains of the above framework (Table 2; Multimedia Appendix 4 [11-16,32,34,40-95,98-107]). Research questions that spanned multiple subdomains were assigned by investigator consensus to the most relevant single subdomain. None of the included systematic reviews posed questions primarily directed at the *physical* infrastructure or *quality assurance* subdomains. We identified 26% (16/61) of questions relating to context, classified into four subdomains: *sociocultural norms*, *institutional norms*, *settings*, and *level of education*. Approximately 15% (9/61) of research questions (3 per subdomain) were identified for the *digital*, *regulatory*, and *human resources* subdomains within the infrastructure domain. Most of the research questions, 48% (29/61) approximately, were categorized in the education domain, which encompasses *modality*, *instructional design*,

content, *engagement*, and *evaluation* subdomains. Approximately 5% (3/61) of *research* questions each were categorized in the *learners* and *research* domains.

Classifying Research Questions Addressed by Existing Systematic Reviews

We also classified the included systematic reviews based on their research questions and using our conceptual framework (Table 3; Multimedia Appendix 3 [11-16,32,34,40-107,109]). The research questions addressed by existing systematic reviews mostly revolved around digital education *modality* (ie, the effectiveness of various digital education modalities delivered as stand-alone or blended interventions) and *content* (ie, the effectiveness of digital education within a particular health care area or discipline). Some reviews assessed interactivity (*engagement*), various aspects of *instructional design* in digital education, the impact of digital education on institutional outcomes (*context—institutional norms*), and the impact of *setting* (eg, low-income and middle-income countries) on learning outcomes.

Table 3. Research questions identified from the included systematic reviews on health professions digital education.

Research questions identified from included systematic reviews	Conceptual framework domain (subdomain)	Systematic reviews' references
How do cost and cost-related outcomes influence the adoption of digital technology in health professions education?	Context (sociocultural norms)	[41,56,58-65]
How can policy makers be organized to adopt digital education as part of health professions education?	Context (sociocultural norms)	[56,66]
How do cultural factors within different countries determine the use of digital education for health professions training?	Context (sociocultural norms)	[66]
How does providing access to digital education improve the learning outcomes of health professionals?	Context (sociocultural norms)	[14,40,41,43,46,53,56,57,66-77]
What is the long-term cost-effectiveness of digital education compared with traditional education for health professionals?	Context (institutional norms)	[12-14,16,47,61,78]
How does health professions' digital education affect individual and health services outcomes and organizational practice?	Context (institutional norms)	[11-14, 16, 32, 34, 40, 42-45, 48, 49, 51-53, 56, 60, 62, 64, 67-70, 75, 79-88]
Is health professions' digital education more time efficient than traditional education?	Context (institutional norms)	[46]
What is the feasibility of implementing digital technology for health professions education in different socioeconomic settings?	Context (setting)	[13,14,16,43,56,57,78,89,90]
What are the short- and long-term effects of using digital technology for health professions education in different socioeconomic settings?	Context (setting)	[32,43,47,50,54,60,78,82,89-91]
Is digital education for health professionals effective in different socioeconomic settings?	Context (setting)	[13,40,91,92]
What are the resource requirements to implement digital education in different socioeconomic settings?	Context (setting)	[85,93]
What are the challenges of setting up digital education for health professionals training in different socioeconomic settings?	Context (setting)	[85]
What is the differential impact of digital education on the clinical performance of trainee or expert surgeons?	Context (level)	[94]
How can digital education for health professionals be integrated into normal work practices?	Context (level)	[68]
How can digital technology be incorporated into current health professions' education and training curriculum to improve learning outcomes?	Context (level)	[42,46,47,54,61,62,78,90]
Is digital education effective in improving health professionals' knowledge and skills performance in the clinical setting?	Context (level)	[11-14, 16, 32, 34, 40, 42-45, 48, 49, 51-53, 56, 60, 62, 64, 67-70, 75, 79-88]
Which features of digital education (eg, technical features, fidelity, safety, and adaptability) affect the learning outcomes of health professions education?	Infrastructure (digital)	[13,95]
What are the minimum requirements for the digital technology used to achieve the effectiveness of digital health professions education?	Infrastructure (digital)	[85]
What are the technical resources needed to deliver digital education to health care professionals?	Infrastructure (digital)	[61]
How should educators delivering digital health education be assessed and accredited?	Infrastructure (regulatory)	[47]
What are the best practices for the development, evaluation, and use of digital health education in health professions education?	Infrastructure (regulatory)	[14]
Is the use of accreditation-related milestones in digital health education effective?	Infrastructure (regulatory)	[78]
What digital skills should instructors facilitating digital health education be competent in?	Infrastructure (human resources)	[47]
How does the digital competence of teachers affect health professions learning outcomes from digital health education?	Infrastructure (human resources)	[96]
What are the workforce resources needed for health professions' digital education?	Infrastructure (human resources)	[61]

Research questions identified from included systematic reviews	Conceptual framework domain (subdomain)	Systematic reviews' references
What type of instructional design is used in the effective digital education of health professions education?	Education (modality)	[47,57,83,87,94]
Which components of digital health education (eg, interactivity and feedback) contribute to enhanced learning outcomes?	Education (modality)	[45,52,58,67,97]
What is the optimal use of video-assisted debriefing for health professionals' simulation-based training?	Education (modality)	[98]
How does the design of digital education interventions (eg, format and modality used) in health professions education and training curriculum affect learning outcomes?	Education (modality)	[34,42,53,64,74,78,93]
Can digital simulation-based training be used to train nontechnical skills in health professionals?	Education (modality)	[44,69]
What is the effectiveness of digital education (mixed or single modality) compared with nondigital education to deliver health professions education?	Education (modality)	[42,71,98]
Can digital education complement (ie, blended) or substitute traditional education for health professionals?	Education (modality)	[54,69,99,100]
Does digital simulation-based psychomotor skills training provide any benefit to the medical trainee?	Education (modality)	[46]
What are the barriers to obtaining digital education materials for health professions education training, and how can they be overcome?	Education (content)	[66]
What content should be included in debriefing (eg, digital data) following simulation-based education to achieve improved clinical outcomes?	Education (content)	[47]
Can digital education be used to overcome challenges in delivering content-specific topics for health professions education (eg, surgical training in rare pathologic states)?	Education (content)	[84,89]
Can digital education be designed to achieve learning outcomes denoted in the Kirkpatrick model?	Education (instructional design)	[101]
What learning theories can be used to inform the development of effective digital health professions education?	Education (instructional design)	[13,14,55,59,63,82,93]
Is mastery learning via digital education more or as effective as traditional education in terms of clinical psychomotor skills improvement?	Education (instructional design)	[41,47,48,53,58-60,78,102]
Is spacing digital simulation-based training more or as effective as traditional education in clinical psychomotor skills development?	Education (instructional design)	[41,47,48,53,58-60,78,102]
How does the frequency and duration of digital simulation-based psychomotor skills training affect health professionals' skills transfer to the clinical setting?	Education (instructional design)	[41,47,48,53,58-60,78,102]
What are the optimal duration, frequency, and intensity of digital health professions education programs to affect the learning and clinical outcomes of health professionals?	Education (instructional design)	[43,54,62,72,83,94,103]
What pedagogy should be used in the digital education of health professionals to improve their knowledge and skills?	Education (instructional design)	[11,14,42,95,104]
What is the effectiveness of using digital education to train and assess nontechnical skills in health care professionals?	Education (instructional design)	[71,87]
What is the effectiveness of digital problem-based learning in health professions education?	Education (instructional design)	[34]
How does the interactivity of digital education programs affect the learning and clinical outcomes of health professionals?	Education (engagement)	[53,62,80,91]
What is the minimal level of haptic feedback required in digital simulation-based training programs to improve health professionals' psychomotor skills?	Education (engagement)	[64]
What are learners' acceptability of digital education with different levels of interactivity?	Education (engagement)	[77]
Which performance metrics or measurement instrument should be used to assess health professionals' knowledge, skills, attitudes, satisfaction, and clinical outcomes from digital technology-based training programs?	Education (assessment)	[12, 14, 44, 45, 51-53, 60, 62, 64, 67-71, 73-75, 77, 78, 83, 87, 90, 92, 93, 95, 102, 103, 105]

Research questions identified from included systematic reviews	Conceptual framework domain (subdomain)	Systematic reviews' references
What is the ideal approach to assessing health professionals' knowledge, skills, attitudes, satisfaction, and clinical outcomes from digital technology-based education and training programs?	Education (assessment)	[12, 14, 44, 45, 51-53, 60, 62, 64, 67-71, 73-75, 77, 78, 83, 87, 90, 92, 93, 95, 102, 103, 105]
Should the evaluation of digital health education include behavior and clinical outcomes?	Education (assessment)	[12, 14, 44, 45, 51-53, 60, 62, 64, 67-71, 73-75, 77, 78, 83, 87, 90, 92, 93, 95, 102, 103, 105]
What is the impact of digital simulation-based training on clinical outcomes in the short and long term?	Education (assessment)	[71,106]
How should learning outcomes in the field of digital health professions education be defined and standardized?	Education (assessment)	[92]
How does the use of digital education affect health professionals' clinical decision-making at the point of care?	Education (assessment)	[68]
How do health professionals' prior learning experiences influence the topics that will benefit from the use of digital education?	Learner	[107]
What are health professionals' attitudes toward digital delivery of education and training programs?	Learner	[16,65,85,91]
What are health care professionals' learning needs, and can they be met by the use of digital simulation training?	Learner	[44]
What are the methodological requirements for studies assessing digital health education?	Research	[12, 16, 48, 53, 58, 59, 63, 65, 66, 70, 71, 74, 82, 83, 92, 95, 97]
How should studies on digital health professions education be reported?	Research	[12, 16, 48, 53, 58, 59, 63, 65, 66, 70, 71, 74, 82, 83, 92, 95, 97]
How should studies of digital health professions education be designed to ensure the generalizability of their findings across different settings?	Research	[12, 16, 48, 53, 58, 59, 63, 65, 66, 70, 71, 74, 82, 83, 92, 95, 97]
What are the barriers and facilitators that affect the continued adoption of digital tools in health professions education?	Context, education, infrastructure, and learner	[68]

Discussion

Principal Findings

We present an evidence map of 77 systematic reviews on digital education for health professionals published between 2014 and July 2020. The reviews mostly focused on the effectiveness of various digital education modalities in surgery, health professions education in general, and nursing. Most reviews have focused on online and offline learning. Only a few reviews focused on other digital education modalities such as m-Learning, VR, digital game-based learning, and virtual patients. We developed a novel conceptual framework outlining key components of digital health professions education, namely context, infrastructure, education, learner, research, and quality assurance. Within these reviews, we identified 61 unique recommendations (questions) for future research, focusing primarily on digital education modality, instructional design, and assessment.

Limitations and Strengths

Our study has some limitations. First, to cover the most recent evidence in the field of digital education for health care professionals, we excluded studies before 2014; earlier reviews might have identified important research questions that remain unanswered. Our focus on systematic reviews also excluded other article types, such as editorials or viewpoints, which might have identified additional research questions. Second, although

extraction and classification of research questions were done in duplicate and using a standardized approach, other classifications could be justified in some instances, which implies a degree of imprecision in the reported frequencies of specific questions. Moreover, our method did not allow us to prioritize the numerous research questions; such prioritization would require input from a representative group of experts and could be the focus of a future study. Third, there are overlaps among different concepts specified within this conceptual framework, which could be delineated and presented differently depending on potential chosen emphasis or entry points. Fourth, reviews classified as *online education* varied substantially in their inclusion of other modalities (eg, some expressly excluded modalities such as virtual patients, digital games, or massive open online courses, whereas others included these and other modalities). Finally, our novel conceptual framework may require revision as our understanding of this field matures and evolves, additional evidence accumulates, and new technologies emerge.

Our study also has several strengths, such as a thorough literature search for relevant studies, encompassing several indexed and gray literature databases without restrictions. We followed an established evidence map methodology and performed the steps in duplicate and independently [17]. In the development of our conceptual framework, we drew from the existing frameworks, our previous work, and discussions with experts.

Integration With Prior Work

We did not find other frameworks presenting a high-level overview of the use and implementation of digital education for health professionals. Therefore, we drew from the general digital education literature and found several relevant frameworks. (Multimedia Appendix 5). The included frameworks, while providing an overview of digital education, often had additional objectives such as exploring the role of specific stakeholders (eg, the private sector or the ministries), identifying barriers to adoption, or analyzing a particular digital education aspect, setting, or configuration [33,35-37,113-117]. Our framework complements other frameworks by pulling together domains previously presented only in isolation and by adding novel subdomains such as the impact of training levels, the role of regulations and accreditations, and the importance of physical infrastructure (Multimedia Appendix 4 [11-16,32,34,40-95,98-107]).

Several viewpoint articles have offered research agendas for digital health professions education [28,118-120]. They focus primarily on the design of interventions and research studies in this field, which correspond to the domains of education (modality, instruction design, assessment, and engagement), research (quality of methods and reporting), and context (setting and level of education) in our framework. The agendas espoused in these viewpoints include questions that probe more narrowly and deeply on specific issues relevant to the design and focus of future studies (eg, the choice of comparison intervention and avoidance of confounding, integration of digital education across different institutions, and the need for interdisciplinary collaboration). Our framework was intentionally broad and comprehensive and enabled us to accommodate a variety of additional questions on previously neglected topics.

Implications for Research and Practice

Most reviews in our evidence map focused on the effectiveness of digital education interventions and rarely addressed issues around their implementation and adoption. These reviews also mostly compared the effectiveness of digital interventions with that of nondigital education. Findings from studies comparing digital and nondigital education have limited generalizability as these studies cannot account for variance within and between these 2 educational formats [118]. Future research should

compare different digital education modalities as such studies are more likely to generate meaningful, generalizable findings. It should also aim to explore potential challenges related to the implementation and adoption of digital education interventions in different settings.

There is also a need for more methodologically robust research and clearer terminology in this field. The quality of the evidence, as reported in the included reviews, was relatively low, with a limited number of studies measuring skills and knowledge retention. Furthermore, it was at times difficult to determine which modality (or modalities) the included reviews focused on because of poorly explained inclusion criteria. Such ambiguity was particularly common in reviews on e-learning and blended, online, and internet-based education.

We also express concerns about the paucity of studies from low- and middle-income countries. Such countries could greatly benefit from digital education, especially by using free or low-cost education (eg, massive open online courses). Although some research findings have a universal application (eg, fundamental principles of effective learning), others (such as implementation, infrastructure, and learners) are more context specific. Given the presence of unique needs of low- and middle-income countries (eg, distinct content priorities, learner demographics, and infrastructure), we urge more research in these contexts.

Our conceptual framework will benefit researchers, funding agencies, and educators, among others. The specific questions identified and classified according to this framework provide a map for future research and can help prioritize original research studies and guide the planning of new or updated systematic reviews. We encourage investigators to broadly consider the questions we identified in this evidence map, especially those specific to areas previously less studied, such as infrastructure, learners, or quality assurance in digital education. Our framework can also be used by funding agencies to better understand the limitations of the existing research and identify areas with limited evidence with the aim of informing their funding calls in this field. Finally, this framework can encourage those developing new courses to anticipate and plan for issues that are important but might be inadvertently overlooked, such as the digital education context, infrastructure, and learners.

Acknowledgments

The authors would like to acknowledge the funding support from Nanyang Technological University, Singapore. The authors would also like to acknowledge Ms Thai My Linh and Ms Christina Tan En Hui for their help with the validation of the findings, Ms Chong Zhuo En for help with data compilation, and Ms Yasmin Lynda Munro for providing advice on our search strategy. Although this review includes the findings from the systematic reviews published by members of the Digital Health Education Collaboration, all reviews were given equal treatment during the review process conducted for this publication. The authors alone are responsible for the views expressed in this paper and do not necessarily represent the views, decisions, or policies of the institutions with which they are affiliated.

Authors' Contributions

JC, LTC, and OA conceived the idea for the review. SP and BMK screened the studies, extracted the data, and synthesized the findings. LTC, SP, and BMK wrote the manuscript. JC, DAC, VW, RA, AM, JJ, RMJJvdK, MM, FVW, ML, NC, OA, and CGP provided insightful feedback on the manuscript.

Abstract

Background: Information in pathology reports is critical for cancer care. Natural language processing (NLP) systems used to extract information from pathology reports are often narrow in scope or require extensive tuning. Consequently, there is growing interest in automated deep learning approaches. A powerful new NLP algorithm, bidirectional encoder representations from transformers (BERT), was published in late 2018. BERT set new performance standards on tasks as diverse as question answering, named entity recognition, speech recognition, and more.

Objective: The aim of this study is to develop a BERT-based system to automatically extract detailed tumor site and histology information from free-text oncological pathology reports.

Methods: We pursued three specific aims: extract accurate tumor site and histology descriptions from free-text pathology reports, accommodate the diverse terminology used to indicate the same pathology, and provide accurate standardized tumor site and histology codes for use by downstream applications. We first trained a base language model to comprehend the technical language in pathology reports. This involved unsupervised learning on a training corpus of 275,605 electronic pathology reports from 164,531 unique patients that included 121 million words. Next, we trained a question-and-answer (Q&A) model that connects a Q&A layer to the base pathology language model to answer pathology questions. Our Q&A system was designed to search for the answers to two predefined questions in each pathology report: *What organ contains the tumor?* and *What is the kind of tumor or carcinoma?* This involved supervised training on 8197 pathology reports, each with ground truth answers to these 2 questions determined by certified tumor registrars. The data set included 214 tumor sites and 193 histologies. The tumor site and histology phrases extracted by the Q&A model were used to predict International Classification of Diseases for Oncology, Third Edition (ICD-O-3), site and histology codes. This involved fine-tuning two additional BERT models: one to predict site codes and another to predict histology codes. Our final system includes a network of 3 BERT-based models. We call this CancerBERT network (caBERTnet). We evaluated caBERTnet using a sequestered test data set of 2050 pathology reports with ground truth answers determined by certified tumor registrars.

Results: caBERTnet's accuracies for predicting group-level site and histology codes were 93.53% (1895/2026) and 97.6% (1993/2042), respectively. The top 5 accuracies for predicting fine-grained ICD-O-3 site and histology codes with 5 or more samples each in the training data set were 92.95% (1794/1930) and 96.01% (1853/1930), respectively.

Conclusions: We have developed an NLP system that outperforms existing algorithms at predicting ICD-O-3 codes across an extensive range of tumor sites and histologies. Our new system could help reduce treatment delays, increase enrollment in clinical trials of new therapies, and improve patient outcomes.

Introduction

Background

Much of the information in electronic medical records (EMRs) required for the practice of clinical oncology and cancer research is contained in unstructured text. As much as 80% of EMR data can be found in narrative text notes and scanned documents [1], ranging from clinic or surgical notes, including pathology, radiology, and ambulatory care, to past medical or family history. The extraction of discrete data elements from this unstructured text, particularly those relating to disease diagnosis and commonly captured in routine pathology reports, is critical for the selection of treatment options, identification of patients eligible for clinical trials, and monitoring of adherence to established clinical treatment pathways.

Natural language processing (NLP) has been used to extract information from medical text for several decades [2-6], and a thorough review of NLP-based information extraction for cancer-related EMR notes can be found in the study by Datta et al [7]. Application of NLP to pathology reports has also been prevalent in the literature during the course of the last decade [8-19]. That said, many early studies used regular expression- and rule-based systems [20,21] that require considerable up-front development and can be difficult to adapt and maintain.

More recently, there has been growing interest in more highly automated deep learning approaches for clinical NLP [6,22]. In late 2018, a powerful new deep learning NLP algorithm was released: bidirectional encoder representations from transformers (BERT) [23]. BERT established new, state-of-the-art performance levels on common nonclinical NLP benchmarks [24]. This success spawned rapid research and development of multiple BERT-inspired and transformer-based neural architectures [25-33]. Several of these have, for the first time, achieved or surpassed human-level performance on tasks as diverse as question answering, named entity recognition, speech recognition, and more [30,33-35]. BERT and related architectures have facilitated significant improvements in multiple medical applications, including processing of electronic health records [36,37], outcome prediction [38-40], identification of medical terms and concepts [41], medical chatbots [42], sentiment analysis [43], recommender systems [44], and others. Despite BERT's success, we are aware of only a single application of BERT to the already promising area of free-text pathology reports [45]. The study focused on classification of text into only a few cancer-related categories, including afflicted organ (15 organ groups), disease type (noncancer, premalignant, or cancer), cancer reason (6 histology groups), and presence of metastatic disease (no, yes: in lymph nodes and yes: in non-lymph node tissue). Our goal is to develop and evaluate a

BERT-based system to extract detailed tumor site and histology information from free-text pathology reports. The availability of manually curated data within the H Lee Moffitt Cancer Center and Research Institute (Moffitt) Cancer Registry (MCR) represented a unique opportunity to train a BERT-based system using a gold standard data set classified using a standard ontology.

BERT's proficiency at question answering prompted us to construct a question-and-answer (Q&A) system to extract clinical data from pathology reports. This concept has long been compelling—Q&A systems for medical data extraction have been pursued for >40 years [46]. Such a system would have several desirable properties: an intuitive user interface, the ability to extract additional data fields by searching for answers to additional questions, and the ability to generalize to other medical documents. Furthermore, it would allow us to make data available for clinical and research use close to real time, thus reducing treatment delays, increasing enrollment in clinical trials of new therapies, and improving patient outcomes. To train such a general-purpose Q&A system on pathology reports, one would need a diverse set of questions on which to train it. Our task in this paper is more modest (and is in essence a classification task of site and histology); however, we view the Q&A portion of our system as a small step toward this broader goal.

Primary Contributions

This work describes three primary contributions:

1. A new BERT language model for comprehension of pathology reports in oncology. We call this *CancerBERT*, or *caBERT* for short.
2. A new Q&A *caBERT*-based system, tolerant to varied terminologies, word orders, and spelling mistakes, to extract tumor site and histology descriptions from free-text pathology reports.
3. A new *caBERT* network (*caBERTnet*) to predict International Classification of Diseases for Oncology, version 3.2 (ICD-O-3.2), codes from the extracted descriptions. This system can handle up to 332 organ sites and 1143 tumor histologies. On an unseen test data set with 214 sites and 193 histologies it achieved overall accuracies that are equal to, or above, those of existing systems, while also expanding on the number of site and histology classes captured by these systems. Although the results in practice still require human validation, they provide a means of early abstraction from unstructured pathology text over a very broad set of sites and histologies and in addition can provide an initial signal to assist expert cancer registrars in their case diagnosis-abstraction workflow.

Methods

Information on our software development tools is provided in [Multimedia Appendix 1](#) [47-53]. To construct our system, we had to achieve three specific aims: (1) extract accurate tumor site and histology descriptions from complex free-text pathology reports, (2) accommodate the diverse terminology used to indicate the same pathology, and (3) provide accurate standardized tumor site and histology codes for use by downstream applications.

Textbox 1. A fragment of text from a pathology report generated at H Lee Moffitt Cancer Center and Research Institute (Moffitt).

Fragment of text from a pathology report generated at Moffitt

- clinical history: not given. preoperative diagnosis: right lower lobe, squamous cell carcinoma. specimen types: a: right station 7 fs b: station # 10 c: right lung fs d: station 4r e: additional station 10 f: additional station 7 final diagnosis: a. lymph node right station 7 biopsy: anthracotic lymph node 1 with lymphoid hyperplasia negative for malignancy. b. lymph node station 10 biopsy: anthracotic lymph node 1 negative for malignancy. c. lung right pneumonectomy: moderate to poorly differentiated squamous cell carcinoma with extensive necrosis see key pathological findings. bronchial and vascular resection margins negative for malignancy. three of 10 hilar lymph nodes with metastatic squamous cell carcinoma. d. lymph nodes station 4r biopsies: anthracotic lymph nodes 5 negative for malignancy. e. lymph node additional station 10 biopsy: minute lymph node 1 negative for malignancy. f. lymph node station 7 biopsy: anthracotic lymph nodes 4 negative for malignancy. key pathological findings tumor type: squamous cell carcinoma with extensive necrosis. histological grade: moderate to poorly differentiated. tumor location: right lung involving right lower lobe. right upper and middle lobes free of tumor.

Next, it required us to train a Q&A model that appends a Q&A layer onto the pathology language model to answer pathology questions. Our Q&A system was designed to search for the answers to two predefined questions in each pathology report:

1. What organ contains the tumor?
2. What is the kind of tumor or carcinoma?

For example, when presented with the report shown in [Textbox 1](#), the system should respond to the question *What organ contains the tumor?* with *C343: lower lobe, lung*, and would respond to the question *What is the kind of tumor or carcinoma?* with *8070/3: squamous cell carcinoma, nos* (not otherwise specified).

This involved *supervised* training on a set of pathology reports, each with ground truth answers to these 2 questions determined by human experts. To do this, we constructed a second *fine-tuning training data set*, described in more detail in the

Extract Tumor Site and Histology Descriptions

Overview

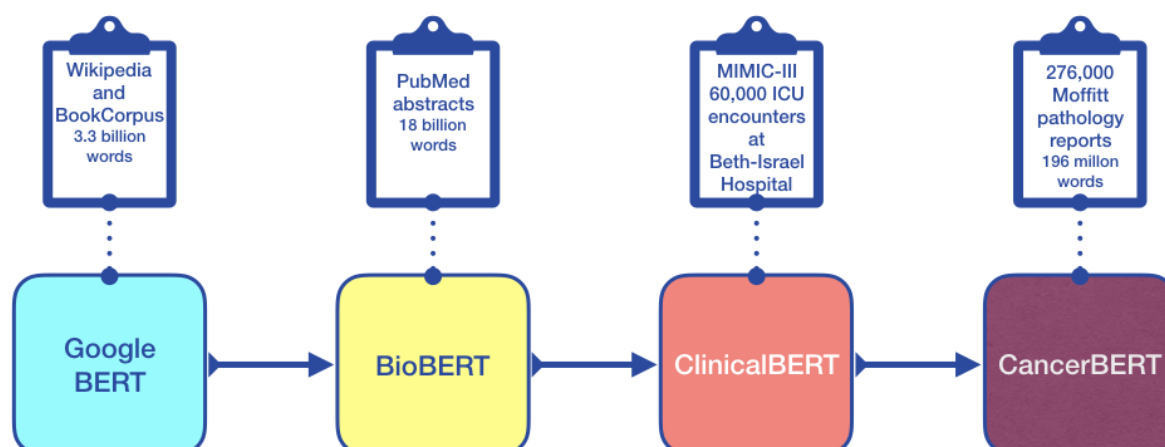

Constructing this system required us to first train a base language model to comprehend the technical language in pathology reports ([Textbox 1](#)). This involved *unsupervised* training on a large corpus of pathology text. For this we constructed a *pathology language-model training data set*, described in more detail in the next section (*Pathology Language Model*).

Pathology Q&A Model section. Finally, we evaluated our system using a sequestered *fine-tuning testing data set*, described in more detail in the *Pathology Q&A Model* section.

Pathology Language Model

Training a base language model to comprehend pathology reports leveraged prior work by several groups ([Figure 1](#)). Lee et al [54] performed transfer learning on BERT using nearly 18 billion words extracted from PubMed abstracts. The result, BioBERT, is tuned for biomedical language comprehension tasks and is publicly available. Next, Alsentzer et al [55] performed transfer learning on BioBERT to tune it for clinical language comprehension. They used EMR notes in the Medical Information Mart for Intensive Care, version 3 (MIMIC-III) data set [56], which includes data from approximately 60,000 intensive care unit stays by patients at Beth-Israel Hospital in Boston, Massachusetts. The model created by Alsentzer et al [55], ClinicalBERT, was also made publicly available.

Figure 1. Sequence of transfer-learning steps used in training the CancerBERT base language model. BERT: bidirectional encoder representations from transformers; ICU: intensive care unit; MIMIC-III: Medical Information Mart for Intensive Care, version 3.

Alsentzer et al [55] created two models built upon BioBERT: one trained on all MIMIC-III notes and one trained on just the MIMIC-III discharge summaries. Initial pretraining experimentation revealed that the latter provided higher accuracies on a separate sample of our pathology reports. We noted that Moffitt pathology reports have a language structure closer to discharge summaries than to general clinical notes. Consequently, our model was initialized with weights from the latter of the two ClinicalBERT models: ClinicalBERT-Bio+Discharge Summary BERT Model.

Transfer learning was accomplished by performing masked-language modeling [23]. Briefly, 15% of the words in the corpus are selected at random and replaced with a *mask* token. The language model is then trained to predict the masked words. The word-masking process is performed automatically at the beginning of each training run.

Our language-model training corpus included electronic pathology reports of solid tumors produced by pathologists at Moffitt between 1986 and 2020. The year 1986 was the earliest date on pathology reports cataloged in our enterprise data

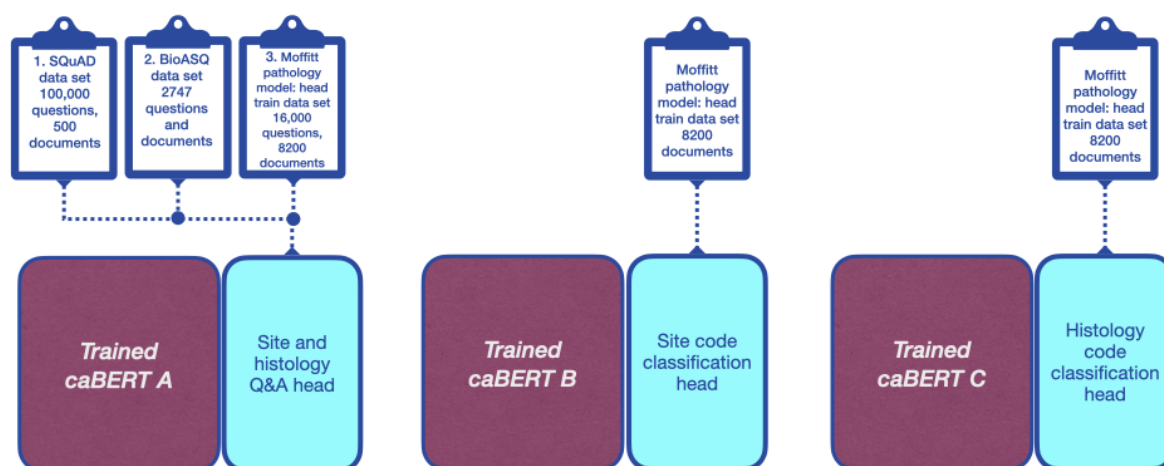

warehouse. The data set was restricted to solid tumors for two reasons: first, to focus the problem domain for this proof-of-concept study, and, second, Moffitt hematologic pathology reports follow a quasi-structured format, reducing the need for extraction of data from unstructured text.

This data set contained both Health Level Seven International messages and plain-text pathology reports. These were minimally processed to extract and clean the text relevant to pathology (more details can be found in [Multimedia Appendix 1](#)). The final language model training corpus included 275,605 electronic pathology reports from 164,531 unique patients and included 121 million words.

Pathology Q&A Model

The pathology Q&A lesson plan involved 3 stages, each intended to improve our system's comprehension of pathology reports and thereby increase the accuracy of question answering ([Figure 2](#)). The three stages involved training the Q&A model to (1) answer general English language questions, (2) answer technical biomedical science questions, and (3) answer questions from Moffitt pathology reports.

Figure 2. Lesson plan for the caBERT network consisting of one question and answering model A and two classification models, one for primary site (model B) and another for histology (model C). BioASQ: Biomedical Semantic Indexing and Question Answering; Q&A: question and answer; SQuAD: Stanford Question Answering Dataset.

Each training stage used supervised learning. This required a training data set that included passages of text, ≥ 1 questions related to each passage, and ground truth answers to those questions that appeared as contiguous phrases within the related passage. At the end of each stage we evaluated our system using the same sequestered test data set constructed from Moffitt pathology reports, as described in more detail later in this section. The experimental parameters used to train the Q&A model were held constant over all stages and are listed in Table S1 in [Multimedia Appendix 1](#).

For the first stage of training we used the Stanford Question Answering Dataset (SQuAD), version 1.1 [57]. SQuAD consists of more than 100,000 questions and answers created by crowdworkers on Wikipedia articles. The SQuAD data format is widely used in NLP research. Therefore, we designed our system to read and process data sets in this format.

For the second stage of training we used the large-scale Biomedical Semantic Indexing and Question Answering (BioASQ) data set [58]. In particular, we used data from BioASQ Challenge 7b: Biomedical Semantic Question Answering. This data set contains 2747 training questions along with their ground truth answers. According to the BioASQ Challenge 7b description: "All the questions are constructed by biomedical experts from around Europe." This data set was converted to SQuAD format by Yoon et al [59] and made available for public use.

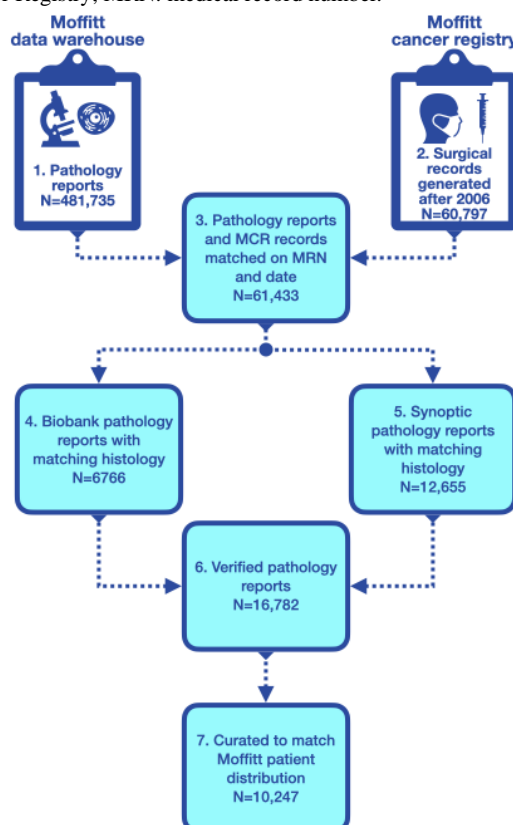

Next, we constructed a Q&A fine-tuning data set in SQuAD format based on Moffitt pathology reports. We obtained ground truth answers to our 2 questions from data abstracted by Moffitt certified tumor registrars (CTRs). CTRs undergo an extensive training and internship program to become proficient at extracting quantitative and categorical data from unstructured pathology reports. They are widely employed by cancer centers

and other organizations to extract data for clinical and research applications and for reporting to state and national agencies. The MCR deploys state-of-the-art quality assurance procedures: its benchmark for quality is 90% and its target accuracy is 95% [60].

Moffitt's enterprise data warehouse was searched to find solid tumor pathology reports generated after 2006 with matched MCR data (Figure 3). These reports were screened to ensure

that they contained a description of a positive diagnosis of a single primary tumor. Next, each report was processed to ensure that it contained an answer to at least one of the questions in the Q&A model. This was accomplished programmatically by searching each report for a phrase contained in a table of acceptable answer phrases (Figure S1 in Multimedia Appendix 1), as described in more detail in the next section (*Accommodate Diverse Terminology*). Our search produced 16782 reports that met these inclusion criteria (Figure 3).

Figure 3. Flowchart depicting the data curation process for creating the Moffitt fine-tuning data sets (used in the site and histology question-and-answer and classification tasks). MCR: Moffitt Cancer Registry; MRN: medical record number.

Next, we curated these reports to ensure that (1) the relative frequencies of the 10 most common tumor sites and histologies in this collection matched the relative frequencies in Moffitt's patient population as a whole and (2) all MCR-assigned tumor sites and histologies reported for Moffitt patients after 2006 were represented in the data set. The final curated collection contained 10,247 reports (Figure 3). We will refer to this data set as the *fine-tuning* data set to contrast it with the caBERT language model data set used to train the base language model as described in the *Pathology Language Model* section.

The curated collection of reports was randomly divided to create two data sets: 79.99% (8197/10,247) of the reports were used to create the Moffitt fine-tuning training data set and 20.01% (2050/10,247) were used to create the Moffitt fine-tuning testing data set. Each data set was saved in SQuAD format using a custom-written Python program. The training data set was used for the final stage of Q&A training and also for ICD-O-3 code predictions, described in more detail in the *Accurate ICD-O-3 Codes* section. The testing subset was used to evaluate the impact of Q&A training at the end of each training stage (Figure S2 in Multimedia Appendix 1) and also to evaluate the performance of the final pipeline (Figure 4).

Figure 4. The final caBERT network (caBERTnet) connects caBERT instances A, B, and C, used for site and histology question and answering, International Classification of Diseases for Oncology, Third Edition (ICD-O-3) primary site and ICD-O-3 histology code classification, respectively.

Question-answering accuracy was evaluated using two metrics: exact match and F1 score. Exact match is true if the caBERT-extracted phrase is an identical word-for-word match with the MCR phrase and false otherwise. We calculated the average number of true results across all test samples. The F1 score is a measure of the degree of overlap among the words in the caBERT-extracted phrase and the MCR phrase. This varies from 0 (no words in common) to 1 (all words in common but not necessarily in the same order). Each exact match corresponded to an F1 score of 1.0. We calculated the average F1 score across all test samples and expressed it as a percentage.

After all training stages were complete, they were repeated using the initial ClinicalBERT model (*ClinicalBERT-Bio+Discharge Summary BERT*) with a new randomly initialized Q&A layer. This allowed us to determine the impact of developing a pathology-tuned BERT model on extraction accuracy over the baseline accuracy of using ClinicalBERT alone (Figure S2 in [Multimedia Appendix 1](#)). The training parameters were set to those optimized for ClinicalBERT and reported by Alsentzer et al [55].

Accommodate Diverse Terminology

Our pathology reports came supplied with ground truth labels for primary site and histology in the form of ICD-O-3 codes [61], which were abstracted by Moffitt CTRs. To train the Q&A model we needed a method to determine the precise location within each pathology report of the actual text corresponding to these labels. This proved nontrivial owing to the rather diverse terminology within each pathology report used to refer to each primary site and histology.

To address this issue, we used data from several canonical sources. Our primary source was the ICD-O-3 standards [62], which we used to define the primary *preferred* terminology for each code. Within the ICD-O-3 standards there are 332 unique site codes and 1143 unique histology codes, each with accompanying preferred terms. Along with the preferred term, many codes also have an additional set of synonyms, which we stored together with the preferred term in a table of acceptable phrases for each code. In addition to the ICD-O-3 tables, we also used terminology from the National Cancer Institute's

Surveillance, Epidemiology, and End Results (SEER) program Site/Histology Validation List [62], along with the SEER Site-specific training module website [63].

To provide a little more detail, the specific sources we used to construct our acceptable phrase tables were as follows. For histology, we used the ICD-O-3.2 morphology table (version 15112019) [64] and supplemented this with terms from the SEER Site/Histology Validation List (version 20150918), current versions of which are both available in Microsoft Excel format from their respective websites. For the site terms, we used the ICD-O-3 mapping table maintained by the National Cancer Institute [65], supplemented again by the SEER Site/Histology Validation List. In addition, for the site terms we also scraped the tables contained in the SEER Site-specific learning module website for any new terms.

The aforementioned sources have the benefit of being subject to an international standard and are useful in designating preferred terms for each histology and site code. However, we should note that there do exist slight discrepancies between the World Health Organization-maintained ICD-O-3 coding standards and the North American Association of Central Cancer Registries coding guidelines, which are followed in the SEER materials. For simplicity, we chose to base our model on the ICD-O-3 standards, but this caveat may prove relevant for any future cancer registry applications of the model.

Although these sources provided us with preferred and alternative terminologies, they did not encompass the full range of language used for every label in our pathology reports, which often included things such as permutations of word orderings as well as acronyms and other typographical differences with the canonical terms. Of note, Moffitt CTRs routinely record a short description of the histology and site for every labeled pathology report in a text-based field. For each histology and site code, we appended these additional phrases to the list of synonyms of the preferred canonical terminology.

Using the sources described earlier, we created two hierarchical tree structures as illustrated in Table S2 in [Multimedia Appendix 1](#): one to hold histology terms and one to hold site terms. To construct these trees, the histology and site codes were first

grouped into broad morphology and site groups as specified in the ICD-O-3 tables. Within each group are a collection of specific codes, where each code has an associated preferred term, and a list of synonyms. For efficient searching, these trees were stored as JSON objects that were imported into Python as nested dictionaries and lists. See Figure S1 in [Multimedia Appendix 1](#) for an example of an entry in our acceptable phrase table.

To search each pathology report for appropriate spans of text, we used the trees to construct a dictionary with keys provided by the specific site and histology codes and values provided by the associated acceptable phrase table. Using this dictionary, for each pathology report we implemented a simple search for an exact match from the list of preferred terms and synonyms for the labeled ground truth histology and site code, giving preference for the preferred term, followed by each synonym ordered by length (with the longest matching synonym given preference over the others).

Even with the diverse terminology within the acceptable phrase table for each code, not every pathology report contained an exact match within the list of allowed terms. For pathology reports that did not contain an exact match, we further refined the search by allowing for matches that only overlapped with a subset of the word tokens within each phrase, again giving preference to the longest synonyms and also using a set of stop terms to avoid overly general terminology. To capture potential word-ordering differences, we allowed these word token subsets to be constructed in an arbitrarily permuted order, which was made efficient by using the *itertools* module available as part of the Python Standard Library.

Using the aforementioned procedure, of the 10,247 pathology reports in the Moffitt fine-tuning training and testing data sets, we were able to find appropriate textual answers within 10,096 (98.53%) reports for primary site (with $n=8070$, 79.93%, in the training set and $n=2026$, 20.07%, in the testing set) and within 10,218 (99.72%) reports for histology (with $n=8176$, 80.02%, in the training set and $n=2042$, 19.98%, in the testing set).

Provide Accurate ICD-O-3 Codes

Overview

The tumor site and histology phrases extracted by the Q&A model ([Figure 2](#)) were used to predict ICD-O-3 site and histology codes. This involved fine-tuning two additional copies of caBERT: one to predict site codes and the second to predict histology codes. Our final system ([Figure 4](#)) includes a network of 3 caBERT-based models. We refer to this system as caBERTnet.

Training the ICD-O-3 Site and Histology Code Classifiers

Classifier training parameters are described in more detail in Table S1 in [Multimedia Appendix 1](#). Briefly, each caBERT instance was trained to perform a classification task: given an input phrase, predict the corresponding ICD-O-3 code. Classification tasks were trained using the Moffitt fine-tuning training data set (*Extract Tumor Site and Histology Descriptions* section). Training samples were screened to ensure that each

contained ground truth site and histology codes and at least one site or histology phrase provided by the MCR. Missing site and histology phrases were filled using SEER preferred terms. These were identified by performing a lookup into the ICD-O-3 table using the site or histology code in the training sample.

After screening, the ground truth phrases were labeled and concatenated to form a single combined phrase. For example, if the MCR phrases were *lung lower lobe* and *squamous cell carcinoma*, then the combined phrase would be *site: lung lower lobe. histology: squamous cell carcinoma*. The combined phrase was used to train both the caBERT site classification model and the caBERT histology classification model. The use of a combined phrase allowed caBERTnet to leverage any correlation between site and histology to improve its performance. For example, astrocytomas are brain tumors. When caBERTnet encountered a previously unseen pathology report during the test phase with the combined phrase *site: frontal. histology: anaplastic astrocytoma*, it correctly predicted a brain site of *C711, frontal lobe* and a histology of *9401/3 astrocytoma anaplastic NOS* (not otherwise specified).

Testing the ICD-O-3 Site and Histology Code Classifiers

After training of the site and histology ICD-O-3 code classification models was complete, caBERTnet performance was evaluated using the sequestered Moffitt fine-tuning test data set described in the *Extract Tumor Site and Histology Descriptions* section. For each test sample, the MCR-generated site and histology phrases were used to create a *ground truth* combined phrase. Next, the site and histology phrases extracted by the Q&A stage of caBERTnet were used to create a *predicted* combined phrase. The predicted phrase was tokenized to prepare it for input into each classification model. Ground truth site and histology codes from the MCR were enumerated, as described earlier, and stored as true labels. Subsequently, the trained site and histology classification models were used to classify the tokenized *predicted* combined phrases for each test sample. The outputs from this classification, logits, were converted into probabilities, sorted, and converted back into ICD-O-3 codes as described earlier, labeled as *predicted* codes, and saved for further performance analysis.

caBERTnet performance was evaluated in 3 different ways. First, the top 5 accuracies were determined. This metric (or its inverse, the top 5 error rate) is commonly used to evaluate classification algorithms [66]. Briefly, it calculates the average probability that the correct site or histology code occurs within the top N predicted codes because N is varied from 1 through 5. Top 1 accuracy, the accuracy of the code scored most highly by the classification algorithm, is equivalent to precision, recall, and F1 score for this classification task.

Second, we examined the effect of culling or removing infrequently occurring codes. Our hypothesis was that the caBERT site and histology code classifiers suffer when they do not have enough training data to learn from. Therefore, to examine the effect of training sample size, we iteratively eliminated site and histology codes from the full 2050-sample test data set when the number of examples with a particular code in the training set (alone) fell below a specified threshold. We varied that threshold from 0 samples (no culling) to 35

samples in increments of 5 samples. At each culling threshold we recalculated the top 5 performance of the site and histology classifiers.

Third, we calculated the overall accuracy of predicting the correct *group* code for each site and histology code. *Group* codes occur higher up in the ontological tree and, as the name implies, encompass a group or range of related tumor sites or histologies. For example, the site codes *C341 upper lobe, lung* and *C349 lung, NOS* have the same group code: *C34 bronchus and lung*. The histology codes *8070/3 squamous cell carcinoma, NOS* and *8051/0 verrucous carcinoma* both have the same group code: *805-808 squamous cell neoplasms*. The ICD-O-3 ontology includes 82 group-level site codes covering the 332 fine-grained site codes. It includes 49 group-level histology codes covering the 1143 fine-grained histology codes.

Group codes are useful for search and summary applications. The group codes for both the predicted and ground truth fine-grained codes were determined by searching in the tree data structures described in the *Accommodate Diverse Terminology* section. For each fine-grained code, the search started at that code's location in the tree and proceeded upward. Finally, we calculated the overall accuracy of prediction within each group code for both site and histology predictions.

Results

Model Accuracy

The accuracy of the both the ClinicalBERT and caBERT Q&A models when tested on the Moffitt fine-tuning testing data set improved at each Q&A training stage (SQuAD, BioASQ, and Moffitt training data; Figure S2 in [Multimedia Appendix 1](#)). ClinicalBERT had higher accuracy than caBERT on the Moffitt test set after each of the first 2 training stages. This suggests that the specialized pathology-language tuning reduced caBERT's ability to learn from the SQuAD and BioASQ training data sets. However, caBERT outperformed ClinicalBERT after training on Moffitt pathology reports. This was true both for exact match (3254/4068, 79.99%, for caBERT vs 3069/4068, 75.44%, for ClinicalBERT) and F1 score (87.76% for caBERT vs 84.85% for ClinicalBERT).

The top N accuracy of predicting fine-grained site codes ranged from 71.58% (1456/2034; top 1) to 91.05% (1852/2034; top 5), without culling (Figure 5). The accuracy for predicting histology codes ranged from 83.87% (1706/2034; top 1) to 94.79% (1928/2034; top 5). Culling 6.39% (130/2034) of the test samples—those site and histology codes with <5 samples in the training data set—improved accuracy for site code prediction to 73.84% (1406/1904; +2.26%; top 1) and 93.28% (1776/1904; +2.23%; top 5). The same culling improved the accuracy of histology code prediction to 85.29% (1624/1904; +1.42%; top 1) and 96.27% (1833/1904; +1.48%; top 5).

Figure 5. The effect of culling rare tumor sites and histologies on the top N accuracy of predicting fine-grained International Classification of Diseases for Oncology, Third Edition codes.

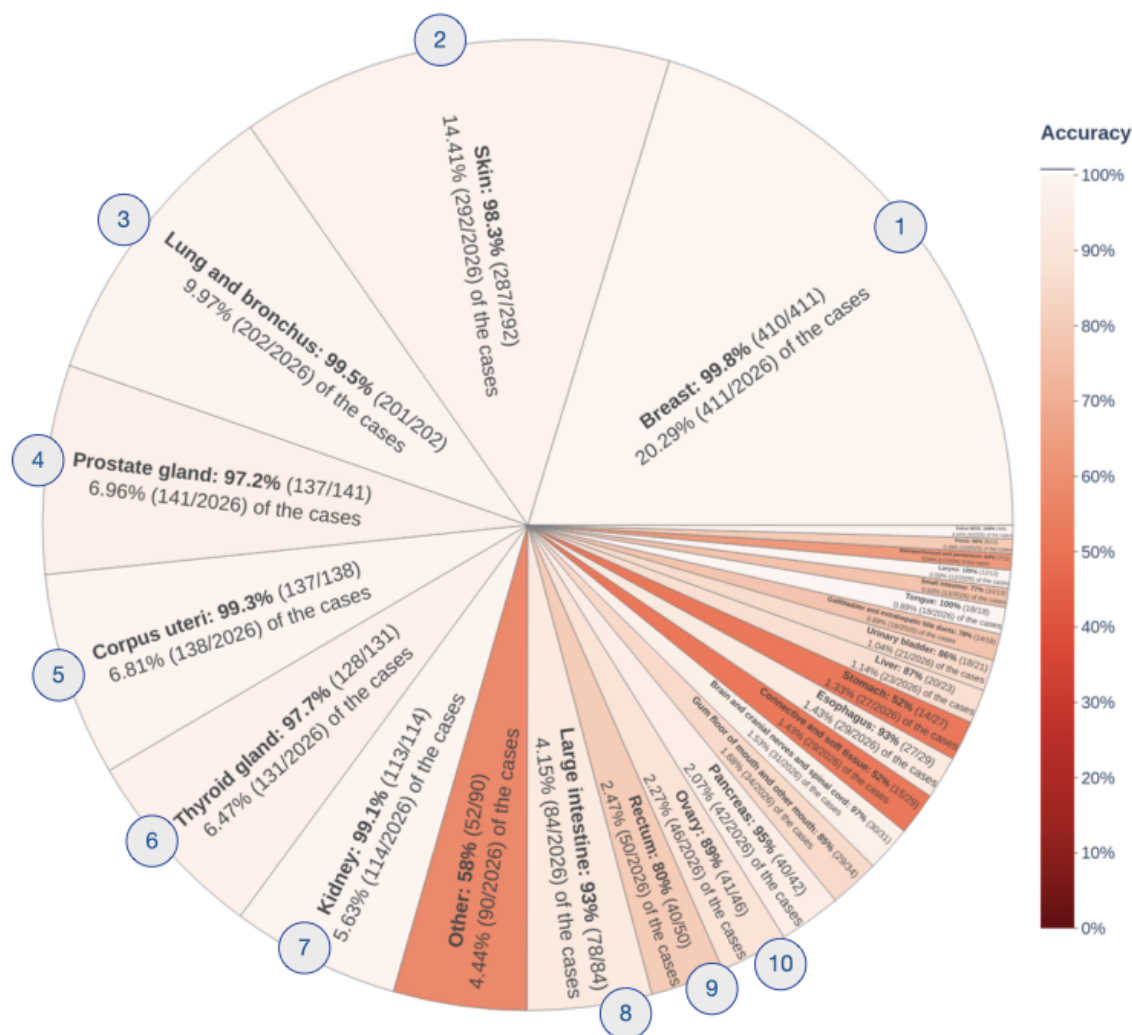

Group-Level Code Predictions

We also computed the accuracy of the more coarse-grained group-level code predictions by mapping each top 1 code prediction to its corresponding group in the ICD-O-3 ontology. The accuracy of predicting group-level site codes was 93.53% (1895/2026) overall (Figure 6). The ten most commonly represented sites—(1) breast, (2) skin, (3) lung and bronchus, (4) prostate gland, (5) corpus uteri, (6) thyroid gland, (7) kidney, (8) large intestine, (9) rectum, and (10) ovary—included 79.42%

(1609/2026) of the test samples and had an accuracy of 97.7% (1572/1609). Accuracies <80% were observed for connective and soft tissues (15/29, 52%, with 29/2026, 1.43%, of the samples), stomach (14/27, 52%, with 27/2026, 1.33%, of the samples), gallbladder and extrahepatic bile ducts (14/18, 78%, with 18/2026, 0.89%, of the samples), small intestine (10/13, 77%, with 13/2026, 0.64%, of the samples), retroperitoneum and peritoneum (7/11, 64%, with 11/2026, 0.54%, of the samples), and other (52/90, 58%, a collection of 27 sites totaling 90/2026, 4.44%, of the samples).

Figure 6. Accuracy of predicting tumor site group codes from unstructured and previously unseen pathology reports on solid tumors, broken down to show performance within each site group. The overall accuracy over all site groups was 93.53% (1895/2026).

The accuracy of predicting group-level histology codes was 97.6% (1993/2026) overall (Figure 7). The ten most commonly represented histologies—(1) adenomas and adenocarcinomas, (2) ductal and lobular neoplasms, (3) nevi and melanomas, (4) squamous cell carcinomas, (5) cystic mucinous and serous neoplasms, (6) transitional cell papillomas and carcinomas, (7)

gliomas, (8) epithelial neoplasms, (9) complex mixed and stromal neoplasms, and (10) lipomatous neoplasms—included 95.84% (1957/2042) of the test samples and had an accuracy of 98.06% (1919/1957). An accuracy of <80% was observed for epithelial neoplasms only (14/18, 78%, with 18/2042, 0.88%, of the samples).

Figure 7. Accuracy of predicting tumor histology group codes from unstructured and previously unseen pathology reports on solid tumors, broken down to show performance within each histology group. The overall accuracy over all histology groups was 97.6% (1993/2042).

Discussion

Primary Contributions

This work describes 3 primary contributions. First, we created caBERT: a BERT-based language model for comprehension of cancer pathology reports. We are aware of only 1 other attempt to create a pathology- and oncology-specific BERT language model [45]. That study included 290,438 pathology reports created between 2005 and 2015 from a tertiary teaching hospital in the United States. However, only 8870 of these reports were cases involving cancer. Our study included 275,605 pathology reports from patients with cancer diagnosed or treated at Moffitt. The larger corpus of cancer-specific reports should help our system achieve higher performance levels with cancer-related NLP tasks. However, because we did not have access to the system described in the study by Ma et al [45], a direct comparison with ours was not possible.

Second, we created a new Q&A system to extract tumor site and histology descriptions from free-text pathology reports. This is the first functional Q&A system for extracting

information from pathology reports that we are aware of. The Q&A format has 2 important benefits. First, it provides a user-friendly interface to the information extraction system. Second, incorporation of additional questions into our system is straightforward. With appropriate ground truth-labeled training data, this should allow us to extract additional data fields from free-text pathology reports.

Third, we created a new caBERT network, caBERTnet, to predict fine-grained ICD-O-3 site and histology codes using the answers extracted through the initial Q&A component. There has been considerable prior work using NLP methods to predict ICD-O codes from pathology reports [11,12,16,67]. Here, we compare our results to 5 of the most highly cited recent publications in this area.

Comparisons With Prior Work

Much of the prior work has focused on a single anatomical site or histology. For example, Coden et al [16] described a system to extract information on tumor site, histology, grade, lymph nodes, tumor size, and reporting date from free-text pathology reports of colon cancer. They achieved precision and recall

values of between 0.95 and 0.98 for both site and histology ICD-O codes. Their system used a rule-based NLP pipeline, with a large number of controlling parameters that required extensive manual tuning to obtain optimal results. In contrast, BERT-based NLP systems can both discover and tune the steps of a traditional NLP pipeline automatically [68]. This has significant advantages in terms of reduced effort; in addition, it allows these systems to be quickly retuned for data sets from other institutions or different applications through transfer learning [69].

The BERT system from Ma et al [45], mentioned earlier, was used to extract information on 15 *primary cancer sites*, 6 *cancer reasons*, and 3 *metastatic disease states*. In all, 11 of their cancer sites corresponded to ICD-O-3 group-level site classifications (eg, breast, lung, or bronchus). The others were broader groupings (eg, colorectal, upper gastrointestinal, and head and neck). Of their cancer reasons, 4 corresponded to ICD-O-3 group-level histology classifications (eg, melanoma and soft tissue sarcoma). The remaining two cancer reasons were very broad groupings: carcinoma and blastoma. They achieved accuracies on the full test set of 96.7% and 98.5% for cancer site and cancer reason, respectively. However, they did not predict ICD-O-3 group or fine-grained codes.

Nguyen et al [70] developed a system to monitor Health Level Seven International electronic pathology reports from across the state of Queensland in Australia. Their system relied on business rules and symbolic reasoning using Systematized Nomenclature of Medicine codes. They tuned their system using 201 pathology reports and tested it on 220 unseen reports. They extracted 8 different cancer characteristics from these reports. These characteristics included ICD-O-3 site codes (both fine-grained, Cxxx, and group, Cxx) and histological type. Their data set included 66 sites and 94 histologies. They achieved F1 scores of 61.1%, 73.2% and 63.7% on fine-grained site codes, group site codes, and histology codes, respectively.

Alawad et al [67] developed a multistage system of deep convolutional neural networks to extract the primary site, histological grade, and laterality from pathology reports. They achieved an F1 score of 77.5% over 12 ICD-O-3 site codes.

Qiu et al [11] also developed a deep convolutional neural network to extract ICD-O-3 codes from breast and lung cancer pathology reports. Training was based on 942 pathology reports annotated by cancer registry experts. The data set included 7 breast sites and 5 lung sites. Of the 12 sites, 6 had at least 50 samples per code. The remaining 6 sites had 10 to 50 samples each. They evaluated their system using a 10-fold cross-validation. Their overall F1 score for predicting tumor sites across all 12 ICD-O-3 codes was 72.2%.

Our study included a greater diversity of cancer cases than previous studies (214 site codes and 193 histology codes), while obtaining similar or better accuracy scores. Many of the site and histology codes in our training data set included ≤ 5 samples, whereas prior studies reported ≥ 10 training samples per code. Culling codes from the test set with ≤ 5 samples in the training set reduced the size of our test data set by 6.39% (130/2034; 130 pathology reports). However, this increased our top-1 accuracy on the test data to 73.84% (1406/1904; +2.26%) and

85.29% (1624/1904; +1.42%) for site and histology, respectively. Our system also ranks and reports the top 5 predictions for ICD-O-3 site and histology codes. This has useful clinical applications: often there is a degree of uncertainty or *hedging* in pathology reports [16]. Listing the top 5 predicted codes could help to reduce this uncertainty. For example, an artificial intelligence–assisted abstraction system that provides the top 5 predicted ICD-O-3 codes for a particular pathology report (in a pull-down menu, for example) could aid the process of abstraction and enhance the workflow in cancer registries. Our top 5 accuracies for fine-grained codes with ≥ 5 training samples were 92.95% (1794/1930) and 96.01% (1853/1930) for site and histology, respectively.

Additional Insights From the Results

Figure 5 shows the top 5 results at various levels of rare-code elimination from the test data set, and it provides 3 additional insights. First, as N increased from 1 to 5, the improvement in accuracy for sites was larger than that for histologies. This suggests that there is more uncertainty predicting site codes than in predicting histology codes. Second, eliminating rare codes, for example, going from E=0 (green lines) to E=5 (blue lines; Figure 5), improved site accuracy more than it improved histology accuracy. This suggests that site prediction was more dependent on sample size. Third, site accuracy failed to improve for E>20. This suggests that 20 samples per code were required to maximize site code prediction accuracy.

The overall accuracy for predicting site group codes was 93.53% (1895/2026) (Figure 6). Nevertheless, several site group codes had accuracies <80%. Here, we will discuss the *Other* group (52/90, 58%, accuracy), along with two of the site group codes with the lowest accuracies: *C49 Connective, Subcutaneous, and Other Soft Tissues* (15/29, 52%, accuracy) and *C16 Stomach* (14/27, 52%, accuracy).

The *Other* site category included 27 group codes. Together, these group codes contained 61 fine-grained codes with at least one sample pathology report each in the training data set, as determined by the MCR. The mean and median number of reports in the training data set for each fine-grained code in the *Other* category were 6.3 (SD 6.3) and 4 (IQR 5), respectively. Consequently, caBERTnet accuracy on these rare sites was likely limited by the availability of training data.

caBERTnet failed to predict the MCR site code for 14 test cases in the group *C49 Connective, Subcutaneous, and Other Soft Tissues*. We manually reviewed 50% (7/14) of these cases, all of which were labeled by the MCR as soft tissue of the limb, shoulder, and hip or pelvis (codes *C491*, *C492*, and *C495*). In 14% (1/7) of these cases, the information required to determine the correct site was not present in the pathology report text. In these situations, CTRs would use additional information in the patient record. However, this information was not available to caBERTnet. In the remaining 86% (6/7) of the cases, the pathology report described characteristics of a lesion that had metastasized from the limb, shoulder, hip, or pelvis to another location. The MCR recorded the originating organ as the tumor site, whereas caBERTnet predicted the metastasis site.

caBERTnet failed to predict the MCR site code for 13 test cases in the group *C16 Stomach*. All these cases were labeled by the MCR as *C160 Cardia, NOS*, and by caBERTnet as lesions of the lower third of the esophagus (*C155*; 12/13, 92%) or as overlapping lesions of the esophagus (*C158*; 1/13, 8%). The MCR labels are due to a rule in the American Joint Committee on Cancer Staging Manual, Eighth Edition [71]. On page 189 in that manual it states as follows:

Cancers involving the Esophagogastric Junction (EGJ) that have their epicenter within the proximal 2 cm of the cardia (Siewert types I/II) are to be staged as esophageal cancers. Cancers whose epicenter is more than 2 cm distal from the EGJ, even if the EGJ is involved, will be staged using the stomach cancer TNM (primary tumor, lymph nodes, and distant metastases) and stage groupings (see Chapter 17).

The pathology reports on these cases did not mention the spatial location of the tumor sample in relation to the EGJ. Consequently, measurement of the tumor location in pretreatment imaging was required to determine the correct tumor site code.

The overall accuracy for predicting histology group codes was 97.7% (Figure 7). Only one group code had an accuracy <80%: *801-804 Epithelial Neoplasms, NOS* (77.8%). caBERTnet failed to predict the MCR histology code for 5 of these cases. In 80% (4/5) of these cases, the pathology report was based on histology at the metastatic site of disease. The MCR coded these as the histology of the originating tumor, whereas caBERTnet predicted the histology at the metastatic site. In 20% (1/5) of the cases, the information required to determine the correct histology code was not present in the pathology report and required the CTR to conduct a review of the patient medical record.

The last case was quite interesting because the pathology report included an initial intraoperative diagnosis that disagreed with the final diagnosis. The former indicated a histological type of *spindle cell carcinoma*. The latter included the following statements: “the differential diagnosis includes sarcomatoid carcinoma and inflammatory myofibroblastic tumor...the histomorphologic and immunoprofile support the diagnosis of sarcomatoid carcinoma.” The MCR coded the histology as *8032/3 spindle cell carcinoma, NOS*, based on the intraoperative statements, whereas caBERTnet predicted *8033/3 pseudosarcomatous carcinoma*. The phrase *sarcomatoid carcinoma* is an alternative form of the ICD-O-3 preferred phrase *pseudosarcomatous carcinoma*. Although caBERTnet’s prediction did not agree with that of the MCR, downstream applications may still value automatic prediction and codification of the final diagnosis.

Potential Applications

There are multiple potential applications of caBERTnet at Moffitt. For example, there is a delay of several months between initial pathology report dictation and CTR abstraction because the CTRs typically wait for enough time to have elapsed for the first course treatment to have been administered to minimize the number of times they have to review the medical record.

caBERTnet can be used to extract information from pathology reports in a timelier way, thus facilitating the use of the data for clinical pathway reporting and screening for clinical trials. Furthermore, CTRs only abstract the subset of pathology reports associated with the cancer diagnosis and first-course treatment. caBERTnet could be used to extract information from pathology reports associated with subsequent biopsies and surgeries that would never be manually curated by the CTRs. To facilitate these use cases, we plan to extract tumor site and histology information close to real time and link these values to other patient data stored in our analytics platform. These data can be incorporated into real-time dashboards and data sets for a wide range of decision support and research applications.

We do not believe that caBERTnet will replace CTRs at cancer clinics. Many complex, difficult, and rare cases require intuition and information outside of the pathology report to determine the correct coding. These cases are beyond the scope of an NLP tool. However, caBERTnet may help simplify and accelerate MCR workflows. For example, caBERTnet could preprocess pathology reports to identify the top 5 site and histology ICD-O-3 codes and their corresponding phrases. The phrases could then be highlighted within the report body. In addition, two pull-down menus could be prepopulated with top 5 code predictions: one for site and the other for histology. The CTR could then quickly choose a code from either pull-down menu. If the correct code was not among the top 5, then the CTR would resort to their current workflow, entering this information by hand.

Limitations of Approach

Although there are immediate applications of the caBERTnet model within our internal workflows, there are a number of aspects of our modeling approach that limit the application of caBERTnet to other use cases. In this section, we provide an overview of several important limitations that we believe should be considered before caBERTnet implementation.

The most critical limitations correspond to issues related to our data curation and preprocessing approaches. In the curation of our Moffitt fine-tuning data set, we restricted the available reports to only those containing a single primary tumor diagnosis. Although this was partly imposed by the nature of the SQuAD Q&A task (which expects a single answer to each question asked of each input), it nonetheless limits the generalizability of our model to reports containing multiple (or zero) positive diagnoses. We are exploring methods of mitigating these issues within the current setup by adjusting the likelihood thresholds for output predictions that could be used to screen out reports with no diagnosis. Another limitation inherent to a Q&A system is the necessity of knowing the precise span of text corresponding to the answer to each question asked of each report. Owing to the sheer number of reports in our fine-tuning data set, it was infeasible to manually curate answer labels. To circumvent this issue, we chose to create our own automated system to determine the answer text in each report. Any such automated preprocessing necessarily leaves a fingerprint on downstream tasks. The drawbacks of our approach in particular relate to the restriction of answers from a predetermined list of possibilities for each site and histology.

Although these phrase sets were diverse (and our approach even allowed for permutations of phrasing within these terms), this process nevertheless limits the allowed terminology and is necessarily incomplete.

In addition, a single pathology report may reference several tissue samples (which can be from related or distant sites from the actual site of diagnosis). Although we limited our automated answer-search preprocessing algorithm to only find terms associated with the known diagnosis label for each report, it is possible that the answer found in the report text by the preprocessing corresponds to a false answer from a different sample in the report; this is particularly relevant for cases with multiple samples from related sites (eg, upper outer quadrant breast vs upper inner quadrant breast). When the 2 samples are in the same site (or histology) group, this issue is avoided by outputting the group code; however, this does not help when the 2 samples belong to different groups altogether.

Future Directions

We plan to continue development of caBERTnet. Of particular interest is extending the system with additional questions and MCR-derived ground truth labels to train it to extract additional tumor characteristics. These include grade, size, involvement of lymph nodes, primary or metastatic status, presence or absence of molecular markers, and others. caBERTnet could also be customized to extract information on hematological malignancies.

A caBERTnet-assisted MCR abstraction tool could also be used for active [72] or human-in-the-loop [73] learning. Briefly, this approach uses human-labeled data to improve the performance of machine learning algorithms over time. It is particularly useful when the subject matter expert (a CTR in our case) provides labels for cases with low-confidence predictions by the machine learning algorithm. However, it would require careful engineering to avoid common pitfalls and ensure seamless operation [74].

The system's accuracy on rare sites and histologies could be improved with additional training data. A potential option may

be to collaborate with other academic cancer centers; distributing caBERTnet for training on local pathology reports at other sites based on ground truth labeling of training and test data sets from highly standardized registry data or the application of federated multitask learning [75] that distributes copies of a central model to multiple spoke sites for tuning of the central model on local data could allow vast improvements in caBERTnet accuracy. Using these methods, information learned at local sites (eg, model weights) is transmitted back to the central node where the information is combined in a pluralistic way that avoids the need to impose consensus on the data distributions at the spoke sites. This allows for both heterogeneity in local data and broad generalizability of the central model. That said, the most effective way to protect private health information when sharing such models remains an unsolved problem, and these kinds of expansions would depend on the development of validated privacy schemes specific to BERT.

Conclusions

Our new NLP system, caBERTnet, is built around a network of 3 cooperating BERT instances. On a sequestered test data set, it produced top 5 accuracies of 92.95% (1794/1930) and 96.01% (1853/1930) for fine-grained ICD-O-3 site and histology codes, respectively. This level of accuracy is on par with existing systems in the literature, while also being accurate over a broader range of site and histology groups.

Pathology report abstraction systems such as caBERTnet cannot be expected to achieve performance on par with CTRs who abstract data ultimately incorporated into population-based cancer registries [76], given the vast amount of ancillary data from within the electronic health record that is required for thorough abstraction and the subtle nuances associated with coding guidelines. However, caBERTnet could expedite access to timely pathology data needed for disease surveillance, cohort identification, and clinical trial matching. Furthermore, it can improve existing workflows, serving as a valuable step toward the ultimate goal of a mostly automated abstraction system.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Additional information on the CancerBERT and CancerBERT network model training and performance as well as an elaboration on the acceptable phrases used to curate labels for pathology reports in the question-and-answer stage.

Abstract

Background: With the increasing sophistication of the medical industry, various advanced medical services such as medical artificial intelligence, telemedicine, and personalized health care services have emerged. The demand for medical data is also rapidly increasing today because advanced medical services use medical data such as user data and electronic medical records (EMRs) to provide services. As a result, health care institutions and medical practitioners are researching various mechanisms and tools to feed medical data into their systems seamlessly. However, medical data contain sensitive personal information of patients. Therefore, ensuring security while meeting the demand for medical data is a very important problem in the information age for which a solution is required.

Objective: Our goal is to design a blockchain-based decentralized patient information exchange (PIE) system that can safely and efficiently share EMRs. The proposed system preserves patients' privacy in the EMRs through a medical information exchange process that includes data encryption and access control.

Methods: We propose a blockchain-based EMR-sharing system that allows patients to manage their EMRs scattered across multiple hospitals and share them with other users. Our PIE system protects the patient's EMR from security threats such as counterfeiting and privacy attacks during data sharing. In addition, it provides scalability by using distributed data-sharing methods to quickly share an EMR, regardless of its size or type. We implemented simulation models using Hyperledger Fabric, an open source blockchain framework.

Results: We performed a simulation of the EMR-sharing process and compared it with previous works on blockchain-based medical systems to check the proposed system's performance. During the simulation, we found that it takes an average of 0.01014 (SD 0.0028) seconds to download 1 MB of EMR in our proposed PIE system. Moreover, it has been confirmed that data can be freely shared with other users regardless of the size or format of the data to be transmitted through the distributed data-sharing technique using the InterPlanetary File System. We conducted a security analysis to check whether the proposed security mechanism can effectively protect users of the EMR-sharing system from security threats such as data forgery or unauthorized access, and we found that the distributed ledger structure and re-encryption-based data encryption method can effectively protect users' EMRs from forgery and privacy leak threats and provide data integrity.

Conclusions: Blockchain is a distributed ledger technology that provides data integrity to enable patient-centered health information exchange and access control. PIE systems integrate and manage fragmented patient EMRs through blockchain and protect users from security threats during the data exchange process among users. To increase safety and efficiency in the EMR-sharing process, we used access control using security levels, data encryption based on re-encryption, and a distributed data-sharing scheme.

Introduction

Background

With the development of information and communication technology, the existing medical information system, which used paper charts to manage medical information such as patient treatment information and clinical results, changed to a digital-based medical information system. As of 2017, more than 94% of the hospitals in the United States have used digital health information systems [1,2]. The digital medical information system uses electronic medical records (EMRs) that store patient medical information (eg, patient demographics, progress notes, medications, vital signs, past medical history, immunizations, laboratory data, and radiology reports) in electronic document format for patient treatment and health management [3]. Moreover, health care practitioners use EMRs to provide improved health care to their patients through clinical decision support tools [4,5]. Of late, EMRs have been actively used in various fields (eg, medical artificial intelligence development [6-8], clinical trials [8-10], customized health care [11,12], and telemedicine [13,14]) by combining EMRs with the core technologies of the fourth industrial revolution. As EMRs are used widely, the value of, and demand for, EMRs continue to increase, and the size of the medical data market is also increasing every year [15,16]. There have been various attempts to share EMRs using networks to supply scarce EMRs, such as image-sharing networks [17,18] or health information exchange mechanisms [19-21]. However, the existing EMR-sharing systems centered on medical institutions that use a trusted third party (TTP) have security vulnerabilities and structural limitations. In the current EMR-sharing system, which manages data through a central database, overall service can be affected if a problem occurs in the database storing the data. Furthermore, if an attacker forges the EMR, it is difficult to determine whether the EMR has been forged if there are no original data for comparison, and in the case of data loss, permanent loss can occur if there is no backup file to recover the data [22,23]. Moreover, as the EMR-sharing process is performed by a third-party data center or cloud service provider, personal information of the patient can be exposed [24-26]. An EMR contains personal information that can identify the patient. Therefore, privacy issues can arise if sensitive information regarding, for example, abortion clinic visits or records of treatment for sexually transmitted disease, is leaked.

Medical information that directly affects a patient's health must have integrity and be reliable. Moreover, the patient's privacy should be protected from exposure to unauthorized users. Therefore, it is necessary to develop a secure EMR-sharing system that can provide the integrity and reliability of an EMR and protect patient privacy by addressing the problems of the existing centralized EMR-sharing systems. Decentralization of the system has been proposed to complement the problems of the existing EMR-sharing system, and blockchain is receiving much attention as a technology suited for this purpose [27,28].

Blockchain stores data using a shared ledger maintained and managed through consensus by nodes participating in a blockchain network. By storing the previous block's hash value created using an irreversible hash function in the newly created block, blocks form a chain structure in which they are sequentially connected [29,30]. Furthermore, because the data stored on the blockchain cannot be arbitrarily modified or deleted, the blockchain provides strong tamper-resistant performance. Because of these technical characteristics, blockchain provides transparency and integrity of data and enables transactions among users without central administrators and third parties [31]. In addition, the blockchain technology that provides data integrity and transparency through a distributed shared ledger can be made scalable by applying automation technologies such as smart contracts. A smart contract is a digital contract written in code and executed automatically, first devised by Szabo [32]. Since then, smart contracts have been used for digital asset trading on Ethereum, a blockchain platform developed by Buterin [33,34]. By using smart contract technology, users can authenticate the contents of a transaction without the intervention of a third party and can be guaranteed an accurate and automated contract by means of a prewritten code. As blockchain has been applied to various fields, the role of smart contracts has also diversified. When smart contracts are applied to the medical field, various medical services such as remote patient monitoring, clinical trials, and drug supply chain management can be automated [35-37]. Moreover, it is possible to control access rights by using smart contracts so that only users who meet access policies (APs) can access medical data. However, blockchain technology is still at the prototype level, lacks technical stability, and suffers from limited performance, including low throughput and high latency [28,31]. In addition, there are some problems that arise when applying blockchain technology to the EMR system. For example, in the process of propagating transactions to nodes to store data on the blockchain, patient information may be disclosed to multiple users if the EMR is not encrypted. Furthermore, because of the limited block capacity, large-capacity data (eg, medical images) cannot be shared, and there are insufficient measures in place to ensure the patient's ownership of the EMR. Therefore, to apply blockchain technology to the EMR-sharing system, measures to resolve the aforementioned problems are required. Because of these issues, analysis studies are being conducted on whether it is appropriate to apply blockchain technology to the EMR-sharing system [38]. Figure 1 is a flowchart adapted from the study by Wüst and Gervais [38] to determine whether blockchain is an appropriate solution to the problems of the existing centralized database. To share an EMR, the system needs a shared database. However, if a TTP such as a certificate authority (CA) supervising the entire sharing process is semitrusted, privacy concerns may arise. Therefore, there is a limitation to the use of a TTP for EMR-sharing systems. In our proposed system, there are many patients as well as physicians who write EMRs. They should be identified for the purpose of sharing certain

patient information with the appropriate physicians, but they may have concerns about one another's privacy. Hence, for the EMR-sharing system, permissioned blockchain can be applied.

The blockchain-based decentralized EMR-sharing system has the opposite characteristics to the existing client–server-based centralized system. Through these opposite characteristics, the blockchain-based EMR-sharing system overcomes the current system's problems and provides various advantages. Unlike the existing centralized system, the blockchain-based decentralized EMR-sharing system exhibits strong resistance to the single point of failure because no central administrator or server controls the system. As multiple nodes operate the decentralized EMR system, data loss or service failure can be prevented even if a specific node fails. Therefore, it is possible to build a more robust system and provide stable service.

In terms of performance, the blockchain-based EMR-sharing system exhibits low throughput and high latency compared with centralized systems because of the data propagation delay between nodes and the consensus mechanism. However, performance problems can be overcome through various

methods, including automation of the system by using smart contracts, lightweight consensus mechanisms, and private blockchain models. In a centralized system, only the central administrator manages the database. Hence, the data stored in the database can be arbitrarily modified or deleted only by the central administrator. However, to modify stored data in the decentralized EMR-sharing system, the consent of most of the blockchain nodes is required; therefore, an arbitrary user cannot modify the data at will. Therefore, the blockchain-based EMR-sharing system provides high data integrity and a transparent process, allowing EMRs to be shared without the intervention of a third party, unlike centralized systems. The decentralized EMR-sharing system prevents data leakage and privacy threats from third parties with these characteristics.

Despite many concerns about technological limitations and suitability, many researchers are studying blockchain-based EMR-sharing systems to take advantage of the benefits of blockchain technology [39–42]. Table 1 shows the differences between a blockchain-based distributed EMR-sharing system and a client–server-based centralized EMR-sharing system.

Figure 1. Decision-making flowchart to determine whether blockchain is an appropriate technical solution to a problem, adapted from the study by Wüst and Gervais [38]. CA: certificate authority.

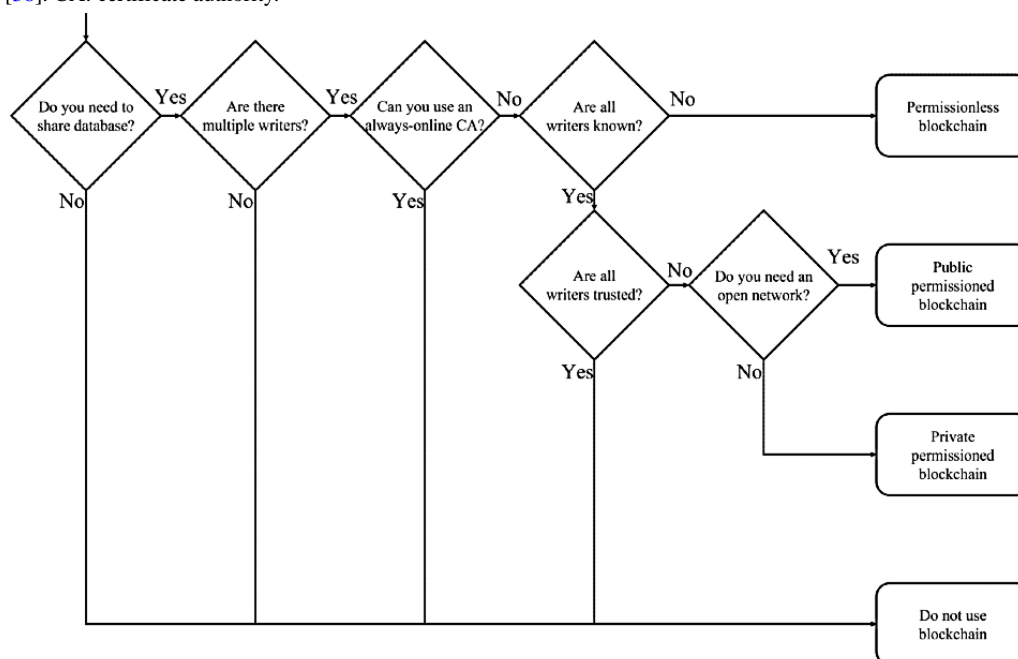

Table 1. Comparison of the decentralized (blockchain) and centralized (client–server) electronic medical record–sharing system.

Characteristics	Decentralized system	Centralized system
System-fault tolerance	Strong	Weak
Throughput	Low	High
Latency	High	Low
Data integrity	High	Medium
Trusted third party	No	Yes
Storage	Distributed ledger	Centralized database
Privacy preservation	Strong	Weak

Related Works: Blockchain Technology in Medical Care Fields

Researchers have proposed various EMR-sharing system models based on blockchain to secure the integrity and reliability of EMRs and build a secure EMR-sharing environment. The studies on EMR-sharing systems based on blockchain technology are presented in [Table 2](#).

Azaria et al [43] proposed MedRec, a decentralized medical record management system based on Ethereum smart contracts. MedRec manages access rights to medical records using smart

contracts and permissions stored in the blockchain. When a client sends a query request, the gatekeeper checks the client's signature and the blockchain contracts to verify access rights. However, because the system proposed by the authors does not encrypt medical data, there is a risk of leakage of personal information and data during the data-sharing process. Besides, when data are shared, the transaction-processing efficiency is degraded because of the additional processing time required as it is necessary for the request queries to be sent from the provider's local database.

^aIoT: Internet of Things.

^bIPFS: InterPlanetary File System.

Hylock and Zeng [47] proposed HealthChain to enhance patient engagement and security in blockchain-based health information exchange systems. Proxy re-encryption (PRE) [50-54] technology was used to prevent leakage of patient private keys and medical data. Furthermore, the authors introduced redactable patient blocks with chameleon hashing to solve the data

fragmentation problem and reduce storage and computation overhead by modifying the data. However, in the system proposed by the authors, there is a fatal problem: patients must share their private keys with an external third party for re-encryption. Moreover, for patients to share and manage their medical data, they must continuously participate in the

blockchain network, burdening patients who have limited resources, unlike hospitals and research institutes.

Wu and Du [48] proposed an EMR security-sharing model based on blockchain for improving privacy and data scalability in medical data-sharing systems. An EMR security-sharing model based on blockchain uses data-masking technology to hide sensitive information stored in the medical data to prevent leakage of personal information. Moreover, the InterPlanetary File System (IPFS) [55], a distributed file-sharing protocol, was used to overcome the difficulty of sharing medical data because of the limited block size. However, depending on the masking level, the privacy protection offered by data-masking technology varies in performance. The problem is that applying excessive masking makes it challenging to use the required information, and when the level of masking is low, specific values can be tracked and predicted.

Abdellatif et al [49] proposed ssHealth, a smart and secure health care system, which is a distributed health care system that enables convenient medical data-sharing among various institutions using blockchain and edge computing. The ssHealth system divides medical data processing, access control, and data sharing into local and blockchain networks and presents a data-sharing security algorithm based on the importance of data to enable safe medical data-sharing. However, there is a problem: it is not possible to guarantee stable service quality because of differences in validation time, depending on the security level. Besides, there is a risk of centralization and privacy breaches because unencrypted medical data and patient personal information pass through edge nodes in the local network.

Existing studies on blockchain-based EMR-sharing systems have used blockchain models designed for cryptocurrencies such as Bitcoin and Ethereum. However, existing blockchain models for cryptocurrency have limitations in providing the security and scalability required in sharing EMRs. The system also failed to meet the requirements of EMR-sharing systems as defined in *Connecting Health and Care for the Nation: A Shared Nationwide Interoperability Roadmap – Version 1.0*, prepared by the Office of the National Coordinator for Health Information Technology (ONC) [56]. Therefore, it is necessary to develop a blockchain-based EMR-sharing system that overcomes the limitations of existing systems and satisfies the security framework defined by the ONC.

In this paper, we propose a patient information exchange (PIE) system. The proposed blockchain-based EMR-sharing system overcomes the limitations of existing blockchain-based EMR-sharing systems and satisfies the privacy and security framework defined by the ONC. Furthermore, our proposed system prevents data loss and privacy breaches in sharing data through the data encryption scheme based on re-encryption, ensuring strong data security. Moreover, data integrity is ensured by preventing the forgery and alteration of EMRs by using the decentralized ledger structure and the unique hash value of the data. Furthermore, allowing patients to set their data-access rights ensures patient ownership of their EMR and establishes a patient-centered medical system. Moreover, the PIE system provides improved performance by solving the low processing

performance and scalability issues due to the limited block capacity of the existing blockchain through the distributed data-sharing method using the IPFS. As a result, we contribute business process optimization, cost reduction, patient outcome improvements, and enhanced compliance in the health care field [57,58].

Methods

System Model

Here, we describe the proposed PIE system. In the *Components of the Proposed PIE System* section, we define the entities that make up the components of the system and describe each entity's role. In the *EMR Transaction Structure* section, we describe the structure and components designed to share EMRs effectively. Finally, in the *Security Levels of EMRs* section, we discuss the security level, which depends on the EMR data type and classifies the data based on the type. The system model of the proposed PIE system is shown in Figure 2.

We propose a blockchain-based PIE system to improve the security and efficiency of the EMR-sharing process. To prevent forgery of EMRs and protect patient privacy, we use a consortium blockchain model in which only authorized users can participate. The medical consortium that operates and manages the blockchain comprises state-approved and trusted medical institutions. As the proposed blockchain-based PIE system uses a private blockchain model, the consensus algorithm in the block generation process is not addressed. Instead, the chain is constructed by sequentially storing the generated EMR transactions to create a block and connecting them. Hospitals and medical institutions serve as blockchain nodes that issue EMR transactions and store them in block form. Health care workers and patients who create and use EMRs participate in the blockchain network as users by using IDs issued according to user type after a certification process by a CA. Users participating in the blockchain network can register their EMRs on the blockchain and use them at any time. The proposed PIE system is a patient-centered EMR-sharing system where patients directly participate in the EMR upload and EMR-sharing process. The patient directly generates a key to encrypt the EMR and defines the categories of users who can access the EMR. By allowing patients to manage their own EMRs, we build a user-centered system that protects patients' privacy and gives them ownership of their EMRs.

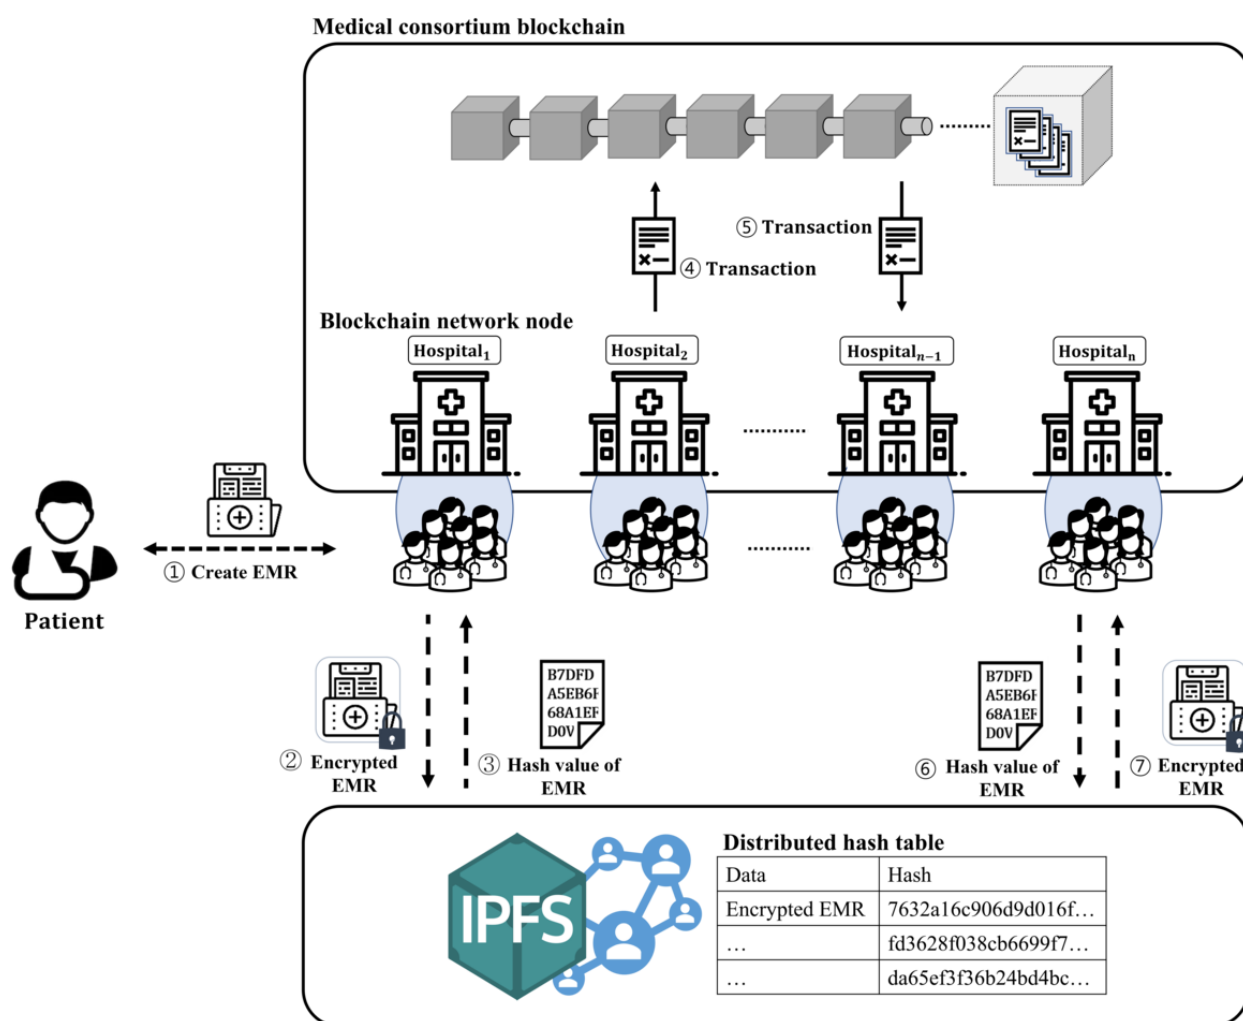

The proposed PIE system securely protects patient EMRs from security threats such as data forgery and personal information leakage, which can occur during EMR management and sharing. To protect EMRs from the aforementioned security threats, we use public key-based asymmetric encryption and our proposed PRE-based decryption authority delegation mechanism. The proposed decryption authority delegation mechanism prevents private key leakage by decrypting data encrypted with the public key. Moreover, delegating authority to decrypt data solves the problem of data access in an emergency when a patient cannot respond to a request for access to their EMR, as de Oliveira et al [59] suggested. The proposed PIE system provides a re-encryption key that enables the physician who created the EMR to act on behalf of the patient in an emergency when the

patient is unable to control access rights to the EMR. The re-encryption key re-encrypts the EMR encrypted with the patient's encryption key into a form that the physician can decrypt with the physician's private key.

The performance and scalability of the PIE system are enhanced by using the IPFS, which supports distributed data-sharing technology. The EMR encrypted with the patient's encryption key is stored on the IPFS network, and the hash value of the

EMR is stored on the medical blockchain in the form of metadata. Instead of storing the data as a whole in the blockchain, it is possible to reduce the load on the system by storing only the hash value of the data. Furthermore, if data are shared using the IPFS, large-capacity data such as magnetic resonance imaging, computed tomography, and endoscopy images can also be shared, improving the scalability of the blockchain system.

Figure 2. The proposed blockchain-based patient information exchange system model. EMR: electronic medical record. IPFS: InterPlanetary File System.

Components of the Proposed PIE System

The proposed PIE system consists of blockchain nodes (medical consortium), users of the blockchain network (patients and health care workers), and the IPFS. The role of each entity is outlined in the following paragraph:

A medical consortium consisting of hospitals and medical institutions that wish to share EMRs builds and manages a distributed ledger as operator of a permissioned blockchain network in which only authorized users can participate. The medical consortium blockchain stores the information of the EMRs generated by each hospital. The information recorded on the blockchain is a hash value of real medical data stored in the IPFS and simplified medical information that users can comprehend. Data registered on the blockchain cannot be

arbitrarily deleted or modified, providing high reliability and medical data integrity. Patients and physicians, who are the users of the blockchain network, share EMR information through the network. Patients can use a decentralized app to share their EMRs in the PIE system. Furthermore, patients set their APs for their EMRs and generate re-encryption keys for re-encryption. Unlike traditional hospital-centered health care systems, the PIE system guarantees the patient's ownership of their EMR. In a patient-centered health care system, where patients have rights to their own EMRs, they have the freedom to choose who can use their EMR and their data at any time. Furthermore, patients may sell their medical data to research institutions or hospitals, in addition to using the data for therapeutic purposes. Health care workers consist of reliable physicians and health care service providers such as medical researchers and insurance agents. Health care workers use

computer systems at hospitals or medical institutions to encrypt EMRs generated during the patient treatment process and upload them to the IPFS. After uploading the EMRs, health care workers submit the EMR information to their hospitals and institutions. Health care workers also serve as consumers of medical data by, for example, sharing EMRs through a blockchain network to treat patients or using the data for clinical research. The IPFS is a distributed file-sharing system that splits data stored on multiple computers worldwide into small pieces and shares only a portion. The distributed data-sharing method used by the IPFS enables rapid sharing of large-capacity data such as magnetic resonance imaging or computed tomography images. In addition, the IPFS prevents duplicate creation and storage of medical data by managing data with hash values based on data content.

Threat Model

In this study, we consider the traditional cryptographic system, not the postquantum cryptographic system. Therefore, we use the discrete logarithm problem, which is one of the difficult problems of 1-way functions. The discrete logarithm problem is one where given $x, y \in Z_q^*$, it is difficult for any probabilistic

polynomial time attacker A to find a value $m \in Z_q^*$ such that $x = y^m$. Therefore, the attacker cannot obtain the private key from a public key or ciphertext. Our system model considers external threats from outside the system and internal threats from the system participants. We assume that both threats are in the form of a logical attack, not a physical attack. The external threats target the patients' private data such as the EMR, insurance details, and other personal information. For example, an external attacker wants to eavesdrop on all communication among the participants to obtain patients' personal information. Internal attackers can include health care researchers or insurance agents. They are allowed access to limited information in the form of an abstract regarding disease and length of hospital stay, not details of the disease or patients' personal information. However, internal attackers are snooping for patients' private data; therefore, they try to access their medical information. In addition, internal attackers attempt to manipulate clinical results or commit insurance fraud by arbitrarily forging a patient's EMR. Table 3 shows the attack scenarios and threat situations considered in the proposed blockchain-based EMR-sharing system.

Table 3. Attack scenarios and threats considered by the proposed system.

Types and attack scenario	Threats
External threats	
Eavesdropping	Private data leakage (eg, electronic medical record and personal information)
Denial of service	Service unavailable
Internal threats	
Abnormal access	Private data leakage
Data forgery	Unexpected output

EMR Transaction Structure

The proposed blockchain-based medical system uses transactions designed to effectively share the desired medical data while preventing leakage of personal information and data when uploading the medical data to the blockchain. A unique identifier or ID is used in the blockchain network by the physician who created the EMR and the patient who is the owner of the generated data. The CA issues a user ID according to the type of user participating in the blockchain network. A user ID is a randomly generated value consisting of numbers and letters; it is possible to identify users but not know who the owner is. Information about users who can map users to user IDs is securely managed by a CA such as the trusted government authority that issued the ID. As the user IDs are correlated, users are protected from the threat of personal information leakage [60,61]. The timestamps record the time the transaction was created. Medical information contains minimal necessary

medical information, excluding sensitive information that can identify the user from the patient's EMR. For example, even if information such as the gender of the patient, type of disease, age, and exercise status is disclosed, it is not a serious problem because the owner of the data cannot be identified. The information is only used in the search process to identify a specific EMR of interest among the various EMRs stored in the blockchain. The metadata contain the hash value, which is the address value of the data received after uploading the encrypted EMR to the IPFS. Using this, a specific EMR can be shared in the IPFS. The contract code contains the code to execute the smart contract, for example, the user's AP. The signature is the one created by using the private key of the physician who created the transaction (the physician who treated the patient and generated the EMR). The structure of transactions for effective and safe EMR management and sharing is shown in Table 4.

Table 4. Transaction structure for electronic medical record (EMR) sharing.

Field	Definition
User ID	IDs of the patient and physician
Timestamp	Time the transaction was created
EMR information	Summary of information in the EMR
Metadata	Hash value of encrypted EMR
Contract code	Patient's defined access permission policy
Signature	Signing with the user's private key

Security Levels of EMRs

Patient EMRs may include data relating to clinical trials and insurance as well as sensor data generated by health care devices, in addition to medical information generated during the process of receiving treatment in hospitals. Depending on the EMR data type, the required security levels will differ. For example, if information such as name, residence, and social security number, which can identify an individual, is leaked to outside parties, it can lead to serious personal information leakage; consequently, a high security level is required. Conversely, information that is not personally identifiable, such as gender, age, eating habits, and exercise status, does not

require a high security level because it is not a serious problem even if this information is disclosed to outside parties. Therefore, it is necessary to provide differentiated security levels and separate management, with respect to the sensitivity of the personal information, according to the EMR data type.

The minimum security level required for each data type is established by categorizing privacy sensitivity according to data type and evaluating accessibility and data potential per user. The security levels assigned according to the sensitivity of private information fall into three classes: private, moderate, and low. [Table 5](#) lists the security levels differentiated according to the type of information contained in the EMR.

Table 5. Security levels required depending on the type of information contained in the electronic medical record.

Division and class	Security level
Medical record	
Medical information	Private
Admission record	Private
Prescription	Private
Medical imaging (x-ray, magnetic resonance imaging, and computed tomography)	Private
Clinical trial	
Medical device	Low
Medicine	Low
Clinical observation	Low
Omics (genomics)	Low
Lifelog	
Sensor data (weight, heart rate, and sleep pattern)	Moderate

EMR-Sharing Process in the PIE System

Overview

This section presents the EMR-sharing process that protects the patient's EMR from various attacks and safely shares it. Moreover, it describes the work performed in each process. A more detailed description of each process-specific algorithm is provided in [Multimedia Appendix 1](#). The proposed EMR-sharing process consists of a user registration phase, an EMR upload phase, and an EMR-sharing phase. The user registration phase

concerns joining the blockchain network so that users such as patients and physicians can manage and share medical data. The EMR upload session concerns registering on the blockchain the medical data generated when treating patients. The process of publishing a patient's EMR on the blockchain involves data encryption, access rights setting, transaction creation, and uploading. Finally, the EMR-sharing phase concerns the process of downloading the encrypted patient EMR from the blockchain, re-encrypting it, and then decrypting it to obtain the original version. The notations used for EMR encryption and re-encryption in the proposed system are listed in [Table 6](#).

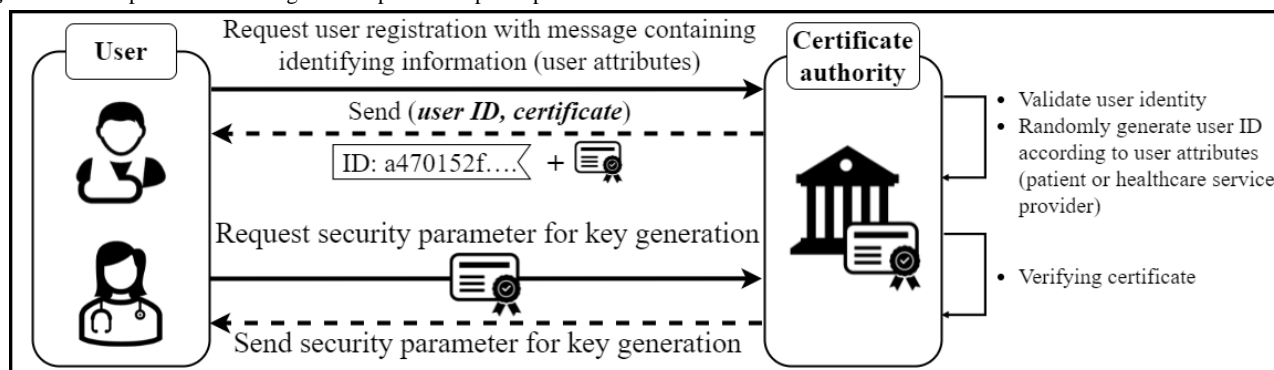

Table 6. Notations used for electronic medical record (EMR) encryption and re-encryption in the proposed system.

Notation	Description
ID	User ID (patient or physician)
SK	Private key of the user
PK	Public key of the user
DEK	Dedicated encryption key to encrypt EMR
RK	Re-encryption key
C_i	Encrypted EMR
P_i	Patient _i
D_i	Doctor _i
AP	Access policy
hash _i	Hash value of the encrypted EMR

Initial Phase: User Registration

Patients and physicians want to participate in the blockchain network to manage EMRs and securely share them with other users. Users participate in the blockchain network through the user registration process, which consists of an identity registration phase to register the user's identity and an authentication phase to obtain security parameters to generate an encryption key. Figure 3 shows the user registration process for users to join the blockchain network. In the ID registration step, the user sends the ID registration request message that contains the user's attributes to a CA. The user attributes identify whether the user is a health worker or a patient. The CA also uses the user attributes to identify the user's ID. Once the identification is complete, if the user is legitimate, the CA classifies the user type based on the user attributes. Subsequently, depending on the user type, a user ID is generated and delivered to the user along with the certificate. Users who are judged to be not legitimate because their attributes are not validated will be denied user registration. A user who has successfully registered an account then sends a message, including the certificate, to the CA requesting security

parameters to generate the encryption key needed for EMR sharing. If the certificate is valid, the CA provides the security parameters to the user. Thus, through the user registration step, users who join the blockchain network generate a public key and a private key using the security parameters received from the CA. First, the user selects a random decimal number corresponding to $x \in Z_q^*$. The selected x is set as the user's secret key and is never shared. Next, users generate a public key for use in the network using their private key and the key generator. Users who can directly generate the encryption key that they use for EMR sharing can generate an encryption key each time an EMR is created, thus protecting the EMR with a different key each time. Because of the nature of an EMR that has been used for a long time, the encryption key must be maintained as is when data are encrypted [62]. However, this introduces security vulnerabilities, endangering EMR and patient privacy. To prevent this, in our system, users create the encryption key themselves, and the existing EMR uploaded to the IPFS is updated with data encrypted with the new key through a data version update. Users who successfully register an account and generate an encryption key can share medical data through the blockchain network.

Figure 3. Initial phase: the user registration process to participate in the blockchain network.

Phase 1: EMR Upload—Block Generation

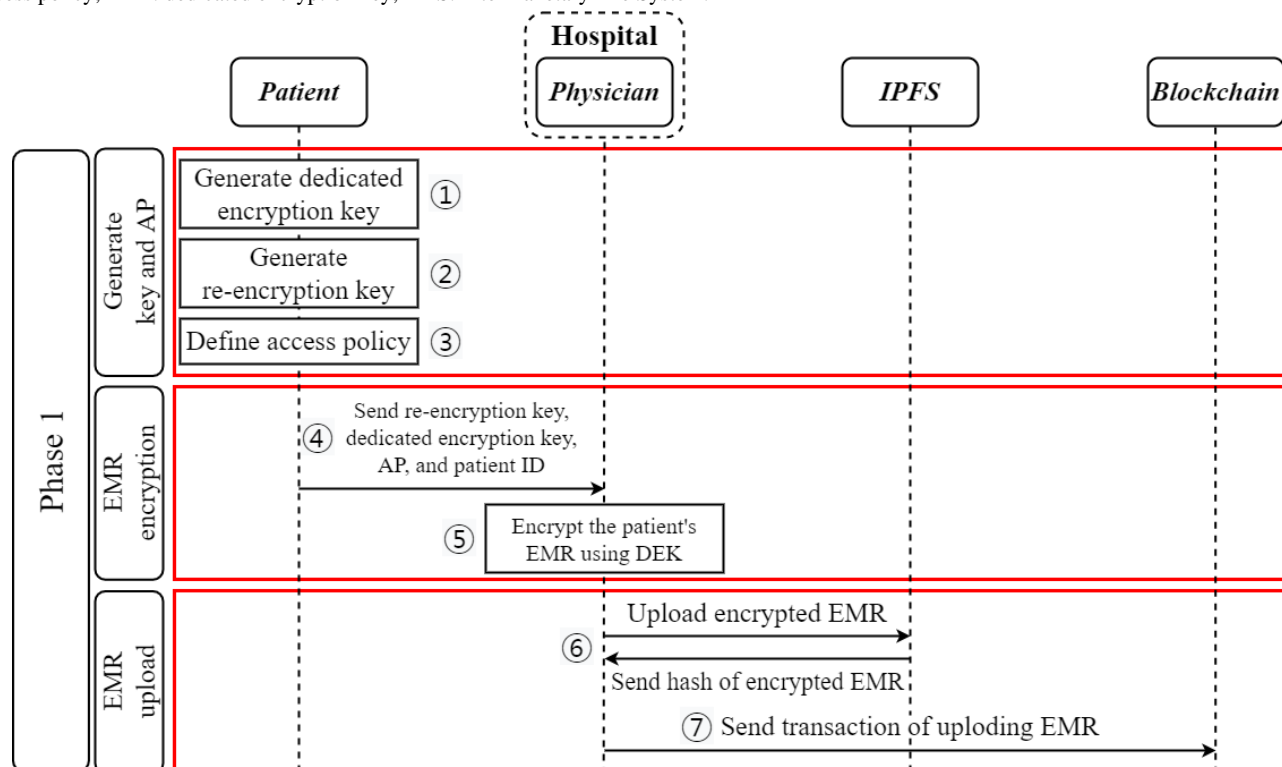

When a medical record is generated for treatment, the patient creates a dedicated encryption key to encrypt their EMR and a re-encryption key RK_{PD_i} to re-encrypt the encrypted EMR. The re-encryption key is generated using the patient's private key

and the physician's public key. At the same time, the patient creates an AP that defines the level of users who can access the EMR. Next, the patient sends the dedicated encryption key RK_{PD_i} , the AP, and the user ID, which was created by the patient, to the physician who provided treatment. Upon receiving the

message from the patient, the physician encrypts the patient's EMR with the patient's dedicated encryption key. The physician then uploads the encrypted EMR, C_p , to the IPFS and receives the hash value, $hash(C_p)$, of the data the IPFS has stored. Next, the physician submits the user ID related to the EMR, the minimum information required to distinguish EMR_p , and

$hash(C_p)$ to the medical institution to which they belong. Finally, the medical institution uses the information in the message to create a transaction and publish it on the blockchain. Figure 4 shows the EMR upload flow diagram of the proposed blockchain-based PIE system. The method of uploading EMR information to the blockchain follows algorithm 1 defined in Textbox 1.

Figure 4. Phase 1: electronic medical record (EMR) upload flowchart of the proposed blockchain-based patient information exchange system. AP: access policy; DEK: dedicated encryption key; IPFS: InterPlanetary File System.

Textbox 1. Algorithm 1: the electronic medical record upload.

Algorithm 1

- Input: Secret key_{Patient}, public key_{Doctor}, dedicated encryption key, user ID_{Patient}, hash($C_{Patient}$), and access policy
- Output: Re-encryption key, access policy, summary information from electronic medical record, hash value returned by the InterPlanetary File System, and transaction
 - The patient selects a random security parameter value r to generate a dedicated encryption key for encrypting their electronic medical record.
 - The patient uses their secret key SK_P and the physician's public key PK_D to generate a re-encryption key $RK_{P \rightarrow D_i}$ for re-encrypting their EMR_p .
 - The patient generates an access policy that defines which users can access their electronic medical record.
 - The patient transmits the dedicated encryption key, $RK_{P \rightarrow D_i}$, access policy, and $UserID_P$ to the physician who treated them.
 - The physician who receives the dedicated encryption key, $RK_{P \rightarrow D_i}$, access policy, and $UserID_P$ from the patient encrypts the patient's medical record EMR_p using the dedicated encryption key.
 - The physician uploads the encrypted patient electronic medical record C_p to the InterPlanetary File System and receives the $hash(C_p)$, the hash value of the electronic medical record.
 - The physician submits the patient's ID, summary information from EMR_p , and hash value to the hospital.
 - The hospital uses the received information to create a transaction and uploads it to the blockchain network.

Phase 2: EMR Sharing

Users who want to share and use a particular EMR can search for it on the blockchain through a smart contract and request a re-encryption key. As the medical field is closely related to human life, the target and purpose regarding the EMR data must be legitimate. However, it would be difficult to find the desired EMR among countless data because it is hidden to protect the patient's privacy. Therefore, in the proposed PIE system, smart contracts are applied so that patients and health care workers who are users of the blockchain network can perform a quick and accurate search for the data they want. Moreover, the efficiency of the EMR-sharing process has been improved by automating the process of requesting decryption rights after searching for an EMR. The requester uses summary information from the EMR and the user ID (the ID of the hospital that uploaded the data or the patient's ID) to quickly search for a transaction containing the information of the desired EMR. Then, the requester downloads the encrypted EMR from the IPFS using the acquired transaction information. As the downloaded EMR is encrypted with a dedicated encryption key, it must be decrypted using the patient's private key or re-encrypted using the re-encryption key before using it. However, because sharing the patient's private key is very dangerous, the requester must send a message to the patient requesting a re-encryption key for re-encryption. The message

requesting the re-encryption key goes through the user verification process of the access check contract. Initially, the user verification process checks whether the requester's security level satisfies the patient's EMR AP. When it is confirmed that the user has met the required security level, a message requesting a re-encryption key is sent to the patient, the owner of the EMR. Upon receiving the message requesting the re-encryption key, the patient sends $RK_{P \rightarrow \text{Requester}}$ to the requester. If a patient cannot issue a re-encryption key because they have been incapacitated by a serious illness such as acute stroke, the physician participating in the EMR generation can temporarily issue a re-encryption key according to the emergency event procedure. The requester who receives $RK_{P \rightarrow \text{Requester}}$ can re-encrypt C_P and then decrypt with their private key. The EMR-sharing procedure is performed in the order specified in [Textbox 2](#). The EMR-sharing flowchart of the proposed blockchain-based PIE system is illustrated in [Figure 5](#). The biggest advantage of using PRE technology for medical data security is that users can decrypt a downloaded EMR encrypted with their key without the patient's private key. Therefore, it minimizes the threat of leakage of the patient's private key and information. Moreover, the proposed re-encryption technology-based medical data encryption method can satisfy the medical field's requirements for sharing medical data while protecting the medical data from other eyes when sharing the EMR. [Figure 5](#) shows the EMR-sharing procedure in the proposed PIE system.

Textbox 2. Algorithm 2: electronic medical record sharing.

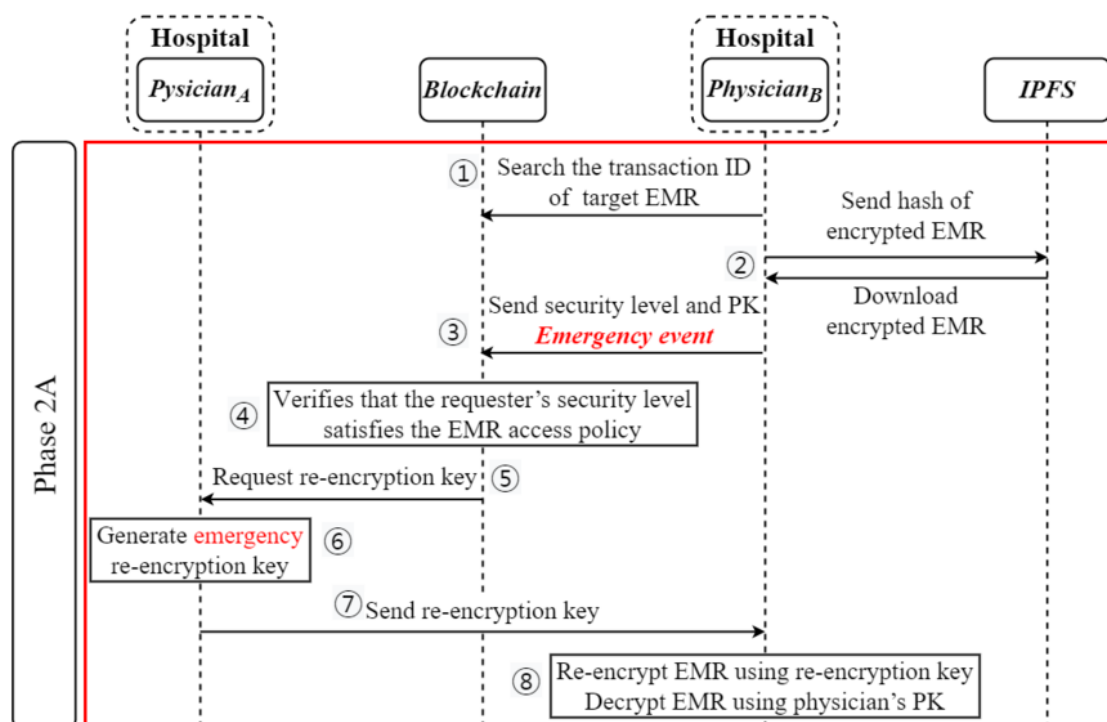

Algorithm 2

- Input: Summary information from the electronic medical record, user ID, and user's security level
- Output: Re-encrypted electronic medical record C_d and $RK_{P \rightarrow \text{Requester}}$
 - The physician executes a smart contract for electronic medical record retrieval to find a transaction containing the information of the desired electronic medical record.
 - The smart contract uses the user ID or the electronic medical record's summarized information to find a transaction containing the desired information and returns it.
 - The physician who receives the transaction information downloads the encrypted electronic medical record C_P from the InterPlanetary File System using the hash value contained in the transaction.
 - The physician executes the re-encryption key request smart contract to request the key RK_{EMRP} for re-encryption from the patient who is the owner of the encrypted electronic medical record.
 - The smart contract for requesting the re-encryption key performs a user authentication step to verify that the security level submitted by the user who requested the message transmission satisfies the access policy set by the patient.
 - If the security level of the user requesting the re-encryption key satisfies the access policy, the smart contract sends a message requesting the re-encryption key to the patient (if the user's security level does not meet the criteria, the request is denied).
 - The patient who receives the message requesting the re-encryption key generates $RK_{P \rightarrow \text{Requester}}$ using the requester's public key and send it to the requester.
 - The physician receiving $RK_{P \rightarrow \text{Requester}}$ uses it to re-encrypt C_P into C_D .
 - The physician uses their private key to decrypt C_D to obtain the original EMR_P .

Figure 5. Phase 2: electronic medical record (EMR)–sharing process flowchart of the patient information exchange system. (A) EMR-sharing process in the general case where the patient controls the re-encryption key, (B) EMR-sharing process in emergencies where the patient has no control over the re-encryption key IPFS: InterPlanetary File System; PK: public key.

(B) EMR-sharing process in emergencies where the patient has no control over the re-encryption key

Results

Simulation Design

A simulation was designed to verify that the proposed blockchain-based medical system sufficiently reflects the medical field's requirements and enables safe data sharing. We simulated the process of sharing encrypted EMRs over a

blockchain network. In the EMR-sharing process of uploading and downloading EMRs over the network, we checked the effect of the time taken to process the data and the size of the data shared on the system's performance. Moreover, the performance of the proposed smart contract–based re-encryption key–sharing method was verified by measuring the execution time of the smart contract. This paper does not cover improvements to the

consensus process performed on the blockchain network; therefore, the improvements were not evaluated.

The test environment was designed based on the data-sharing process defined in the *Methods* section. The simulation consisted of 2 physicians, a patient, a medical consortium, and a public IPFS network participating in the blockchain network as the minimum unit for sharing an EMR. Entities on the network were classified into two categories: a host operating a blockchain network and a guest operating on the network. All processes in the proposed system can be viewed as interactions among guests. In the test environment, there was a consortium to which many hospitals belonged, and each hospital had a Flask server with a different port. The code of the software development kit used to implement the blockchain network is Node.js. The host computer was a PC running Windows 10 Pro 64x (Microsoft Corp) in a wired environment, with 32 GB memory and Intel

Core i7-10700K central processing unit at 3.80 GHz. The guest computer was a PC running Ubuntu 18.0.4 64x (Canonical) in a wired environment, with 10 GB memory and Intel Core i7-10700K central processing unit at 3.80 GHz. The communication rates considered were the download and upload rates in megabits per second: host upload and download rates and guest upload and download rates.

The simulation was performed on 1 PC to directly compare the host's and guest's processing times. Blockchain implementation was performed using Hyperledger 2.3.1 [63]; Apache CouchDB [64] was the state database. The network consisted of 4 orderer nodes, 3 organizations, 2 peer nodes for each organization, and 1 channel. The chain code for smart contracts used Go. Table 7 shows the parameters used for the proposed PIE system simulation.

Table 7. Simulation parameters.

Parameters	Values
Data size	0.4 kB, 1 MB, 10 MB, 100 MB, and 1 GB
Data type	CSV (text) and DICOM ^a (images and videos)
Number of orderer nodes	4
Number of organizations	3
Number of peer nodes	6
Number of channels	1
Data rate	100 Mbps
Block size	1 MB
Block timeout	2 seconds
Database	Apache CouchDB

^aDICOM: Digital Imaging and Communications in Medicine.

Simulation Results

To evaluate the performance of the proposed PIE system, we measured the time required for the EMR-sharing process and the execution time of the smart contract for re-encryption key sharing. The EMR-sharing process was divided into upload and download processes, and the time taken to perform each process was measured. The execution time of the EMR upload process was defined as the time taken to upload the EMR to the IPFS and post the returned EMR hash value to the blockchain. The execution time of the EMR download process was a measure of how long it took users to download the EMR over the IPFS. Considering the characteristics of an EMR that supports various types of data, the simulation was performed using various data, ranging from text format (0.4 kB) to medical images (1 GB). The simulation measured only the time required in the communication process for exchanging data among users and did not consider the impact on the process of the data encryption and decryption operations. To objectively evaluate the performance of the proposed system, we performed a comparative analysis with existing blockchain-based medical information exchange systems. Simulations were performed for three types of systems (an on-chain-based system designed for cryptocurrency, an Ethereum-based system using the IPFS, and

a PIE system); the results of the simulations for the EMR upload process are shown in Multimedia Appendix 2 [47,48].

Through the EMR upload simulation it was confirmed that the larger the data to be uploaded, the longer it takes; the larger the amount of data to be uploaded, the higher the required data rate. As a result, the processing time increased dramatically for data that exceeded the acceptable data rate (100 Mbps) in the simulation environment. In an on-chain-based system that stores data in the original form in blocks, the size of data that can be uploaded is limited to 1 MB, which is the maximum size of the block; therefore, there is no simulation result for data beyond that size. Most of the time taken to upload an EMR was when a query request needed to be made to the blockchain network, which took an average of 2.1 (SD 0.0343) seconds. The actual time taken to upload an EMR to the IPFS increased depending on the size of the data, but it was very short. A graph of the time it takes to upload EMR to IPFS can be found in Multimedia Appendix 3. The time required to upload data that ranged from 0.4 kB to 100 MB was relatively short compared with the query request time; therefore, it did not significantly affect the overall EMR upload time. Again, when uploading data that ranged from 0.4 kB to 100 MB, the overall EMR upload time was comparable with the query request time (average of 2.1 seconds, SD value

= 0.2947). However, when uploading >500 MB of data, the time taken to upload the EMR to the IPFS was longer than the query request time, which affected the overall EMR upload time. Uploading 500 MB and 1 GB of data took an average of 4.5 (SD 0.1329) seconds and 5.7 (SD 0.21) seconds, respectively, for the Ethereum-based system and the proposed PIE system. The PIE system and the Ethereum-based system showed similar performance in that the EMR was distributed and shared using the IPFS. However, in the Ethereum-based system, there is a problem: to decrypt the shared medical data, the patient's private key needs to be shared or the patient needs to directly decrypt the shared medical data. This gives rise to a fatal security problem: the patient's private key and EMR can be leaked directly to others. In contrast, the PIE system prevents the leakage of the patient's private key and EMR by using a re-encryption scheme and enables users who have shared their EMRs to decrypt them smoothly, providing high security along with the same performance as that of the Ethereum-based system. Uploading the actual EMR to the IPFS and sharing it through a decentralized technique has 3 important implications in a blockchain-based medical data system. First, medical data can be shared without capacity limitation through a peer-to-peer network. This advantage can thus alleviate the problem of low processing efficiency and data scalability because of the blockchain's limited block capacity. Second, by storing the hash value, which is the unique address value of the data, it is possible to reduce the blockchain's storage burden and solve the EMR reduced redundancy storage problem. When sharing an EMR, the PIE system reduces the burden on the nodes and allows data to be shared faster. The distributed data-sharing method using the IPFS determines the performance according to the number of users sharing data, showing higher performance as the number of users increases. Therefore, EMR sharing using the distributed data-sharing method is effective for the medical system because it can share data faster while reducing the burden on the node. However, the data-sharing method using the IPFS has a problem in that there must be at least one node that stores the data to be shared in the IPFS network. If the data are not stored (pinned) on the IPFS network, the shared system can fail. To prevent this, the hospital that created the EMR needs countermeasures such as storing data in a local database in preparation for the worst-case scenario after uploading.

The simulation results for downloading the EMR posted on the blockchain are presented in [Multimedia Appendix 4](#) [47,48]. The simulations we conducted used various data sizes ranging from 0.4 kB to 1 GB. The IPFS used in the simulations is an open network, with a variable number of users participating in data-sharing operations. Therefore, even with a blockchain system using the same IPFS, differences in performance may occur depending on the number of users participating in the network. The Ethereum-based blockchain system [48] and the PIE system we propose use the IPFS to alleviate the blockchain's scalability problem. However, there is a big difference between the 2 models in the pieces of information they store. In the model proposed in the study by Wu and Du [48], only the detailed information of the EMR is stored, whereas in the PIE system we propose, the original EMR is stored as is. Storing the original data of the EMR generated in the medical process can ensure the integrity of medical data and

increase its usability in medical systems. The simulation results show the difference in performance between storing only the detailed information of the EMR and storing the original EMR as is. Even considering that the performance of the IPFS may fluctuate depending on the number of participating users, it takes less time to download the original EMR than it takes to download the details of the EMR. These results mean that the proposed PIE system provides higher scalability in that it can provide the original EMR to users more quickly. The average time taken to download 1 MB of medical data encrypted using the unique address value of the medical data uploaded to the IPFS in the proposed PIE system is 0.01014 (SD 0.0028) seconds. This is approximately 5.5 times faster than the average download time of 0.0562 (SD 0.0052) seconds taken by the on-chain-based blockchain model without the IPFS. Existing blockchain systems that publish and share data without using the IPFS increase the burden and have limitations in scalability as the size of the data to be shared increases. However, there is no limit to the size of the EMR posted on the blockchain in the proposed method, ensuring high scalability and higher processing performance than that of existing systems. Therefore, for medical systems that need to share medical data, it is more effective to use the distributed data-sharing method.

We performed a simulation of the smart contract-based re-encryption key-sharing process. The re-encryption key-sharing process verifies the user requesting the re-encryption key to use the patient's EMR and passes the re-encryption key to the user. The user who receives the re-encryption key performs the re-encryption process and finally decrypts the encrypted EMR using their private key to use the patient's EMR. A graph of the smart contract simulation results for re-encryption key sharing is in [Multimedia Appendix 5](#). The simulation was performed with 4000 epochs, and the quarterly smart contract execution time and average time required are presented. As the re-encryption process and decryption process are performed by the user alone, they are not included in the smart contract's execution time for sharing the re-encryption key. The average time taken to verify a user requesting a re-encryption key to use the patient's EMR and grant decryption rights to an authorized user is 3.3543 (SD 0.4959) seconds. The data security process using the re-encryption method effectively protects medical data; in addition, it can provide convenience to users while protecting data from various security threats. The simulation results confirmed that the proposed PIE system provides higher scalability and stronger security performance than existing blockchain-based medical systems.

Security Analysis

In this section, we will check how the proposed PIE system effectively responds to security threats and analyze whether it is possible to share secure medical data using the proposed PIE system.

Strong Privacy Preservation

When medical data are shared using a network, an external attacker can obtain the medical data through a sniffing or eavesdropping attack. If medical data are leaked, the patient's privacy in the EMR is also exposed. In the proposed PIE system, medical data are encrypted using the dedicated encryption key

for the safe sharing of medical data. As encrypted medical data can only be decrypted by the patient or by a user approved by the patient, the information in the data is not exposed even if the data are stolen. By granting data decryption authority using the PRE technique, the user approved by the patient can decrypt the data using their private key during the data decryption step. The proposed EMR-sharing method prevents the leakage of private information during the EMR-sharing process and ensures safety by eliminating the private key-exchange process for data decryption. If an internal attacker attempts unauthorized access to the patient's information, in our proposed system, *Smart contract_{RRrequest}* verifies the requester's security level and accepts or declines the request depending on the AP set by the patient. The access control scheme using a smart contract can protect the patient's privacy from internal threats.

Data Integrity

The internal attacker can perform forgery attacks by accessing the medical data that medical institutions manage independently. If the original data stored at a medical institution are damaged, it is difficult to recover the data; moreover, it is also significantly challenging to determine whether the data have been forged or altered. These attacks can be effectively prevented by storing and managing EMR-related information such as the hash value of medical data, publicly available medical information, and hospital ID in the blockchain. As the EMR information recorded on the blockchain contains the information at the time of creation, it is easy to check whether the data are damaged. If the data are damaged, they can be quickly restored using the distributed data-sharing method. For an attacker to forge the data stored in the blockchain, they must possess the mighty hash computation power of more than 50% of the entire network and create new blocks faster than other honest nodes propagate them to the network. As meeting the necessary conditions to forge blockchain data is challenging, attackers cannot delete or modify data. Therefore, using a blockchain-based medical system ensures medical data integrity and reliability, thereby enabling safe medical data management and sharing.

Network Security

The external attacker can perform denial-of-service attacks on the PIE system. As a result, the system's operation becomes abnormal and it produces unexpected outputs. The system we propose is directly or indirectly related to patients' lives; therefore, high availability is important. Hence, we use distributed systems such as a medical consortium blockchain and the IPFS. If the attacker breaks down the sharing system, patients cannot share their medical data and physicians or health care providers cannot obtain the required information. However, in the proposed sharing scheme based on blockchain, if the attacker makes a few of the blockchain nodes unavailable, the other nodes can provide the needed services.

Discussion

Principal Findings

The study's principal findings concern implementing integrated management of fragmented EMRs, preventing leakage of personal information of patients during the EMR-sharing

process, and establishing a patient-centered medical data system by granting decryption authority, as outlined in the following list:

1. We designed a blockchain-based PIE medical system that effectively manages and shares medical data. EMRs generated by different medical institutions are managed through a blockchain network to prevent the fragmentation of medical data. Moreover, through the PIE system, duplicate EMRs can be avoided, reducing the cost and wastage of storage space.
2. The PIE system encrypts the patient's medical data and uploads and shares the encrypted EMR and data identification parameters to the network with minimal medical information. Thus, the proposed method fundamentally overcomes the problem of possible leakage of personal data when the data are posted on the blockchain for sharing with other network members. Therefore, privacy preservation required in a system handling sensitive EMR information is guaranteed, making safe EMR management and sharing possible.
3. Our system reinforces the patient's role in the medical system by allowing them to grant decryption rights to their data to other users using re-encryption techniques. If other users (eg, physicians or researchers) wish to use a patient's EMR data, they must obtain a re-encryption key and re-encrypt the EMR data. Building a patient-centered medical data system differs from the existing hospital-centered medical data system in that the patient's role is reinforced in our system.

Limitations and Future Work

Blockchain-based medical systems receive considerable attention as next-generation medical systems that will replace existing medical data management systems, and numerous researchers are conducting various studies. However, blockchain-based medical systems' technological maturity remains at the prototype level. Moreover, as the medical data formats used by different countries or institutions vary considerably, it is challenging to share the medical data. Consequently, research into standardized medical data formats such as the Health Level 7 Fast Healthcare Interoperability Resources [65] is required. To successfully create the next-generation medical environment through a blockchain-based medical system, various and complex issues such as backlash from the medical field, legal ramifications related to medical care, technical limitations, and data standards must be addressed [66,67]. We aim to conduct research on public medical data systems that enable safe sharing of medical data in public networks as well as data security techniques so that EMRs can be used in more diverse fields in the future [68].

Conclusions

This paper presented the PIE system based on a consortium blockchain that allows patients to manage their medical data. The PIE system can securely manage and share EMRs by overcoming the existing blockchain-based medical system's problems. The PIE system uses a distributed data-sharing method and lightweight transaction structure to solve scalability and privacy issues, a chronic problem of blockchain-based

medical systems. By rapidly sharing large-capacity data such as medical images using a distributed data-sharing method, the issues of low processing speed and block sizes of existing blockchains are addressed. Lightweight transactions can store more information in blocks because they contain only minimal information, such as the encrypted EMR metadata and EMR summary information. The vast amount of medical data generated daily is effectively processed and managed using a lightweight transaction structure. The re-encryption-based data encryption method is used to resolve the problem of leakage of data and personal information when sharing EMRs. Even if the EMR encrypted with the dedicated encryption key is leaked

during the sharing process, it cannot be decrypted; therefore, it is safe from the threat of leakage. Honest users wishing to use the patient's data can re-encrypt the EMR by obtaining a re-encryption key from the patient. The EMR-sharing process was performed using smart contracts. Security level-based access control was performed using smart contracts to prevent unauthorized users from using medical data, and re-encryption keys were delivered only to authorized users. As a result, the proposed blockchain-based medical system provides improved security and scalability, enabling efficient and safe medical data sharing.

Abstract

Background: Recent advancements in digital pathology resulting from advances in imaging and digitization have increased the convenience and usability of pathology for disease diagnosis, especially in oncology, urology, and gastroenteric diagnosis. However, despite the possibilities to include low-cost diagnosis and viable telemedicine, digital pathology is not yet accessible owing to expensive storage, data security requirements, and network bandwidth limitations to transfer high-resolution images and associated data. The increase in storage, transmission, and security complexity concerning data collection and diagnosis makes it even more challenging to use artificial intelligence algorithms for machine-assisted disease diagnosis. We designed and prototyped a digital pathology system that uses blockchain-based smart contracts using the nonfungible token (NFT) standard and the Interplanetary File System for data storage. Our design remedies shortcomings in the existing digital pathology systems infrastructure, which is centralized. The proposed design is extendable to other fields of medicine that require high-fidelity image and data storage. Our solution is implemented in data systems that can improve access quality of care and reduce the cost of access to specialized pathological diagnosis, reducing cycle times for diagnosis.

Objective: The main objectives of this study are to highlight the issues in digital pathology and suggest that a software architecture-based blockchain and the Interplanetary File System create a low-cost data storage and transmission technology.

Methods: We used the design science research method consisting of 6 stages to inform our design overall. We innovated over existing public-private designs for blockchains but using a 2-layered approach that separates actual file storage from metadata and data persistence.

Results: Here, we identified key challenges to adopting digital pathology, including challenges concerning long-term storage and the transmission of information. Next, using accepted frameworks in NFT-based intelligent contracts and recent innovations in distributed secure storage, we proposed a decentralized, secure, and privacy-preserving digital pathology system. Our design and prototype implementation using Solidity, web3.js, Ethereum, and node.js helped us address several challenges facing digital pathology. We demonstrated how our solution, which combines NFT smart contract standard with persistent decentralized file storage, solves most of the challenges of digital pathology and sets the stage for reducing costs and improving patient care and speed of diagnosis.

Conclusions: We identified technical limitations that increase costs and reduce the mass adoption of digital pathology. We presented several design innovations using NFT decentralized storage standards to prototype a system. We also presented the implementation details of a unique security architecture for a digital pathology system. We illustrated how this design can overcome privacy, security, network-based storage, and data transmission limitations. We illustrated how improving these factors sets the stage for improving data quality and standardized application of machine learning and artificial intelligence to such data.

Introduction

Background

Digital pathology, a subfield of pathology, deals with information management enabled by digital technologies such as high-resolution imaging, computer storage, and network connectivity [1,2]. In digital pathology, the information generated from digitizing slides containing microscopic images of biological samples is shared over a computer network, with the expectation of faster diagnosis and remote access to medical experts. Digital pathology has several advantages over conventional pathology, which bases diagnosis on glass slides and microscopic examination of images on slides [3]. In digital pathology, extremely high-resolution images enable physicians to tag, expand, share, and analyze specific sections of the image slides to diagnose a disease. More recently, the deployment of deep learning algorithms to recognize patterns in high-resolution digital images has been shown to reduce the time taken to diagnose particular diseases [3,4]. Digital pathology also allows pathologists and referring physicians to share data with other experts in clinical diagnostics to concur concerning diagnosis and treatment pathways for specific diseases. As an example, trained superspecialists in oncological pathology, such as the coauthor (SS) of this paper, can provide a very detailed clinical diagnosis of the specific type of cancer, the rate of spread, the speed of spread, the stage, and the types of cells and tissues affected by detailed examination of slides.

Furthermore, the slides and diagnosis can be shared with other senior experts to confirm the diagnosis. These specialists can further suggest and approve treatments for the patients, thus reducing cycle time and improving diagnosis accuracy through

telediagnosis [5]. Thus, digital pathology can provide an accurate, timely, and concise diagnosis of the disease while providing the ability to share such diagnoses with other specialists.

Digital pathology uses technology that includes high-resolution remote and internet-based microscopy and high-resolution scans of glass slides, which can have multiple advantages. First, digital pathology benefits patients in locations where access to medical care is challenging and where the number of clinicians, physicians, qualified pathologists, and hospital systems are scarce [6]. Second, digitizing images at high resolution provides physicians and specialists with ease of use, thereby reducing the use of a microscope. However, they can view high-resolution images on a computer screen, thus reducing fatigue to the eye [1,7]. Third, physicians and doctors can focus on specific areas of the digital image by using input-output devices such as keyboards, mice, and digital pencils to write notes on specific areas of the images. Figure 1 shows the images and magnified sections of imaged slides that pathologists use to diagnose the medical condition. Fourth, physicians can share such data with other experts or senior practitioners in the field, who can later arrive at a consensus concerning the diagnosis about the progress of disease and recommend treatment pathways for patients. Owing to these advantages of personal ease of use and shareability, the role of digital pathology in providing timely, accurate, and concise prognosis and pathways to clinical recovery has been recognized by the medical fraternity. Hospital systems are slowly transitioning to a fully digital diagnosis mode, reducing physical storage requirements for glass slides and partially automating the transmission, attainment of agreement among experts, and treatment pathway recommendations for patients [5].

Figure 1. An illustration of a digital pathology image from a slide used in an actual diagnosis by the coauthor (SS). The image is from a high-resolution microscopic scan and digitized slide that is presented to the clinical pathologist on a computer screen for further diagnosis.

Infrastructure Challenges for Digital Pathology

However, there are several challenges with the adoption of digital pathology to make it widely accessible. These challenges relate to the transmission, storage, retrieval, and uniform clinical diagnosis using algorithms from slide or slides and image or images derived from tissue and biosample scans. Digital image scans are made possible by remote and internet-based microscopy or through a high-resolution scan of microscopic slides into images of much higher resolution (100,000 dpi to 1,000,000 dpi). Such scanned images also require high-resolution storage, for the data not to be compressed. While transmitting such high-resolution images, transmission could lead to data loss if images are compressed and decompressed, potentially affecting the consensus for diagnosis across the network. Compression and decompression of data lead to loss of information, which can potentially lead to an inaccurate diagnosis or inaccurate data training from these samples [8]. In addition, inaccurate images and matched diagnoses create flawed training data sets, reducing the prediction accuracy when deep learning models are applied to such data sets. Although network-attached storage, cloud-based storage, commercial databases, and workflow systems such as enterprise resource planning frameworks are plausible solutions to accomplish security and transmissibility of related data (ie, image scans or diagnoses), these centralized software systems are expensive to own and increase the total cost of ownership for pathological systems, which makes disease diagnoses via pathology unaffordable [6].

In centralized systems, the cloud provider or database network administrator controls the security of the network and patient data. Such centralized data control could often violate patient privacy and be susceptible to security breaches, ransomware attacks, and other data security problems. As a result, both the storage and network-based transmission of such high-resolution images are challenging. Second, obtaining the necessary audit or data transmission logs of such algorithms is difficult in centralized systems, which are database-centric and often need to interface between different hospital and clinical systems managed by different entities [9,10]. Third, although most research in the digital pathology area has automated deep learning techniques for pattern recognition with images, such application of algorithms will only fructify when a sufficient corpus of images combined with human-expert classification or training is present. Specialized diagnosis required to detect rare diseases such as sickle cell disease or certain types of cancer such as bone marrow cancer makes it increasingly challenging to obtain large training samples of digital images in high-resolution biosamples with human classification. A decentralized, secure, and standardized storage of high-resolution images and appropriate expert classification of such data that includes specific sections of tissue scans, physically marked and noted with the clinical disease diagnosis, can potentially solve this problem. Such uniform storage of images, diagnoses, and associated metadata information such as sections of the images, which help physicians diagnose the disease, is essential. Such data can lead to the creation of a proper training data set for deep learning, which can enhance the capabilities of automated disease diagnosis in the future.

The fields of artificial intelligence and machine learning, such as deep learning, are applied to remote and internet-based microscopy-derived images, using high-quality training samples, wherein the trained models can aid in faster diagnosis [1,3,4,11]. Such machine-assisted diagnoses can aid physicians by complementing their knowledge through pattern detection.

This paper highlights the challenges in digital pathology associated with secure data storage, secure data transmission, data privacy, and storage and transmission of high-resolution images and associated diagnosis from physicians. Furthermore, we propose a unique design with smart contracts and the Ethereum blockchain, which uses the Ethereum Request for Comments (ERC)-721 standard to store and transmit images while tracking ownership [12]. We propose an innovative decentralized storage and encryption scheme separate from the public blockchain [13]. We also document how these challenges can be overcome. We outline why and how such a design using smart contracts and blockchains can overcome issues in training accuracy using machine learning and artificial intelligence techniques for pattern detection from slides with a higher image resolution.

Advantages of Digital Pathology

The primary responsibility of practicing pathologists is to maintain the confidentiality of patient data and diagnoses. In digital pathology, it is a typical pattern that multiple pathologists and diagnostic programs have access to the data uploaded from one of the following sources: (1) high-resolution tissue photography, (2) scanned slides that constitute images from microscopes, or (3) remote and internet-based microscopes that image human tissue samples and store and transmit these images. The patient's medical record and diagnosis should be shared with those with the *right to know*. Data stored are expected to adhere to laws such as Health Insurance Portability and Accountability Act and General Data Protection Regulation. Similarly, only the pathologist who accesses the digital pathology platform should view these high-resolution images, make modifications, and make a diagnosis. Although pathologists and other specialists can access these images and slides on a case-by-case basis, the primary owner of the data is the patient. The patient can choose to remove access to the physician, or the hospital system might invalidate the data access after a legally mandated time frame (eg, 3 years).

In addition, these images should be stored only for an extended period, as mandated by law, and retrieved cost-effectively for purposes such as reference [5]. As discussed in the previous section, these high-resolution images will require significant storage and secure high-bandwidth transmission to transfer images, diagnoses, and audit logs. If these conditions are not met, digital pathology costs will become financially unviable to adopt and use for diagnosis. In the long term, storage requirements and cost reduction are essential for pathologists to ensure data accuracy, privacy, and access control [9,10]. Long-term storage costs, the transmission of high-resolution images about digital pathology to different owners on the network, and the high costs associated with the security, privacy, and auditability of such data create 3 main issues for the success

of digital pathology as an effective practice. The challenges in digital pathology are summarized in [Figure 2](#).

In digital pathology, the image resolution of slides containing images of tissues or other human body samples such as blood vessels is comparatively high. It often ranges between 1× and 400× of slides obtained using traditional microscopy in nondigital pathology [14]. The advantage of such platforms is that multiple pathologists can simultaneously access the slide if they have the corresponding software and authorized access to the slides. In addition, pathologists can share independent diagnoses on the web after analyzing these images. As a result, significant time is saved in prognosis or diagnosis and the treatment compared with scenarios where microscopic glass slides would have to be transported physically. A second or third opinion must be obtained to draw a fail-safe conclusion if the severity of the disease is high, in which case reports, images, and other patient data must be shared by maintaining the privacy and patient confidentiality protocols.

Artificial intelligence algorithms can aid physicians in detecting patterns from images, especially in pathology, where cancer growth creates patterns in body tissues. Deep learning models can be trained with sufficient samples to detect and code sections of images with a specific diagnosis [3,11]. Such models can recognize patterns of spread, the spread stage, and the spread level in cancerous cells after appropriate training from a large corpus of samples that physicians have accurately classified. In addition, prognostic factors that can aid in treatment can be determined. Although storing and documenting preliminary case data for human diagnosis is equally important, such data can later be used downstream as inputs to training and classification algorithms to automate the detection and diagnosis of pathological conditions. The use of deep learning algorithms

such as convolutional neural networks and recurrent neural networks combined with support from graphical processing units offered by NVIDIA and AMD provides significant strength to such automated analysis [3,11]. Often, such trained algorithms have lower accuracy than required because of the uniqueness of individual cases. If irregular patterns do not fit into the diagnosis, then such cases have to be manually studied, and such cases could be labeled independently as a rare possibility.

The goal of such a digital pathology could evolve to enable automatic diagnosis through the accrual of a proper training data set and human classification algorithms. When such data sets become available and deep learning algorithms are trained appropriately on human-classified data, the time to diagnosis will naturally decrease. In addition, data from digital pathology can be used for multiple purposes such as teaching, research, and continuing medical education seminars. Here, data retrieval is fast; access is provided on a distributed platform that caters to both privacy and security, and search and retrieval and display of data in the digital formats used in traditional pathology is proper. [Figure 3](#) shows a sequence diagram that captures a typical pathology workflow for diagnosing a patient's condition using digital pathology.

Pathologists can choose to expand and focus on certain sections of the slides at a higher resolution to diagnose the disease involved and create notes on these slides by annotating sections of the scanned images. Later, multiple pathologists or other specialists can view the same slides to create a diagnosis and discuss treatment pathways. These modified slides with annotations from experts are stored back in the centralized system for retrieval and use, in other cases, for research or teaching purposes.

Figure 2. Technical challenges in digital pathology.

Figure 3. Workflow of digital pathology system.

Blockchains, Nonfungible Tokens, and Decentralized Storage (Interplanetary File System) Applied to Health Care

Blockchains address the challenges of system interoperability, security, privacy, nonrepudiation, storage persistence, decentralized storage, decentralized validation of transactions, and accessibility for all data [13]. Before the advent of blockchains, anonymized and privacy-controlled single point of access for multiple data sources was provided for each user. Similarly, assuring privacy and user-controlled data and tracing or auditing data transmission records was difficult because the data resided in private centrally controlled repositories. Such data repositories are administered by a central administrator, who is often the single weak link for ensuring data security and privacy. In medical record storage systems, owing to multiple disparate administration end points involving different organizations, data are shared among multiple administrators, creating a weak link for a privacy violation. Because blockchains remove the need to centralize data storage and control data flow and modifications, they have several applications in health care [15]. Blockchains have been shown to provide a cost-effective and robust decentralized technology for a variety of health care applications, such as tracking clinical trials [16], enabling tamper resistance [17] for mobile health data, removing trust deficiencies during the COVID-19 pandemic [18], and eliminating substandard drugs from the supply chain [19].

Blockchains have evolved to support programming logic by including variables and loop structures using high-level programming languages such as Solidity [20] and a remote and internet-based machine that interprets and executes the compiled programs. These programs are compiled and deployed onto remote and internet-based machines that validate transactional and semantic logic in programs. Remote and internet-based machines understand opcodes (or machine-interpretable code), which are outputs of a compilation of a higher-level programming language such as Solidity. Examples of blockchains include Bitcoin (which supports a rudimentary scripting language), Ethereum, Cardano, and Solana. These smart contracts enable web- or mobile-based decentralized applications that interact with the underlying blockchain and remote and internet-based machine based on user input.

Although blockchains such as Hyperledger, Ethereum, and Cardano have been shown to support data storage and programmability of contracts, it remains challenging to ensure that such data storage can happen cost-effectively on the blockchain (on-chain storage). The governance structures of public blockchains require application writers and data creators to pay a transaction fee, which is often proportional to the bandwidth and space used on the blockchain.

This is because storing even small amounts of binary data on a public or private blockchain, that is, on-chain, as a transaction record would cost several hundred dollars. Although several papers in the medical informatics field have chosen this costly approach to store data on the blockchain (or have used a Hyperledger framework with a private blockchain or a consortium blockchain to store data), such storage mechanisms are inefficient for digital pathology, which requires more extensive storage and other challenges, as shown in Figure 2.

This is because image storage requires large quantities of cost-effective data storage. Image transmission on the network with such large images is nearly impossible, given today's email client and other networking protocols, such as Simple Mail Transfer Protocol. The only possible likelihood is to store images from a local repository that distributes the image onto a network file storage and makes the file addressable.

Another challenge with such an approach is that the data stored in the blockchain are public information and can be effectively downloaded from the remote and internet-based machine by any user as it is stored. Therefore, unless the stored data are encrypted in an unidentifiable way using the user identifiers of both the sender and the recipients, such data are of no use. In this study, we propose a 2-layer blockchain solution for nonfungible tokens using the ERC-721 standard for nonfungible tokens (NFTs) that separate metadata from file storage and promises authenticity, security, distributed storage, and ease of use [21]. We use this 2-level architecture that provides affordability for use cases such as digital pathology, which requires extremely high-resolution and high-density storage. In addition, we use an existing well-used standard supported by sizable open-source marketplaces in the context of digital art to support all use cases necessary to create a cost-effective digital pathology system. Such a system will provide traceability

of each transaction by using transaction records and logs and cost-effectively enable storage and transmission. We propose application-level encryption of metadata URI's stored on-chain and associated with the nonfungible token. We prototype a system and demonstrate how such a decentralized workflow for storage, retrieval, and transmission occurs while catering to various design requirements for such a system.

Decentralized Data Storage Using the Interplanetary File System

Although blockchain technology provides several advantages noted above and health care can be shared efficiently among peers (hospitals or physicians) in a health care system, there has never been a justification to store such health care data on-chain [22]. Particularly in digital pathology, where high-resolution image scans require significant storage, the feasibility of storing data on-chain is impossible because of the infrastructure costs involved in storing, validating, and retrieving such data. Particularly for mass-adoption blockchains such as Ethereum, Solana, and ADA, data storage and transaction fees would significantly exceed the affordability of the digital service compared with the traditional mechanism of glass slides. A simple estimate for the Ethereum blockchain stated that it costs between US \$17,000 and US \$76,000 to store 1 MB of data on-chain. In addition, the blockchain does not provide version control or other features to optimize data storage such as the Interplanetary File System (IPFS). The operation of the IPFS for file storage and retrieval is described as follows.

When a file is added to the IPFS, it is split into smaller chunks, cryptographically hashed, and given a unique fingerprint called the content identifier (CID). The CID acts as a permanent record of the file as it currently exists. When other nodes (or a program using JavaScript Object Notation and Remote Procedure Call) look up the file using the unique CID, they ask their peer nodes about storing the content referenced by the file's CID. The IPFS provides a mechanism to identify (pin) records to hosts on the network. If the content is not pinned, it can be deleted to access the more recently accessed files. Versioning of files is maintained by creating a new CID because of which files stored on the IPFS are resistant to tampering and censorship on the network. The IPFS uses a distributed hash table to identify addresses and images. The IPFS facilitates the removal of duplicate files and enables the creation of version-control history [2]. The IPFS optimizes the storage and retrieval of frequently accessed files through a cache mechanism, where frequently accessed files are prioritized using hash tables that rank files based on their access frequencies. On the IPFS, each file can be individually accessed with its hash address from the internet; the IPFS is a content-addressed block storage system with features such as high throughput, security with hash mapping of transactions, and concurrent access of files.

NFT Standard for Digital Pathology

The NFT standard is a unique and noninterchangeable unit of data (or a data pointer) stored on the blockchain. Although other token standards such as the cryptocurrency token standard ERC-20 have been popular, the NFT standard authenticates and associates reproducible digital files such as photos, videos, and audio on the Ethereum blockchain. The ERC-20 standard is

used to implement the cryptotoken functionality. It is usually used to create a token for sourcing funding during an initial coin offer and other such uses, enabling token holders to participate in blockchain governance. The major feature of ERC-20 is that it is tradable against any other ETH-compatible token, on crypto exchanges, or coin-swapping liquidity provider platforms such as Uniswap. As a result, we have to use the ERC-721 or NFT standard to implement the image storage, authentication, ownership, and digital rights in the context of digital pathology. NFTs use a digital ledger to provide a public certificate of authenticity or proof of ownership. The NFT standard has wide adoption for various multimedia-based token creation and has seen significant adoption among the art collectors. Similarly, more recent innovations in virtual reality, augmented reality, and the metaverse have enabled the creation and sale of digital assets using this standard.

Overall, if we store the characteristics of the image off-chain on the IPFS (eg, in a metadata file) and have the metadata's unique CID referenced on the blockchain and then minted into an NFT, then it is possible to separate token ownership from token access. The ownership is documented in the metadata file, whereas the access is implemented via functions supported by the ERC-721 standard. This architecture provides us with the flexibility to enable the separation of ownership of the token from the access properties. It also enables us to securely transfer access (or replicate access) after signing the token by the owner, enables token burn, and assigns access to others. In addition, such a design enables the process of minting, replication, and burning of the token. The NFT standard uses these two technologies, that is, the NFT standard smart contract on the Ethereum blockchain and the IPFS for decentralized file storage.

The Goal of This Study

In this paper, we analyze the following two research questions (RQs) using the design science research methodology:

RQ1: How does blockchain-enabled digital pathology improve data sanctity, privacy, data validity, and cost-effective, secure network storage?

RQ2: Does such a system design improve physician diagnosis by reducing the cost of storage, improving security diagnosis times, and improving machine learning capabilities by improving the accuracy of data stored?

Methods

Overview

We use the design science research process (DSRP) methodology used in information systems and computer science disciplines and expert recommendations. Our solution prototype proposes an innovative smart contract-based digital pathology system using public infrastructure to simplify high-resolution image storage and provide a decentralized, secure, and privacy-preserving data-sharing solution. Figure 4 shows the research methodology [23].

DSRP is a well-established research methodology in information systems, computer science, and information technology management. It is used mainly to create design-based system

solutions for practical problems, for which there are no previous solutions. As the name states, DSRP applies design science to create a software- or system-based prototype that addresses the research problem. Using the prototype, researchers validate the assumptions they made. We use the following steps in DSRP to implement and test our prototype: First, we describe the problem and define its importance. The challenges in digital pathology are described in the *Introduction* section. We obtain the problem definition (challenges) from practicing pathologists—the coauthor (SS) of this paper—through a formal procedure of requirement gathering. We share a questionnaire about using the digital pathology system and record how they faced challenges in day-to-day work. Second, the objectives of the solution are clarified in terms of the benefits of improving the quality of care and maintaining accurate data for creating clean data sets. These questions are documented in [Multimedia Appendix 1](#). [Table 1](#) defines the key problems that we aim to address using our solution and the main objectives.

In step 3, we design and implement a proof-of-concept use principles of systems analysis and design to create a model-view-controller architecture-based system with JavaScript, web3.js, node.js, and Ethereum stack combined with the IPFS for long-term data storage. The following section describes the creation of the NFT-based IPFS that meets the various objectives of the solution. We later discuss the confidentiality requirements and application-level encryption of metadata files for storage. In the fourth step, we demonstrate the artifact and the solution prototype. Fifth, we evaluate the artifact for whether it indeed met all the design objectives for the problem it indeed set out to solve. Finally, we document the results of our experiments and describe how our solution benefits the wider digital pathology community and the contributions of this study. We also believe that our solution can be appropriated for other high-density storage requirements in the medical world.

Figure 4. Diagram represents the steps in the design science research methodology.

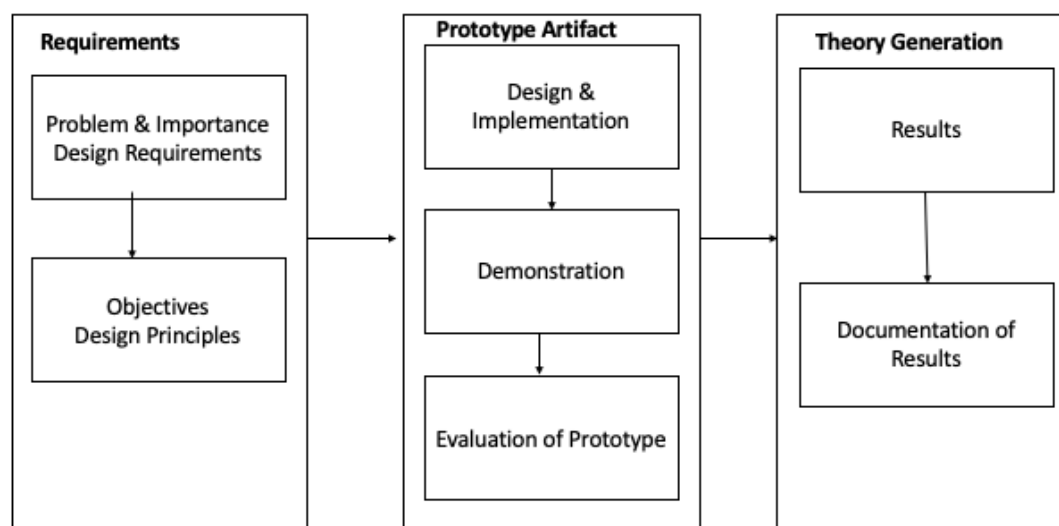

Table 1. Problem definition and objectives.

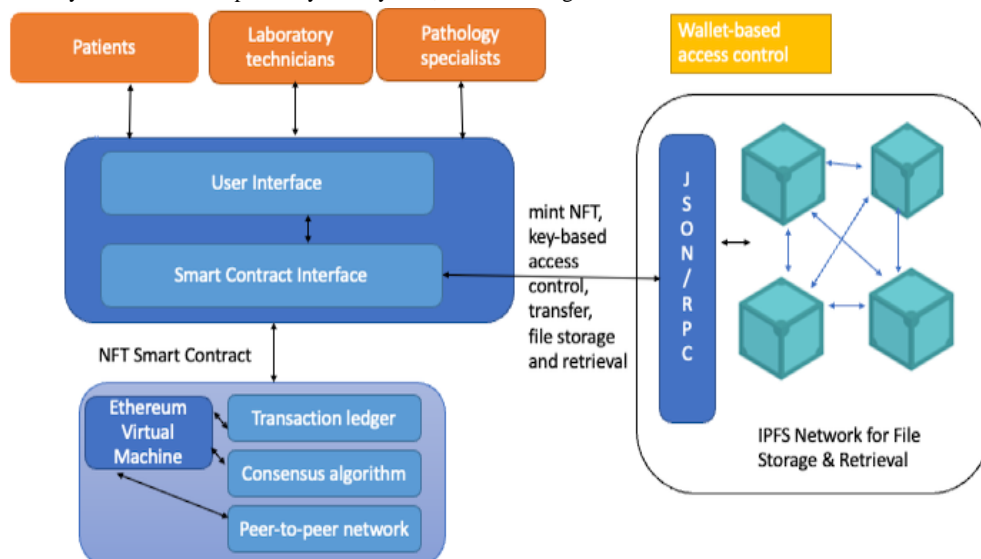

Problem definition	Importance and business outcome	Objectives of the solution
Long-term distributed and cost-effective storage of high-resolution images, metadata, and diagnoses provided by multiple users	Reduce the cost of adoption and utilization	Evaluation of alternate technologies that provide such storage; possibly separate the storage from the data transmission mechanism
Network transmission or the ability to share such high-resolution images and associated data	Improve speed of diagnosis for the disease	Mechanism to share data with others through the internet in a secure way
Data security	Improve security for all clinical data and provide access control	Mechanism to prevent unauthorized access of data
Data privacy	Improve the privacy of data in the system such that only the physician, pathologist, and patient can access these data	Mechanism to share the data on a need-to-know basis
Ability to maintain audit data transmission or data from shared access logs	Improve compliance using Health Insurance Portability and Accountability Act, General Data Protection Regulation, and privacy laws	A mechanism to trace how data have been shared among different users; store of logs should be perennial
Ability to maintain accuracy for creating a high-quality training data set for future application to artificial intelligence or deep learning models	Better training data can be stored on the network, and such data can facilitate better machine learning and artificial intelligence prediction	The mechanism above should have the ability to be audited, verified, and analyzed by third parties independent of the system
Reduce cost to the patient	Public infrastructure with well-established cryptographic protocols can enable the solution to scale significantly; network transmission is avoided by design	Network-attached storage costs are reduced for the solution; telemedicine and remote diagnosis are enabled easily
Improve the quality of care for the patient	Once higher accuracy for training data is established, the quality of care for the patient would have improved significantly	Machine-assisted diagnosis is possible
Ability to separate artifact ownership from token access	The pathological data record should explicitly state that the patient is the data owner, regardless of other individuals accessing the record	The metadata always explicitly records the ownership of the digital image by storing the patient's pseudonymous information such as ID or wallet address that are unique to the patient
Ability to remove access after a prespecified time interval as per the legal and regulatory conditions	After a prespecified interval, the record should automatically be burned for all nonowners; those health care professionals who received the record should no longer have access to it	This functionality provides the ability to remove access to specific records and adhere to health care data storage and retrieval laws

Architecture and Design Components

Figure 5 depicts the software architecture of the decentralized digital pathology system. The system architecture conforms to

the model-view-controller architecture pattern, and the system's main components are described in the next section.

Figure 5. Software architecture of the digital pathology system with blockchain and IPFS used for tokenizing, storing, and sharing access to the digital outputs of the health care system. IPFS: Interplanetary File System; NFT: nonfungible token.

Description

We use a model-view-controller software architecture pattern [24] to prototype the digital pathology system capable of addressing the requirements described in the *Introduction* section. The model stores the data about image scans and uses the interfaces provided by the view and controllers. Data are stored on the IPFS [25] and are usually of two types:

1. High-resolution image files about scans and any modifications made by the pathologist or other professionals, such as notes and image markings, to identify specific disease patterns, and
2. The JSON files containing metadata about the scans stored on the web or the diagnosis provided by the physician.

The IPFS provides a decentralized store for data and is based on caching data where file access frequency provides users with performant file storage.

We use Solidity programming language for programming the smart contract, which runs on the Ethereum test network. We use several JavaScript toolkits, namely, web3.js, node.js, and essential libraries associated with HTML5 and bootstrap.css, to code the front end. For testing the prototype, we used the Ganache command line toolkit (CLI), the VSCode library extensions for Solidity and HTML5 and JavaScript, and the integrated development environment for programming using Remix smart contract editor. We use the Ethereum Kovan and Ropsten test networks to implement the prototype and to validate our solution against the objectives set out in this paper.

The user interface provides a visual interface for physicians, laboratory technicians, and patients to view the data that they own or share with their wallets. While physicians, laboratory technicians, and patients can access the same image addressed using the CID on the IPFS, the main controlling file is the JSON, which interacts with the smart contract infrastructure and mints the token. The address stored (ie, the CID of the JSON file that contains metadata about the image or diagnosis) in the minted token is hidden from public access by encrypting the CID with the user's keys. The security aspects of the proposed system are described in the following section. The user interface then interacts with a controller consisting of a series of smart contract methods that mint new tokens, transfer tokens from the laboratory technician to the physician and from one physician to another using the NFT protocol, and so on. The decentralized application is responsible for creating newer images and minting the NFTs, which can potentially generate notes from physicians, clinical pathologists, or patients to enable data to be stored within the IPFS. This data model is described in the JSON file and indicates the different types of files used by such a system.

Because the IPFS stores each image file separately (as a unique addressable and unalterable hash), a JSON schema file similar to code listing 1 ([Multimedia Appendix 2](#)) creates a JSON file that contains the address for the CID for each NFT. Each time a new file is added, a new JSON metadata file is generated and stored within the IPFS. As a caveat, although the IPFS is a public infrastructure consisting of thousands of nodes from voluntary contributors, token-based decentralized storage mechanisms such as FileCoin and Storj are also available,

providing decentralized storage and enabling application developers to access guaranteed distributed storage on the network. Both Storj and FileCoin incentivize users to participate in decentralized file storage by rewarding contributors with cryptocurrency. The price for Storj is approximately US \$4 per month for 1-TB storage and US \$7 per month per TB of bandwidth, which is lower than most other web hosting or cloud service provider costs, thereby reducing storage and network transmission costs for high-resolution images.

From code listing 1, that is, the JSON metadata file, we obtain a unique CID that addresses each image location along with the pseudonymity of the owner of the image in the form of the owner's name and wallet ID. This information is unique and used to separate ownership from access rights. The blockchain provides the encryption and security for this JSON metadata file of the images used in the data set.

The CID of the metadata file is used as the input to the NFT mint (ERC-721) and provides the originator of the file access to this token. This token can then be transferred to other individuals on the network by simply using their wallet addresses. Every JSON metadata file associated with the record should contain the owner name and ID, and the patient's public wallet address that uniquely identifies the patient. When the metadata file must be shared among multiple people, the sender will have to mint multiple tokens with separate metadata files (CIDs) to transfer the token to other individuals. However, the base file will remain the same, and the image data file is referenced in each JSON file independently. The source code for minting the NFT in Solidity is listed in code listing 2 ([Multimedia Appendix 2](#)).

The original NFT can be transferred by sending the token to the recipient's wallet address using the *SafeTransfer* function described in code listing 3 ([Multimedia Appendix 2](#)).

Decentralized Application Functions to Mint, Store, Transfer Ownership of, and Expire (Burn) the Token

In the decentralized app, we use the smart contract code of the NFT standard (ERC-721) to mint an NFT on the Ethereum network and use the JSON file's IPFS URL (code listing 4 in [Multimedia Appendix 2](#)). The web interface invokes the smart contract from the Ethereum remote and internet-based machine to transfer the token from the source address to the destination address. Further, we transfer the token ownership to a receiver's blockchain wallet. This mechanism ensures that only the NFT owner has access to the JSON metadata file, which points to the IPFS URI of the pathological image sample. Further, the web interface allows us to create new files for diagnosis, upload new image files, mint new NFTs, and transfer ownership of NFTs, all of which originate and require the user to access a cryptocurrency wallet such as MetaMask. Once the user signs into the wallet, the wallet provides multilayer security for accessing original content stored within the IPFS and access the application. Within each wallet is access to the NFT for which the current wallet has ownership. The NFT will contain a unique CID for the JSON metadata file, containing further pointers to scanned images, diagnostics from physicians, and prescriptions. Code listing 3 shows how the NFT is minted based on the user input.

Code listing 5 ([Multimedia Appendix 2](#)) shows how to access the smart contract on the remote and internet-based machine from the front-end JavaScript of the decentralized application. We use Ethereum events and event listeners within the web3.js implementation standard to invoke the mint functionality of the smart contract. Code listing 5 shows that MintURI is the JavaScript function that captures and returns the token ID once the token is minted. MintURI retrieves the token ID and associates the token ID to the IPFS CID of the JSON file, which contains the metadata (as described in code listing 1).

Regarding privacy of data, this CID can be encrypted by a key pair stored in the wallet by the application when minting to give only the owner access to the URI where the JSON file is stored.

Transferring Ownership of the Pathological Record

In the code snippet (code listing 6 in [Multimedia Appendix 2](#)), we see the URI, the JSON file's CID being transferred to the MedContract.methods.mint(...). The token is associated with the wallet (Ethereum) address 0x138a93...A8. Overall, once the token is minted, the owner can securely transfer the NFT over the network to another user. This transfers both the owner of the diagnosis file and the URI to the receiver. However, the actual data stored on the IPFS has never moved. The only transfer happening is the token's ownership (which points to the CID of the JSON file data), which was initially associated with the sender's wallet address. It will now be accessible only to the receiver. Code listing 6 describes the main functionality and how the user interface sends the code to other users.

The code listing 6 shows how data ownership is transferred from the senders to the receiver. The underlying CID (IPFS) and its contents can now be accessed by the receiver, who then examines the high-resolution image and either contributes by creating a new diagnosis file or creates a new image for minting the NFT.

Creating an Expiration Date–Driven NFT Access Control

One of the key requirements is for the token to expire as per the expiry date. Different state and local laws dictate how long each hospital can store a patient record and conditions around the storage of the record. For example, in the health care system that the coauthor of this paper works for, the hospital system stores the records (glass slides containing high-resolution microscopic scans and digitized images of these scans) for 3 years, after which they are securely discarded from their storage. However, the owner or patient can choose to retain their copy for as long as they choose.

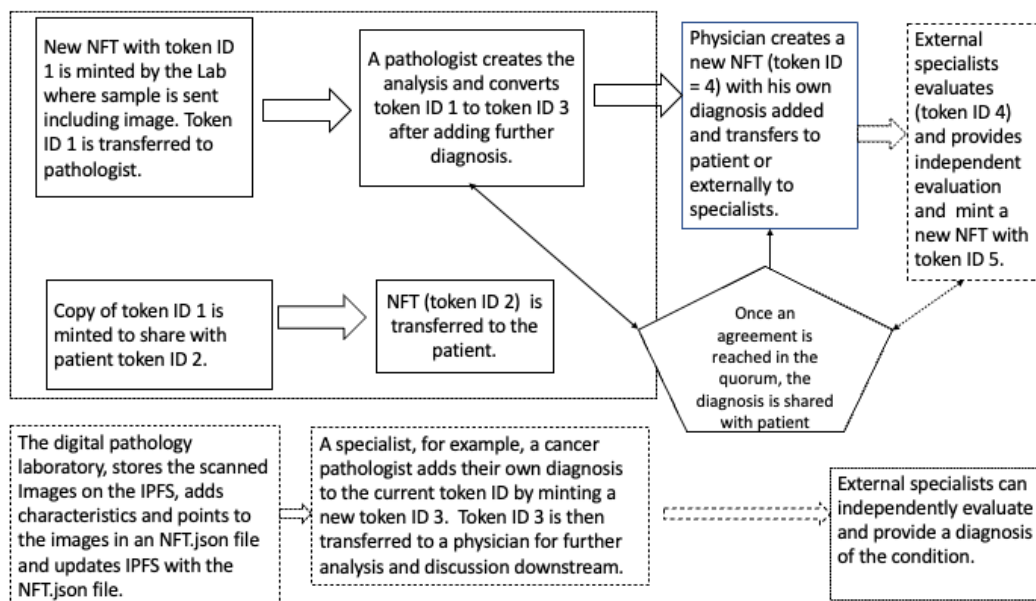

The approach we chose to replicate this functionality on the blockchain is as follows: The smart contract code supports the burn functionality for the token, which subsequently makes it inaccessible by any of the system's users. Then, the web3.js application scans each record for the creation date and the owner's wallet ID and burns those for all those token owners whose wallet IDs do not match the owner's wallet ID, which is stated in the JSON record. Code listing 7 ([Multimedia Appendix 2](#)) displays the burn functionality for the token ID when the token was burned.

Upon execution of the contract within each user's (eg, physician's or even pathologist's) decentralized application, those token ID's with creation dates exceeding the expiration date would be burned and inaccessible to anyone else on the system. Only the record owner (or patient) would never execute the burn function, preserving original access to the NFT.

Use Cases Supported by Design and Implementation of the System

Several use cases are supported by the design and implementation of our system. One such user flow is shown in [Figure 6](#), which directly refers to the aforementioned design requirements.

Figure 6. Illustration of a digital pathology workflow with nonfungible tokens applied to scanned images overall. NFT: nonfungible token.

Securing Data Storage for Privacy and Data Control

Access control, ownership, and confidentiality of data are three challenges in storing health care–related data on blockchain platforms. Because data reside on the blockchain and either the data or pointer to the data is publicly accessible and available to all users, how can users ensure that their data are accessed only by authorized individuals and that others do not have access to it? Furthermore, how do users ensure an audit trail for the accessed data, as auditability is one of the legal requirements from Health Insurance Portability and Accountability Act or General Data Protection Regulation? Similarly, how are ownership rights of data separated from the right to share the data with health care professionals for specific contexts of diagnosis?

To solve these challenges, we describe and implement the prototype for the security architecture in [Table 2](#) in the context of our digital pathology system on a public blockchain. The security architecture of the digital pathology system is multilayered based on the different access requirements in the system. The principal fundamental functions of the security system include authentication, data integrity, confidentiality, notarization or signature, access control, assurance of availability, and ownership. By authentication, we mean that the data are accessed only by those individuals who handle the data. Data integrity means that the data are never tampered with

by anyone in the system. The confidentiality property alludes to the fact that the actual data are not exposed to others, although pointers to the data reside in the blockchain. By notarization, we ensure that every time the data are transmitted or accessed and restored on the system, there is a valid signature of the individual who has accessed the record stored on the system. By access control, we mean that data access is tracked in the system, and only those allowed to access the data through a valid identifier can access the data. Finally, by assurance and availability, we ensure that data are available only to those individuals who have the right to know legally, and the security mechanism is available to all participants in the network (ie, the rules for access control and security are available to all users uniformly). The unique aspect of data record ownership is now added to these properties to the blockchain. The data record ownership ensures that only the primary owner of the data record, that is, the patient, has perennial access to the NFT. In addition, for all those who are not primary owners of the health care record (ie, the nonpatients) to whom the NFT has been transferred, the application would automatically invoke the smart contract's burn functionality after a preassigned period.

In [Table 2](#), we discuss the different levels of data security and privacy enforcement at three layers, namely, the application layer, smart contract layer, and data storage layer, that is, the IPFS layer for such a system.

Table 2. Security layers, property of the security architecture, and implementation.

Layers of the stack	Property of the security architecture	Implementation
Application layer and smart contract layer	Authentication	Users who require access to data are authenticated by their wallet (which contains a hash of the user's public key and a private key). Each time a message is sent, it is signed and verified using ECDSA ^a . Only those users who can sign in to their wallets can access their corresponding data in the form of the NFT ^b .
IPFS ^c layer and smart contract layer	Data integrity	Data integrity is managed and maintained by the underlying blockchain and IPFS layers. One of the properties of the blockchain is that the data cannot be manipulated ever. Similarly, the original image or diagnosis file stored in the IPFS cannot be altered. Changing the file will give rise to a new CID ^d , which will need minting a new token with different access controls.
Application layer for encryption and smart contract layer for storing the encrypted CID on the blockchain	Confidentiality of data	Although data stored on the blockchain is public information, the NFT being minted is minted off a JSON file's CID stored in the IPFS. The application can encrypt and store the encrypted CID on the block in the associated NFT accessible only to the wallet owner. The encryption is done by the application and not by the blockchain or the blockchain's smart contract. Each time a new token is minted, the resulting metadata file is uploaded onto the IPFS. The CID of the metadata file is encrypted by the application and stored on the blockchain as part of the contract.
Smart contract layer	Notarization	After signing with the owner's public key, each piece of information is notarized and stored on the blockchain. Each time the NFT is transferred to a new owner, at the application layer, the NFT is signed by the new owner's public address and later encrypted using the new owner's keys for storage on the blockchain at the application level, so that only the new owner can access the contents of the NFT.
Application layer and smart contract layer	Access control	Access control for a token is currently maintained by means of a wallet (both public and private keys). However, this access control can be maintained and moderated by the user.
Blockchain and IPFS layer	Availability	This is moderated by the underlying blockchain and IPFS infrastructure that has a 99.99% availability. The only limitation is network availability, which controls the rate at which data can be deposited and pulled from the network.

^dCID: content identifier.

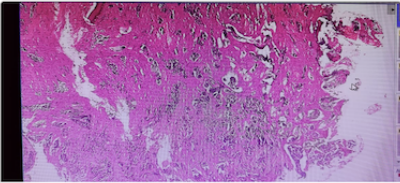

Results

After proof-of-concept implementation, we test and describe how the main objectives of digital pathology solutions are met. Furthermore, using our solution, we evaluate how this solution addresses the challenges associated with storage, transmission, cost-effectiveness, and security concerning digital pathology. [Figure 7](#) shows the screenshots of the prototype digital pathology and the system's user interface. In addition, these screenshots demonstrate how such a system works and the mode of operation of the digital pathology system.

In [Figure 7](#), we see how these images are accessible to the owner of the data set and now surface at the user interface. The pathologist and other experts who have access to the image

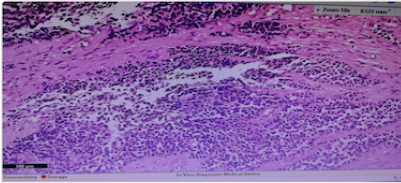

through the assignment of the NFT can now click on each image, open the image, and analyze the image through visual inspection or by the assistance of various artificial intelligence algorithms. The respective professional can then save the modified image and diagnosis onto the IPFS, mint a new NFT, and share it with the patient or other specialists in the group. Similarly, access to all such images occurs by signing in to the corresponding wallet of the user. Once signed in, the user has access to the corresponding NFT through a wallet. Such a design that separates the user actions from storage and records each action atop the blockchain creates a valuable chain of record. [Table 3](#) presents the benefits of our design vis-à-vis the original requirements, the implementation details, and the benefits of such a solution.

Table 3. Solution requirements and how they are addressed in the implementation.

Requirement	Implementation details	Benefits
Security	There are 2 layers of security for data in such a system. First, the IPFS ^a that stores images provide a high-security level by encrypting and splitting data into chunks stored on the network. Data are accessible only via a CID ^b , which is a large 256-byte hex code. Next, the JSON metadata file, which addresses the CID that is encrypted within the blockchain, is only accessible by those who use their keys to access the contract address where the data are stored. Refer to Table 2 for the implementation details.	The 2-layer security of smart contract data will only enable the wallet owner to access the record's contents. IPFS's CID is impossible to guess randomly.
Privacy of data	Only the user who has access to the corresponding wallet can access the data on the blockchain, and all other users will be blind to the use of data. Refer to Table 2 for an explanation of how data confidentiality and privacy are handled in the design.	This feature of the blockchain provides users (patients), physicians, and others the additional layer of security.
Low-cost, high-fidelity file storage	The IPFS is a public infrastructure secured by nodes running globally. The smart contract code can communicate with the IPFS if contracts prefer pinning (or converting to static storage) the data. An alternate public storage mechanism is FileCoin, which builds an incentive mechanism atop the IPFS to reimburse users for providing high-end storage and availability.	There is no need for compression of data or the manipulation of original data files for long-term storage. Such a storage method enables storage of the original files at high fidelity for further analysis.
High performance	Data and smart contract access is enabled to the high-throughput data storage via the IPFS and metadata file that contains a data pointer (ie, CID of the actual image). We also refer to other decentralized storage systems such as FileCoin and Storj, which are paid alternatives to the IPFS wherein crypto tokens enable the QoS ^c layer to ensure data availability. As a result, the actual file is never moved on the network, and only access controls to the CID containing JSON files are altered.	Data transfer does not occur on the network, except for the image being scanned and stored on the IPFS. Data access is provided via metadata files that are minted into NFTs. The NFTs, once transferred on the network, transfer the ownership of the underlying token to the receiver. As a result, the only piece of data transferred on the blockchain is the token through a transaction. This improves the performance of any system compared with a networked system infrastructure or a permissioned database structure where entire data files will have to move on the network.
Low transmission cost	Data transmission is accomplished by just transferring the token ownership on the blockchain corresponding to the file. Therefore, the original file is not transmitted over the network; instead, the JSON file's CID ownership is transferred to a different wallet on the blockchain.	The network transmission of the IPFS record means that only the minted token is transferred in ownership. The details of the token ID are stored and encrypted on the blockchain. Therefore, no actual data are transferring on the blockchain, reducing and improving bandwidth significantly.
Improve data accuracy	Every time the data are modified by the physician or other intermediaries, newer version-controlled files are created on the IPFS.	Higher accuracy of the data helps train artificial intelligence and machine learning models to improve prediction accuracy.
Ownership	Every specific period when NFT ^d ownership expires for legal reasons, such access is removed automatically through the smart contract's burn functionality. Only patients who own the token obtain a chance to hold onto the token and access-associated digital images. The rest of the owners will not have access after the expiry (burn of the token).	The ownership of the digital asset is separated from the functionality of the smart contract. Although the NFT can be shared with multiple practitioners, the actual access is determined by the legal policy of the health care system for nonpatient access. Only patients can access their own NFTs after the record's expiry date, where the NFT access is restricted for all others.

Discussion

Principal Findings

In this study, we introduced several innovations in decentralized digital pathology that help offset the costs of imaging, sharing, and distributing high-resolution slide scans for medical

diagnosis. Using private infrastructure mechanisms responsible for the maintenance of nodes and consensus mechanisms and administration of such systems controlled by a few firms would defeat the entire purpose of using digital pathology to improve the speed of diagnosis and the cost of patient care. Although other health care applications have discussed frameworks to store health care data on the blockchain or to use permissioned

networks with different types of encryptions, such a design would increase health care costs and system expenses. In addition, with private blockchains or consortium blockchains, the cost for maintaining the infrastructure and governance would centralize the blockchain system.

Although, on private permissioned blockchain, it is feasible to implement such on-chain storage without additional costs for storage, our design uses decentralized public storage as the back end, combined with established NFT standards. At the same time, private or permissioned blockchain architectures could lead to incompatibility among different chains and prevent external sharing of data because private blockchain with on-chain storage operates within network boundaries. Essentially, there would be a need to implement such permission blockchains across the hospital supply chains, including laboratories, partners, verification agencies, and clinics. These costs would prohibit the mass adoption of digital pathology, whose promise is to reduce costs, increase speeds, and use machine-assisted artificial intelligence and machine learning algorithms to communicate with others. In addition, software and hardware upgrades, technology obfuscation, network speeds are left to the blockchain maintainers in the case of private blockchains. As a result, a trade-off between private permission and consortium blockchains without permission would make a design such as the one presented here suitable. The public maintains the infrastructure with a consortium-driven networks and private and public networks.

We relied on a public blockchain infrastructure combined with decentralized storage in our solution, which we believe will drastically reduce the costs for storage transmission and provide a privacy-enabled and secure system for public health care. At the same time, the participants can also contribute to such infrastructure by offering nodes on which they could pin their

files for the IPFS. Alternatively, an inexpensive decentralized storage system such as Storj could be used, providing permissioned access to ample storage at a very affordable cost. The only piece of data that the blockchain stores is the encrypted CID for the IPFS metadata file. Although the IPFS metadata file is addressable and accessed outside the blockchain by users whose wallets have the authority to access the contents (image scans, diagnosis, treatment pathways, and other associated metadata), our security architecture prevents the public or other users from accessing the contents, thus providing security.

We reduced the cost of storage of high-resolution images by proposing the use of the IPFS, a secure and distributed peer-to-peer network with high availability. We used cryptocurrency wallets and smart contracts to create NFTs using the widely accepted ERC-721 standards. This design precludes the need to add a separate security layer for data storage, transmission, and access. Although we separated the storage of the actual image from its metadata, the transmission of the image entails changing the permission for accessing the metadata file through encryption with the receiver's keys. Our design approach does not require moving the entire high-resolution image to a different address on a network, which would likely consume much more network bandwidth and is inefficient, although this can also be accomplished.

Conclusions

Overall, the data transmission, data storage, and use of the ERC-721(NFT) standard for pathology-based image storage will improve the prospects for mass adoption of digital pathology. Such an architecture can significantly reduce the cost of the infrastructure required for digital pathology and, over time, improve the speed for diagnosis and affordable medical care.

Abstract

Background: Tumor boards constitute the main consensus and clinical decision-making body of multidisciplinary teams (MDTs) in cancer care. With the increasing clinical complexity of treatment options (eg, targeted therapies, multimodal treatments) and the progressive incorporation of new areas of intervention (eg, survivorship care), tumor boards are now required to play a central role in all cancer processes. However, although frameworks are in place to evaluate MDT quality, only few web-based tools are available for this purpose; indeed, no web-based MDT evaluation tools have been developed for or adapted to the Spanish National Health System.

Objective: The first aim of this study was to develop a web-based self-assessment model (Autoevaluación de Equipos Multidisciplinares de Atención al Cáncer [AEMAC]) for evaluating multidisciplinary cancer teams in Spain and the second aim was to validate this tool by testing its metric properties, acceptability, and usability.

Methods: We designed and validated the AEMAC program in 3 stages. In the first stage (research), we reviewed the available scientific evidence and performed a qualitative case study of good practice in multidisciplinary care within the Spanish National Health System (n=4 centers and 28 health care professionals). The results were used to define the thematic areas and quality criteria for the self-evaluation model, which were then discussed and validated by a group of experts. The second stage (development) involved the technological development of a web app that would be accessible from any mobile device. In the third stage (piloting and validation), we conducted 4 pilot tests (n=15 tumor boards, 243 professionals) and used the results to analyze the acceptability and usefulness of the tool.

Results: We designed a self-assessment model based on 5 thematic areas encompassing a total of 25 quality components, which users rated on a 3-option development scale. The evaluation process, which was managed entirely from the web app, consisted of individual self-assessment, group prioritization, and creation of an improvement plan. Cronbach alpha (.86), McDonald's omega (0.88), and various fit indices (comparative fit index between 0.95 and 1 and goodness-of-fit index between 0.97 and 0.99

for all 5 aspects) confirmed internal consistency. The mean rating for overall satisfaction with the tool and for consistency between the content of the tool and the reality of tumor boards was 7.6 out of 10.

Conclusions: The results obtained during the period of research and piloting of the AEMAC program showed that it has an appropriate structure and metric properties and could therefore be implemented in a real context and generalized to other hospitals. As a virtual tool, it helps to measure the key aspects of MDT quality, such as effectiveness of collaboration and communication, leadership, and the organizational environment.

web-based tool; multidisciplinary care; cancer; evaluation; quality assurance

Introduction

Background

Tumor boards constitute the main consensus and clinical decision-making body of multidisciplinary teams (MDTs) in cancer care [1]. The direct and indirect benefits of MDTs have been confirmed through extensive analysis [2-8], and the proper organization and systematic implementation of these bodies has become the central focus of cancer control policies [9]. With the increasing clinical complexity of treatment options (eg, targeted therapies, multimodal treatments) and the progressive incorporation of new areas of intervention such as attention to survival as well as health care objectives such as the reduction of waiting times, MDTs have come to assume a central role in cancer care [10].

Rationale of MDT Assessment

Tumor boards are generally based on regular work sessions that require the participation of a large number of professionals and departments, but hospitals often fail to define the internal organization of these boards, the scope of their work, or the resources needed. Tumor boards should be subject to analysis and intervention based on their importance for patients and the economic costs involved to assess their degree of usefulness and the quality of their decisions and to establish necessary changes. From this perspective, the multiple benefits they may provide do not inevitably result from a policy decision [11]. In the context of the Spanish National Health System (SNS), although the cancer strategy set out by the Ministry of Health defines MDTs as a reference framework for oncology services [12], the degree of MDT formalization and work capacity varies substantially between hospitals [13,14]. Moreover, although many scientific societies and European organizations have made attempts to strengthen MDTs by establishing quality criteria and work procedures, only few web-based tools are in place for evaluating the effectiveness of teamwork. The tools currently available, such as MDT-FIT (MDT-feedback for improving teamworking) [15], MDT-OARS (MDT-observational assessment rating scale) [16,17], MDT-QuIC (MDT-quality improvement checklist) [18], and MDT-MoDe (MDT-metric of decision making) [19] vary in terms of methodology (eg, checklist, observation) and availability as a virtual tool [20].

Routines and Gaps in the Work of Tumor Boards in Spain

The large number of professionals involved in cancer care and the complexity of the diagnostic therapeutic process mean that coordination problems and poor communication are very likely to occur. The evidence points to the importance of these aspects, which can contribute to improving the survival and quality of life of patients with cancer. Thus, the implementation of a developed model of multidisciplinary care is one of the greatest challenges to progress in improving the quality of care for patients with cancer. In Spain, within the context of the SNS, the complexity of multidisciplinary care and its impact on cancer care depends on many factors: the different organizational forms according to the territories, decision making in the diagnostic and therapeutic process, or the cultural resistance to change that working in a multidisciplinary manner may entail. Since there are many barriers to the implementation of multidisciplinary care, this interactive tool can enable the diagnosis of MDTs, thereby offering a map of interventions for the proper functioning of the teams. Other international experiences [15-19] highlight the fact of having an instrument to perform self-diagnosis; the tool presented here additionally makes it possible to have the tool available in a web-based format, which facilitates the rapid creation of a roadmap for the appropriate management of the tumor committee within the SNS.

Autoevaluación de Equipos Multidisciplinares de Atención al Cáncer Program

To promote multidisciplinary cancer care within the SNS, we developed a program for the self-assessment of MDTs in cancer care (AEMAC, by its acronym in Spanish [Autoevaluación de Equipos Multidisciplinares de Atención al Cáncer]). The AEMAC program is a web-based tool designed to facilitate the evaluation of critical components related to the internal structure, coordination and communication, organizational context, and development possibilities of MDTs. The objective of this study was to research, develop, and validate the AEMAC program as a quality self-assessment tool for MDTs.

Methods

This study was performed in 3 stages.

Research and Expert Assessment

The first stage, focused on the design of the tool, drew on 2 sources of information: the available scientific literature (including gray literature) and the experiences of tumor boards

from hospitals of varying structure, size, and capacity to attend patients with cancer.

First, we updated a systematic review that had been conducted in 2014 by 2 of the authors of this paper (JP and JMB), extending the search to November 2016 while maintaining the same search criteria [10]. We also consulted a set of strategic documents to analyze organizational principles and standards in multidisciplinary care [17,21-27]. We decided to base the first version of the AEMAC program on the document *Policy Statement on multidisciplinary cancer care* [21], which defines the core elements that all tumor-based MDTs should include. By synthesizing the information collected in this systematic review, we were able to draft the interview script to be used in the development stage.

Second, we performed a qualitative case study on practices of excellence in multidisciplinary care in Spanish public hospitals in the period spanning May 2017 to September 2017 [28,29]. We included tumor boards specializing in specific tumors of all prognoses and locations and more general boards (eg, digestive system tumors) with a structured MDT that had been operating for at least 3 years in SNS hospitals located in all regions of Spain. A further inclusion criterion was the presence of a clinical unit for centralizing the whole care process of specific pathologies. After the selection process, we planned on-site visits to study in detail the work of MDTs in the following hospitals: Hospital Universitario del Mar, Barcelona (lung cancer); Hospital Universitario Ramón y Cajal, Madrid (breast cancer); Complejo Hospitalario de Navarra (digestive system tumors); and Hospital Clínico de Salamanca (multiple cancers). This sample of hospitals was endorsed by the scientific

societies involved in the program (Table S1 of [Multimedia Appendix 1](#)). Additionally, we interviewed 20 professionals from the following specialties: medical oncology (n=4), radiation oncology (n=4), other medical-surgical specialties (n=4), pathological anatomy (n=2), radiology (n=4), and nursing (n=2). These visits and interviews were aimed at identifying the key thematic areas and components to include in the MDT self-assessment model.

The resulting preliminary matrix was assessed by 6 SNS experts who were selected according to the criteria of territorial representativeness, different specialties, levels of care, and scientific or management experience (as of September 2017). Specifically, they assessed the readability, face validity, and content of the tool according to the legibility of the identified components and coherence of the model and its elements; the adaptability of the components to the reality of the SNS; the weighting of the components according to their level of importance; and the definition of future components.

Information Technology Development and Phases in the Self-assessment Process

The second stage consisted of developing the web-based tool. The AEMAC program was conceived from the beginning as a web app that could be activated and managed from any mobile device. The web-based tool [30] was designed to facilitate consensus within the tumor board on areas for improvement and possible interventions and to establish the work schedule for achieving these improvements and ensuring their sustainability. The self-assessment was structured in 3 phases (see [Textbox 1](#), [Multimedia Appendices 2-4](#), and [Figure 1](#)).

Textbox 1. Phases in the Autoevaluación de Equipos Multidisciplinares de Atención al Cáncer program self-assessment process.

Phase 1: Individual self-assessment ([Multimedia Appendix 2](#))

- All board members independently fill out the web-based questionnaire.
- Each component has 3 evaluation possibilities, ranging from least development (first option) to greatest development (third option), with an intermediate category (second option).
- The evaluation process for each component is completed with a subquestion on the “possibility of improvement” if option 1 is chosen or on the “risk of worsening” if option 3 is selected. These items are evaluated based on a scale of 0 to 10 points, and this score is included in the prioritization algorithm. For example, components with poor ratings and without the possibility of improvement obtain a lower relative weight.

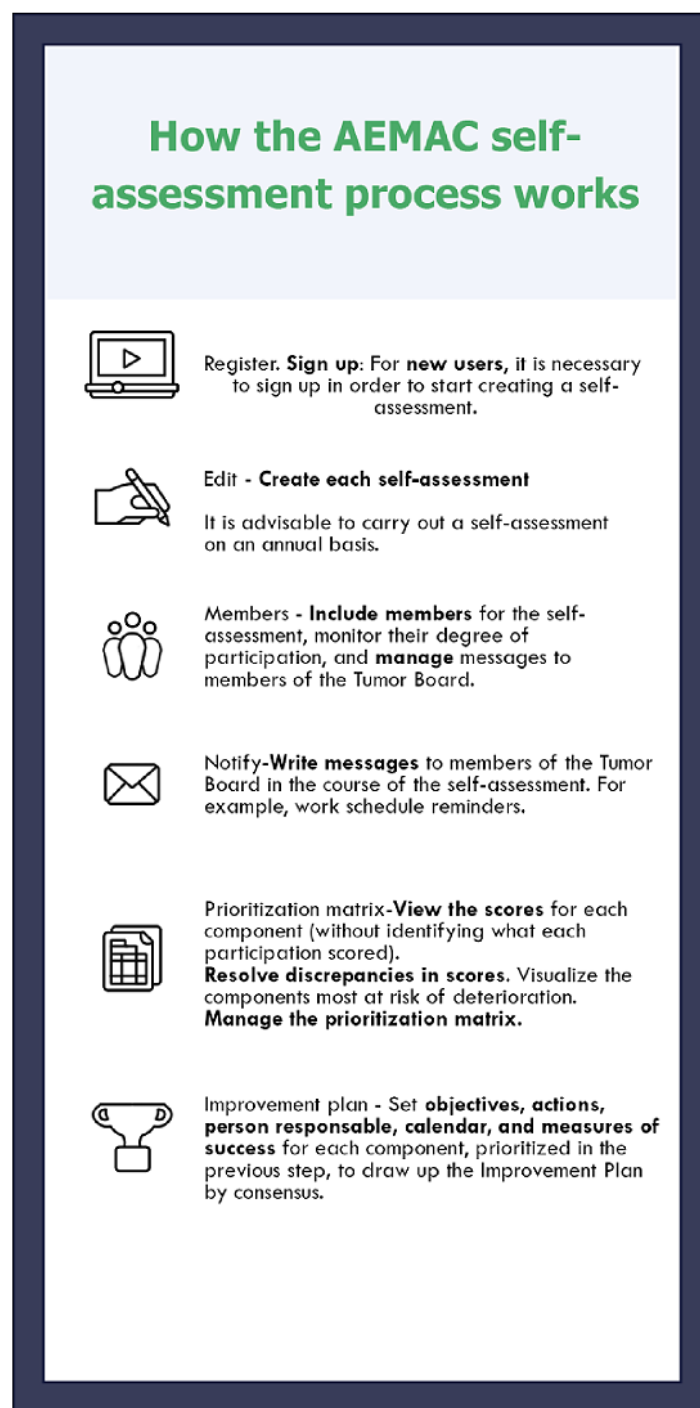

Phase 2: Group prioritization process ([Multimedia Appendix 3](#))

- The team (or a subgroup of 3 team members) assesses the results, resolves any team discrepancies that emerged in phase 1, and prioritizes areas for improvement.
- Discrepancies occur when none of the 3 response options accounts for at least 60% of the responses for any component.

Phase 3: Creating an improvement plan ([Multimedia Appendix 4](#))

- The team sets objectives and actions for an improvement plan spanning 1 to 2 years.
- Responsible parties are assigned and indicators are established so that the degree of achievement can be measured.

Figure 1. Working of the AEMAC self-assessment process. AEMAC: Autoevaluación de Equipos Multidisciplinares de Atención al Cáncer.

Data are stored and participants' identities are protected on the server at Miguel Hernández Public University to ensure anonymous data management. This is fundamental because the AEMAC program automatically shares compared information with other MDTs of the same hospital level and pathology to enhance benchmarking. The hospital level is captured through the postal code of the hospital that was provided during the initial registration of the self-assessment process.

Piloting and Validation

The third stage included a pilot study to test the adequacy of the procedure and to analyze the metric characteristics of the developed instrument. To test the acceptability and usefulness of the AEMAC program, pilot tests were performed in 4 SNS hospitals—Hospital Universitario del Mar (Barcelona), Hospital Universitario de Fuenlabrada (Madrid), Hospital Universitario Doctor Peset (Valencia), and Hospital Universitario La Paz (Madrid)—including a total of 15 tumor boards and 243

professionals. These hospitals belonged to 3 different regional health services and were representative of the different types of Spanish public hospitals. The number of beds ranged from 400 to 1000. Three researchers attended these meetings as observers, information technology consultants, and evaluators of the experience (JJM, MG, JP).

The first main objective of the pilot tests was to observe the clarity of the concepts used in each component and the consistency of the criteria used to define these concepts. These criteria include correlation (ie, if the tumor board hypothesized that good multidisciplinary work was being done in different areas, the self-assessment of the professionals on the tumor board should be in segment 3 of the areas they considered to be strengths), variability (ie, the second option should not be selected by default), and acceptability (ie, professionals should not feel penalized by “negative” language). The second aim of the pilot tests was to assess the usability and functionality of the website, considered as critical elements in the time for individual completion of the questionnaire and the general usability of the instrument (eg, interface user friendliness, ease of transition between phases). Additionally, the responses to each of the components were analyzed considering both floor and ceiling effects to rule out elements with little variability, elements that could not be implemented, and elements that were already fully implemented.

We also analyzed the degree of discrepancy in the evaluations of different members of the tumor boards for each component, acknowledging that systematic discrepancies between all participants of all boards must represent inappropriate wording. Finally, through confirmatory factor analysis, the coherence of the grouping of components by thematic area was analyzed using the comparative fit index, Jöreskog and Sörbom’s goodness-of-fit index, adjusted goodness-of-fit index, root mean square residual, standardized root mean square residual, and root mean square error of approximation. The model was accepted when comparative fit index, Jöreskog and Sörbom’s goodness-of-fit index, and adjusted goodness-of-fit index scores were greater than 0.95 and root mean square residual, standardized root mean square residual, and root mean square error of approximation scores were less than 0.08 [31,32]. The internal consistency of the resulting factorial solution was analyzed using Cronbach alpha and McDonald’s omega statistical indicators.

A total of 243 pilot study participants were asked to complete a survey to assess the critical issues of the tool ([Multimedia Appendix 5](#)). The anonymized responses were analyzed using descriptive statistics. The first part of the survey was designed to assess user experience of the AEMAC program and included 5 items with a response scale ranging from 0 (unsatisfactory) to 10 (totally satisfactory). The questions covered ease of answering the AEMAC questionnaire, coherence between questions, adequacy of the response options, and the method for establishing an improvement plan. The second part of the survey aimed to evaluate the adequacy of the established critical and semicritical components.

Ethics Approval

The study was approved by the Ethics and Research Integrity Committee of the Miguel Hernández University (AUT.DPS.JMS.02.21).

Results

Research and Expert Assessment

By the end of the research stage, we were able to define the following 5 thematic areas: (1) preparation and organization of the tumor board, (2) board decision-making process, (3) continuity of care, (4) organizational context, and (5) cross-disciplinary roles and team cohesion. These 5 thematic areas encompassed a total of 27 components considered to have a potential impact on quality of care. The following changes were made following the expert assessment of the preliminary matrix:

1. *Legibility of the identified components and coherence of the model and its elements.* Two components were added, and changes were made in the wordings to improve clarity and relevance and to avoid any overlaps.
2. *Adaptability of the components to the reality of the SNS.* It was decided to ensure adaptability of the AEMAC program to any MDT, regardless of hospital level (university, community, or local hospital).
3. *Weighting of the components according to their level of importance.* The experts agreed on different weights for the components according to the categories “normal,” “high,” or “very high” importance. This had an impact on the prioritization algorithm used during the self-assessment.
4. *Definition of future components.* Six components were defined with the prospect of being included in 5 years to replace outdated components.

The adjusted matrix can be seen in Table S2 of [Multimedia Appendix 1](#).

Information Technology Development and Phases in the Self-assessment Process

The AEMAC program was developed as a 3-phase process with the dual objective of gathering individual and aggregated perspectives on the quality of teamwork and encouraging dialogue, negotiation, and formulation of possibilities for improvement based on the critical aspects identified.

Piloting and Validation

The pilot study participants agreed that the website format and the fact that the questionnaire could be completed on any mobile device made the tool easy to use. Discrepancies could be resolved by a subgroup of professionals, which facilitated the process, although some teams had reservations in this regard. When faced with certain questions, some professionals stated that they required more information to give their opinion, usually because of lack of direct contact with patients. We, nonetheless, agreed to maintain the obligation of answering all the standards included in the self-assessment questionnaire. The time taken to complete the AEMAC questionnaire ranged from 12 to 14

minutes, which was considered satisfactory. The average group discussion time was 15 minutes for phase 2 (range, 10-20 minutes) and 30 minutes for phase 3 (range, 20-50 minutes). The aspect with the lowest acceptability rating was the registration process for initiating a self-assessment. MDTs in the SNS usually have no administrative support, which means registration has to be managed by the professionals themselves.

For most components of the thematic areas “Preparation and organization of the board” and “Continuation of the care process,” the third option (“Representing greater development”) was selected more frequently than either of the other two. Regarding “Board decision-making process” and “Organizational context,” the bulk of the responses fell between options 1 and 2. Finally, great variability in the responses was observed in “Cross-disciplinary roles and team cohesion”. Table S3 of [Multimedia Appendix 1](#) shows the combined scores from

all boards, indicating the range of scores observed and the response frequencies of each option for each component. The results of this first analysis identified no ceiling or floor effects to substantiate eliminating any of the 27 components. However, after reviewing the confirmatory factor analysis results, we eliminated the components “Patient information process” (from the thematic area “Board decision-making process”) and “Team-patient communication framework” (from “Cross-disciplinary roles and team cohesion”). We also moved the “Team cohesion” component to the thematic area “Board Preparation and Organization.” The fit indices of this model confirmed that the various components were well assigned to the thematic areas. [Table 1](#) shows the goodness-of-fit indices for each thematic area of the resulting model. The “Board decision-making process” obtained the best fit indices according to the previously defined benchmark.

Table 1. Confirmatory factor analysis adjustment indices.

Adjustment indices	Preparation/organization	Decision making process	Continuity of care	Organizational context	Cross-disciplinary roles
Comparative fit index ^a	0.95	1.00	0.96	0.96	0.99
Jöreskog and Sörbom’s adjusted goodness-of-fit index ^b	0.94	0.99	0.97	0.94	0.98
Jöreskog and Sörbom’s goodness-of-fit index ^b	0.97	0.99	0.99	0.98	0.99
Root mean square residual ^c	0.02	0.01	0.01	0.02	0.01
Standardized root mean square residual ^c	0.05	0.02	0.03	0.04	0.02
Root mean square error of approximation (90% CI)	0.05 (0-0.08)	0 (0-0.1)	0.04 (0-0.1)	0.08 (0.03-0.1)	0.03 (0-0.1)

^aRanges from 0 to 1, with a value of 0.9 being the minimum required to defend the model.

^bGoodness-of-fit index and adjusted goodness-of-fit index: range between 0 and 1 and those models that exceed 0.9 are considered adequate models.

^cRoot mean square error of approximation and standardized root mean square: indicators of a good fit with values less than 0.05.

[Table 2](#) shows the revised structure of the AEMAC program. The optimized model can be seen in [Figures 2-6](#) (optimized model of the questionnaire factorial structure based on confirmatory factor analysis from the validation study performed for each factor, factors 1-5, Structural Equation Modelling Path Diagram chart). The values shown in [Figures 2-6](#) represent the standardized solution of the confirmatory factor analysis equations. The values above the lines in the figures are the estimates of the regression coefficients of the common factors and of the specific factors, that is, the contribution of each item

to the factors, which is also called factor loadings. The R^2 is the variance explained by the factor for each of the items.

In the internal consistency analysis, the AEMAC program achieved a Cronbach alpha score of .86 and a McDonald’s omega score of 0.88. [Table 3](#) and [Table 4](#) show the combined responses of the survey evaluating the AEMAC program. In total, 40 out of 243 professionals responded (16.5% response rate). Seven (88%) of the 8 components that were considered critical and all 3 components that were considered semicritical received a high adequacy rating.

Table 2. Structure of the revised Autoevaluación de Equipos Multidisciplinares de Atención al Cáncer program following confirmatory factor analysis.

Thematic area	Items

Discussion

Overview of This Study

The AEMAC program is a web-based tool designed to facilitate the self-assessment of multidisciplinary cancer care teams with a view of improving their internal organization and scope of care. By analyzing the internal and external processes that frame the work of MDTs, we were able to identify 27 critical components that are implemented to a varying degree in the context of the SNS, as well as establish a range of possibilities for the intervention. When the AEMAC program was tested by 15 MDTs, it obtained good results on the content, acceptability, and time required, and showed reasonable psychometric properties, including internal consistency and item discrimination. The perspective acquired during the research process, which included content validation by experts, and the consistency of the results obtained in the pilot study show that the AEMAC program could be implemented in a real context.

Framework of This Study

In accordance with other authors, we consider that tumor boards stimulate the knowledge and development of the professionals involved in the care of patients with cancer, thereby encouraging teamwork and improving the quality of health care [33,34]. In this regard, several government-produced documents defining

MDTs such as the principles of multidisciplinary care in Australia [23], multidisciplinary cancer conferences in the Canadian province of Ontario [22], and the characteristics of an effective MDT in the United Kingdom [17] highlight the importance of internal cohesion and positive leadership styles. The desired consensus of a tumor board should not mask the valuable technical perspectives of its members nor should it be vulnerable to what has been called ego-based medicine [35].

The rationale and health care objectives of the AEMAC program multidisciplinary care model are based on the principles and priorities set out in the reference document *Policy Statement on multidisciplinary cancer care* [21]. For example, one component that reflects a well-developed tumor board according to the AEMAC program is that all cases treated in the hospital for a specific pathology are presented at the board meeting. While this topic “all cases discussed” has some controversy, many health professionals consider that this measure simply implies ensuring evidence-based decisions. European initiatives such as the European Reference Networks [36] share the view of securing evidence-based opinions, which is also reflected in the criteria and standards of various European cancer organizations [24-27]. These bodies are raising awareness in the SNS of the need to have well-structured and well-equipped MDTs that are answerable to a national health authority. The available evidence suggests that significant variability exists

between MDTs in terms of objectives, roles, organizational implications, performance, and access [37,38]. In the context of the SNS, these differences are accentuated by considerable decentralization in health care [13].

Comparisons With Other Instruments and Tools

The AEMAC program follows the inspiring principles of instruments such as the MDT-FIT [15]. In this case, the 3-stage process to perform the self-assessment of the MDTs and the availability of a web-based tool to perform the process have been elements that the AEMAC program has taken into account in the development of the self-assessment process, wherein the time needed to perform the whole process was 10-12 weeks, while the AEMAC program considers that the whole process can be performed in the same morning, leaving a sufficient time interval to perform the process of implementing the Improvement Plan (approximately 6-12 months). MDT-OARS [16,17], which is supposed to be a development and validation model to be followed in the case of the AEMAC program, consists of 47 items and a 5-point scale and is an instrument that each tumor committee must apply. In the case of MDT-QuIC [18], the instrument applies more like a checklist, and in its development study, the attitudes of the people who used it were assessed. The AEMAC program followed this model to assess the experiences of the people who used it. MDT-MODE [19] is based on an observational evaluation tool, where 2 professionals evaluate the behavior of the MDT. The AEMAC program is based on the individual evaluation of each of the committee members in the first phase and then sharing of the results achieved and the areas of top priority.

Strengths and Weaknesses

Strengths of the AEMAC Program

Implementing the AEMAC program could benefit clinicians, managers, and patients. For clinicians, the program not only enables comparison of tangible aspects such as technological resources (eg, use of videoconferencing) but also takes the human factor into account. Elements related to communication style or cooperation (eg, trust, implementation of decisions) are critical but tend to be ignored in evaluations or accreditation systems. For managers at all levels of the SNS, the AEMAC program offers guidance on implementing and developing an effective organizational ecosystem. In Spain, MDTs are not incorporated into the care pathway through mandatory criteria as part of health policy, as they are in the United Kingdom. The AEMAC program facilitates assessment of MDT uniformity in this context. Finally, although the defined model is for professional use, patients stand to benefit to the extent that the quality criteria include the consideration of oncogeriatric and psychosocial aspects, personalization of the information delivered to patients, and proactive organization of patients' agendas.

Weaknesses of the AEMAC Program

Although most evaluations of the content and functionality of the AEMAC program were positive, 80% of the professionals who were asked to evaluate the tool were unable to because of scheduling or other problems. We did not manage to obtain this information subsequently, although we contacted these team members individually after the on-site visits. The main feedback on the experience with the tool was provided by the people who had responsibility for the tumor board (chair and secretary). Given the uniqueness of the AEMAC questionnaire, it was validated through confirmatory factor analysis. Similarly, the difficulty of accessing teams and activating self-assessment processes during the pilot test—mainly due to the gatekeepers being informal contacts or the health professionals showing inconsistent interest in participating—meant that we were unable to include a larger sample of tumor boards. Another limitation was that the boards of only 4 hospitals participated in the pilot tests. These hospitals were similar to a majority of Spanish hospitals: accreditation for teaching, residents, students, and number of beds. As a result, adaptability issues may arise if the program is rolled out in a real context, as the AEMAC program is designed for any MDT of the SNS, and the research process and piloting covered only a few regions of Spain. If the AEMAC program is to become a reference tool, it must be promoted not only by scientific societies but also by the health authorities of each region.

Future Developments

As MDT work dynamics and structures evolve, future evaluations will determine which elements should be replaced. The AEMAC program is a dynamic quality model based on the improvement cycle that must periodically adapt to reality. The elements incorporated in the future will follow the same principle.

Conclusion

The AEMAC program is the first web-based quality self-assessment tool for evaluating MDTs in the SNS. The results obtained during the research and piloting period suggest that it could be implemented in a real context. Consensus and multidisciplinary work undoubtedly contribute to clinical effectiveness insofar as professionals specialized in tumor pathologies (eg, esophageal cancer), organ systems (eg, gynecological tumors), or patient profiles (eg, pediatric oncology) are responsible for clinical coordination and communication with patients and families throughout all stages of the disease. To this end, the AEMAC program can provide a comprehensive reflection on the organizational, technological, and cultural elements that must be taken into account to improve the care received by patients with cancer.

Acknowledgments

The Autoevaluación de Equipos Multidisciplinares de Atención al Cáncer (AEMAC) program has benefited from the involvement of the most relevant scientific societies in cancer care in Spain: Spanish Association of Surgeons, Spanish Society of Medical Oncology, Spanish Society of Radiation Oncology, Spanish Society of Pathological Anatomy, Spanish Society of Medical

Radiology, Spanish Society of Oncology Nursing, Spanish Society of Pediatric Hematology and Oncology, Spanish Society of Hospital Pharmacy, and Spanish Society of Healthcare Quality. With their assistance, we were able to validate the tool, identify experts, and find contacts for the pilot study. In addition, all the societies promoted the use of the AEMAC program by publishing on their respective websites the agreement on the development of multidisciplinary cancer care teams in the Spanish National Health System and the use of the AEMAC program. The authors would like to thank all the hospitals that participated in the development and validation of the AEMAC program and would like to thank the members of PROMETEO 173 Research Group (Generalitat Valenciana, 2017) for their assistance. This work was supported by nonrestrictive funding from Merck Sharp & Dohme, Spain. No staff from Merck Sharp & Dohme participated in the design, execution, data capture, interpretation of results, or elaboration of the conclusions of this study.

Authors' Contributions

JP and JMB were in charge of the design of the Autoevaluación de Equipos Multidisciplinares de Atención al Cáncer (AEMAC) Program and all the theoretical underpinning. MG and JJM carried out all the pilot tests of the tool in the 4 hospitals. IM, LF, and JAG acted as leaders in the collection of information from the different tumor committees for the validation process of the tool. All members of the AEMAC program research team actively participated in the piloting of the tool in each of the phases. JP, MG, JMB, and JJM drafted and reviewed the final manuscript.

The AEMAC program research team consisted of Gemma Mancebo (Servei de Ginecologia i Obstetrícia, Coordinadora de la Unitat Funcional de Càncer Ginecològic, Hospital del Mar, Barcelona), Ruth Vera (Servicio de Oncología Médica, Complejo Hospitalario de Navarra, Pamplona), Ignacio Inchaurreaga Álvarez (Servicio de Oncología Médica, Hospital Universitario Dr. Peset), Segundo Gómez Abril (Servicio de Oncología Médica, Hospital Universitario Dr. Peset, Valencia), Margarita Cueto Callejón (Servicio de Ginecología y Obstetrícia, Hospital Universitario de Fuenlabrada, Fuenlabrada), Belén Pérez-Mies (Servicio Anatomía patológica Hospital Universitario Ramón y Cajal, Facultad de Medicina de Alcalá de Henares, Instituto Ramón y Cajal para la investigación y CIBERONC, Instituto Carlos III), Gonzalo Varela (Profesor titular de cirugía torácica de la Universidad de Salamanca), and Marta Moro Agud (Subdirección médica, Hospital Universitario La Paz).

Conflicts of Interest

Merck Sharp & Dohme, Spain financed the design and management costs of the website where the responses were recorded. During this study, JJM and MG were supported by a grant from the Generalitat Valenciana (reference Prometeo 2017/0173).

Abstract

Background: Most of what is known regarding health information engagement on social media stems from quantitative methodologies. Public health literature often quantifies engagement by measuring likes, comments, and/or shares of posts within health organizations' Facebook pages. However, this content may not represent the health information (and misinformation) generally available to and consumed by platform users. Furthermore, some individuals may prefer to engage with information without leaving quantifiable digital traces. Mixed methods approaches may provide a way of surpassing the constraints of assessing engagement with health information by using only currently available social media metrics.

Objective: This study aims to discuss the limitations of current approaches in assessing health information engagement on Facebook and presents the social media content and context elicitation method, a qualitatively driven, mixed methods approach to understanding engagement with health information and how engagement may lead to subsequent actions.

Methods: Data collection, management, and analysis using the social media content and context elicitation method are presented. This method was developed for a broader study exploring how and why US Latinos and Latinas engage with cancer prevention and screening information on Facebook. The study included 20 participants aged between 40 and 75 years without cancer who participated in semistructured, in-depth interviews to discuss their Facebook use and engagement with cancer information on the platform. Participants accessed their Facebook account alongside the researcher, typed *cancer* in the search bar, and discussed cancer-related posts they engaged with during the previous 12 months. Engagement was defined as liking, commenting, and/or sharing a post; clicking on a post link; reading an article in a post; and/or watching a video within a post. Content engagement prompted questions regarding the reasons for engagement and whether engagement triggered further action. Data were managed using MAXQDA (VERBI GmbH) and analyzed using thematic and content analyses.

Results: Data emerging from the social media content and context elicitation method demonstrated that participants mainly engaged with cancer prevention and screening information by viewing and/or reading content (48/66, 73%) without liking, commenting, or sharing it. This method provided rich content regarding how US Latinos and Latinas engage with and act upon cancer prevention and screening information on Facebook. We present 2 emblematic cases from the main study to exemplify the additional information and context elicited from this methodology, which is currently lacking from quantitative approaches.

Conclusions: The social media content and context elicitation method allows a better representation and deeper contextualization of how people engage with and act upon health information and misinformation encountered on social media. This method may be applied to future studies regarding how to best communicate health information on social media, including how these affect assessments of message credibility and accuracy, which can influence health outcomes.

Introduction

Background

The rise of health misinformation in today's social media landscape has prompted a need to better understand how and why individuals engage with this content, as well as its ramifications on health outcomes. Although this topic has gained notoriety in light of the COVID-19 pandemic and its accompanying infodemic, calls for research addressing health misinformation and its unique impact on underserved populations have been present since late 2018 [1]. These calls acknowledge that in addition to defining the prevalence and trends of health misinformation, researchers need to develop approaches that better understand the context of misinformation exchange on social media, the intra- and interpersonal dynamics that influence engagement with content, and how health consequences may stem from these interactions [1].

Reaching populations with evidence-based content through social media has become an important effort to counteract the spread of health misinformation [2,3]. If leveraged correctly, these platforms can be used to encourage participatory communication by fostering user engagement via posts, pictures, videos, and other forms of information sharing [4]. This conceptualization of social media as participatory frames engagement as a way for health organizations to communicate with audiences directly [5] and is typically assessed by evaluating how users respond to content posted on the platform. By playing an active role in conversations about health topics, organizations can also ensure that trust and credibility are established through the dissemination of accurate information [5].

Quantitative methods have undoubtedly helped identify health misinformation trends on social media [6-9]. However, these data are increasingly difficult to obtain [10], do not provide important contextual information regarding what motivates engagement and dissemination among vulnerable populations with poor health outcomes, and cannot capture the effects of misinformation on behavior. Mixed methods approaches that explore the role of these components in the spread of misinformation are necessary to design interventions that minimize and halt dissemination. Mixed methods research comprehensively and purposefully uses both qualitative and quantitative techniques to address an overarching research question that cannot be fully explored and contextualized by either method independently [11]. As such, this paper presents the social media content and context elicitation method, which is a novel approach that incorporates qualitative methods to better contextualize engagement with health information on

social media and how this may lead to subsequent actions. This paper first discusses the limitations of the current operationalizations of engagement with health information on social media. This is followed by a detailed description of the social media content and context elicitation method, which was developed to obtain survey data, interviews, and computer screen recordings of cancer-related posts on Latino and Latina participants' Facebook accounts for quantitative and qualitative analysis. Then, 2 case studies are presented to exemplify the additional information elicited from this methodology, which is currently lacking from other approaches. Finally, we discuss how incorporating qualitative methods, such as those outlined in this paper, allows a better representation of how people engage with health information in reality and provides insights for researchers interested in this type of work.

Assessing Engagement With Health Information on Facebook

Facebook is among the most popular social media platforms worldwide, with >2.3 billion active users [12]. Second in popularity only to YouTube, 74% of US Facebook users visit the platform on a daily basis [13]. Entertainment, social interaction, and passing time are among the reasons individuals report using Facebook [14]. Facebook has also been a source of health information and social support [15], making it a useful place to engage with general audiences about health topics. Many public health organizations have established a presence on Facebook by creating a Facebook page, which provides a space for businesses and organizations to publicly share information with platform users. Facebook pages provide a direct way for these organizations to deliver evidence-based health information to Facebook users, which is of paramount importance in a social media environment with increasingly unreliable information [3]. Facebook page administrators also have the ability to monitor social media metrics, providing a way for health organizations to operationalize audience engagement with posted content.

Assessing engagement with health-related information on social media is of particular importance as it is a precursor to multiple outcomes, such as increased awareness, knowledge, and behavior change [16,17]. Most studies have assessed engagement by collecting and analyzing data on the likes, comments, and/or shares of posts within an organization's Facebook page [18-24]. For example, Strekalova and Krieger [24] reported that cancer-related posts on the National Cancer Institute's Facebook page had a significantly higher number of likes, comments, and shares when they contained images (vs videos, embedded links, or text). Similarly, Srivastava et al [18] found that posts on the American Cancer Society's Facebook

page were more likely to be liked or shared when they contained images or videos, whereas text-based posts were more likely to elicit user comments. Meanwhile, Klippert and Schaper [25] expanded their definition of engagement by including metrics for post reach and clicks on embedded links—both of which are also available to Facebook page administrators. Finally, other studies have captured engagement with cancer information publicly available on Facebook [19,20,26] or Facebook groups [27–30]. Facebook groups differ from Facebook pages in that they can be public or private but do not offer detailed social media metrics and audience insights (although group administrators may extract raw data for analysis through Facebook's application programming interface). In such cases, engagement has been assessed by quantifying likes, comments, and shares, as these metrics are visible to anyone with access to the posted content.

Limitations of Quantitative Assessments of Engagement

Measuring engagement with health-related content through these metrics is useful for organizations wanting to assess the success of a social media campaign. It can also provide insight into message factors that may enhance engagement with health information on social media [31]. However, the existing metrics have important limitations. On Facebook, one of these limitations relates to how users are exposed to content. In order for a post from a Facebook page to appear on a person's news feed, a person must either follow the page or have a Facebook friend who engages with a post from the page. Additional ways users can be exposed to health-related content from a Facebook page are through paid advertising or a Facebook video recommendation, which is based on a video's popularity or other people and pages a person follows [32]. Even then, the appearance of this content on a person's news feed is influenced by Facebook's constantly changing algorithm, which favors content that individuals engage with most often [33]. This has an impact on whether specific health information emerges on a person's news feed when they log into their Facebook account. As such, engagement with content on a health-related Facebook page may not be emblematic of how the general population engages with such information on Facebook. It is likely that many individuals following a health-related Facebook page are already interested in that particular topic. However, there are many people who may not have an active interest in health information that health organizations are trying to reach, such as healthy individuals who are the target audience for prevention and screening messages. Furthermore, focusing on measuring engagement with evidence-based content posted by health organizations does not fully capture the health information landscape on Facebook, which includes user-generated or shared health misinformation that may not come from reliable sources (eg, a COVID-19–related post dispelling misinformation about vaccine efficiency shared by a Facebook friend with no links to original sources).

Another limitation to quantifying likes, comments, and shares is that these are crude measures of engagement. Although these metrics allow researchers to quantify how some Facebook users visibly engage with health information that is publicly available or posted within a Facebook group, they exclude individuals

who do not perform these actions yet still consume health information on the platform [18,24]. Information consumption and lurking—generally defined as reading posts on the web without responding—have been seen as an active and participative form of web-based behavior [34]. Lurking may occur because of environmental, relationship, security, and individual reasons [35]. For example, the quality of a message may be poor (environmental), the user may not feel part of the web-based community (relationship) or have privacy concerns (security), or the person's needs may be satisfied by just reading a post (individual) [35].

Moreover, although newer Facebook applications, such as CrowdTangle, allow researchers to capture additional engagement metrics (such as post views) [36], these metrics are limited in only establishing general trends with content that is publicly available on the platform. Furthermore, these crude measures fail to capture if and how engagement with health information and misinformation may influence individuals to act upon this information elsewhere. Potential actions may be as small as discussing the information with a friend through messaging apps or as large as incorporating preventive behavior into one's lifestyle. Understanding these complexities inevitably requires new approaches to help contextualize the impact of engagement on health outcomes.

In response to these needs, we developed the social media content and context elicitation method. This method elicits data concurrently during one-on-one in-person encounters where the participants access their social media profile, scroll through relevant content, and contextualize content engagement with the researcher. In the following sections, we outline the process of collecting, managing, and analyzing elicited data and provide examples of the robust findings that this method provides. We hope that such detail—particularly surrounding data collection and management—enables other scholars to replicate and/or adapt these methods for related studies.

Methods

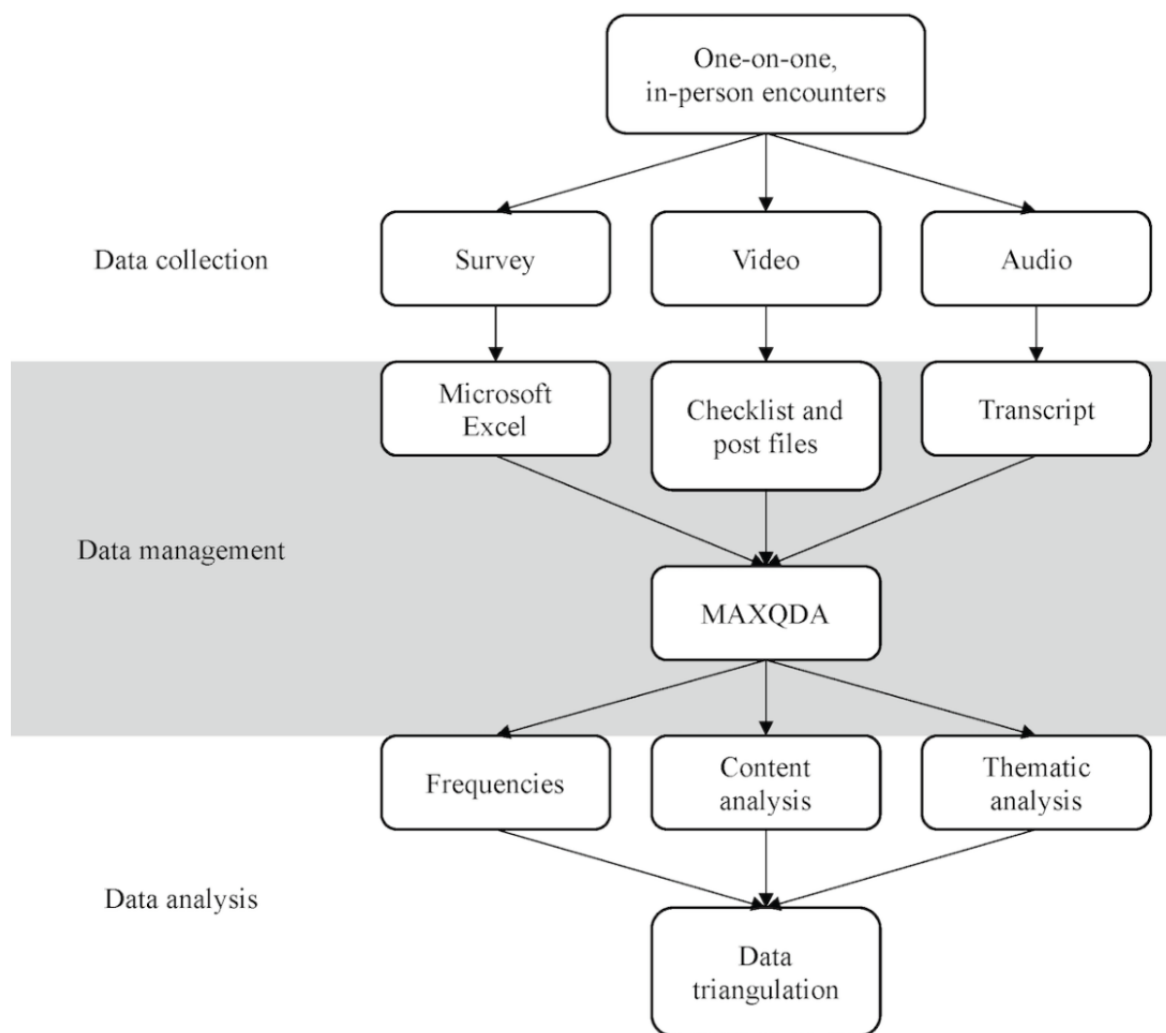

Overview

The methods discussed in this paper were developed for an exploratory, convergent parallel study assessing how and why Latino and Latina adults aged 40 to 75 years without a history of cancer engage with and act upon cancer prevention and screening information or misinformation on Facebook (published elsewhere) [37]. For this study, 20 self-identified Latinos and Latinas aged 40 to 75 years with no history of cancer participated in semistructured, in-depth interviews to discuss their Facebook use and engagement with cancer information on the platform. This diverse population not only avidly uses Facebook but also faces high cancer health disparities: cancer is the leading cause of death among US Latinos and Latinas [38], and cancer incidence rates are highest for screenable cancers linked to preventable behaviors (breast, prostate, and colorectal) [39]. Please refer to the original publication for a full description of the study and the main findings [37].

The social media content and context elicitation method developed for this study comprised three parts: (1) a short survey collecting demographics, health-related information seeking, and Facebook use data; (2) computer screen recordings of cancer posts appearing on participants' Facebook during the past 12 months; and (3) semistructured, in-depth interviews discussing Facebook use and engagement with cancer posts on Facebook

(Figure 1). Participants were recruited through flyers, word of mouth, and Facebook advertisements. Interviews were conducted in the participants' language of preference (English or Spanish) by the lead researcher, who is bilingual. All interviews were conducted during the summer of 2018 and lasted approximately 2 hours.

Figure 1. Study design using the social media content and context elicitation method to capture engagement with cancer information on Facebook. Each participant underwent all points of data collection.

Data Collection

After providing oral consent, participants completed a short survey collecting demographic variables, basic health-related information seeking, and Facebook use information. This survey provided descriptive insight into the uses and gratifications experienced by Latinos and Latinas on Facebook and other contextual factors that may affect engagement with cancer prevention and screening information on the platform. Following the survey, the researcher began the semistructured interviews, which were audio recorded in their entirety. Using the survey responses as a guide, the researcher asked participants to elaborate on their regular Facebook use patterns and interactions, the extent to which they encountered health information (including cancer information) on Facebook, and what they believed Facebook's role was in sharing information. Afterward, participants logged into their Facebook account using a private

browser on a research laptop and proceeded to turn off the Facebook Messenger feature to avoid being interrupted during the study. The researcher then documented the total number of friends, groups, and pages the participants followed, including how many of these were cancer-related groups or pages.

The participants then went to the search feature on Facebook, which allows Facebook users to search for content posted on the platform. This feature allows users to sort search results using multiple filters, such as *Sort by*, *Posted by*, and *Date posted*. For this study, participants were asked to enter the term *cancer* into the search bar. Once the search results emerged, they were filtered chronologically (*Sort by Most recent*) and by friends and groups the participant followed on Facebook (*Posted by Your friends and groups*). The resulting posts represented all posts that included the word *cancer* that could have potentially appeared on participants' news feeds when they

previously logged into Facebook and corresponded to content either posted by their friends or groups or any other publicly available posts that a friend liked or commented on. The researcher then proceeded to explain the process of jointly scrolling through the past 6 to 12 months of cancer-related posts to discuss posts they recalled seeing and engaging with. Any questions that participants had about the process were discussed before beginning.

Once the participant agreed, the researcher began recording the computer screen using QuickTime Player (version 10.4; Apple), which captures both audio and the computer screen. The researcher and participants jointly scrolled through the content to identify any posts the participants recalled having seen and whether they engaged with the post. Engagement was defined as any combination of the following: liking a post; commenting on a post; sharing a post; clicking on a post link; reading an article in a post; or watching a video within a post. If the post included any video or embedded link, participants were asked if they recalled watching the video or clicking on the link. If so, these were opened to capture the full content.

In addition to capturing the cancer posts that appeared on participants' Facebook through computer screen recordings, engagement with content prompted the researcher to use a semistructured, in-depth interview guide to ask questions regarding the reasons participants interacted with the post and whether engagement triggered further action. Examples of action included (but were not limited to) searching for additional cancer information or scheduling a cancer screening appointment. In-depth interviews were selected for this study as they allow for the exploration of new issues in depth and elaborate on individuals' thoughts and behaviors [40], an important facet in exploring how source and content characteristics influence engagement with cancer information on Facebook and any potential subsequent action. Interview guide questions were informed by the Uses and Gratification Theory [41] and the Comprehensive Model of Information Seeking [42,43]. The interview guide covered the following domains: reasons for engagement with cancer information, relationship to the cancer information source, roles of the cancer information source in delivering information on Facebook, perceptions about posted cancer information content and attributes, the ways that source credibility and content accuracy are assessed, and actions triggered by engagement with this information. In cases where participants recalled engaging with a post in ways other than liking, commenting, and/or sharing the post, the participant was asked to elaborate on this type of engagement. The researcher also collected notes regarding each post the participant either recalled or engaged with using a checklist.

Throughout the scrolling process, multiple participants had copious amounts of cancer-related information emerging in their searches, most of which were not specific to prevention and screening topics (eg, survivorship, cancer research, and fundraising). As the purpose of this study was to understand how participants specifically engaged with cancer prevention and screening information, searches were refined midway through the interview. The search terms *cancer prevention* and *cancer screening* were entered in all interviews approximately 30 minutes into the scrolling process to narrow the search

results. For each refined search term, the content was scrolled through up to 12 months prior and discussed as previously stated. On several occasions, when guided by the participant and the discussion at hand, additional search terms were added to find specific cancer prevention and screening information participants recalled engaging with. For example, one participant specifically recalled engaging with a post containing information about cancer and soursop (*guanábana*), a Latin American fruit commonly assumed to have curative properties. The post was elicited by searching for *cancer guanábana*. Similarly, another participant recalled a post about cancer diets and asked to search for *cancer diet*. A final search was performed using the term *cancer* and the filter *Posted by you*. This revealed any cancer information posted by the participant on their own Facebook profile.

After discussing the posts, participants were asked wrap-up questions regarding what would make cancer information more appealing on Facebook, who they considered the most influential and trustworthy sources of cancer information among their Facebook friends, and whether Facebook was a source of cancer information they trusted. Notes were taken throughout the interviews and used to inform data management and analysis.

Data Management

The data collection processes described above elicited rich data: in addition to survey responses, >20 hours of computer screen video and >30 hours of interview audio were captured (Figure 1). Survey responses were entered into a Microsoft Excel spreadsheet. Interview audio recordings were deidentified and transcribed verbatim. The process of capturing discussed posts and deidentifying data recorded on the computer screen is described in the following sections.

The first step in managing all computer screen recordings was to develop a checklist to document all the decision points for each interview video. This checklist collected the time stamps for both the audio and video versions of each interview, which allowed the research team to map interview transcripts with the discussed posts during analysis. Audio and video time stamps were collected at the beginning of the video recording and at the beginning of each post discussed. In addition to marking the time stamps for each post, the checklist was used to summarize the content of each post and to highlight relevant points discussed during the interview. These notes were incorporated as memos associated with each post during the analysis. The checklist was also used to document any search term refinements and outline preliminary codes for subsequent codebook development.

After using the checklist to document each post discussed in the interview, the post was captured through a screen grab and deidentified by cropping and/or covering any identifying images or names with white boxes and saved as a new file identified with the participant's unique ID; 2 additional files were saved in addition to the post screen grabs when applicable. First, if the post also included a video, the video was captured in its entirety in one of two ways: (1) if the video was part of a publicly available post, the lead researcher recorded the full video by searching for the post on Facebook or (2) if the video was no longer available on Facebook, the segment of the

recorded computer screen was trimmed and cropped using iMovie to ensure that the video was deidentified. Second, if a post included a link to an external website that was visited during the interview, the website was captured in one of two ways: (1) if the website link was still accessible, the lead researcher saved a web archive and PDF version of the website page or (2) if the website link was broken or no longer accessible, the recorded segment was deidentified, as described above. All deidentified files (posts, videos, web archives, surveys, and interview transcripts) were saved in a secure cloud-based file sharing and file storage service through the Johns Hopkins University and in an encrypted folder on a password-protected computer. The deidentified data were managed using the MAXQDA (Version 12; VERBI GmbH).

Data Analysis

The last step was to analyze multiple data elicited through the aforementioned methods. This was performed using traditional data analysis approaches (ie, frequencies, content analysis, and thematic analysis) that were triangulated to explain how and why engagement with cancer prevention and screening content occurred and how this engagement led to further actions. In the following sections, we summarize these analytical approaches; a detailed description of these analyses can be found in the original study [37].

First, we conducted descriptive statistics on all survey data. These findings were used to assist in contextualizing our sample. Then, a content analysis was conducted on all cancer prevention and screening information participants engaged with on their Facebook accounts. Content analysis was used to assess message patterns in a variety of formats, including those available on internet platforms [44]. A codebook was developed using the preliminary codes documented in the checklist during the data management process described in the previous section. The initial coding framework was applied to a sample of 10 cancer posts publicly available on Facebook by the lead researcher and a second bilingual study team member. Discrepancies were discussed and resolved, and a final codebook was developed [37]. Codes were developed for the following areas: post features, post source, post content, and credibility assessment. A total of 2 coders independently coded 10% of the sample. Intercoder reliability was calculated (0.89-1.0) [45], and any discrepancies were discussed until consensus was reached. The lead researcher coded the remaining posts, and code frequencies were calculated upon completion.

Finally, a thematic analysis was conducted on all the interview transcripts. This method allowed for the identification, analysis, and interpretation of patterns or themes in rich interview data sets [46,47], allowing a detailed description of how multiple themes and factors work together to explain engagement with cancer information. Transcriptions were analyzed in their original language to ensure that no meanings were lost in translation. The transcripts were preliminarily coded using emerging codes that aligned with the research questions using a constant comparison method [48]. A coding tree was created to outline the discovered themes and concepts. In addition, memos were composed with exemplary quotes for each theme; any exemplary quotes collected in Spanish were translated into

English. Memos were discussed with the study team to ensure dependability and credibility in theme development [49]. The data were placed into larger themes and factors to comprehensively explain how the phenomena occurred. Further data validation was conferred by triangulating the thematic analysis results with those of the content analysis [50] and is discussed in the original paper [37].

Ethics Approval

This study was approved by the Johns Hopkins School of Public Health institutional review board (IRB8484).

Results

Overview

Our study sample comprised 20 self-identified Latino and Latina Facebook users aged 40 to 75 years without a history of cancer (average age 54.2, SD 7.4 years) and represented 7 distinct Latin American subethnic groups from the Caribbean, Central America, and South America; 9 (45%) participants were fully bilingual, 6 (30%) preferred Spanish, and 5 (25%) preferred English. Participants were mainly female (15/20, 75%) and heavy Facebook users, with most (17/20, 85%) reporting checking their Facebook at least once a day. Facebook was most commonly used for social interaction (17/20, 85%) and information sharing (15/20, 75%). Participants had a median value of 357 (IQR 189.5-544.5) Facebook friends and followed a median of 20 (IQR 4.5-56) Facebook groups; only one of the participants followed cancer-related Facebook groups. A detailed description of the sample is available in the main study [37].

Overall, participants reported engaging with 66 posts containing cancer prevention and screening information (4.1 average posts per participant) in the previous year. Data emerging from the social media content and context elicitation method demonstrated that participants mostly engaged with cancer prevention and screening information by viewing and/or reading content (48/66, 73% posts) rather than by liking, commenting, or sharing posts (18/66, 27% posts). Furthermore, it provided rich content regarding how Latinos and Latinas engage with and act upon cancer prevention and screening information on Facebook [37]. In the following sections, we explore 2 sample cases to illustrate how a mixed methods approach provides rich insight that is otherwise missed when quantitative methods are used alone. These 2 cases were selected as they were emblematic of the broad range of information elicited from our sample that goes beyond only quantifying engagement. Participants' names have been changed to protect their identities.

Case 1: Rogelio

Rogelio was a bilingual Cuban male aged 61 years. He had >1800 Facebook friends and followed 131 Facebook groups, none of which were related to cancer. He considered himself a very active Facebook user, logging in multiple times a day and using the platform for social interactions, searching for and sharing information, seeing what others are doing, and maintaining his cultural identity. During the interview, 13 cancer-related posts were discussed, all of which had a video or image, for he believed that "if it doesn't enter through the eyes, it doesn't reach you." Although he engaged with all 13

posts by reading the content, he did not like, comment, or share any of these on his profile. All but 1 of these posts were shared by friends in his network; the other was shared by a Facebook group to which he belonged. A total of 6 posts were related to natural remedies or foods with curative properties against cancer, 1 was about a free skin cancer screening event, and 1 was about free colorectal and prostate cancer educational sessions for Latino men; the remaining posts were related to cancer survivorship and prayer requests.

Although Rogelio used his Facebook account frequently throughout the day, he explained that he rarely liked, commented, or shared content on his profile as he could not let others know he was on Facebook during work hours. Therefore, instead of engaging with a post through these metrics, he would send himself interesting posts through Facebook Messenger

(the platform's messaging tool). In this manner, he could read the post at a later time. He also explained how he and his wife regularly shared information related to diet and foods with preventive and/or curative properties through Facebook Messenger. Many times, after discussing content that either one engaged with on Facebook, he would decide whether they would incorporate these natural remedies into their daily lifestyle; he mentioned doing this with the 6 posts discussed during the interview. For example, he described how he and his wife started to eat papaya seeds after he read a post stating that "they are [sic] magical cure for gut, kidney, liver, cancer and many other diseases" (Figure 2). This post described how to consume papaya seeds and outlined 8 benefits, including that papaya seeds "have agents that can stop the growth of tumors and cancer cells, [and] contain isothiocyanate, which helps with breast, colon, leukemia, lung and prostate cancer."

Figure 2. Image of the papaya seed post that Rogelio discussed.

Rogelio also stated that, although Facebook was one of his main sources of information, he rarely—if ever—verified the information he engaged with on the platform. Instead, he relied on the seriousness of the people who post content on their profiles, stating that his friends from church or those aged >40 years are serious and do not share *fake news*. He also relied on his previous knowledge about a topic and believed that posts about the curative properties of foods are more credible than other topics. For Rogelio, engaging with information through a post was sufficient for him and his wife to incorporate natural remedies into their diets, regardless of whether the post cited an information source.

Finally, his cultural values and Cuban heritage came up frequently during the interview. He tended to have a fatalistic view about cancer, which emerged in multiple discussions. For example, he recalled seeing a post pertaining to 2 educational events for men about colorectal and prostate cancer. When he saw it, he immediately said he never attended such events as

speaking about these topics is like inviting the disease into your life:

It's like not wanting to speak about the topic, so it doesn't happen to me. As if talking about [colorectal or prostate cancer] puts it in my cabinet.

He believed this avoidance is a very negative Latin American custom; however, he claimed Latinos and Latinas rather *look the other way* when these topics emerge.

Case 2: Luisa

Luisa was a Puerto Rican female aged 63 years who preferred English. She had 370 Facebook friends and followed 268 Facebook groups, none of which were related to cancer. She also considered herself an avid Facebook user, logging on multiple times a day and using the platform for social interactions, searching for and sharing information, passing time, entertainment, relaxing, expressing her opinions, seeing

what others are doing, advocacy, and convenience. During the interview, 11 cancer-related posts were discussed, 5 of which contained cancer prevention and screening information she engaged with. Another 2 posts containing cancer prevention and screening information were discussed as they grabbed her attention during the interview; she had not recalled seeing them previously but stated that she would have read them if she had as they were posted by a friend who she deemed a trustworthy source of health information. The remaining discussed cancer-related posts pertained to cancer survivorship and requests for prayer for survivors of cancer. She shared only 1 post on her profile; she did not like, comment, or share any of the other posts discussed.

When discussing her Facebook use patterns, Luisa stated that she sometimes did not engage through likes, comments, or shares as she was just scrolling through her timeline and did not stop to perform these actions. However, she said this does not mean that she failed to read or watch the content. She gave an example of being at the grocery store line while scrolling through her Facebook: she might watch an interesting video but does not stop to share it with others, only sharing content when “relaxed.”

Luisa was very interested in topics pertaining to cancer prevention, particularly those related to a healthy diet. She discussed superfoods frequently and stated her preference for natural remedies over medication. For example, when discussing a video that included “10 alkaline foods that prevent and treat diabetes, gout, heart disease, and cancer,” she stated that it was the images of different superfoods that initially grabbed her attention, not the cancer prevention claims. She also mentioned that repetition surrounding the benefits of superfoods confirms the credibility of such information. She gave an example of this while discussing engagement with a post about soursop, which stated that it “has been used by many people to fight against cancer cells.” Luisa said that she was familiar with the curative properties of soursop as she had heard this often from friends and family in Puerto Rico. In fact, she had tried to incorporate it into her diet but had not been able to find it in any local supermarket.

Throughout the interview, Luisa continuously mentioned having seen a post about juicing as a way of preventing cancer. She recalled having seen the post on Facebook and copying the recipe on her phone’s notepad app. In discussing this, she also mentioned using Facebook Messenger to send herself articles. At the end of the interview, we were able to find the post by entering the search term *cancer juice*. The post claimed that the super juice recipe “is designed to help us combat breast cancer, as well as helping to starve off all potential cancer cells within the body.” It also stated that the juice cannot be blended as it is a *therapy tonic* that must be prepared using a juicer. The recipe called for broccoli, kale, cauliflower, fresh ginger root, apples, and carrots. She shared that she had since incorporated this juice into her diet, asking for it to be prepared for her when she goes to the supermarket. When asked, she said she decided to include this juice as part of her diet as she considered the friend who posted the recipe to be an extremely trustworthy source of health information. This friend came up 4 times during the interview as she often shared information about natural remedies against

many diseases on Facebook, a topic Luisa was very interested in. As Luisa considered this person a trustworthy source of information, she said she rarely further verified the content she posts and might instead just send her any questions through Facebook Messenger. She trusted that her friend had already verified the content shared, although all the websites shared by her friend lacked sources of evidence-based information. When she does decide to verify any information she finds on Facebook, she goes to Google and WebMD.

Discussion

Principal Findings

This study presented a qualitatively driven, mixed methods approach to explore how individuals engage with health information on Facebook (specifically, cancer prevention and screening information) and the impact engagement may have on subsequent behavior. In doing so, it expands upon what is known regarding cancer information engagement on social media, which predominantly stems from quantitative methodologies. The current literature operationalizes engagement with information on Facebook through likes, comments, and shares, with some studies further categorizing engagement into levels by type of engagement [16,18-20,25,31]. However, the social media content and context elicitation method adds yet another layer of nuance to public health’s current conceptualization of engagement by providing insight into the different ways people may process and act upon information, particularly individuals who would rather not like, comment, or share posts they consume. As exemplified in the aforementioned case studies, individuals may choose to read, discuss, or even change their behavior based on cancer prevention and screening information they consume without liking, commenting, and/or sharing the information. The aforementioned case studies also show that some individuals may circumvent liking, commenting, and/or sharing by using other messaging platforms to store or share information with others, such as Facebook Messenger and WhatsApp. These findings highlight the importance of exploring how platform interconnectivity affects health information engagement. As such, the presented methodology can assist in developing more comprehensive models describing engagement with health information on social media, responding to calls for a more thorough understanding of engagement on the social media landscape [15].

Consistent with previous literature [35], there are many reasons individuals do not engage with content in ways visible to others on social media. However, this decision is not indicative of a lack of engagement: both cases discussed in this study demonstrate ways in which individuals engage with and even disseminate posts while circumventing likes, comments, and shares. Discounting these aspects of engagement provides a limited explanation of the impact of health information in the social media landscape. This is of paramount importance in the current web-based environment, which is increasingly bombarded with misinformation on a broad range of topics. The social media content and context elicitation method is able to obtain a robust account of how individuals engage with health

misinformation, what grabs their attention, how they perceive it, and how they incorporate this information into their daily lives. These insights are necessary to counteract the impact misinformation may have on the uptake of cancer prevention and screening recommendations, which is a growing area of research interest [1]. Although we explore the ramifications of engagement with cancer prevention and screening misinformation in a forthcoming publication, other researchers have already adapted the social media content and context elicitation method to explore the factors related to engagement and disengagement with COVID-19 information on the web [51]. As such, the social media content and context elicitation method may be of particular interest to public health efforts developing social media campaigns targeting misinformation among populations with lower digital and/or health literacy. This method can also provide further insight into features that affect engagement and contribute to the dissemination of accurate cancer information, particularly those conveying prevention and screening recommendations. This method may also be applied to future studies regarding how to best communicate health information on these platforms, an important step toward addressing health disparities.

The process of developing this mixed methodology led to several insights. First, it is important to have a thorough understanding of the social media platform to be explored and its features to maximize how data can be accessed and used for research. In this study, understanding the features that Facebook provides when searching for content on the platform allowed the development of a detailed process to access content alongside participants that may otherwise not be accessible. It also allowed researchers to chronologically discuss content in person with participants, which overrides any algorithms that may affect the visibility of content, while also providing a glimpse to the overall cancer information landscape participants encounter on Facebook. This content not only included cancer prevention and screening information but also information about cancer survivorship, treatment, research, and other cancer topics. In fact, posts with cancer information unrelated to prevention and screening were more common than posts about cancer prevention and screening. Another important observation is that research teams must adapt to the quickly changing nature of social media platforms when embarking on such research efforts. For example, midway during data collection, it was observed that Facebook added a new filter option to their search, which enables users to look only at *Posts you've seen*. Although details on how Facebook determines which posts a person has seen are not readily available, including this filter in future research using the methods described in this paper would reduce potential participant recall bias [52].

There are also important ethical considerations researchers must take into account when developing new methodologies to explore content in an increasingly unreliable information landscape on social media. One of these considerations entails privacy concerns. This study took place several months after Facebook's Cambridge Analytica scandal, where the information of 50 million American Facebook users was used to identify voters' personalities and influence voting behaviors in the 2016 election [53]. In an additional measure of clarity, the study team

developed an additional information sheet for participants that outlined privacy expectations, what data would be captured, and what would and would not be done with captured data once deidentified. It also included images that provided an example of how the discussed posts would be deidentified before analysis. This sheet was discussed in person during the informed consent process and served as a useful resource to ensure participants fully understood the study methods and measures taken to protect the privacy of secondary data. Thus, it is important to be up to date on current events pertaining to social media platforms and issues concerning privacy and other policies that may increase perceptions of mistrust among the general public. It is also important to ensure that potential participants are extremely clear in their understanding of data safeguards in studies that use the aforementioned methods or any other mixed methodologies that capture information from a participant's social media account or accounts.

This study has several limitations. First, on a practical level, the method described is labor intensive and requires a detailed data collection and management protocol, increasing the resources needed to conduct similar research on a larger scale. This approach may also not be appropriate for more sensitive health topics or individuals who may find these in-depth methods too strenuous. Second, although participants accessed their Facebook accounts on a study laptop, 60% (12/20) of participants reported only accessing their accounts on their cell phones. The visual layout of Facebook's website version is different from that of its mobile app. This difference in visualization may have affected the ability of some participants to fully recall some posts they previously engaged with as they looked different on the computer screen. Future studies conducting this type of methodology may want to explore using a mobile device to collect data. They may also incorporate the aforementioned new *Posts you've seen* filter to minimize recall bias more generally, as self-reported recall may capture only content that people more deeply engaged with rather than all content to which they were exposed and maybe glanced over. Finally, only posts that included the search terms in the text emerged in the search during the data collection process, inevitably excluding posts that did not contain some kind of text feature (eg, posts with only a picture or a direct link to a video). It also excluded posts that discussed cancer-related topics but did not, at minimum, include the word *cancer*, whereas it included posts unrelated to the disease (eg, astrology-related posts or those equating current events in Latin American politics to cancer). Future studies should ensure they possess a comprehensive list of search terms encompassing multiple areas of the study topic while understanding that an increase in search terms adds time to the interview.

Conclusions

The social media content and context elicitation method shows potential for a deeper contextualization of engagement with health information on social media. Conducting interviews to complement the quantitative content analysis of elicited posts allows a deeper understanding of the reasons and ways engagement with health information on social media occurs, which cannot be done by observing web-based content alone [54] or by asking questions that require recall about a topic that

may not be salient to most (ie, cancer prevention and screening information engagement). This mixed methodology also allows a discussion of how message engagement may be a result of offline interactions and relationships and how these affect assessments of message credibility and accuracy. Our findings provide insight into the preferred source and content characteristics of information on social media that triggers engagement and subsequent action among specific groups and vulnerable populations, laying foundational work for the

development of future measures and empirical research exploring innovative and participatory health communication on social media platforms. Future steps for the research described in this paper include data integration and the development of a final conceptual model to help visualize the process of engagement with cancer prevention and screening information on Facebook among Latinos and Latinas in the United States.

We read the paper by Dewa et al [1] with interest. The authors performed a meta-analysis to conceptualize, appraise, and synthesize evidence on quality social connection (QSC) within digital interventions (D-QSC) and the impact on depression and anxiety outcomes for young people aged 14-24 years. They demonstrated that “D-QSC is an important and underconsidered component for youth depression and anxiety outcomes. Researchers and developers should consider targeting improved QSC between clinicians and young people within digital interventions for depression. Future research should build on our framework to further examine relationships among individual attributes of QSC, various digital interventions, and different populations.” After carefully reading, I wish to put forth the following suggestions.

Two studies [2,3] in Table 2 (“Data extraction and quality assessment of included studies”) were created by the same author team (Radovic et al) with similar characteristics (year, country, study design, setting and participants, digital intervention, and outcomes and measures). This duplicate inclusion of data would affect the credibility of the final results of the meta-analysis. I recommend that the authors exclude duplicate works in the meta-analysis and that a correction and reliable checking of the data insertion is required.

Due to these mistakes, I suggest that the authors further refine the inclusion criteria for the included studies to avoid duplication of inclusion.

Acknowledgments

We are supported by the Department of Gastrointestinal and Gland Surgery at the First Affiliated Hospital of Guangxi Medical University.

We congratulate Margus and colleagues on their interesting study documenting emergency medicine physicians' use of Twitter preceding surges in COVID-19 cases [1]. The correlations discovered between tweet count and hospital case numbers represent a unique instrument to assess epidemiologic trends related to the COVID-19 pandemic [1]. An additional subanalysis by geographic region may provide enhanced insight into the efficacy of social media utilization as a predictive tool for emergency medical resource allocation. We commend the authors for their extensive search criteria employed to accurately identify US emergency medical physicians; however, this study's complex methodology highlights the lack of an official role and verification process for physicians on social media.

On Twitter, there is no specific criteria listed for verification of medical professionals. Instead, verification is based on notability criteria associated with representing a notable individual or brand [2]. These criteria exclude any physicians without a sufficiently large following from being verified on Twitter, making it more difficult for Twitter users to identify legitimate medical professionals lacking a large following. As health professionals and researchers are further encouraged to utilize social media for professional purposes, additional verification

criteria specific to medical professionals may prove beneficial in the future [3].

In 2010, the American Medical Association issued guidelines regarding the ethical use policy to aid physicians in navigating social media [4]. However, the role of physicians on these online platforms has not been uniformly described. Physicians may interact with one another, and this is evident with Med Twitter, an open-source, decentralized forum for information sharing, medical education, and professional networking, as well as the increasing use of social media in residency recruitment [5]. The observed correlation by the authors of this study may be indicative of such communication by emergency medicine physicians. Continued use of such platforms across medicine may reveal additional relationships such as this predictive model. Perhaps a potential role may be to extend physicians' professional impact in education and patient advocacy.

As time moves forward, the use of social media in medicine will continue to expand beyond prediction as will its potential pitfalls. Margus and colleagues' article [1] brings up a positive prospect of social media in medicine, and it is important that physicians understand the current limitations of these innovative platforms. We believe that physicians need medicine-based

verification for social media in addition to clearly established roles for physicians from national governing bodies.

KEYWORDS

cost analysis; costs and cost analyses; economic advantage; electronic medical records; electronic records; health care; hospitals; computerized medical records system; quality of health care; secondary data

The review paper by Uslu and Stausberg [1] certainly sheds some light on the positive impacts of electronic medical records (EMRs) in the hospital context. The emergence of such papers, as fruitful as they could be for minimizing skepticism among hospital executives and managers and compelling them to embark on the digitization journey, could introduce hasty and immature uptake of the technology, if biased. As a researcher heavily focused on health care digitization, I can debate that the results presented in the format of a review in the said paper are not impartial.

As highlighted by the literature, the improvement of processes caused by EMRs, as valuable as it is, may not contribute to patient outcome criteria (ie, mortality rate), and this has been one of the lengthiest debates in the field of digital health [2]. Thus, the authors' statement “the review also showed improvements in quality of care by all respective studies” struck me as a great surprise. Further examination of the paper has brought to light that this statement was overpowered by some flaws in the study.

The bias toward declaring positive results from studies that either lacked or presented statistically insignificant positive outcomes (as noted in the original paper) is the major downside of this review. For example, Uslu and Stausberg [1] noted a positive association between EMR adoption and efficiency in the study by Adler-Milstein et al [3]. Surprisingly, in the original study, the authors clearly declared no significant association with regard to efficiency.

Additionally, Uslu and Stausberg [1] did not draw a clear line between the types of quality criteria (safety, timeliness, process, and patient outcomes), which not only is confusing to readers but also does not demonstrate the magnitude of improvement in each dimension. As such, a criterion such as mortality rate that does not normally show a significant improvement would be overpowered by process outcomes, which often behave reversely.

The aim of the study to “summarize empirical studies about the value of electronic medical records (EMRs) for hospital care” does not justify the inclusion of a few studies [1]. For example, “Higher rates of adoption of key EHR functions among

high-quality hospitals” was reported as the result of Elnahal et al [4]. The aim of the said study can show the association between the presence of high quality in targeted hospitals and the presence of IT (information technology). Thus, it is not clear if high quality was derived by the EMR or whether high-quality hospitals adopted EMRs to maintain their status as a high-quality hospital. As the authors noted, “high quality and EHR adoption may be linked”; however, this is no strong evidence on which review studies can rely. On the other hand, the exclusion of

computerized physician order entry (CPOE) was not explained by the authors as many EMRs already incorporate CPOE functions. By contrast, some studies included in the review, for example, Elnahal et al [4], mentioned the existence of CPOE in most high-quality hospitals in their sample.

To conclude, since the outcomes of secondary studies are often consulted by managers and politicians in the health care sector, researchers must be vigilant of the extensive impacts of research bias on fundamental decisions that they may cause.

KEYWORDS

cost analysis; costs and cost analyses; economic advantage; electronic medical records; electronic records; health care; hospitals; computerized medical records systems; quality of health care; secondary data

We thank Shakibaei Bonakdeh [1] for the critical comment on the positive impact of digital interventions. It would be the ultimate success of medical informatics research to be recognized by hospital executives and managers. However, we are not convinced that the previous national initiatives for the implementation of electronic records were evidence-based, neither in England, Germany, nor the United States. Following the scene of electronic records for 30 years, recognizing the literature of 50 years, and having been responsible for the selection and management of electronic records in hospitals, our view was truthfully impartial. We were willing to accept scientific evidence independently of pre-existing opinions even if the clear result was a surprise [2].

First, we want to clarify that we did not evaluate digital interventions in general, as indicated by the letter's headline. In our study, we sought to focus on electronic medical records (EMRs) as specific types of electronic records. However, we were confronted with several challenges concerning the definition and specification of the technology, as partly

addressed in the letter. For example, excluding studies focusing on computerized physician order entry (CPOE) on the one hand did not mean excluding studies on EMRs that offer CPOE support on the other hand. It would be a step forward to have a standard not only for the reporting of results such as PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) but also for the labeling of digital interventions.

Concerning the results of the included studies, we aimed to draw the utmost benefits from the details. This could mean overriding the studies' conclusions, as stated in our limitations. In the case of Adler-Milstein et al [3], we probably overweighted the improved efficiency in the post meaningful use period (2010/2011). We apologize if we did not meet the common appraisal in all cases. However, the results of Adler-Milstein et al [3] fully support the conclusions from the whole set of included studies with a clear positive effect on the quality of care and an ambiguous economical implication. The appropriate evaluation criteria of EMRs should be put up for discussion. It may be unreasonable to expect a reduction of mortality from

its implementation. We would be honored if our series of reviews contribute to realistic expectations toward the effects of EMRs on different types of quality criteria.

Second, the other points of criticism were related to the context of EMR implementation. Studies about the effects of EMRs are faced with a double complexity [4]. The implementation of an EMR will involve the whole organization of hospital care, will alter health care processes, and will include a wide range of functionalities (EMR as a complex intervention). The setting of the implementation of an EMR is complex too, with different professions, different specialties, different levels of care, etc (complexity of the context). For example, the readiness for change and managing change might be more important for the success of an EMR implementation than specific technological issues [5]. It could be argued that well-prepared organizations will benefit more from an EMR than less prepared organizations. In extreme cases, less prepared organizations will get worse with the same EMR solution that helped well-prepared organizations to further improve patient outcomes. We agree

with Shakibaei Bonakdeh [1] that there could be a coexistence effect in studies using secondary data. Hospitals attempting to improve care by implementing an EMR should be advised to analyze thoroughly their current state, to eliminate reasons for inappropriate care in advance, and to be well prepared for the technology.

Medical informatics science is confronted with the digitization of health care independently from its input and participation. Due to the high penetration of electronic records, interventional studies will no longer be possible for this technology in developed countries. Nevertheless, at times, society will seek help from medical informatics science, especially if political expectations fail. Frequently, low-hanging fruits determined the reaction of researchers in the past. It would be a major step forward if medical informatics science is willing to act as a collective community grounded on scientific evidence. With this regard, we express our appreciation for Shakibaei Bonakdeh's [1] feedback.

We welcome feedback from the authors Deng and Qin through their comment [1] on our paper "Quality Social Connection as an Active Ingredient in Digital Interventions for Young People With Depression and Anxiety: Systematic Scoping Review and Meta-analysis" [2]. They suggest that two included studies [3,4] should not be included in our review as individual studies as data extraction and quality assessment of both studies is the same, and that this impacts the quality of the meta-analysis. We have the following response. First, our review is scoping in nature, therefore we included and extracted any study that matched our inclusion criteria and appropriately extracted each study separately. Second, both studies have different designs and methodologies, and obtain different outcomes. For example,

one study is a co-designed study, and the other is a qualitative study; therefore, neither study should be included in the meta-analysis itself. Third, these studies are included and discussed in the review in relation to indicators of quality social connection within digital interventions and each study finding is different. In this case, different data are presented and referenced in relation to distinct digital intervention mechanisms that facilitate quality social connection and they are appropriately presented separately. For example, the importance of anonymity is mentioned in one but not the other. Finally, we have already discussed the statistical and methodological variation within our scoping review as a potential limitation.

Thank you for considering our response to the comment.

We would like to respond to Wee et al's paper, "Measurement Properties of Patient-Reported Outcome Measures for Diabetes: Systematic Review" [1]. We appreciate the herculean effort undertaken to summarize all diabetes-related patient-reported outcome measures (PROMs). However, we have some concerns.

First, despite the large amount of identified PROMs (N=238), there are still many PROMs missing [1]. In our systematic review of PROMs measuring health-related quality of life (HRQOL) in people with type 2 diabetes (currently under review), which was performed in the same time period and using the same databases, we identified 116 HRQOL PROMS. Of these, >50 were missing in Wee et al's review [1]. Missing PROMs include, for example, the National Diabetes Register Survey [2], which in our review showed the best content validity. We think this incompleteness is due to a lack of alternative search strategies, such as checking references. We were surprised that the authors [1] identified no papers through hand-searching, while about one-fourth of the included papers in our review were identified through reference checking.

Second, the authors [1] used the COSMIN (Consensus-Based Standards for the Selection of Health Measurement Instruments) methodology to summarize the evidence on the quality

(measurement properties) of the PROMs. However, contrary to the COSMIN guidelines, the quality of the PROMs was not rated for each PROM subscale separately, even though measurement properties can vary among subscales.

The limitations of this review [1] underscore the problematic status of PROMs in diabetes: there is no consensus on what doctors and scientists want to measure, and it is unclear what is most relevant to measure. The content of the existing PROMs is very heterogeneous; there are too many PROMs out there and many are of questionable validity. This hinders value-based health care and limits the value of PROMs when attempting to determine which treatment works most optimally. More awareness is needed, supported by recent initiatives on developing core outcome sets for people with diabetes [3-5]. We should start using those core outcome sets in our research and care for people with diabetes.

In conclusion, there is still a need for a high-quality systematic overview of all available PROMs for people with diabetes, with emphasis on the constructs being measured, and a comprehensive evidence synthesis of the measurement properties of all (subscales of) PROMs. This would allow researchers and doctors working with people with diabetes to

make informed choices on which PROMs to use for value-based health care.

systematic review; measurement properties; patient-reported outcome measures; methodological quality; level of evidence; PROMs; patient reported outcome; diabetes

We would like to respond to the letter written by Rutters et al [1] with regard to our paper, "Measurement Properties of Patient-Reported Outcome Measures for Diabetes: Systematic Review" [2]. We noted the concerns from Rutters et al [1], but we would like to offer some explanations.

First, the selection criteria of our systematic review were restricted to patient-reported outcome measures (PROMs) that are tested in patients with type 2 diabetes mellitus (T2DM) only. The study on the development and validation of the National Diabetes Register Survey included patients with other forms of diabetes (ie, type 1 diabetes) [3], and, therefore, was excluded from our analysis. We focused on T2DM since existing evidence has demonstrated that patients' behaviors influencing disease

management differ by different diabetes subtypes [4,5]. Therefore, the PROMs used to guide interventions and patient care may be different and should be reviewed separately. Another consideration was related to our concerns that combining all validation studies of PROMs in different forms of diabetes would reduce the readability of the paper due to the large number of studies available.

Second, due to the large number of PROMs included in the review, we decided to analyze the measurement properties of the PROMs on a per-PROM basis instead to maintain the readability of the paper. We also agree with Rutters et al [1] that many health-related quality of life (HRQOL) PROM subscales do not measure HRQOL but actually measure overall

quality of life, and that characteristics of the individual or environment should be considered patient-reported experience measures. This is further complicated by the issue of problematic definitions of HRQOL in the literature [6]; thus, further study detailing the different constructs measured by subscales of PROMs is warranted.

We are grateful that the authors have taken the effort to provide constructive comments on our paper. The issues brought up by Rutters et al [1] echoed the need to have consensus between clinicians and psychometrists to measure what is relevant to patients. The content of the existing PROMs is indeed heterogeneous, and there are too many PROMs that have

questionable validity. We agree that more awareness is needed, including developing and implementing core outcome sets for patients with diabetes.

In conclusion, there is a need for a systematic review to summarize all available PROMs for patients with diabetes with emphasis on the constructs being measured, as well as a comprehensive evidence synthesis of the measurement properties of all subscales of PROMs (which was not the focus of our systematic review). Clinicians and researchers should work with patients with diabetes to develop a core outcome measurement set for use in diabetes care and research.

Abstract

Background: One of the most significant changes in the majority of postsecondary educational institutions was the closure of those institutions and the shift of educational activities to online distance learning formats as a result of the COVID-19 pandemic. Closure combined with forced online distance education (FODE) was a cure with many side effects, 1 of them being the effect on students' mental health and, more specifically, levels of stress. Due to the novelty of the situation, there have been no studies so far designed to link satisfaction with online study, feelings toward the study obligations, and stress among students.

Objective: The aim of the study is to assess the perceived stress of Slovenian postsecondary students in order to identify the online study-related factors affecting or acting as a covariate during the COVID-19 lockdown.

Methods: Data collection was conducted through a self-reported survey as part of a large cross-sectional study based on data collected from postsecondary students from a number of higher educational institutions. The random sample consisted of 4455 individuals. The Perceived Stress Scale (PSS-4), Satisfaction with Online Study Scale (SAT-5), and Feelings Towards Study Obligations Scale (FETSOS) were used to assess the constructs and the relations observed within the study.

Results: The results indicate that more than half of all respondents reported high levels of stress. The difference in the reported levels of perceived stress between genders were statistically significant ($N=4454$, $F_2=56.719$, $P<.001$, Cohen $d=0.35$). Overall, the results suggest that a decline in the motivation to study, the quality of internet and mobile connections, and the presence of distracting factors in the study space were the 3 main factors related to the students' negative emotions as associated with the timeliness, performance, and quality of the study obligations. Furthermore, the results show that the level of satisfaction with online study affected stress such that the higher the satisfaction, the lower the stress. Moreover, the more positive feelings connected with the timeliness, performance, and quality of the study obligations that the students felt, the more satisfaction they reported with online study and, thus indirectly, lower stress and less negative feelings.

Conclusions: The findings of this study call for implementing structures and measures targeted at stress reduction, working conditions, and pedagogy with regard to FODE.

KEYWORDS

online study; stress; COVID-19; postsecondary students; pandemic; epidemiology; educational institutions; online education; pedagogy; mental health

Introduction

Academic environments have always been known for the presence of stress, anxiety, and depression [1,2]. The closure of postsecondary educational institutions induced by COVID-19 brought about many changes to almost all areas of study. In this context, study mostly takes place online and at a distance. Because of its compulsory nature, it has been recognized as forced distance education (teaching, learning) and in its online form as forced online distance education (FODE) [3]. Moving lectures and courses online has not only changed the format of courses but also brought with it several side effects [4]. One of the most often reported side effects of FODE is the impact on students' mental health, with stress, anxiety, and depression being the most commonly reported impacts worldwide [5-7], with some subpopulations being more vulnerable than others [8]. Students seem to be at greater risk of mental health problems due to social distancing, as well as FODE and other measures to prevent or reduce the risk of transmission of coronavirus (SARS-CoV-2), such as restrictions on movement and gatherings [9]. Previous research has shown a link between psychological distress and symptoms of mental disorders or problems with outbreaks of infectious diseases [10,11]. Research has shown that during the COVID-19 pandemic also, psychological reactions, such as stress, anxiety, and depression, have been common [12,13] among students as well [14-21]. Several studies have reported high or increased prevalence of stress among this population [6,8,17,19,22,23], associated with factors such as fear and worry about one's own health or that of loved ones, difficulties concentrating, disrupted sleeping patterns, reduced social interaction, and increased concerns about academic performance [19], which raises concerns about the mental health of postsecondary students.

The studies reviewed most often searched for predictors of increased mental health problems during a lockdown in socioeconomic domains, previous (mental) health episodes, living conditions, and, more rarely, the domain of education [24-26]. The majority of studies, produced by professionals from the fields of psychology and psychiatry, most often suggest solutions for building resilience among students, counselling, and, at the last instance, medication [8,27]. However, the solution for students can lie not only in improving self-supportive and institutionally supported measures for those with mental health problems but also in reducing sources of stress where and when possible. However, many studies of online distant (remote) education in the educational research domain are from the pre-COVID-19 era. The pandemic has put these previous findings into a new context. Those pre-COVID-19 findings cannot be easily transferred, because the earlier studies were based mostly on voluntary decisions, while at least during the first lockdown, the transition was forced and not tailored to the best standards of remote education. In the words of Hodges et al [28], "Everyone involved in this abrupt migration to online learning must realize that these crises and disasters also create disruptions to student, staff, and faculty lives, outside their association with the university."

In recent research, perceived stress has been measured as an output variable, as a covariate with several manifestations of

mental health problems, such as anxiety and depression (among numerous others), commonly associated with pandemic measures [12,29]. The input constructs included factors extracted from the exploratory analysis of variables believed to be stressors produced in relation to learning experiences, and thus can be manipulated by educational institutions and educators. As an intellectual framework, we followed the Sternberg theory of successful intelligence [30], as elaborated for FODE in Dolenc et al [4], which claims that educators "have the choice of adapting to the new environment, adapting the environment or changing the environment, while students can only adapt to the environment."

Postsecondary students can be regarded as 1 of the most important investments of every society in its future prosperity [1]. It is obvious that the share of individuals with higher education should and will rise in the coming generations [31]. There is also a trend toward the digital transformation of education, with the transition to more or less blended forms of education with promises of "anywhere (any place) – any time" learning experiences [32,33]. These trends call not only for an increase in the number of study places and the digital transformation of communication channels at educational institutions (colleges, higher schools, academies, faculties, universities, etc) but also for greater support for student well-being. In the transitional period between adolescence and adulthood, postsecondary educational institutions should be concerned with the quality of the learning outcomes of diverse student populations in line with student health and well-being. As such, the findings and experiences from the COVID-19 lockdowns should not be forgotten but should be taken not only as an opportunity to identify problems that may have been masked and unacknowledged before the lockdown but also as an incentive to address them. In line with these intentions, the first part of this study is descriptive, with the second part suggesting prescriptive measures.

The aim of the study was twofold. The primary focus was on assessing the mental health of Slovenian postsecondary students and identifying the online study-related factors affecting or acting as a covariate with it during the COVID-19 lockdown. The data used in this study were collected from postsecondary students from various higher educational institutions as part of a project titled "Measures in the Field of COVID-19 Spread Management With a Focus on Vulnerable Populations" [34]. The assumptions of the study were that technology was not neutral and that satisfaction with online experiences and with forced and involuntary study conditions during the lockdown could work as an incubator to raise perceived stress, as shown in previous studies [34]. The authors are aware that a number of factors and variables may correlate with, be influenced by, or predict stress. Among others, we can list (in no particular order) anxiety, depression, resilience, fear of COVID-19, previous mental illness, substance abuse, and addiction. However, at this point, such relationships were not explored. This was not because they were unimportant but because the primary goal was to explore the effects of FODE on stress within a simple and robust model.

The study was divided into 2 parts, in line with the research questions (RQs):

- RQ1: What are the latent structure, reliability, and construct validity of the instruments used in the survey?
- RQ2: What are the strength and direction of paths between latent variables?

The study results may help us produce prescriptive measures to help improve study conditions and the mental health of postsecondary students and also help those who may be concerned with the problem and have the ability and means to take action during and after the COVID-19 pandemic.

Methods

Procedures and Instruments

Data collection was conducted through a self-reported survey as part of a large cross-sectional study in Slovenia. The data collection took place between February 9 and March 8, 2021. Data collection was conducted through the web-based survey platform 1KA (Centre for Social Informatics, at the Faculty of Social Sciences, University of Ljubljana) [35]. Simple random sampling was used, and invitation letters to participate in the study were sent by email to all universities, private faculties, and student organizations, with a request to forward the invitation to all their students. To obtain as much feedback as possible, a reminder letter with the invitation to participate was sent to all addresses after 1 week and, after another week, to those from whom we had not received any feedback. Respondents were informed about the various aspects of the study, including their right to voluntarily participate in and withdraw from it.

An online questionnaire (see [Multimedia Appendix 1](#)) was used for data collection. In addition to demographic data, metric tools were used to assess perceived stress, satisfaction with online study, and feelings toward the study obligations.

The Slovenian translation of the Perceived Stress Scale (PSS-4; see [Multimedia Appendix 2](#)), a shortened version of PSS-10 and PSS-14, was used for the assessment of psychological stress [36-38]. The items in the instrument ask respondents to report on how they have coped with various situations over the past month. The instrument has 4 items, 2 of which (items STR2 and STR3) have a reverse score. The response format is 0=never; 1=almost never; 2=sometimes; 3=fairly often; and 4=very often, with higher totals indicating higher levels of stress (the scores range from 0 to 16). The perceived stress level was categorized as low versus high perceived stress based on a median split (<8 vs ≥8) in analogy with application of the PSS-10 instrument in the Slovenian sample [39].

The Satisfaction with Online Study Scale (SAT-5; see [Multimedia Appendix 3](#)), initially developed by Debevc et al [40] and adapted by Ploj-Vrtič et al [3], was used for assessment of satisfaction with online study. The scale is rooted in flow theory [41] and was applied in slightly different versions [3,42]. The measurement encompassed a 7-point Likert scale ranging from 1=strongly disagree to 7=strongly agree, with a total score ranging from 5 to 35 and higher scores indicating higher perceived satisfaction. The scale shows unidimensionality and Cronbach α values >.80 in all studies in which it was used.

The severity of several factors inducing negative feelings connected with the timeliness, performance, and quality of the study obligations were assessed using the Feelings Toward Study Obligations Scale (FETSOS; see [Multimedia Appendix 4](#)). The scale was designed for the purpose of this study. The authors consulted the outcomes of the study by Dolenc et al [4] and transferred some of their findings into statements (items) of the scale. The response format was 1=no impact; 2=very weak impact; 3=weak impact; 4=moderate impact; 5=strong impact; 6=very strong impact; and 7=absolute impact. The scale has 12 items. Because of their diversity, it was not expected to be unidimensional, which was later confirmed. Theoretically, the span of the scale is between 12 and 84, with higher numbers indicating more negative impacts. Three subscales can be identified: descriptors of working conditions, descriptors of pedagogy, and descriptors of well-being and health.

Quantitative measures of all subscales are provided in the Multimedia Appendices.

Ethics Approval

Ethical approval to conduct the study was obtained from the National Medical Ethics Committee of the Republic of Slovenia (NMEC), Ministry of Health (no. 0120-48/2021/3).

Statistical Analyses

We collected responses from 5999 full-time students. Due to the planned analyses, attrition, and random missing responses, the database was cleared and only data sets from those individuals who provided full responses for all the constructs were selected (4455/5999, 74.26%). We calculated the frequencies and measures of central tendencies for each item and the sums of items, when appropriate. Factor analysis was conducted to examine and validate the factor structure of the data matrix of the scales. In the factor analysis, the total sample (N=4455) was randomly divided into an exploratory factor analysis (EFA) sample (n=2235, 50.17%) and a confirmatory factor analysis (CFA) sample (n=2220, 49.83%). EFA was conducted to examine the underlying factor structure of the constructs in the EFA sample using principal axis factoring (PAF) analysis. Because correlations between components were expected, direct oblimin rotations were applied. Parallel analysis was used to determine the number of factors extracted from the EFA [43]. Cronbach α >.70 and unidimensionality of the construct were the entrance criteria to be included in CFA.

Two approaches were used for building the models. The first was based on correlations between the sums of the extracted constructs, where a path direction was not guessed. Spearman ρ was used for this. The second model was based on structural equation modeling (SEM) analysis [44,45], where hypothesized models were tested to fit the data. The maximum likelihood method was used, and analysis of the residual covariance matrix and inspection of the modification indices were applied to improve model fits. The whole data set (N=4455) was included in the final SEM analyses. We chose a selection of fit indexes, as proposed by Gaskin and Lim [46], and applied it using the IBM AMOS plugin proposed by Hu and Bentler [47]. The cut-off criteria recognized as acceptable are as follows: comparative fit index (CFI)>0.90, standardized

root-mean-square residual (SRMR)<0.08, and root-mean-square error of approximation (RMSEA)<0.06. CFA with maximum likelihood estimation [48] was used for model fitting with the application of IBM AMOS 27 and IBM SPSS Statistics 27 for EFA.

Research Model

The hypothesized research models were based on the following hypothesized paths:

- Hypothesis 1 (H1): Level of satisfaction with online study influences (correlates with) stress.
- H2: Feelings toward online study (working conditions, pedagogy, and well-being) influence (correlate with) satisfaction.
- H3: Feelings toward online study (working conditions, pedagogy, and well-being) influence (correlate with) stress.

It was assumed that satisfaction would work as a mediator between feelings toward online study (working conditions, pedagogy, and well-being) and stress (Figure 1).

Figure 1. Framework of the study.

Results

Characteristics of the Survey Respondents

The demographic characteristics of the students (Table 1) included in the study show there were more males (n=3234, 72.59%) than females included in the sample and more than

half of the students were single (n=2467, 55.38%). The majority were bachelor's degree students (n=2696, 60.52%). The most numerous study fields were health and medicine (n=886, 19.89%), science and mathematics (n=871, 19.55%), noneducational social studies (n=801, 17.98%), and humanities (n=707, 15.87%).

Latent Structure, Reliability, and Construct Validity of the Instruments

EFA of PSS-4 ($n=2235$, 50.17%) revealed that it is a unidimensional factor (latent variable), with Cronbach $\alpha=.80$. The explained variance was 50.3% (eigenvalue=2.496). Measures of the central tendencies of 2 positively (reversed) and 2 negatively worded items, as well of the results of PAF, can be seen in [Multimedia Appendix 2](#).

CFA ($n=2220$, 49.83%) was performed with 1- and 2-factor models. The difference is that in the 1-factor model, all 4 items load on a single factor, whereas in the 2-factor model, the positively loaded items load on the first factor and the negatively loaded items load on the second factor. A 1-factor solution, even if the 2-factor model shows a slightly better fit, was chosen to be included in the models used to predict the hypotheses. The reason was that we wished to include PSS-4 as a complete and valid instrument. The values of the FIT indexes with constrained STR2 and STR3 ($r=0.38$) were as follows: chi-square

(CMIN)=31.824, $df=1$, CMIN/ $df=31.824$, CFI=0.995, SRMR=0.013, and RMSEA=0.081.

According to EFA, SAT-5 is a unidimensional tool (Cronbach $\alpha=.88$), and the first factor (eigenvalue=3.399) explained 67.971% of the variance. The values of the FIT indexes for the SAT-5 were as follows: CMIN=36.181, $df=3$, CMIN/ $df=12.060$, CFI=0.995, SRMR=0.016, and RMSEA=0.071. Constrained pairs of error terms were between SAT2 and SAT5 ($r=-0.36$) and SAT3 and SAT4 ($r=-0.22$). Measures of central tendencies, communalities, and factor loadings of SAT-5 are presented in [Multimedia Appendix 3](#).

Analysis of the results obtained by FETSOS (Cronbach $\alpha=.88$) revealed a 2-factor structure, cumulatively explaining 56.30% of the variance. The first factor included all 12 listed items (eigenvalue=5.295, variance=44.126%, Cronbach $\alpha=.88$), while the second factor consisted of 2 items (equipment, and mobile and internet connections) negatively cross-loading to the first factor as well (eigenvalue=1.461, variance=12.173, Cronbach $\alpha=.90$; see [Multimedia Appendix 4](#)). The structure obtained did

not follow the theoretically predicted subscales (pedagogy, working conditions, and well-being; see [Multimedia Appendix 4](#)). Measures of central tendencies, communalities, and factor loadings of FETSOS are presented in [Multimedia Appendix 4](#).

Differences of Perceived Stress, Satisfaction With Online Study, and Feelings Toward Study Obligations Between Genders and Study Enrolment Levels

Analysis of perceived stress level categorized as low versus high perceived stress based on a median split (<8 vs ≥ 8 ; $N=4455$) revealed that the sample mean was 7.97 (SD 3.32) and that 1938 (43.50%) of the 4455 students belonged to the lower-stress group and more than half of them to the high-stress group. The upper quarter (≥ 13) contained 412 (9.25%) of the 4455 students.

The difference in the means of the reported levels of perceived stress ([Table 2](#)) between genders were statistically significant, with the highest for those who reported a nonbinary gender, followed by females, both above the median split. Males were

below the median split. The effect size between males and females could be regarded as a small effect.

When comparing students from the 2 educational levels ([Table 3](#)), it appeared that those studying for a bachelor's degree experienced a higher level of stress than those studying for a master's degree or a doctorate. The effect size between both levels, calculated as Cohen d , could be regarded as a small effect.

Regarding satisfaction with online study, an examination of the measures of central tendencies (see [Multimedia Appendix 3](#)) revealed that most of the students thought that their online experiences were comprehensible, successful, and instructive but not easy or entertaining.

The difference between genders based on the means of the responses to SAT-5 was not statistically significant ($N=4454$, $F_2=0.18$, $P=.98$). Therefore, the results are not reported in the table.

Table 2. Differences between genders for PSS-4^a and FETSOS^b scores ($N=4454$).

^aPSS-4: Perceived Stress Scale.

^bSAT-5: Satisfaction with Online Study Scale.

^cFETSOS: Feelings Towards Study Obligations Scale.

When comparing students from the 2 educational levels, it appeared that those from the bachelor's level were less satisfied than students from the master's or doctoral levels ([Table 3](#)). The effect size between both levels was negligible, which can, in practice, be regarded as the absence of an effect. Furthermore, regarding feelings toward the study obligations, according to the opinions of the students (see [Multimedia Appendix 4](#)), the top 3 items that negatively influenced their feelings connected with the timeliness, performance, and quality of the study obligations are (1) a decline in the motivation to study, (2) quality of internet and mobile connections, and (3) the presence of distractions in the study space (eg, other people). In contrast,

the 3 items with the least negative impact were (1) the need to earn an income, (2) health problems directly related to distance learning, and (3) health problems not directly related to distance learning.

The difference between genders based on the means of the responses were statistically significant, with the highest for those who reported a nonbinary gender, followed by females and males ([Table 2](#)). From the SD values, a huge variation in the responses could be observed. The effect size between males and females, calculated as Cohen d , could be regarded as a small effect.

When comparing students from 2 educational levels, it appeared that those from the bachelor's level reported overall higher negative feelings than students from the master's or doctoral levels (Table 3). The effect size between both levels, calculated as Cohen d , could be regarded as a small effect.

Strength and Direction of Paths Between Latent Variables

Correlation analysis between sums of scales (Table 4) showed that negative feelings toward online study (FETSOS) moderately and negatively correlated with (SAT-5) and moderately correlated with stress (PSS-4).

Furthermore, the results of SEM analysis with SAT as a moderator variable (Figure 2) revealed that 18% of the variance of SAT-5 could be explained by FETSOS and 17% of the variance of stress as the main outcome variable could be explained by the joint influence of FETSOS and SAT-5. The

values explaining model fits were CFI=1, SRMR=0, and RMSEA=0.359, which led us to build alternative models.

The hypothetical model followed all 3 proposed hypotheses, and all variables were included without constraints (Figure 3). It was found that the model fit measures were outside the acceptable levels (CMIN=10380.95, df =186, CMIN/ df =55.812, CFI=0.779, SRMR=0.097, and RMSEA=0.111). We therefore started procedures to improve the model fit. Because we did not want to delete items, as proposed by an examination of the standardized residual covariances in order to preserve the established scales, we applied constraint of error variances. We ended the procedure when acceptable fits were achieved (CMIN=4068.80, df =179, CMIN/ df =22.731, CFI=0.916, SRMR=0.076, and RMSEA=0.070).

The values of the regression coefficients followed the same pattern as the correlational and SEM analysis of sums, but all the values were somewhat higher. We could explain 25% of the stress using the proposed model.

Discussion

Principal Findings

The long-lasting COVID-19 pandemic, with its numerous accompanying preventive measures, imposed a variety of challenges affecting the mental health of the population, with young and emerging adults, which coincides with the beginning of postsecondary education, being more significantly affected [49]. This group already faces a number of stress-related and mental health difficulties due to the characteristics of this transitional period of life, such as instability owing to changes in education, living arrangements, and relationships. COVID-19-related challenges might additionally impact the latter [49,50]. The aim of this study was therefore to examine the levels of stress of Slovenian postsecondary students during the forced online distance learning occasioned by COVID-19 lockdowns and to identify the factors influencing it.

In response to the pandemic, many countries replaced face-to-face education with distance education. This could potentially result in negative social, psychological, and academic consequences for postsecondary students [51]. The results of this study indicate that more than half of the students reported higher levels of stress, with students studying for bachelor's degrees reporting higher levels than those studying for a master's degree or a doctorate. This is in line with previous research, which showed higher levels of stress among students engaged in distance education [5,6,17-20,22,23,52-54]. Stress levels also differed significantly between gender groups, with females reporting higher levels of perceived stress than males. This could be attributed to the greater vulnerability of women to the

development of mental health problems in general [55,56], as well during the COVID-19 pandemic [18,20,49,51,57].

Although the students who participated in our study reported the online study experience as being comprehensible, successful, and instructive, the overall satisfaction with online study was the lowest among bachelor's degree students, with no significant differences between the gender groups. Overall, the results show 3 main factors to be related to students' negative emotions associated with the timeliness, performance, and quality of the study obligations: a decline in the motivation to study, the quality of internet and mobile connections, and the presence of distractors in the study space (eg, other people). Once again, bachelor's degree students reported higher levels of negative emotions associated with the aforementioned factors compared to other student groups. These findings are in line with previous reports, which show COVID-19 to have had a negative impact on the academic experiences of postsecondary students [49,58,59], with distance education resulting in higher levels of stress and isolation; a negative mood; and lower levels of relatedness, concentration, focus, motivation, and performance compared to face-to-face education [58].

All 3 initial hypotheses were tested and supported. We were able to explain 25% of stress measured by PSS-4 with the SEM full model and 17% by use of the sums of the responses. The results from correlational and regression analyses showed that the level of satisfaction with online study influences stress (H1) in such a way that the higher the satisfaction, the lower the stress (Spearman $\rho = -.361$, path coefficient $= -.25$). These results are in line with Lee and Jang's findings [60], indicating a negative correlation between students' overall stress and satisfaction

scores with their study life, although their research was not specifically focused on online study.

The second hypothesis, that feelings toward online study (working conditions, pedagogy, and well-being) influence satisfaction, was also confirmed. The results (Spearman $\rho = -.390$, path coefficient = .32) suggest that more positive feelings connected with the timeliness, performance, and quality of the study obligations result in more positive satisfaction with online study and thus indirectly in lower levels of stress. These results were expected as they have been produced by previous, as well pre-COVID-19 studies [51,52].

The third hypothesis, that feelings toward online study (working conditions, pedagogy, and well-being) influence stress, was also confirmed. The results (Spearman $\rho = -.316$, path coefficient = .32) suggest that higher scores or less negative feelings connected with the timeliness, performance, and quality of the study obligations reduce stress. Similar results were found in a qualitative study conducted among university students during the COVID-19 lockdown, which showed that the quality of internet connections and the study environment were among the main sources of students' stress [61].

The results clearly show that more positive satisfaction with online study and more positive feelings toward study obligations during COVID-19 lockdowns are moderate predictors of stress. FETSOS is a negative predictor of SAT-5, meaning that positive feelings (opinions) toward the study obligations result in higher satisfaction and that lower satisfaction and more intense negative feelings toward the study obligations are predictors of higher stress. Academic struggles may therefore increase already elevated distress among the postsecondary population [62]. Based on the findings of this study, the levels of perceived stress are higher in female and bachelor's degree students. However, differences in the terms of effect sizes are small. The differences in FETSOS and SAT-5 in both categories are almost nonexistent in terms of effect size.

The results of this study show higher levels of perceived stress among Slovenian postsecondary students during the COVID-19 pandemic, although the fact that the survey was conducted during the exam period might also have influenced the stress levels. Moreover, an upward trend in feelings of stress was also reported before the pandemic. Data from the international research study "Mladina 2018–2019" [63] show a high increase in the share of Slovenian young people aged 14–29 years who reported, over a 5-year interval, feeling stressed most of the days of the week. Similarly, data from a national study titled "Health-Related Behavioural Style of Slovenian Residents" [64] show that approximately a quarter (23.2%) of Slovenian people aged between 25 and 74 years reported regular or daily feelings of stress, with stress more commonly reported by women and younger individuals (28.3% of those aged between 25 and 34 years). To obtain a better insight into the trend in perceived stress in postpandemic times, a longitudinal study that also includes other potential impact factors would be desirable.

Prolonged, recurrent stress and poor stress management are among the key factors in the deterioration of an individual's health, as they increase the risk of many diseases and disorders.

Conversely, reducing stressors and strengthening an individual's resilience to stress make an important contribution to maintaining and improving mental health. From the findings of this study, we can therefore recommend that implementing structures and measures targeted at stress reduction, such as the establishment of psychological support, is crucial, especially in cases where stress levels call for mental health treatment. However, any measures should target working conditions and pedagogy as well, which calls for the elimination of or at least a reduction in the obstacles identified by FETSOS. It is outside the scope of this paper to suggest practical measures to postsecondary educational institutions, but those related to pedagogy are completely within its domain. At the top of the scale is motivation. This should therefore be raised (or at least not decreased) by all means possible at institutional and individual levels, showing students that the future is not dark and without hope. There is also no excuse not to make expectations about outcomes clear, and to increase access to necessary resources, at least in digital format. Organizing an e-library, for example, should not present a big problem. Problems with internet connections and adequacy of the workspace are factors that were induced by the lockdown and confinement to the home environment. Stress would also be reduced by keeping campuses and dormitories open, and by providing an online structure and ensuring that libraries are close by. However, it can be reasonably expected that due to the higher virulence (even with lower severity) of the new strains of coronavirus [65], or even the possible emergence of new zoonotic viruses [66], the experience gained over the past two years should be incorporated into efforts to minimize the negative impacts of internet-based education.

Limitations

The main limitation of the study was the self-selection of the respondents. Even if a high number of respondents were included in the data set, they are representative of a population who responded to all of the items. It is therefore impossible to make inferences about the population of individuals who did not respond to the study. Furthermore, the fact that the study featured a preponderance of male respondents could have influenced the results, as certain mental health problems may be more frequent among female students. Although other mental health problems (anxiety, depression, etc) and other variables that interact with or influence stress are important, they were not included in any recent study and we did not report them in this paper. The missing links remain to be explored.

Directions for Future Research

We suggest that the survey be repeated after the lockdowns have ended to find out whether there are differences in levels of stress and the factors impacting it. Additionally, an international comparative study would shed light on the differences that are based on various sociocultural factors.

Conclusion

In conclusion, the side effects caused by FODE [3], as well as the ad hoc educational practices resulting from the pandemic [3], resulted in higher stress, which is known as 1 of the main causes of mental health problems, such as anxiety and

depression. We can only hope that these effects are just people with mental health problems well into the future. transitional. If they are not, society will see a higher number of

Abstract

Background: The COVID-19 pandemic and its associated lockdown measures impacted mental health worldwide. However, the temporal dynamics of causal factors that modulate mental health during lockdown are not well understood.

Objective: We aimed to understand how a COVID-19 lockdown changes the temporal dynamics of loneliness and other factors affecting mental health. This is the first study that compares network characteristics between lockdown stages to prioritize mental health intervention targets.

Methods: We combined ecological momentary assessments with wrist-worn motion tracking to investigate the mechanism and changes in network centrality of symptoms and behaviors before and during lockdown. A total of 258 participants who reported at least mild loneliness and distress were assessed 8 times a day for 7 consecutive days over a 213-day period from August 8, 2020, through March 9, 2021, in Germany, covering a “no-lockdown” and a “lockdown” stage. COVID-19–related worry, information-seeking, perceived restriction, and loneliness were assessed by digital visual analog scales ranging from 0 to 100. Social activity was assessed on a 7-point Likert scale, while physical activity was recorded from wrist-worn actigraphy devices.

Results: We built a multilevel vector autoregressive model to estimate dynamic networks. To compare network characteristics between a no-lockdown stage and a lockdown stage, we performed permutation tests. During lockdown, loneliness had the highest impact within the network, as indicated by its centrality index (ie, an index to identify variables that have a strong influence on the other variables). Moreover, during lockdown, the centrality of loneliness significantly increased. Physical activity contributed to a decrease in loneliness amid the lockdown stage.

Conclusions: The COVID-19 lockdown increased the central role of loneliness in triggering stress-related behaviors and cognition. Our study indicates that loneliness should be prioritized in mental health interventions during lockdown. Moreover, physical activity can serve as a buffer for loneliness amid social restrictions.

Introduction

The outbreak of COVID-19 is an unprecedented global health challenge; as of November 2021, there are 259,502,031 confirmed cases and 5,183,003 deaths globally [1]. To mitigate the spread of SARS-CoV-2, most countries enforced lockdown measures, including social restrictions, travel bans, stay-at-home orders, and business shutdown. Together with the pandemic per se, these lockdown measures increased global mental health problems [2,3]. Reasons for this are an increase of distress or loneliness during the COVID-19 lockdown [4-7], yet most studies are overlooking the directionality between behavior and cognition over time. Recently, a network approach to psychopathology proposed that changes in mental health result from a temporal dynamic interaction between mental states, such that one mental state at one moment in time (eg, worry) can trigger other mental states at the next moment in time (eg, feeling stressed) [8]. We set out to examine whether lockdown measures can alter the dynamic network structure of behavior (eg, physical activity) and pandemic-related mental states (eg, worry). To do so, we compared differences between moment-to-moment time-lagged associations of pandemic-related cognitions, behaviors, and mental health, and tested for changes in centrality between lockdown stages. Comparing centrality (ie, an index to identify variables that have a strong influence on the other variables) can be informative in finding the most protective or detrimental temporal influence on mental health amid a lockdown [9,10]. This knowledge can be transferred to prioritize targets for pandemic-related mental health care interventions.

Psychological distress and social isolation are risk factors for developing mental disorders [11-15]. Therefore, we focused on a subpopulation who were experiencing at least mild levels of psychological distress and loneliness amid the COVID-19 pandemic. Moreover, we gathered real-life data using ecological momentary assessments (EMAs) via smartphone technology and measured objective physical activity via wrist-worn actigraphy devices. We investigated the temporal associations between loneliness, stress, physical and social activity, and COVID-19-related behaviors and cognitions.

We measured three COVID-19-related cognitions: perceived restriction in everyday life due to the pandemic, seeking information about the pandemic, and worrying about the pandemic's impact on one's life. Worries about the COVID-19-related economic downfall and the possible health impact on oneself or others can increase psychological distress [7,16]. In addition, distress, anxiety, depression, and anger are further increased by physical and social distancing measures [17,18]. People who stayed at home often acquired more COVID-19-related information through digital media, which increased anxiety and psychological distress [19-22]. Thus, COVID-19-related worrying, perceptions of restrictions, and information-seeking can be central causes of mental health issues.

Prior to the COVID-19 pandemic, loneliness was already recognized as one of the most pressing issues in modern societies [23]. Loneliness is an aversive state resulting from a

discrepancy between an individual's desired and realized social relationships [24]. Limiting social contacts and closing off social spaces can help to halt the spread of COVID-19; however, they also increase feelings of loneliness [7,25]. Loneliness has serious consequences for health, including increasing the risk of cardiovascular disease and immune dysfunction, depression, anxiety, and suicidal ideation [26]. To buffer against feelings of loneliness during lockdown, it can be essential to receive social support and engage in digital social activities [27,28].

A second buffer against mental health problems during the pandemic might be physical activity. Physical activity can relieve stress [29]; enhance cognitive abilities [30]; and reduce the risk of diabetes [31], cardiovascular disease [32], cancer [33], and mental disorders [34,35]. Conversely, sedentary behavior, defined as low-energy-expenditure behavior (≤ 1.5 metabolic equivalents), increases the risk for negative health outcomes, including type 2 diabetes mellitus, cardiovascular disease, and all-cause mortality [36-38]. Physical activity can lead to physiological reactions associated with decreased depression, such as an increase in neuroplasticity, cerebral blood flow, delivery of neurotrophic factors and oxygen, and resistance to oxidative stress [39]. Finally, exercise can improve self-efficacy and self-esteem [40]. We assessed physical activity through actigraphy (ie, a wrist-worn device that obtains objective measures of physical activity) [41].

Our study was performed in Germany during a no-lockdown stage (August 8 to November 1, 2020) and a lockdown stage (November 2, 2020, to March 9, 2021). During the no-lockdown stage, the restrictions were lenient (eg, no private or public meeting restrictions, and leisure facilities, bars, and catering facilities were open). To counter the steep increase in active COVID-19 cases, the German government announced a lockdown on November 2, 2020, including social restrictions, travel bans, closing of restaurants and cinemas, and business shutdowns. In addition, these lockdown measures were further tightened on December 16 (eg, closing of most retail; see Supplement A in [Multimedia Appendix 1](#)).

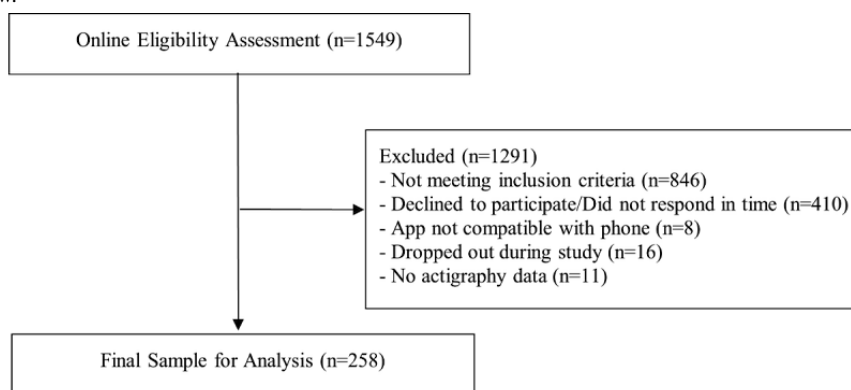

The aim of this study was to examine the temporal dynamic interplay between COVID-19 pandemic-related cognitions, behaviors, and mental health states. This is the first study to use a dynamic network approach to compare moment-to-moment time-lagged associations between pandemic-related cognitions, behaviors, and mental health states between lockdown stages. Moreover, we examined whether the lockdown affects the centrality of loneliness and specific pandemic-related behaviors and cognitions (ie, a more central variable has more and stronger connections to other variables). This helps to identify the most protective or detrimental influences on mental health during a lockdown. This knowledge, in turn, can be used to prioritize mental health intervention targets. Specifically, we hypothesized that a lockdown, in comparison to a no-lockdown period, increases the centrality of stress, physical activity, social contacts, and loneliness. Finally, we hypothesized that stress and loneliness will have a stronger influence on COVID-19-related behaviors and cognitions during lockdown than during no-lockdown.

Methods

Participants and Sampling

We assessed 1549 participants for eligibility in an online questionnaire. The final sample size was 258 (see Figure 1 for the recruitment flow). On average, participants missed 17.5%

Figure 1. Recruitment flow.

Inclusion criteria were (1) a minimum age of 18 years, (2) not working a night shift, (3) not being infected by COVID-19, (4) using an Android smartphone, and (5) speaking fluent German. Moreover, we targeted individuals who reported (6) perceived mild to moderate psychological distress and (7) sometimes felt lonely during the COVID-19 pandemic. We used the COVID-19 Peritraumatic Distress Index (CPDI [43]; cut-off score=28, indicating mild distress) questionnaire and the short-form of the University of California Los Angeles Loneliness Scale (ULS-8 [44]; cut-off score=16, indicating mild loneliness), respectively. The CPDI was designed for evaluating changes in mental health status, cognitive skills, avoidance and compulsive behavior, physical symptoms, and loss of social functioning due to the COVID-19 pandemic. The questionnaire has been previously validated in Germany [43].

Study Design and Procedure

The study was conducted in Germany over a 213-day period between August 8, 2020, and March 9, 2021, covering a no-lockdown and a lockdown stage. Participants were recruited via online advertisements on university websites, Twitter, and eBay classifieds. Participants had to fill in an online screening questionnaire on the Siuvo Intelligent Psychological Assessment Platform. After an initial contact via phone or email, we sent participants our study information, accelerometer, informed consent, and a QR code (to install a smartphone app) by mail. After they completed the study, participants sent back the study material by mail.

We conducted the EMA via the smartphone app “movisensXS” (movisens GmbH, Karlsruhe, Germany) developed for research purposes. This app is compliant with the General Data Protection Regulation (European Union) and Berlin Data Protection Act (Berliner Datenschutzgesetz). The app consists of a sociodemographic assessment (eg, age, gender, and years of education) and measures participants’ current experiences in real time. Participants filled in questionnaires for 7 consecutive days, in which they received 8 prompts (randomized within 1 hour and 45-minute blocks between 8 AM and 10 PM). We

of the questionnaires, no participants missed more than 50% of the sent questionnaires, and 117 data points were marked by the GGIR package [42] as “nonwear” and subsequently excluded from the analyses. Specifically, the accelerometer nonwear score was estimated based on the standard deviation and range of the raw data from each accelerometer axis [42].

performed an EMA that involves repeated sampling of individuals’ current behaviors and experiences in real time and in their natural environments. EMA minimizes recall bias, maximizes ecological validity, and allows approximating temporal causality (ie, Granger causality) [45]. A time series X is said to Granger-cause Y if it can be shown, usually through a series of t tests and F tests on lagged values of X (and with lagged values of Y also included), that the X values provide statistically significant information about future values of Y [46].

Moreover, we measured physical activity via the “GENEActiv” Original (Activinsights) monitor (dynamic range ± 8 g, sampling frequency range 10-100 Hz). Participants wore the actigraphy device on the left wrist.

Ethical Considerations

The study was approved by the ethics committee at Charité–Universitätsmedizin Berlin (reference EA2/143/20) and Freie Universität Berlin (reference 030/2020).

Measures

EMA Items

Stress was measured with the following question: “In this moment I feel stressed.” Other items started with “During the last hour...” followed by “to which extent did you feel constrained by the pandemic in your everyday life?” (perceived restriction), “to which extent did you worry about how the pandemic affects your personal situation?” (worry), “to which extent did you seek information about the Corona pandemic?” (information-seeking), and “to which extent did you feel lonely” (loneliness). Each of these items was measured on a visual analog scale (0-100: 0=not at all, 100=most frequent or severe). Duration of social activity was measured with the question “How long did your last social contact last?” via a Likert scale ranging from 1=“0 minutes” to 7=“50-60 minutes.”

Actigraphy Data

Physical activity data were collected using the actigraphy devices worn by each participant on the left wrist.

Statistical Analysis

Overview

All analyses were performed using R statistical software (version 3.5.3). In this section, we describe the data preparation procedures, averaged values of our measured items, estimation of the dynamic networks, and the permutation procedure used to test for group differences in centrality indices and dynamic association.

Data Preparation

We calculated the Euclidean norm (vector magnitude) of the raw signals of the three-measurement axis, which is a summary score of body acceleration and a validated measure for physical activity [47]. The Euclidean norm minus one (ENMO) is defined as $r_i - 1000$ [48], where

The actigraphy data from GENEActiv (100 Hz; .bin files) were downloaded using GENEActiv PC software V3.3. The GENEActiv .bin files were then exported into R statistical software V4.0.3 for processing using the GGIR package V1.2-0. We autocalibrated the raw triaxial accelerometer signals and computed the average ENMO metric for 1 hour before each beep. To exclude time frames in which participants did not wear their actigraphy device, we used the nonwear score of the GGIR package. We excluded time frames above the cut-off score of 1. As the EMA items were nonnormally distributed, we transformed all variables using the nonparanormal transformation [49]. To test for nonstationarity, we calculated a two-level autoregressive model for each lockdown group, in which each score of the variable included in our model was regressed on the immediately preceding score of that variable (ie, moment-to-moment inertia). A moment-to-moment inertia value larger than 1 indicates a nonstationary process [50]. We assumed stationarity, as the average moment-to-moment inertia ranged between 0.13 and 0.37 for all 7 included variables for

each lockdown group (see Supplement B in [Multimedia Appendix 1](#)). In addition, a Kwiatkowski-Phillips-Schmidt-Shin (KPSS) test was performed separately for every subject and variable. The KPSS test indicated that the data were stationary (approximately 99.9%). The R code of the statistical analyses is available online [51].

Dynamic Network Estimation

We built a first-order vector autoregressive model (VAR) with the R package mlVAR. Each variable at time point t was predicted by all variables (including itself) at the next time point of measurement (lag 1). The results of the network models consisted of nodes (variables) and directed edges (statistical relations) that were visualized via the R package qgraph [52]

Permutation Testing of Centrality Indices and Edge Differences

Permutation tests were used to compare individual path and network centrality between the lockdown and no-lockdown stages. The permutation procedure was developed by Wolfgang Viechtbauer and compares the results of the observed data with a distribution derived from repeated permutation (100,000) of the data under the null hypothesis [53-55]. To assess the importance of specific variables in the network of two groups, in-strength and out-strength were calculated from all (including nonsignificant) edges in the network. In-strength reflects the sum of ingoing edge weights, whereas out-strength reflects the sum of outgoing edge weights to the specific node [56,57]. A detailed description of the permutation procedures can be found in Supplement C in [Multimedia Appendix 1](#).

Results

Sociodemographics

Sociodemographic characteristics of the final sample ($N=258$), as well as results of independent t tests or χ^2 tests comparing these characteristics between a no-lockdown and lockdown stage are shown in [Table 1](#). As we had more women in our lockdown group, we tested the effect of gender on all measured variables. We found that, except for social duration, gender did not significantly affect our variables (see Supplement G in [Multimedia Appendix 1](#)).

Table 1. Sociodemographic characteristics of participants.

Characteristic	Total (August 8, 2020, to March 9, 2021; N=258)	No-lockdown period (August 8 to November 1, 2020; n=131)	Lockdown period (November 2 to March 9, 2021; n=127)	<i>P</i> value ^a
Age (years), mean (SD)	30.78 (11.16)	31.18 (10.52)	30.16 (11.67)	.55
Education (years), mean (SD)	15.28 (3.69)	15.1 (3.69)	15.46 (3.69)	.44
Gender, n (%)				.008
Male	77 (29.8)	49 (37.4)	28 (22.0)

^aBased on independent *t* test or χ^2 test; unequal variance was assumed, and we applied the Welch approximation to the degrees of freedom.

^bCPDI: COVID-19 Peritraumatic Distress Index.

^cULS-8: University of California Los Angeles Loneliness Scale.

Average-Based Lockdown Differences

To compare the no-lockdown and lockdown stages, we performed independent *t* tests using overall averages for each person. As shown in Table 2, the lockdown significantly

increased COVID-19 worries, perceived restriction, and duration of social contacts. Moreover, the lockdown significantly decreased physical activity. There was no statistically significant influence of lockdown on information-seeking, stress, and loneliness.

Table 2. Differences between no-lockdown and lockdown stages.

Variables	No-lockdown period (n=131), mean (SD)	Lockdown period (n=127), mean (SD)	<i>P</i> value ^a
EMAb items			
Loneliness	22.62 (20.82)	21.45 (19.80)	.64
COVID-19 worries	24.59 (18.36)	29.12 (17.33)	.04
COVID-19 perceived restriction	23.86 (17.83)	28.16 (17.05)	.05
COVID-19 information-seeking	22.85 (15.57)	23.46 (13.94)	.74
Social contacts	2.64 (0.95)	3.05 (1.00)	<.001

Physical activity from actigraphy (microgravity)	40.15 (13.37)	35.24 (11.42)	.002

^a*t* test; unequal variance was assumed and we applied the Welch approximation to the degrees of freedom.

^bEMA: ecological momentary assessment.

Network Estimation

We wanted to investigate how a lockdown affects the temporal dynamics of pandemic-related cognitions, behaviors, and mental

health states. To do so, we first estimated the temporal (ie, time-lagged) and bidirectional associations between detrimental and beneficial factors via multilevel VAR models [58-60]. These VAR models were then used to estimate temporal dynamic

Figure 2 displays the “full” dynamic symptom networks for the lockdown and no-lockdown groups, which include only statistically significant *edges* (ie, time-lagged partial correlations with $\alpha < .05$). Permutation tests revealed that 7 of the edges were significantly different between the no-lockdown and lockdown groups at the uncorrected α level (indicated with an asterisk in Figure 2).

More information on the time-lagged partial correlations (ie, edges) that were significantly different during the lockdown can be found in [Table 3](#) (all, including nonsignificant, edge differences are shown in Supplement F of [Multimedia Appendix 1](#)).

Predictor (1-lag)	Outcome	Partial correlation coefficient		Difference in partial correlation coefficient	P value
		No-Lockdown	Lockdown		
Information-seeking	Perceived restriction	0.0548	−0.0062	0.0609	.02
Loneliness	Perceived restriction	0.001	0.115	−0.114	<.001
Information-seeking	COVID-19-related worry	0.0689	0.0212	0.0477	.05
Loneliness	COVID-19-related worry	0.0274	0.1042	−0.0767	.03
Information-seeking	Information-seeking	0.1721	0.0967	0.0754	.02
COVID-19-related worry	Loneliness	−0.0129	0.0315	−0.0444	.05
Perceived restriction	Social activity	0.0043	−0.0021	0.0065	.01

Centrality Indices

In-strength is the sum of *incoming* edge weights to a specific node and *out-strength* is the sum of the *outgoing* edge weights to a specific node. During the no-lockdown stage, worrying about COVID-19 had the highest out-strength, indicating that when a participant reports worries about COVID-19 at one measurement occasion, it is likely that this participant will report other COVID-19–related behaviors and cognitions at the next measurement occasion. During lockdown, loneliness had the highest out-strength, indicating that when a participant reports feeling lonely in one moment, this participant is likely to report

COVID-19–related behaviors and cognitions in the next momentary assessment.

Permutation tests revealed a significant higher out-strength for “loneliness” during lockdown (difference -0.1975 , $P=.04$) and significant lower out-strength for “information-seeking” (difference 0.1452 , $P=.03$) at the uncorrected α level (as indicated by asterisks in Figure 3). More information on centrality indices that were significantly different can be found in Table 4 (all, including nonsignificant, differences between centrality indices can be found in Supplement E of Multimedia Appendix 1).

Figure 3. The standardized centrality indices out-strength and in-strength among ecological momentary assessment and physical activity data within the networks of the no-lockdown and lockdown stages. The statistically significant indices (permutation tests using a two-sided P value at the uncorrected α level) are marked with asterisks.

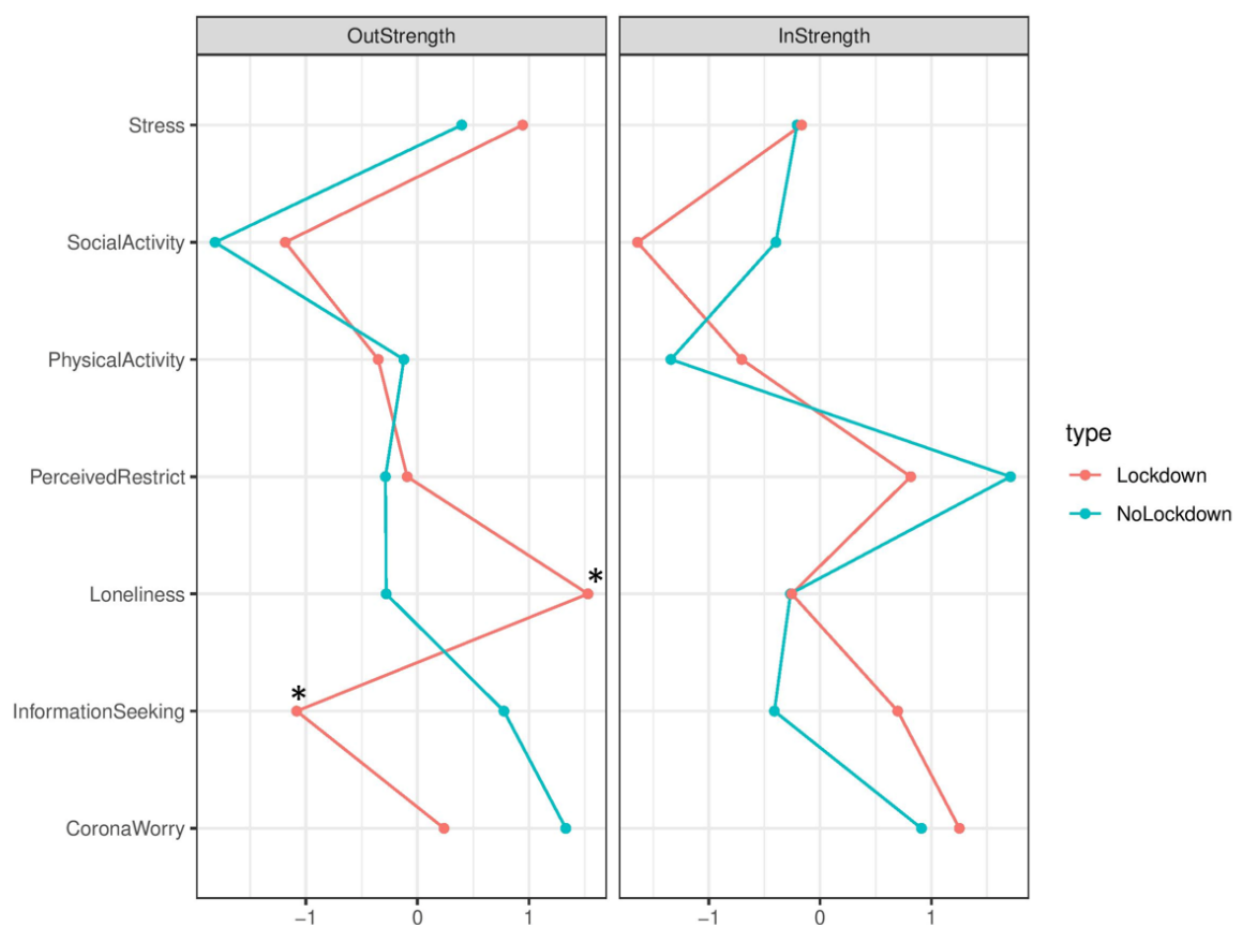

Table 4. Significant differences in variable out-strength between lockdown and no-lockdown stages.

Variable	Out-strength		Difference	P value
	No-lockdown	Lockdown		
Information-seeking	0.3129	0.1677	0.1452	.03
Loneliness	0.4109	0.6084	−0.1975	.04

Discussion

Principal Findings

The COVID-19 pandemic increased mental health problems worldwide [2,61]. Our study sheds light on the mechanisms

with which a lockdown affects mental health during the COVID-19 pandemic. Compared to no-lockdown, during lockdown, loneliness had a stronger impact on pandemic-related cognitions and behaviors such as perceived restrictions and worries about the pandemic. In turn, pandemic-related cognitions

and behaviors reinforced each other and increased stress across lockdown stages. Finally, we found engaging in daily physical activity to be an effective strategy against feelings of loneliness during lockdown. In sum, our results suggest that when strict lockdown measures are in place, loneliness is the central trigger of stress-related behaviors and cognitions. Thus, loneliness should be prioritized in mental health interventions in the context of pandemic-related psychological distress.

Loneliness is a distressing emotional state in which one experiences a discrepancy between the desired and perceived quantity and quality of social relations [62]. Previous studies showed that lonely individuals exhibit a negative information bias such as increased attention for social threatening stimuli, negative and hostile intent attributions, expectation of rejection, and rumination [63]. We found that during lockdown, feelings of loneliness had the highest out-strength, indicating that loneliness is the central trigger of stress-related behaviors and cognitions. Compared to a no-lockdown, a lockdown increased the out-strength of loneliness, which indicates that loneliness has a more central role in affecting stress-related cognitions and behaviors during lockdown. Moreover, during lockdown, the influence of loneliness on perceptions of restriction and COVID-19-related worry increased. Thus, a lockdown changes the way loneliness interacts with pandemic-related behaviors and cognitions.

COVID-19-related-worries, feelings of restriction, and information-seeking were mutually reinforcing over time in both the no-lockdown and lockdown stages, resulting in a vicious stress-inducing cycle from which it can be increasingly difficult to escape. Information-seeking had less out-strength during lockdown compared to the no-lockdown stage, which indicates that COVID-19-related information-seeking has a more central role during a no-lockdown period. During lockdown, information-seeking at one moment led to less information-seeking at the next moment (ie, weaker autocorrelation), and its influence on perceived restrictions and COVID-19-related worry decreased. These findings contrast earlier reports concluding a more significant influence of information-seeking during lockdown, based on findings of increased averaged information-seeking [19,21]. Moreover, during the no-lockdown stage, “feeling restricted” increased information-seeking, whereas during lockdown, “feeling restricted” decreased information-seeking. This suggests that during a no-lockdown stage, people are in a type of information-approach state, whereas during lockdown, people are more likely to be in an information-avoidance state. Therefore, the best moment to communicate COVID-19-relevant information such as safety behaviors might be an early pandemic stage when no lockdown measures are in place.

Physical activity increased social activity in both the no-lockdown and lockdown stages. This association might result from public health recommendations that suggest meeting people only outside enclosed spaces. During COVID-19, people might have combined physical and social activity (ie, they found a companion to go for a walk or hike outside). Physical activity can also help to form interpersonal relationships (eg, attending a virtual group fitness class). Moreover, physical activity

decreased feelings of loneliness during lockdown. A possible reason is that physical activity can mediate contextual influences on loneliness (eg, being in nature and physically active rather than sitting at home and leading a sedentary lifestyle) [64]. Meeting more people did not decrease feelings of loneliness in either of the lockdown stages. A potential explanation is that feelings of loneliness are not caused by the number of social contacts but rather the perception that current relationships do not match desired relationships (eg, the other person being attentive to one's needs) [65]. Finally, physical activity and social activity were associated with decreased stress only during the lockdown stage, indicating that during lockdown, these stress-buffering behaviors become effective.

Perspectives on Mental Health Interventions

We found that loneliness has the highest temporal effect on all measured moment-to-moment pandemic-related cognition and behaviors during lockdown. This, in turn, suggests that loneliness can be a central trigger of stress-related behaviors and cognitions. Our study suggests that mental health interventions during the pandemic lockdown should prioritize the feeling of loneliness rather than pandemic-related rumination, feelings of restriction, or information-seeking. This could be achieved by a digital mental health approach (eg, online therapy or smartphone-based interventions) that fosters a sense of belonging and community [66-70]. To our knowledge, this is the first study to use a temporal network model comparison approach to identify and refine mental health intervention targets. This approach might be valuable to identify possible temporal causal trigger variables for negative cognitions and behaviors in other types of mental health interventions as well.

Limitations

This was a natural experiment with high ecological validity but low control for extraneous variables, including seasonal effects [71]. Moreover, we cannot exclude the possibility that the observed interactions are influenced by other unmeasured underlying factors [72]. In addition, we have independent samples for comparisons of lockdown and no-lockdown stages. Thus, we cannot exclude the possibility that differences in sample characteristics may have influenced the results. However, except for the loneliness score and gender distribution, the samples did not differ in any of the measured variables. We assume that the slightly higher loneliness measure (ULS-8) in the lockdown sample was due to the lockdown. However, it cannot be ruled out that we recruited participants who were generally lonelier in the lockdown sample by chance. Gender did not have an influence on any of the measured variables, except for time spent on social activities. Here, women reported higher values than men or diverse genders. Taken together, it is unlikely that there is a major bias in our central findings due to differences in sample characteristics.

Conclusion

To develop effective pandemic mental health interventions, it is crucial to understand the temporal dynamics of mental health factors during a COVID-19 lockdown. In comparison to a no-lockdown stage, a lockdown increased the central role of loneliness in triggering pandemic-related behaviors and

cognition. In turn, pandemic-related cognitions and behaviors such as perceived restrictions and worries about the pandemic reinforced each other and increased stress. In addition, we found that physical activity can be an effective buffer against stress

and loneliness during lockdown. Our results suggest that loneliness can be the central trigger for stress-related behaviors and cognitions during lockdown and therefore should be prioritized in mental health interventions.

Abstract

Background: Although timely and accurate information during the COVID-19 pandemic is essential for containing the disease and reducing mental distress, an infodemic, which refers to an overabundance of information, may trigger unpleasant emotions and reduce compliance. Prior research has shown the negative consequences of an infodemic during the pandemic; however, we know less about which subpopulations are more exposed to the infodemic and are more vulnerable to the adverse psychological and behavioral effects.

Objective: This study aimed to examine how sociodemographic factors and information-seeking behaviors affect the perceived information overload during the COVID-19 pandemic. We also investigated the effect of perceived information overload on psychological distress and protective behavior and analyzed the socioeconomic differences in the effects.

Methods: The data for this study were obtained from a cross-national survey of residents in 6 jurisdictions in Asia in May 2020. The survey targeted residents aged 18 years or older. A probability-based quota sampling strategy was adopted to ensure that the selected samples matched the population's geographical and demographic characteristics released by the latest available census in each jurisdiction. The final sample included 10,063 respondents. Information overload about COVID-19 was measured by asking the respondents to what extent they feel overwhelmed by news related to COVID-19. The measure of psychological distress was adapted from the Posttraumatic Stress Disorder Checklist for Diagnostic and Statistical Manual of Mental Disorders 5 (DSM-5). Protective behaviors included personal hygienic behavior and compliance with social distancing measures.

Results: Younger respondents and women ($b=0.20$, 95% CI 0.14 to 0.26) were more likely to perceive information overload. Participants self-perceived as upper or upper-middle class ($b=0.19$, 95% CI 0.09 to 0.30) and those with full-time jobs ($b=0.11$, 95% CI 0.04 to 0.17) tended to perceive higher information overload. Respondents who more frequently sought COVID-19 information from newspapers ($b=0.12$, 95% CI 0.11 to 0.14), television ($b=0.07$, 95% CI 0.05 to 0.09), and family and friends ($b=0.11$, 95% CI 0.09 to 0.14) were more likely to feel overwhelmed. In contrast, obtaining COVID-19 information from online news outlets and social media was not associated with perceived information overload. There was a positive relationship between perceived information overload and psychological distress ($b=2.18$, 95% CI 2.09 to 2.26). Such an association was stronger among urban residents, full-time employees, and those living in privately owned housing. The effect of perceived information overload on protective behavior was not significant.

Conclusions: Our findings revealed that respondents who were younger, were female, had a higher socioeconomic status (SES), and had vulnerable populations in the household were more likely to feel overwhelmed by COVID-19 information. Perceived information overload tended to increase psychological distress, and people with higher SES were more vulnerable to this adverse psychological consequence. Effective policies and interventions should be promoted to target vulnerable populations who are more susceptible to the occurrence and negative psychological influence of perceived information overload.

Introduction

Background

The COVID-19 pandemic has posed unprecedented challenges to public health and daily life worldwide. A cluster of COVID-19 cases was first reported in December 2019 in Wuhan of Hubei Province in China. Due to the proximity and various links to China, COVID-19 badly hit Asia early on. By imposing strict public health measures, some countries in Asia and the Pacific had better performance in containing the spread of COVID-19 compared with the rest of the world. However, the outbreaks of the Delta variant in several Asian countries and regions, including India, Singapore, Taiwan, and Thailand [1], show the difficulty in suppressing COVID-19 even with the implementation of social distancing and the availability of vaccines. As of May 31, 2021, cumulative cases in Asia had reached over 51.07 million—nearly one-third of the total cases reported globally—and the number deaths had reached over 682,000 [2].

The unpredictable course of the pandemic along with prolonged social distancing can negatively affect people's mental health, regardless of exposure to the disease itself [3]. A study of the general population in Hong Kong between March 2020 and May 2020 revealed that almost two-thirds of the respondents reported depression or anxiety disorders and about one-quarter met the criteria for risk of psychosis [4]. Also, about 45% of South Korean residents experienced moderate or higher symptoms of depression, anxiety, or stress, as shown by a survey from March 2020 to June 2020 [5]. Similarly, a study of the general population in Taiwan in April 2020 found that 55.8% of the participants reported sleep disturbance and 10.8% reported having suicidal thoughts in the previous week [6].

In addition, the psychological impact of COVID-19 has been fueled by an “infodemic,” which refers to “an overabundance of information—some accurate and some not—that makes it hard for people to find trustworthy sources and reliable guidance when they need it” [7]. An infodemic may cause a feeling of information overload when the amount of information to which people are exposed exceeds the optimal level that they can process and understand effectively [8]. Such a feeling of information overload may worsen when the information contains contradictory or uncertain contents [9,10]. As COVID-19 is a sudden disease outbreak with unknown causes and unpredictable course, its related information involves a high level of uncertainty. For instance, the prevention guidance for COVID-19 is ambiguous and changing as experts and authorities present different perspectives, particularly in the early stage of the outbreak [11]. The complexity of COVID-19 information (eg, contains too much scientific jargon) also contributes to a perception of information overload, as processing COVID-19 information requires great cognitive resources.

Although timely and accurate information during the pandemic helps individuals develop adequate risk perceptions, take preventive measures, and reduce mental distress, an infodemic and information overload can trigger unpleasant emotions, cause confusion and distrust among people, and impede effective public health responses [12-14]. Prior research has revealed that health information overload was negatively associated with one's attitudes and willingness to use medical services. Health information overload may also hinder the dissemination of health knowledge and affect public health decision-making. For example, cancer information overload may increase individuals' susceptibility to cancer fatalism [14], reduce the willingness to undergo cancer screening [15], and decrease self-management of chronic diseases [16]. Information overload and its related psychological discomfort can lead to information avoidance [17], reduce motivation for information sharing [18], and reduce health behaviors [19]. During the COVID-19 pandemic, people have been exposed to a great deal of information, which not only is based on scientific evidence but also contains misinformation and rumors from unreliable sources. Exposure to too much ambiguous information may pose an obstacle to appropriate responses and undermine trust in health institutions and programs [20]. As such, researchers and public health authorities should be mindful of the causes and consequences of information overload on emergency responses.

To date, only a few studies have investigated the prevalence and consequences of perceived information overload during the COVID-19 pandemic, most of which discussed the effect of information overload on compliance with protective behaviors [21-25]. In light of the psychological and emotional impacts of COVID-19 information (eg, fatigue and anxiety) [26,27], scholars have suggested that “future studies would add more valuable insights if they aim to investigate psychological and emotional responses of information overload” [25]. Although information overload is a stress indicator, previous findings indicated that information overload measured different concepts of perceived stress and the scales for measuring perceived information overload and perceived stress do not overlap [28].

Besides a lack of research on the psychological consequences of information overload about COVID-19, most existing studies only examined the impact of information overload in the general population while ignoring the potentially stratified impact of information overload in different subpopulations. Moreover, the scope of previous studies on information overload is limited. A recent systematic review of health information overload pointed out that most research has been conducted in the United States, focusing on cancer information overload perceived by cancer patients and thus called for extending the scope to other health issues in different contexts [29].

To fill the gaps, this paper aimed to systematically examine the level, associated factors, and psychological and behavioral consequences of perceived information overload about COVID-19 and explore the sociodemographic variances in the

susceptibility to and impact of information overload. The data were collected from a large-scale, cross-sectional survey of 10,063 residents in 6 jurisdictions in Asia, including Hong Kong, Taiwan, Japan, South Korea, Singapore, and Thailand, in May 2020. We focused on 4 research questions: (1) Which segments of the population perceived higher levels of information overload during the COVID-19 pandemic? (2) How has information-seeking behavior (ie, the frequency of accessing and perceived trustworthiness of COVID-19 information from different sources) affected the perception of information overload? (3) Would perceived information overload negatively affect psychological well-being and preventative behavior during the pandemic? (4) If so, which subpopulations are more vulnerable to the psychological and behavioral consequences of information overload? The findings would help identify vulnerable groups who are more susceptible to information overload about COVID-19 and its psychological and behavioral consequences and thus contribute to a nuanced understanding of the correlates and consequences of an infodemic and information overload during the COVID-19 pandemic.

Prior Work

As information overload arises when there is much more information available than an individual's information processing capacity [30], people who are more attentive to information or have a lower level of cognitive capacity for dealing with relevant information tend to perceive higher levels of information overload. Previous studies have shown that older adults [31] and women [32-35] experienced greater information overload. Also, those who are less educated [31,36,37] and of lower socioeconomic status (SES) [38,39] were more likely to feel overwhelmed by information, which may be due to their lower capacity for processing information.

The empirical results of the relationship between media exposure and information overload were mixed [38,40,41]. Moreover, the effect of various media types on perceived information overload may be different [36]. During the COVID-19 pandemic, information overload was higher among individuals who used social media as a source for COVID-19 information [42,43], perhaps because misinformation and rumors tend to spread more rapidly on social media platforms [44,45]. Thus, we proposed the following hypotheses: Hypothesis 1 (H1) is that the frequency of obtaining COVID-19 information from traditional sources (eg, newspaper, television, and family and friends) is negatively associated with perceived information overload. Hypothesis 2 (H2) is that the frequency of obtaining COVID-19 information from social media is positively associated with perceived information overload.

Although access to timely and quality health information during outbreaks of infectious diseases can effectively contain the spread of diseases and reduce depressive and anxious feelings [46,47], an overabundance of information can make people feel powerless and anxious, experience information fatigue, and use heuristic rather than systematic information processing [17,48]. Prior research has documented the adverse impact of excessive media consumption on psychological well-being during infectious health outbreaks such as the 2014 Ebola outbreak and the swine flu pandemic [49,50]. Likewise, during the current

COVID-19 pandemic, people are likely to develop negative emotions when experiencing information overload [51]. Based on the broadly consistent findings of the negative effect of information overload on psychological well-being, we posited the following hypothesis: Hypothesis 3 (H3) is that perceived information overload is positively associated with psychological distress during the COVID-19 pandemic.

Researchers have also investigated the role of various information sources in psychological well-being and coping behavior during the COVID-19 pandemic. Previous studies in mainland China [52] and Taiwan [53] have revealed that exposure to social media was positively associated with mental distress during the COVID-19 pandemic. In contrast, no such relation was found with traditional media (mass and print media) [42]. We thus proposed the following hypotheses about the effect of information sources and psychological well-being during the COVID-19 pandemic: Hypothesis 4 (H4) is that the frequency of obtaining COVID-19 information from traditional sources (eg, newspaper, TV, family, and friends) has a limited effect on psychological well-being during the COVID-19 pandemic. Hypothesis 5 (H5) is that the frequency of obtaining COVID-19 information from social media is positively associated with psychological distress.

Despite the well-documented relationship between perceived information overload and psychological distress, limited studies have investigated the socioeconomic differences in the relationship between perceived information overload and psychological well-being. Prior research suggested that confusing and ambiguous information is especially problematic for those experiencing communication inequality, such as the lack of access to relevant health information or the ability to make sense of information [54]. Populations at risk of communication inequality disproportionately consist of older adults, people with low educational levels and incomes, ethnic minorities, and residents of rural areas [54,55]. Thus, structurally vulnerable populations with communication disadvantages may experience higher levels of psychological distress because of perceived information overload. Therefore, we hypothesized the following: Hypothesis 6 (H6) is that the effects of perceived information overload on psychological distress are stronger among older people. Hypothesis 7 (H7) is that the effects of perceived information overload on psychological distress are stronger among respondents with lower SES.

In addition to psychological responses to information overload, people's health behavior is also likely to be influenced by information overload. Previous studies on health information overload have consistently shown that those who perceive higher information overload are less likely to perform health behaviors [19,56-58]. However, there were mixed findings on behavioral consequences of information overload during the COVID-19 pandemic. A study of 225 participants in Finland showed that perceived information overload had a negative effect on protective health behavior (eg, self-isolation) during the COVID-19 pandemic [59]. Nevertheless, other studies found no direct impact of information overload about COVID-19 and intention to adopt protective behavior [25]. Some studies even found a positive relationship between information overload and the adoption of protective behavior [23,60]. Given the ambiguity

in the empirical evidence, we tentatively hypothesized a negative relationship between perceived information overload and compliance behaviors during the COVID-19 pandemic: Hypothesis 8 (H8) is that participants who perceived higher levels of information overload about COVID-19 were less likely to adopt protective behaviors.

Methods

Study Design and Data Collection

The data for this study were obtained from a cross-national survey of public attitudes and responses toward COVID-19 in 6 jurisdictions in East and Southeast Asia, including Hong Kong, Taiwan, Japan, South Korea, Singapore, and Thailand. The survey was conducted by a group of scholars at the City University of Hong Kong between May 11, 2020 and May 26, 2020. The 6 regions were selected due to their geographical proximity to mainland China, the original epicenter of the COVID-19 pandemic, and were hardly hit by the pandemic since late January 2020. In late March 2020, they all entered a second wave of the pandemic as more imported cases from Europe and the United States were detected. They are the Tiger economies characterized by relatively high economic development and governing capacity in Asia. Yet, they also vary in regime types, media development, the stringency of public health measures, and effectiveness in containing the pandemic. Thus, these cases provide an ideal mixture of similarities and differences to examine the impacts of information-seeking behavior, perceived information overload, and psychological well-being during the COVID-19 pandemic.

The surveys were completed using online panels provided by a globally recognized professional survey company. The company's online panels consist of an opt-in list of 56,000 to

1,440,000 individuals relative to the population size in the 6 jurisdictions surveyed in this study. Online panels have been used increasingly among psychological, social, and medical research [61-64]. Using a panel provider for online research can help obtain a representative sample of the required size and facilitate quick completions for time-sensitive projects [65], especially during the COVID-19 pandemic. We reported our methods in line with the Checklist for Reporting Results of Internet E-Surveys (CHERRIES) [66].

For this study, we requested nationally representative samples of around 2000 adults aged 18 years or older in each of the 6 jurisdictions. Age and gender sampling quotas were set to match the latest available census estimates for age and gender in each jurisdiction. Participants were invited through email messages with an embedded link. The panel provider continuously invited participants until the predetermined quota was met. To increase the response rate, participants would get modest monetary rewards upon completion of the survey. Participation was voluntary, and all responses were anonymous. Details of the survey method of this project can be found elsewhere [67].

We developed a questionnaire that includes questions on perceived information overload about COVID-19, information-seeking behavior, psychological well-being, and protective behavior during the pandemic. We conducted a pre-test of the survey questions and modified wordings based on the feedback from the pre-testers. The questionnaire was available in English, Chinese, Korean, Japanese, and Thai for participants from different jurisdictions. A total of 12,062 representative respondents was collected, with approximately 2000 individuals in each jurisdiction. Cases with incomplete information were excluded from the analysis. The final sample size was 10,063 (see Table 1 for more details).

Table 1. Sample characteristics.

Variable	Full sample (N=10,063), n (%)	Hong Kong (n=1813), n (%)	Japan (n=1372), n (%)	Singapore (n=1681), n (%)	South Korea (n=1749), n (%)	Taiwan (n=1695), n (%)	Thailand (n=1753), n (%)

Ethical Review

The study was approved by the Human Subject Ethics Committee of the City University of Hong Kong (Ref No: 8-2020-04-E295-18). All necessary participant consent was obtained.

Measures

Psychological distress was gauged by the Posttraumatic Stress Disorder Checklist for Diagnostic and Statistical Manual of Mental Disorders (DSM-5; PCL-5) [68]. Five items were selected according to their relevance to COVID-19, such as

“Having trouble falling or staying asleep” and “Having trouble concentrating.” The responses ranged from 0 = “Not at all” to 6 = “Very much.” The scores of the 5 items were summed to represent psychological distress, with higher values indicating higher levels of psychological distress. The theoretical score range of the variable was 0-30. The internal reliability of the scale was satisfactory (Cronbach $\alpha=0.80$).

Protective behavior was assessed by asking the respondents to rate on a 7-point Likert scale the level of compliance with 6 protective behaviors suggested by the government (eg, “kept a distance of at least 2 meters to other people” and “wore a mask in public space”) in the past week. Higher scores indicated higher levels of compliance.

Perceived information overload about COVID-19 was measured by the question, “To what extent do you feel overwhelmed by news related to the COVID-19 pandemic?” (0 = “Not at all” to 6 = “Very much”). This item was selected and adapted from the Perceived Information Overload scale [28] and the Cancer Information Overload scale [14,69].

Information-seeking behavior was assessed by the frequency of accessing COVID-19 information from the following platforms: newspapers, television, online news outlets, and social media (jurisdiction-specific examples were included in blanket statements based on the most popular social media tools in each jurisdiction; 0 = “Never” to 6 = “Very frequently”). We also controlled for perceived source credibility and time spent searching for COVID-19 information. Perceived source credibility was gauged by asking the respondents to rate how trustworthy they considered news about COVID-19 from the sources mentioned above on a 7-point Likert scale (1 = “Not at all trustworthy” to 7 = “Very trustworthy”). We also controlled for the average time (in hours) the respondents spent viewing information about COVID-19 each day.

We adjusted for demographic variables, such as age (18-29, 30-39, 40-49, 50-59, ≥ 60 years) and sex (male vs female). We also included a series of socioeconomic factors, including education (secondary school or below vs college or above), rural or urban residence, employment status (working full-time vs other), and housing type (privately owned housing vs other). We also assessed perceived social status by asking the respondents to declare their perceived social position (lower or lower-middle class, middle class, upper or upper-middle class). In addition, we controlled for the perceived threat of COVID-19 and level of worry about contracting COVID-19. To assess the impact of having a vulnerable household member, we asked whether the respondent lived with a pregnant woman or an adult older than 65 years and whether they had a child aged 12 years or below.

Statistical Analysis

Descriptive statistics are reported as mean and SD for normally distributed continuous variables or median and IQR in the case of skewed distributions (Table 1). Normality of the distribution of statistics was tested using skewness or kurtosis tests for normality. For the regression analysis, we first used ordinary least squares (OLS) regression to examine the effects of sociodemographic variables and information-seeking behavior

on perceived information overload (outcome variable). Next, OLS regressions with robust standard errors were carried out to examine the effects of perceived information overload and information-seeking behavior on 2 outcome variables (psychological distress and protective behavior) after adjusting for various sociodemographic variables. Lastly, 2-way interaction terms were computed between perceived information overload and each sociodemographic factor (ie, age, sex, education, employment, urban or rural residence, perceived social status, and housing types) to examine whether the effects of information overload on psychological distress (outcome variable) varied across different sociodemographic groups. As the main effect of perceived information overload on protective behavior was not significant, we did not further examine the sociodemographic differences in such an effect. We used graphical and numerical tests to verify OLS assumptions, and the results showed no evident violation of OLS assumptions (detailed information is included in Multimedia Appendix 1). To account for potential heteroscedasticity, we obtained robust standard errors in OLS models [70]. All the analyses were performed using Stata 15.0. Unstandardized coefficients with 95% CIs are reported. A *P* value of .05 was set as the level of statistical significance.

Results

Sample Characteristics

Table 1 displays the background characteristics of the respondents. In the full sample, about one-half (4885/10,063, 48.54%) of the respondents were under 40 years old. There were slightly more men (5258/10,063, 52.25%) than women. Most respondents had a college education or above (8373/10,063, 83.21%), lived in urban areas (8147/10,063, 80.96%), worked full-time (6278/10,063, 62.39%), and lived in privately owned housing (6043/10,063, 60.05%). About 40% (4034/10,063, 40.09%) of respondents perceived themselves as lower or lower-middle class, while about 49% (4915/10,063, 48.84%) and 11% (1114/10,063, 11.07%) of respondents perceived their status as middle class or upper or upper-middle class, respectively. About 14% (1378/10,063, 13.69%) of respondents had a chronic illness. About one-third (2958/10,063, 29.39%) of respondents had family members vulnerable to COVID-19 (eg, pregnant women, older adults aged over 65 years, children under 12 years old at home).

Descriptive Statistics

Table 2 presents the description of key variables. Of a theoretical score range of 0 to 35, the mean psychological distress score among the full sample was 14.27 (SD 8.00). Respondents in South Korea reported the highest level of distress (mean 16.21), followed by residents in Hong Kong (mean 14.90), Thailand (mean 14.48), Singapore (mean 13.74), and Japan (mean 13.14). Taiwan residents reported the lowest level of psychological distress (mean 12.83). As for involvement in protective behaviors, the median for the full sample was 6 (out of a range of 1 to 7), with respondents in Taiwan reporting the lowest level of compliance (median 5.55) and respondents in Singapore reporting the highest compliance (median 6.50). The median level of perceived information overload was 3 (0-6; mean 3.35,

SD 1.64). Respondents in South Korea (mean 3.96) and Taiwan (mean 2.65) experienced the highest and lowest levels of information overload, respectively. Residents in Japan, Hong Kong, Singapore, and Thailand reported levels of information overload between 3.02 and 3.76. As for media use, respondents were less likely to use newspapers for COVID-19 information (median 3) and more likely to get COVID-19 information from

TV (median 5) and online news outlets (median 5), with social media (median 4) and family and friends (median 4) falling in between. As for perceived source credibility, COVID-19 information on traditional media (television, online news outlets, newspapers, and family and friends) was rated by the respondents as more trustworthy (median 5) than that from social media (median 4).

Table 2. Descriptive statistics of key covariates (N=10,063).

Key covariates	Results	Range
Psychological distress, mean (SD)	14.27 (8.00)	0-30
Preventative behavior, median (IQR)	6 (6.33-6.67)	1-7
Perceived information overload, median (IQR)	3 (3-5)	0-6
Perceived susceptibility to COVID-19, median (IQR)	5 (4-7)	1-7
Perceived severity of COVID-19, median (IQR)	6 (5-7)	1-7
Frequency of seeking COVID-19 information from various sources, median (IQR)		
Newspaper	3 (1-5)	0-6
TV	5 (3-6)	0-6
Online news outlet	5 (4-6)	0-6
Social media	4 (3-6)	0-6
Family and friends	4 (3-5)	0-6
Trustworthiness of COVID-19 information from various sources, median (IQR)		
Newspaper	5 (4-6)	1-7
TV	5 (4-6)	1-7
Online news outlet	5 (4-6)	1-7
Social media	4 (4-5)	1-7
Family and friends	5 (4-6)	1-7

Sociodemographic Factors and Perceived Information Overload

Table 3 shows the OLS regression models for perceived information overload and sociodemographic variables. The results showed that older respondents were less likely to experience COVID-19 information overload. Compared with those aged 18 years to 29 years, respondents aged between 40 years and 49 years ($b=-0.11$, 95% CI -0.20 to -0.01 ; $P=.02$), between 50 years and 59 years ($b=-0.13$, 95% CI -0.23 to -0.04 ; $P<.007$), and at least 60 years ($b=-0.21$, 95% CI -0.33 to -0.08 , $P<.001$) expressed lower levels of information overload. Female respondents were more likely to feel information overload ($b=0.20$, 95% CI 0.14 to 0.26 , $P<.001$). In addition, respondents with higher SES were more likely to experience information overload about COVID-19. Compared with those who perceived themselves as lower or lower-middle class, respondents self-perceived as upper or upper-middle class ($b=0.19$, 95% CI 0.09 to 0.30 ; $P<.001$) experienced more COVID-19 information

overload. Those with full-time jobs also tended to perceive higher information overload ($b=0.11$, 95% CI 0.04 to 0.17 ; $P=.003$) than those without full-time work. The relationship between education and perceived information overload was marginally significant, with respondents with at least a college education more likely to be overwhelmed by COVID-19 information. There were no discernible differences in perceived information overload between people living in rural or urban areas and between housing types. In addition, respondents who had pregnant women or older adults (>65 years old) at home ($b=0.16$, 95% CI 0.09 to 0.23 ; $P<.001$) and with children under 12 years in the household ($b=0.35$, 95% CI 0.28 to 0.43 ; $P<.001$) were more likely to perceive COVID-19 information overload. As for RQ1, about which segments of the population experienced greater information overload, our findings revealed that young people, women, full-time workers, those who perceived themselves as upper or upper-middle class, and those with vulnerable populations in the household were more likely to experience COVID-19 information overload.

Table 3. Association between sociodemographic variables and perceived information overload.

Information-Seeking Behavior and Perceived Information Overload

We then examined the effects of using different sources for COVID-19 information on perceived information overload after adjusting for perceived source credibility, average time spent on viewing COVID-19 information, and various sociodemographic variables (Table 4). Inconsistent with H1, the results revealed that seeking COVID-19 information from traditional sources was positively associated with perceived information overload. Specifically, respondents who more

frequently sought COVID-19 information from newspapers ($b=0.12$, 95% CI 0.11 to 0.14; $P<.001$), television ($b=0.07$, 95% CI 0.05 to 0.09; $P<.001$), and from family and friends ($b=0.11$, 95% CI 0.09 to 0.14; $P<.001$) were more likely to feel overwhelmed by the information. In contrast, seeking COVID-19 information from online media, including online news outlets ($b=0.00$, 95% CI -0.03 to 0.03 ; $P=.98$) and social media ($b=0.02$, 95% CI -0.00 to 0.04 ; $P=.10$) was not significant associated with perceived information overload, which showed limited support for H2.

Table 4. The association between information seeking behavior and perceived information overload.

Information-seeking behaviors	b ^{a,b}	95% CI	P value
Frequency of seeking COVID-19 information from various sources			
Newspaper	0.12	0.11 to 0.14	<.001
TV	0.07	0.05 to 0.09	<.001
Online news outlet	0.00	-0.03 to 0.03	.98
Social media	0.02	-0.00 to 0.04	.13
Family and friends	0.11	0.09 to 0.14	<.001
Trustworthiness of COVID-19 information from various sources			
Newspaper	-0.00	-0.03 to 0.03	.94
TV	-0.05	-0.08 to -0.01	.01
Online news outlet	0.05	0.01 to 0.08	.01
Social media	0.10	0.07 to 0.13	<.001
Family and friends	0.06	0.03 to 0.10	<.001

^aThe model was adjusted for sociodemographic variables, including age, sex, education, area, perceived social status, employment, housing types, a history of chronic diseases, having pregnant women or older adults (>65 years old) in the household, having children aged under 12 years in the household, and survey locations.

^bUnstandardized coefficient.

The relationships between perceived source credibility and perceived information overload were mixed. Specifically, people who trusted COVID-19 information on television more experienced lower levels of information overload ($b=-0.05$, 95% CI -0.08 to -0.01 ; $P=.005$). In contrast, perceived trustworthiness of COVID-19 information from online news outlets ($b=0.05$, 95% CI 0.01 to 0.08; $P=.005$), social media ($b=0.10$, 95% CI 0.07 to 0.13; $P<.001$), and family and friends ($b=0.06$, 95% CI 0.03 to 0.10; $P<.001$) was positively associated with perceived information overload. The perceived trustworthiness of COVID-19 information on newspapers was not associated with perceived information overload.

Perceived Information Overload and Psychological Distress

Next, we investigated the effect of perceived information overload and information-seeking behavior on psychological distress. Model 1 in Table 5 shows the OLS regression models

for psychological distress and protective behaviors after controlling for sociodemographic variables. As for psychological distress, a positive and significant effect of perceived information overload and psychological distress existed ($b=2.18$, 95% CI 2.09 to 2.26; $P<.001$), which lent strong support for H3. As for the role of information-seeking behavior in psychological well-being, the results showed mixed support for H4 and H5. Specifically, more consumption of COVID-19 information from newspapers ($b=0.58$, 95% CI 0.51 to 0.65; $P<.001$) and family and friends ($b=0.29$, 95% CI 0.18 to 0.40; $P<.001$) resulted in higher levels of psychological distress. In contrast, obtaining COVID-19 information from online news outlets was associated with less distress ($b=-0.32$, 95% CI -0.44 to -0.21 ; $P<.001$). The frequency of getting COVID-19 information from TV and social media was not associated with psychological distress. For perceived source credibility, the perceived trustworthiness of information from newspapers ($b=-0.27$, 95% CI -0.39 to -0.15 ; $P<.001$) and TV ($b=-0.26$,

95% CI –0.39 to –0.12; $P<.001$) was negatively associated with psychological distress caused by COVID-19. In contrast, the perceived credibility of information obtained from social media

($b=0.56$, 95% CI 0.43 to 0.68; $P<.001$) and family and friends ($b=0.24$, 95% CI 0.11 to 0.37; $P<.001$) was positively related to psychological distress.

Table 5. Association between perceived information overload and psychological distress and preventive behaviors.

Variables	Model 1 ^a : psychological distress			Model 2 ^a : preventive behavior		
	b^b	95% CI	P value	b^b	95% CI	P value
Perceived information overload	2.18	2.09 to 2.26	<.001	0.01	–0.09 to 0.07	.85
Frequency of seeking COVID-19 information from various sources						
Newspaper	0.58	0.51 to 0.65	<.001	–0.06	–0.13 to 0.00	.06
TV	–0.03	–0.13 to 0.06	.55	0.19	0.10 to 0.29	<.001
Online news outlet	–0.32	–0.44 to –0.21	<.001	0.37	0.26 to 0.47	<.001
Social media	0.05	–0.05 to 0.15	.38	0.18	0.09 to 0.28	<.001
Family and friends	0.29	0.18 to 0.40	<.001	0.01	–0.10 to 0.11	.86
Trustworthiness of COVID-19 information obtained from various sources						
Newspaper	–0.27	–0.39 to –0.15	<.001	0.08	–0.03 to 0.19	.17
TV	–0.26	–0.39 to –0.12	<.001	0.14	0.01 to 0.27	.03
Online news outlet	0.05	–0.09 to 0.19	.55	–0.00	–0.13 to 0.13	.98
Social media	0.56	0.43 to 0.68	<.001	–0.16	–0.27 to –0.03	.01
Family and friends	0.24	0.11 to 0.37	<.001	0.18	0.06 to 0.31	.004
Perceived susceptibility	0.80	0.71 to 0.88	<.001	0.41	0.33 to 0.49	<.001
Perceived severity	0.30	0.20 to 0.39	<.001	0.55	0.46 to 0.63	<.001

^aThe model was adjusted for sociodemographic variables, including age, sex, education, area, perceived social status, employment, housing types, a history of chronic diseases, having pregnant women or older adults (>65 years old) in the household, having children aged under 12 years in the household, and survey locations.

^b Unstandardized coefficient.

Sociodemographic Differences in the Adverse Psychological Effect of Information Overload

Finally, we assessed whether the impacts of COVID-19 information overload on psychological distress varied by different sociodemographic characteristics. A series of 2-way interaction terms between perceived information overload and sociodemographic variables were computed. Table 6 presents the regression results of psychological distress on interactions between perceived information overload and sociodemographic factors. The interaction between information overload and age groups was not significant, suggesting that the effect of information overload was not dependent on the respondents' age—such a finding showed limited support for H6. The results revealed a significant sex difference in the psychological consequences of perceived information overload, with women experiencing more psychological distress in the midst of information overload about COVID-19 ($b=0.24$, 95% CI 0.10 to 0.39; $P=.001$).

As for SES, there was a positive interaction between COVID-19 information overload and an urban residence ($b=0.23$, 95% CI

0.04 to 0.41; $P=.02$), suggesting that the detrimental effect of COVID-19 information overload on psychological distress was more salient for urban residents than their rural counterparts. The interaction between information overload and middle-class status was also significant ($b=0.18$, 95% CI –0.02 to 0.33; $P=.03$), suggesting that self-perceived middle-class respondents were more likely to experience psychological distress when faced with COVID-19 information overload than respondents self-perceived as being lower or lower-middle class. Similarly, full-time employees were likely to experience higher levels of psychological distress when perceiving information overload about COVID-19 ($b=0.24$, 95% CI 0.09 to 0.39; $P=.002$). Also, the association between perceived information overload and psychological distress was more salient among respondents living in privately owned housing than their counterparts residing in other types of accommodation ($b=0.20$, 95% CI 0.05 to 0.35; $P=.01$). Inconsistent with H7, such results suggested that those with higher SES were more likely to develop psychological distress when experiencing COVID-19 information overload.

^bAll the models adjusted for sociodemographic variables, including age, sex, education, area, perceived social status, employment, housing types, a history of chronic diseases, having pregnant women or older adults (>65 years old) in the household, having children aged under 12 years in the household, and survey locations. The model also controlled for perceived susceptibility to and perceived severity of COVID-19.

^cIO: information overload.

^dN/A: not applicable.

Perceived Information Overload and Protective Behavior

Model 2 in Table 5 shows that the association between perceived information overload and adoption of protective behaviors was not significant after adjusting for sociodemographic variables and perceived susceptibility and severity of the pandemic ($b=0.00$, 95% CI -0.01 to 0.01 ; $P=.88$). Such results did not support H8. More frequent exposure to COVID-19 information on TV ($b=0.33$, 95% CI 0.01 to 0.04 ; $P<.001$), online news outlets ($b=0.06$, 95% CI 0.04 to 0.08 ; $P<.001$), and social media ($b=0.03$, 95% CI 0.01 to 0.04 ; $P=.001$) could promote the adoption of protective behaviors against COVID-19. Also, respondents who perceived higher trustworthiness of COVID-19 information obtained from TV ($b=0.03$, 95% CI 0.01 to 0.05 ; $P=.007$) and family and friends ($b=0.03$, 95% CI 0.01 to 0.05 ; $P=.008$) were more likely to take protective measures. In contrast, there was a negative association between perceived trustworthiness of COVID-19 information on social media and engagement in various protective behaviors ($b=-0.02$, 95% CI -0.04 to 0.00 ; $P=.04$).

Discussion

Principal Findings

This study is among the first to investigate the antecedents and consequences of information overload about COVID-19 among Asian populations. Using data from a cross-sectional survey of 10,063 residents of 6 jurisdictions in East and Southeast Asia, our study showed a high level of perceived information overload during the pandemic. Regression results further revealed that young people, women, people with a higher SES (ie, full-time workers, self-perception as being upper or upper-middle class), and those with vulnerable populations in the household were more likely to experience COVID-19 information overload. As for the behavioral consequence of information overload, the results showed no significant relationship between perceived information overload and protective behaviors during the pandemic. Consistent with previous studies, we found a positive relationship between perceived information overload and psychological distress. Notably, the association between perceived information overload and psychological distress was more substantial among women and people with a higher SES (urban residents, self-perceived as middle class, full-time workers, and people living in privately owned housing). The findings of this study contribute to a better understanding of the

level and correlates of information overload during the COVID-19 pandemic and help identify subpopulations that are particularly susceptible to information overload and its potential downstream consequences. We discuss the main findings in the following sections.

Comparison With Prior Work

Although the occurrence of information overload has been documented in other disease outbreaks, the level and consequences of information overload during the current global pandemic are unparalleled. On the one hand, the unprecedented scale and impacts of COVID-19 on public health and individual lives have led to intensive media coverage. Other epidemics such as Zika, Ebola, Middle East Respiratory Syndrome (MERS), and H1N1 (swine flu) have caused great damage in daily life. Still, the level of panic caused by COVID-19 is much more severe and has resulted in a large volume of news attention to COVID-19. Also, the high scientific uncertainty and rapidly evolving settings of COVID-19 create opportunities for generation of ambiguous, inaccurate, and conflicting information, which may amplify information overload. On the other hand, the media environment and spreading of information have significantly changed over the past several decades. When another deadly viral disease—Severe Acute Respiratory Syndrome (SARS)—broke out in 2003, none of the major social media outlets was present. In pandemics before the social media era, a multilayered process involving careful review by experts, editing by journals, and releasing essential information under embargo to journalists who seek third-party comments would be performed before releasing scientific knowledge to the public [71]. In contrast, social media platforms can host an enormous amount of user-generated content. During the COVID-19 pandemic, there has been a rush to publish unverified information or even deliberately spread misinformation on various social media platforms, which is likely to cause panic and noncompliance to preventive behaviors.

As for the first research question about which segments of the population perceived higher levels of information overload during the COVID-19 pandemic, our results showed that younger people (18–39 years old), women, and respondents with higher SES (having a college education or above, having a full-time job, and self-perceived as upper or upper-middle class) expressed higher levels of perceived information overload about COVID-19. The finding that women tended to experience more information overload about COVID-19 than men is consistent with findings of previous studies [40–42]. Globally, 70% of the

workers in the health and social sectors are women [72]. Women provide the majority of health services and are more likely to take the caregiving lead in the family. Women's caregiving roles and higher risk exposure during the pandemic have prompted them to pay more attention to COVID-19 information and take COVID-19 more seriously than men [73,74].

Though not consistent with previous studies [31], the finding that older people experienced lower levels of information overload about COVID-19 may be justified by the following reasons. First, increased age is often associated with decreased motivation for health-related information seeking, especially from online media, as older adults typically have lower levels of internet literacy and may experience more difficulties navigating websites [75]. Moreover, older people may be more experienced with information content, even on online platforms. In contrast to younger online users, who mainly browse entertaining and social network sites, older adults are more likely to use the internet for information purposes [76]. Thus, the older generation is less likely to feel cognitively overloaded as they may not seek COVID-19 information as frequently as young people, and they are more experienced in dealing with information [45].

Although several studies have suggested that people with higher SES may experience less information overload [31,36-39], our results showed a positive relationship between education, employment, and perceived social status with perceived information overload about COVID-19. Such unexpected findings may be due to the widening digital divide between socioeconomic groups during the COVID-19 pandemic. The divides in internet coverage and quality of service have exposed people to different levels of life disruptions caused by the pandemic. Although those with adequate internet infrastructure and capacity can work from home, engage in online teaching and learning, and order food and groceries online, people with limited digital access and skills can hardly overcome the economic hardship and life inconvenience caused by the COVID-19 pandemic. More importantly, the costs for timely information for digital "have-nots" tend to be high, as they may need to wait for information to arrive informally rather than obtaining the information online in real time. Given that people with lower SES are more likely to be digitally disadvantaged, they may be involved in fewer information-seeking behaviors and, consequently, less likely to feel overwhelmed by COVID-19 information.

Moreover, the socioeconomic disparities in perceived information overload may gradually emerge as the pandemic unfolds. A study of South Korean residents found no sociodemographic differences in perceived information overload about COVID-19 during the early stage of the pandemic [25]. It may be because their study was conducted at the peak of media coverage of COVID-19 in South Korea (mid-March 2020), and there may be a ceiling effect of perceived information overload when most people were highly attentive to the COVID-19 information. Moreover, the data collection was confined to Seoul residents, and the sample overrepresented young and highly educated people, which limited the socioeconomic differences in the perception of information overload. In contrast, our study was carried out in May 2020

when the 6 jurisdictions surveyed were in their fifth month of the pandemic. Our findings suggested that the disparities in the perception of information overload may gradually emerge as the pandemic unfolds. Also, our study included representative samples in the 6 jurisdictions in East and Southeast Asia, which reduced sampling bias and increased the generalizability of the findings to the target population. Future studies may further examine whether the current results are consistent across different contexts and stages of the pandemic.

In addition, respondents with vulnerable family members were more sensitive to the threats from COVID-19 and, accordingly, were more attentive to relevant information. Our results support that argument by revealing that respondents with vulnerable significant others at home (eg, pregnant women, young children, or people over 65 years old) were more likely to feel overwhelmed by COVID-19 information. However, inconsistent with previous studies showing that people who perceived themselves to have less-than-excellent health were more susceptible to information overload [77], our results indicated an insignificant relationship between chronic illness records and perceived information overload about COVID-19. More studies are needed to explore the association between pre-existing health conditions and perceived information overload during the COVID-19 pandemic.

As for the effect of information-seeking behavior on perceived information overload (second research question), we found that the use of traditional media (eg, newspaper, television) for seeking COVID-19 information was positively associated with perceived information overload. In contrast, the effect of getting COVID-19 information from online news outlets was not significant. Given that the internet and online media contribute to the over-proliferation of health information available to the lay public [51], such results seem unreasonable. A possible explanation is that, while offline seekers have little or no control over what is aired but receive information passively, online information seekers can adjust the search terms anytime to suit their search needs, thereby getting tailored information. Compared with traditional media, internet media are active channels that require greater cognitive effort and are often used by highly motivated and engaged individuals [78]. Moreover, online users can easily search other websites for clarification or fact-checking whenever they find the information received from a single online source is unreliable [17]. Thus, the motivation to authenticate earlier information obtained may prohibit online seekers from being overwhelmed with the information received. Future studies should take the route of information acquisition (eg, active search vs passive exposure) into account.

Our results underscore the critical role of trust in information sources in crisis management. Interestingly, the perceived reliability of COVID-19 information from various media channels exerted differential effects on perceived information overload in our study. Perceived trustworthiness of COVID-19 information from television was negatively associated with perceived information overload. It was consistent with prior research that higher trust in information sources predicted less distress by information and benefited crisis management [79]. However, respondents were more likely to experience

information overload when they perceived COVID-19 information from online media (ie, online news outlets, social media) as more trustworthy. It may be because misinformation, disinformation, and rumors about COVID-19 were more prevalent on online media than other forms of media [44], which may engender greater confusion and require more cognitive effort to process such inaccurate and inconsistent information for those who believe in the information. As mentioned earlier, the frequency of seeking COVID-19 information online was not associated with perceived information overload. Thus, the level of perceived information overload seems more attributable to the perceived credibility of information on the internet rather than the online information-seeking behavior.

As for the third research question about the psychological and behavioral consequences of information overload, we found that an overabundance of COVID-19 information can harm mental well-being by increasing the likelihood of experiencing posttraumatic stress disorder. Such a finding was consistent with previous studies about the negative psychological impact of information overload [17]. During an unprecedented global pandemic like COVID-19, people are understandably attentive to health information and, by doing so, try to reduce the negative affect caused by the previously unknown and unpredictable disease. However, when information flow exceeds one's capacity to process, the perceived information overload may cause a detrimental effect on psychological well-being. Moreover, deteriorated mental health caused by information overload may lead to information avoidance when people deliberately avoid seeking health information to lessen the cognitive burden and negative affect [76]. Information avoidance is detrimental for public health because the acquisition of health information helps individuals make informed medical decisions and engage in preventive behaviors [80]. Given the unintended consequences of information overload, our study highlighted the importance of keeping a balance between information transparency and information overload.

However, our results did not show a significant effect of perceived information overload on protective behaviors during the COVID-19 pandemic, which was consistent with a study conducted during the COVID-19 pandemic in Korea [25]. Despite no direct effect, information overload may indirectly reduce compliance via increasing heuristic processing and decreasing systematic processing [25]. Compared with systematic processing of information, judgments based on heuristic processing tend to be less stable and weakly tied to subsequent behaviors [81], which may discourage one's willingness to adopt protective measures. When the risk perception of COVID-19 decreases and the anxiety associated with this pandemic fade over time, the detrimental effect of perceived information overload on protective behaviors may emerge. Future studies are warranted to investigate the behavioral consequences of information overload in different time frames.

The fourth research question focused on who was more vulnerable to the psychological and behavioral consequences of information overload. Since there was no significant effect of perceived information overload on protective behaviors, we did not further examine whether such an effect may be different

across various sociodemographic characteristics. As for psychological distress, we found that women and people with a higher SES were more vulnerable to the adverse effects of perceived information overload on psychological well-being. Female respondents were more likely to experience psychological distress when exposed to information overload, possibly because women are more likely than men to perceive the pandemic as a severe health problem and to agree and comply with restraining measures [53]. Besides, we speculated that people with a higher SES might be less psychologically resilient in the face of the COVID-19 pandemic and thus perceived more significant information overload. Previous studies have suggested that people with a higher SES were more concerned and worried about the pandemic [82] and may have been experiencing a more drastic relative change in their lifestyles, leading to a sharper decline in their psychological well-being.

Meanwhile, individuals with a lower SES tend to experience more everyday stressors even when there is no global pandemic. Thus, they may not undergo a significant change in their subjective well-being when reading pessimistic news about COVID-19. Besides, people with higher education care more about the quality of information and may feel frustrated if they cannot find trustworthy sources during the pandemic. Given the ambiguous information and inconsistent guidance about COVID-19, especially during the early stage of the outbreak, it is hard to identify valuable and reliable information even for people with a higher SES who are believed to have more access to health information and a higher ability to process such information.

Since information overload can harm mental well-being and potentially reduce compliance during the pandemic, it is urgent to manage the overload of information that exceeds people's cognitive ability to process. From the information provider side, government and media should disseminate evidence-based and transparent information swiftly and widely among the public. Social media technology companies must constantly review content shared on their platforms and closely verify the reliability of information related to the pandemic. Since there are stratified mechanisms and consequences of information overload as shown in this study, information policies and management should be accordingly "stratified" as well. It is essential to develop efficient health communication strategies targeting people with different sociodemographic characteristics. Certain subgroups may be more frustrated with the uncertainty caused by the pandemic and eagerly look for sources to fill their information needs. It is necessary to formulate different information dissemination strategies in terms of information content and channels for different groups. It is also essential to establish interventions to help people vulnerable to information overload to cope with information anxiety and mental health concerns.

On the receiver side, individuals should carry out an "information diet" by controlling the extent and type of information they consume. Researchers have suggested that people visit authentic and official websites for COVID-19 information and try to verify suspicious news on one of the many fact-checking websites dedicated to debunking myths

[8,83]. For example, the World Health Organization's (WHO) risk communication team launched a new information platform known as the WHO Information Network for Epidemics, which actively reports details related to COVID-19. A team of WHO "myth busters" works with search and media companies like Facebook, Google, Pinterest, Tencent, Twitter, TikTok, YouTube, and others to counter the spread of rumors. Also, enhancing information literacy skills, particularly health literacy skills, can facilitate the critical evaluation of health information and help people make appropriate health-related decisions. It is argued that information and health literacy is vital to reducing information overload and its consequences [84,85]. Thus, extensive training and guidelines for improving information and health literacy should be promoted to the public, particularly regarding crisis management.

Limitations

Despite the significant findings, this study is not without limitations. First, the data were obtained from a cross-sectional survey, and it is hard to ascertain the causal relationship between variables. For example, our results showed a negative effect of perceived information overload on psychological well-being. However, trait anxiety was significantly associated with higher levels of perceived information overload [24]. Thus, longitudinal studies are needed to ascertain the psychological consequences of information overload. Second, only one item was used to measure perceived information overload, which presents a significant limitation of this study. We recognized that information overload is a multidimensional construct and a single proxy item limits our ability to make clear-cut

generalizations from our findings. Future studies may adopt validated scales regarding COVID-19 information overload (eg, Corona Information Overload Scale [65]). Third, this study has limited information on knowledge and attitudes related to COVID-19, though we have adjusted for perceived susceptibility and perceived severity of COVID-19 in the analysis. Future studies may further examine how knowledge and attitudes may be associated with information overload.

Conclusion

Perceptions of information overload are prevalent during the COVID-19 pandemic and have caused significant psychological and behavioral consequences. This study is among the first to examine how the antecedents and consequences of perceived information overload vary between different sociodemographic groups among the Asian population. A cross-sectional survey with representative data of 10,063 residents in 6 jurisdictions in Asia was conducted in May 2020. Regression results confirmed a positive relationship between perceived information overload and psychological distress. Also, people with a higher SES were more exposed to information overload about COVID-19 and suffered more psychological distress because of perceived information overload. Our findings suggested that the provision of trustworthy information and reduction of the perceived information overload can significantly ameliorate psychological distress during the pandemic. Effective policies and interventions should be promoted to target higher-SES populations who are more susceptible to the occurrence and adverse psychological influence of perceived information overload.

Abstract

Background: A low test positivity rate is key to keeping the COVID-19 pandemic under control. Throughout the pandemic, several migrant groups in Norway have seen higher rates of confirmed COVID-19 and related hospitalizations, while test positivity has remained high in the same groups. The Norwegian government has used several platforms for communication, and targeted social media advertisements have in particular been an important part of the communication strategy to reach these groups.

Objective: In this study, we aimed to investigate whether such a targeted Facebook campaign increased the rate of COVID-19 tests performed in certain migrant groups.

Methods: We randomly assigned 386 Norwegian municipalities and city districts to intervention or control groups. Individuals born in Eritrea, Iraq, Pakistan, Poland, Russia, Somalia, Syria, and Turkey residing in intervention areas were targeted with a social media campaign aiming at increasing the COVID-19 test rate. The campaign message was in a simple language and conveyed in the users' main language or in English.

Results: During the 2-week follow-up period, the predicted probability of having a COVID-19 test taken was 4.82% (95% CI 4.47%-5.18%) in the control group, and 5.58% (95% CI 5.20%-5.99%) in the intervention group ($P=.004$).

Conclusions: Our targeted social media intervention led to a modest increase in test rates among certain migrant groups in Norway.

Trial Registration: ClinicalTrials.gov NCT04866589; <https://clinicaltrials.gov/ct2/show/NCT04866589>

Introduction

Several migrant groups have been disproportionally affected by COVID-19 in Norway [1,2]. These groups are also considered difficult to reach through traditional communication

platforms [3,4]. Adapting, translating, and targeting communication to ensure equal access to information regardless of health literacy and language skills, is an important part of crisis communication. Consequently, Norwegian health authorities have used a wide range of platforms to communicate with these groups during the pandemic: public COVID-19

websites, traditional media outlets such as television, radio, boards and printed advertisements, as well as content marketing, contextual digital ads, targeted cell phone messaging, influencers, and a wide array of social media such as Twitter, Instagram, Snapchat, TikTok, YouTube, and Facebook. Certain migrant groups have seen particularly high COVID-19 prevalence and low test rates [5], and social media campaigns can be crucial to reach these groups. Although such campaigns have been monitored in house in terms of outreach and reactions on the social media platform, their effects on behavioral change have not been assessed.

Testing is key to detecting cases and limiting outbreaks. In this study, we aimed at assessing whether a targeted social media advertising campaign encouraging selected migrant groups to get tested affected testing behavior (ClinicalTrials.gov NCT04866589; protocol is provided in [Multimedia Appendices 1 and 2](#)). The intervention described in this paper was an extension of the “Get tested” campaign, which had been launched after the Norwegian Institute of Public Health (NIPH) published findings that indicated higher rates of undetected cases among certain migrant groups compared to the general population; that is, lower test rates, higher test positivity rates, and higher rates of hospitalization [1]. The “Get tested” campaign was a part of a larger effort directed at the migrant population, which included drop-in testing stations [6] and dialogue meetings with migrant groups.

The campaign was launched by the end of May 2021, when the COVID-19 incidence rate in Norway was decreasing, but the test positivity rate—that is, the share of all tests that are positive—remained high in many migrant groups [5]. Furthermore, there were indications of confusion concerning when to test and whether testing was free. In order to assess the campaign’s effect on the rates of testing, we ran a cluster randomized trial with users of Facebook. According to numbers from the Ipsos SoMe-tracker, 82% of the Norwegian population, aged ≥ 18 years, have a profile, and 69% of them are daily users on this social media platform [7]. The campaign targeted users residing in Norway, who were born in Eritrea, Iraq, Pakistan, Poland, Russia, Somalia, Syria, and Turkey. The groups were chosen because of their previous high test positivity levels. This study aimed to establish whether the targeted Facebook campaign increased the rate of testing in the selected migrant groups.

Methods

Trial Design

The trial was designed as a parallel group, 2-arm, superiority cluster randomized trial. The clusters—that is, municipalities and city districts—were allocated either to the intervention

group or to the control group, where the intervention group received the campaign message and the control group did not receive the campaign message. All municipalities or city districts with at least one person in the target group were included in the study. Randomization was carried out at the cluster level as it was not technically possible to target the campaign to individual persons. The clusters were split evenly between treatments through block randomization with block size two. Before block randomization took place, the list of municipalities and city districts were sorted in accordance with the total number of migrants residing in each area. Partial concealment was ensured as team member 1 created and sorted the list, while team number 2 created a list of pairwise random orders of pairs of A and B, using randomization software [8]. Team number 3 combined these two lists.

Intervention

Norwegian health authorities have, since the onset of the pandemic, carried out campaigns on social media directed toward the migrant population, using language-based and geographic targeting segments. In December 2020 a “Get tested” campaign was launched, aiming to increase the test rate among migrant populations. Prior to our trial, there were indications of an increased disinterest toward the message, as measured by reach and reactions, and the campaign was paused. To prevent message fatigue [9,10], campaign messages were continuously reviewed, performance measured and customized, and A/B testing conducted—this involved testing different colors, visuals, or creatives to determine which visual received more attention and the time spent on the message. As the “Get tested” campaign had been running for a while, there was by the end of May a small concern that the public had become disengaged or blind to the message; hence, it was decided to roll out new versions. The new versions used short, direct messaging on an A/B-tested colored background. The message remained the same.

We decided that the distribution of the new campaign would be randomized by municipality or city district in order to facilitate an effect evaluation. The content of the relaunched campaign was a sponsored Facebook post from the Norwegian Directorate of Health, distributed in Tigrinya, Polish, Urdu, Somali, Russian, Kurmanji, English, Arabic, Turkish, and Sorani, and focused on the importance of testing for COVID-19 and that testing is free of charge and easy to take. The English message read the following: “COVID-19 tests are free, simple, and completely safe. Get yourself tested to stop the spread of the infection.” Facebook users were free to comment under the post and to share it. [Figure 1](#) shows a screenshot of the post in Polish. Facebook was chosen as a platform in particular because of the high number of Facebook users in Norway in general, and because this platform allowed us to target the position of users with high accuracy.

Figure 1. Screenshot of the social media post in Polish.

The campaign was disseminated using targeted Facebook Ads and was launched separately for each municipality or city district and each language. Target groups on Facebook were created by specifying the geographic position and language setting. It was not possible to launch a Facebook campaign when fewer than 100 users matched the targeting criteria. In cases where not enough users matched the language setting, target groups were formed on the basis of behavioral attributes such as “living abroad,” and interest segments specific to the users’ native country. Examples of the latter are as follows: “Syria national football team,” “BBC Urdu,” and “Turkish Kurdistan.” At the time of the trial, Somali and Tigrinya were not available as languages on Facebook. Users who spoke these languages were solely targeted on the basis of behavioral attributes. Lastly, the English campaign was disseminated on the basis of the attribute “living abroad” and the English user language setting.

The campaign was live for a 7–14-day period. The variation in timing was due to the time needed to roll out all the campaigns. Of the 117,436 participants in the intervention group, 52,565 lived in areas where it was possible to target the campaign in accordance with Facebook’s language settings, 58,336 lived in areas where it was only possible to target the campaign on the basis of behavioral attributes or interests, and 4700 lived in areas where it was not possible to launch the campaign, neither based on the participants’ background or language. We cannot know for certain to what extent the intervention group, living

in areas where the campaign was rolled out in their language, was actually exposed to the intervention.

Participants

The sample included 233,903 persons with a Norwegian national identity number, who are registered as a resident of a Norwegian municipality or city district (in Oslo, Bergen, and Trondheim), aged 18 years or older at the time of assignment, and registered are as having been born in Eritrea, Iraq, Pakistan, Poland, Russia, Somalia, Syria, or Turkey.

Data Source and Outcomes

We used registry data from the emergency preparedness register for COVID-19 (Beredt C19), which was established by the NIPH in April 2020 [11]. The register contains data on all individuals in the Norwegian Population Register. Individuals were linked across data sources and over time, using an encrypted version of the unique personal identification number provided for every resident of Norway at birth or upon first immigration. In this study, we used individual data from the Norwegian Surveillance System for Communicable Diseases (MSIS) and the National Population Register. MSIS contains data on all polymerase chain reaction (PCR) and rapid tests taken in Norway at official test stations.

Data were also obtained from Facebook on whether it was possible to roll out the campaign, and on the reach, exposure, and frequency of the campaigns that were run in each cluster. These data were anonymized and used only in descriptive

analyses, as data from Facebook cannot be linked directly to data on testing.

Data were aggregated into two time periods: baseline data included data collected 14 days to 1 day before the campaign commenced. Outcome data were measured from day 1 to day 14 and from day 1 to day 21 after the campaign started. Day zero was excluded from the analysis. The exclusion of day zero was prespecified in the protocol, and the rationale was that it was unlikely that the effects of the campaign could be observed on the first day.

The outcome was a dichotomous variable, measured at the individual level, indicating whether a person had taken a PCR or antigen test for SARS-CoV-2.

Time invariant covariates included country of birth, sex, and age. These variables were obtained from the National Population Register.

Statistical Analysis

The coefficient of interest was β_1 in regression analysis:

$$y_{j|i} = \alpha_{j|i} + \beta_1 \text{Treated}_i + \beta_2 y_{i0} + \mathbf{X}_i \beta_3 + \varepsilon_{j|i},$$

where $y_{j|i}$ indicates whether the individual i in municipality or city district j has taken a COVID-19 PCR or rapid antigen test during the 2 weeks the campaign lasted. y_{i0} is the baseline value indicating whether the individual i has taken a COVID-19 test in the 2 weeks prior to campaign commencement. We adjust for the baseline value as is customary in randomized controlled trials (RCTs) [12,13]. \mathbf{X}_i is a vector of control variables.

As the outcome is binary, measured at the individual level, and the treatment was assigned at the cluster level, j , multilevel logistic regression analysis was performed to account for intraclass correlation.

The main specification does not take into account that it was not possible to administer the intervention in every municipality or city district assigned to the intervention group. As such, the results represent an “intention to treat” estimate.

Sample Size Estimation

The sample size relied on the number of persons aged 18 years and older, born in Eritrea, Pakistan, Poland, Russia, Somalia, Syria, or Turkey, and residing in Norway. The number of languages and countries was determined by the availability of campaign material in the different languages, the distribution of these groups across Norway, and the size of the groups. The language groups were also selected on the grounds of a higher test positivity rate as opposed to the general population. Thus, our sample consisted of all eligible individuals, not a selected sample. Consequently, we performed no prior sample size estimation.

Ethics and Privacy Issues

This study does not qualify as health research in the legal sense and hence does not need formal ethics approval. Participant

consent was waived because this study was an evaluation of an intervention, using anonymous registry data already collected.

Personal data protection was ensured through the rigorous set up of the Beredt C19 where data on testing and country of birth were linked to the encrypted version of the unique personal identification number. Data from Facebook were collected and aggregated by Mindshare, and could not be linked directly to the registry data.

Results

The campaign was live from June 1 to June 14, 2021. In 119 out of 189 municipalities or city districts, the campaign was rolled out on June 1, while in the remaining 70 municipalities, the campaign was live from June 6, 2021. In total, the campaigns reached more than 351,000 individual users. The users were likely exposed to the same campaign several times but in a different language, which was expected, as there were multiple languages per target country. The number of individual users far exceeds the 233,903 persons included in our target group, which likely entails that it also reached other users; for example, nonmigrant users, nonmigrants born to migrant parents, or migrants not born in 1 of the 8 target countries.

Summary statistics on the sample that was randomized are shown in Table 1 (Figure S1 in Multimedia Appendix 3 shows their localization on the map). The different migrants were quite evenly distributed between the intervention and control groups. In total, 42.7% of individuals in the intervention group and 42.2% of those in the control group were female. The average age was 41 years in the intervention group and 42 years in the control group. The average cluster sizes were similar in the intervention and control groups.

A striking difference between the groups is the preintervention COVID-19 fortnightly incidence rate, indicating that the randomization process did not yield a completely balanced sample. The number of fortnightly cases was much higher in the intervention group (123.6 cases per 100,000 population) than in the control group (79.6 cases per 100,000 population). This difference is likely to have influenced postoutcome testing, as the test-isolate-trace-quarantine strategy implies that a high number of persons will be tested in conjunction with COVID-19 outbreaks. In Figure S2 in Multimedia Appendix 3, we show that the higher number of cases is driven by a few observations, notably outbreaks in Hammerfest and Larvik municipalities. We therefore controlled for whether the individual had taken a COVID-19 test during the baseline period, and conducted a separate sensitivity analysis where we excluded the two pairs of clusters with the biggest preintervention differences in COVID-19 incidence.

Figure 2 shows the proportion tested daily in the intervention and control groups. The proportion of individuals tested daily in the intervention group was higher than that in the control group on most days both before and after the intervention was carried out.

Table 1. Baseline demographic characteristics of participants and clusters by experimental arm (N=233,903).

Variable	Intervention group (n=117,436)	Control group (n=116,467)
Individual-level characteristics		
Gender, n (%)		
Female	50,194 (42.7)	49,176 (42.2)
Male	67,242 (57.3)	67,291 (57.8)
Country of birth, n (%)		
Eritrea	9562 (8.1)	9662 (8.3)
Iraq	11,395 (9.7)	10,256 (8.8)
Pakistan	12,153 (10.3)	8387 (7.2)
Poland	45,319 (38.6)	49,247 (42.3)
Russia	8107 (6.9)	9204 (7.9)
Somalia	12,575 (10.7)	12,192 (10.5)
Syria	11,425 (9.7)	12,057 (10.4)
Turkey	6900 (5.9)	5462 (4.7)
Age, mean (SD)	41 (12)	40 (12)
Cluster-level characteristics		
Clusters, n	191	191
Cluster size, mean (SD; range)	609.8 (1154.5; 5-6931)	614.8 (1186.8; 2-7804)
Population, n (mean)	2,858,940 (14,968.3)	2,649,940 (13,874.0)
COVID-19 baseline fortnightly incidence (per 100,000)	79.6	123.6

Figure 2. The daily proportion of the participants tested in the control and in the intervention groups. Error bars represent 95% CIs.

Table 2 and Table S2 in the [Multimedia Appendix 4](#) display the results of regression analysis. The odds ratio (OR) for the intervention group was 1.17 (95% CI 1.05-1.30; $P=.004$); that is, the campaign had a significant positive effect on the likelihood of undergoing a COVID-19 test. Whether a person had taken a COVID-19 test during the baseline period was a strong predictor of whether that person would take a test during the follow-up period (OR 5.34, 95% CI 5.12-5.56; $P=.001$). Controlling for age and sex did not affect the effect estimate.

Figure 3 shows the predicted probability of undergoing a COVID-19 test in the 14-day follow-up period—this was 4.82% (95% CI 4.47%-5.18%) in the control group (areas without exposure to the campaign) and 5.58% (95% CI 5.20%-5.99%) in the intervention group (areas with exposure to the campaign). The 0.76 percentage point difference between the control and intervention groups converts to a 15.7% relative increase in test rates attributed to the campaign.

Table S1 in the [Multimedia Appendix 3](#) shows the effects of the campaign when the follow-up period was 1-21 days after the campaign commenced rather than 1-14 days considered for our main analysis. The effect on testing remained significant (OR 1.13, 95% CI 1.02-1.25; $P=.02$). The results are also robust to the exclusion of the two pairs with the largest preintervention (baseline) differences in COVID-19 incidence. When we examined whether the effects differed in accordance with which targeting criteria was used to segment target groups, the results show that targeting based on the users' language settings yielded a larger effect (OR 1.29, 95% CI 1.16-1.44; $P<.001$) than that based on behavioral attributes or interest (OR 1.11, 95% CI 1.00-1.24; $P=.045$). Not surprisingly, there was no significant difference in testing rates between individuals in the control group and those in areas where it was not possible to launch the campaign (OR 0.99, 95% CI 0.83-1.18; $P=.89$).

Table 2. Results of regression analysis.

Discussion

Principal Findings

We conducted this trial to assess the effect of a targeted social media campaign on the rates of testing among Norwegian residents born in Eritrea, Iraq, Pakistan, Poland, Russia, Somalia, Syria, or Turkey. We found a 15.7% relative increase in the proportion taking a COVID-19 test among those who were exposed to the campaign, or an absolute increase of 0.76 percentage points. A distinctive feature of this trial, that strengthens the significance of our findings, was that we were able to assess the effects on actual behavior and not only on intentions or beliefs [14].

We found that targeting in accordance with the users' language setting yielded a larger effect than that based on behavioral attributes or interest. The content and message remained the same for both targeting approaches. A probable explanation is that the targeting based on users' language settings reached a higher share of the participants than that based on behavioral attributes or interests.

Comparison With Prior Work

We are aware of some trials with a similar objective, assessing the effects of social media campaigns on COVID-19–related preventive behavior, COVID-19 knowledge, and intent toward COVID-19 prevention.

We identified 3 RCTs that test the effect of social media campaigns on COVID-19 prevention knowledge. Alsan et al [15] examined how messages read by physicians who varied in age, gender, race, and ethnicity influenced knowledge, beliefs, and practices related to COVID-19. Physician-delivered

messages increased knowledge of COVID-19 symptoms and prevention methods for Black and Latinx respondents. The results illustrate that tailoring the message to the targeted groups may increase the effectiveness of the interventions. Similarly, Vandormael et al [16] have conducted a web-based RCT to investigate the effect of a short video on improving COVID-19 prevention knowledge and behavioral intent toward COVID-19 prevention. They concluded the following: “Short, wordless, animated videos, distributed by health authorities via social media, may be an effective pathway for rapid global health communication during health crises” [16]. Lastly, the results of Alatas et al [17] suggest that celebrity endorsement in a social media campaign in Indonesia influenced beliefs about vaccination and knowledge of immunization.

Only Breza et al [18] investigated how social media advertisements affect actual COVID-19 preventive behavior. They showed that short messages recorded by health professionals before the winter holidays in the United States and sent as advertisements to social media users led to reductions in travel (–0.993 percentage points in high-intensity counties, $P=.002$) and a decrease in COVID-19 infection at the zip code level in the 2-week period starting 5 days post holiday (3.5%, $P=.01$) [18].

Our results are aligned with those of the aforementioned studies. We demonstrated that targeted advertisements on social media with short, simplified messages can be a valuable tool in the authorities' toolbox in times of a pandemic. Targeted advertisements can reach audiences that are not easily reached by traditional modes of communication. Furthermore, conveying the message in the mother tongue of the audience can increase trust in the message, although we did not test this specifically.

The effect size was small, which was not unexpected, considering that the COVID-19 prevalence was quite low in the weeks before campaign onset, and that the intervention was a part of a longer ongoing campaign. Norway saw a large increase in test rates among migrants toward the end of 2020 and in early 2021, after the “Get tested” campaign was launched and amid media attention on the high incidence of COVID-19 among migrant groups [19]. It is therefore likely that toward the end of 2021, the target groups were experiencing a certain advertisement fatigue, and that the main message of the campaign was well known both in the control group and the intervention group.

Limitations

There are some limitations associated with the findings of this study. First, the design of the trial limited the scope and content of the campaign, and the likely external validity. Because we needed to roll out separate campaigns in all areas, it was too arduous to also put out videos or other types of campaign material. In a real-life setting, it would not be necessary to limit users to a very specific geographic unit, the costs of administering the campaign would be lower, and there would be room for other modes of communication.

Another limitation was that it was not possible to identify the exact effect of actually seeing the posts on testing behavior, as data on reach could not be directly linked with registry data on testing. We know that 82% of the population aged 18 years or

older has a Facebook profile [7], but this is only one of many social media platforms. Nevertheless, the total number of users speaking different languages, who were reached, suggests that a large share of the target group was exposed to the campaign.

A related limitation is that the campaign may have had spillover effects on the control group; for example, persons in the intervention group may have shared the post to their Facebook friends and followers. Such organic reach could not be measured, nor was it avoidable. Similarly, the message could have spread from the intervention group to the control group by word of mouth. Spillover effects may have led to an underestimation of the true effect.

Future research could look into effects of communication campaigns on other types of COVID-19 preventive behavior. We also suggest that future campaigns consider using the emergency broadcast capability inherent in cell phone services to deliver targeted advertisements.

Conclusions

Seeing a native-language post on Facebook, in a clear language easily understood manner regardless of health literacy, explaining that testing is simple and can be taken at no cost rendered our target group more likely to take a COVID-19 test. This study demonstrated that targeted social media advertisements sponsored by health authorities can influence individual behavior in an infection control–friendly direction during a pandemic.

Abstract

Background: The development and approval of COVID-19 vaccines have generated optimism for the end of the COVID-19 pandemic and a return to normalcy. However, vaccine hesitancy, often fueled by misinformation, poses a major barrier to achieving herd immunity.

Objective: We aim to investigate Twitter users' attitudes toward COVID-19 vaccination in Canada after vaccine rollout.

Methods: We applied a weakly supervised aspect-based sentiment analysis (ABSA) technique, which involves the human-in-the-loop system, on COVID-19 vaccination-related tweets in Canada. Automatically generated aspect and opinion terms were manually corrected by public health experts to ensure the accuracy of the terms and make them more domain-specific. Then, based on these manually corrected terms, the system inferred sentiments toward the aspects. We observed sentiments toward key aspects related to COVID-19 vaccination, and investigated how sentiments toward "vaccination" changed over time. In addition, we analyzed the most retweeted or liked tweets by observing most frequent nouns and sentiments toward key aspects.

Results: After applying the ABSA system, we obtained 170 aspect terms (eg, "immunity" and "pfizer") and 6775 opinion terms (eg, "trustworthy" for the positive sentiment and "jeopardize" for the negative sentiment). While manually verifying or editing these terms, our public health experts selected 20 key aspects related to COVID-19 vaccination for analysis. The sentiment analysis results for the 20 key aspects revealed negative sentiments related to "vaccine distribution," "side effects," "allergy," "reactions," and "anti-vaxxer," and positive sentiments related to "vaccine campaign," "vaccine candidates," and "immune response." These results indicate that the Twitter users express concerns about the safety of vaccines but still consider vaccines as the option to end the pandemic. In addition, compared to the sentiment of the remaining tweets, the most retweeted or liked tweets showed more positive sentiment overall toward key aspects ($P<.001$), especially vaccines ($P<.001$) and vaccination ($P=.009$). Further investigation of the most retweeted or liked tweets revealed two opposing trends in Twitter users who showed negative sentiments toward vaccines: the "anti-vaxxer" population that used negative sentiments as a means to discourage vaccination and the "Covid Zero" population that used negative sentiments to encourage vaccinations while critiquing the public health response.

Conclusions: Our study examined public sentiments toward COVID-19 vaccination on tweets over an extended period in Canada. Our findings could inform public health agencies to design and implement interventions to promote vaccination.

Introduction

The development and approval of COVID-19 vaccines have generated optimism for the end of the COVID-19 pandemic and a return to normalcy. Current data from clinical trials and real-world studies show that these vaccines have high efficacy and effectiveness in preventing infection and severe disease [1-3]. Since the start of vaccination in Canada and many countries with high vaccine coverage, deaths among vaccinated groups have plummeted, and most new infections and hospitalizations are occurring among unvaccinated individuals, although recently more breakthrough infections have been reported with the Omicron variant. However, the overall impact on reduction in transmission, morbidity, mortality, as well as the easing of restrictions will depend on vaccine coverage and uptake. Vaccine acceptance and uptake remains one of the most important public health concerns in many countries. Vaccine hesitancy—often fueled by misinformation surrounding the importance, safety, or effectiveness of the vaccine—poses a major barrier to achieving herd immunity [4]. The failure to eradicate other infectious diseases including polio, for instance, has been blamed on conspiracy theories that fueled vaccine hesitancy [5]. The same concern is now threatening the successful implementation of mass COVID-19 vaccination campaigns. A systematic review of 126 surveys published before November 2020 showed an increasing worldwide hesitancy toward the COVID-19 vaccine [6].

In an era of misinformation and disinformation, identifying and understanding vaccine hesitancy are key to containing the spread of the virus and crucial to framing public health messaging [4]. In addition to individual views on the vaccine, negative discourse and misinformation related to it on social media could create doubt. Similar to infection, misinformation on social media spreads within the social network (echo chambers) and could affect acceptance among people. A recent study noted a decline in vaccine acceptance from exposure to misinformation on social media [7]. In addition to broader vaccine hesitancy, vaccine hesitancy in local areas or networks could also increase the risk of transmission within the community even if the broader population is immune. Tackling misinformation about the vaccine on social media will be critical to achieving herd immunity and a path out of the pandemic.

Various studies have investigated people's attitudes toward COVID-19 vaccination and addressed vaccine misinformation in social media. Puri et al [8] discussed digital health strategies to handle vaccine misinformation on social media such as

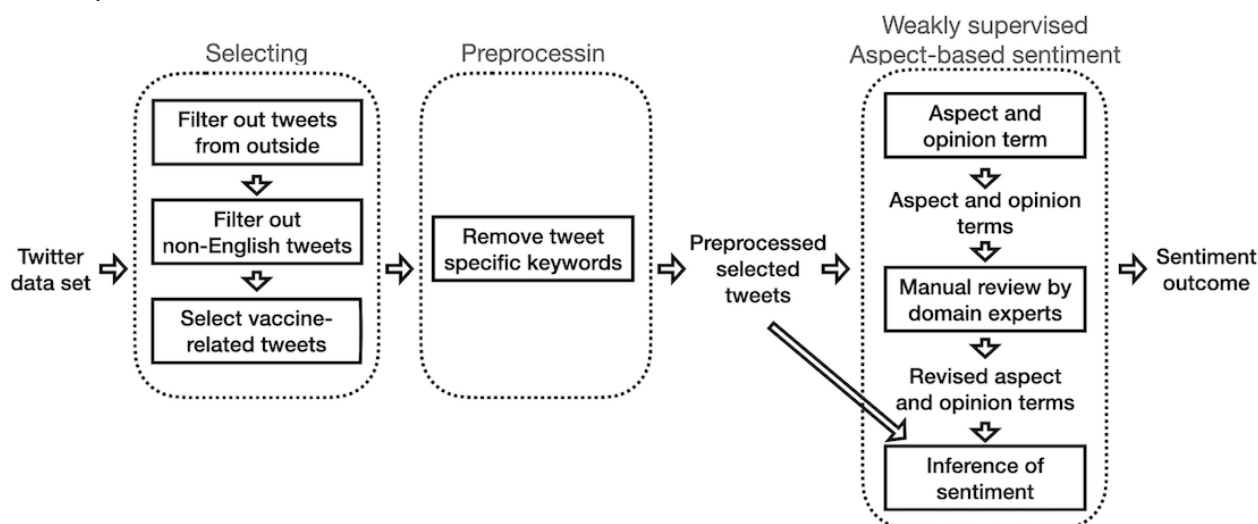

framing messages and leveraging celebrities. Chou and Budenz [9] reported that people's reactions to the COVID-19 vaccines are emotionally charged, and emphasized the role of emotion in vaccine communication efforts to address vaccine hesitancy. Thelwall et al [10] manually categorized 446 COVID-19 vaccine-hesitant tweets in English (March 10 to December 5, 2020) into 14 classes on the basis of what types of vaccine hesitancy information are shared. Some of these classes were efficacy, safety, and conspiracy. Hussain et al [11] performed sentiment analysis on Facebook and Twitter data to understand public sentiments toward COVID-19 vaccines in the United Kingdom and the United States. Guntuku et al [12] reported geographical and temporal variation in concerns about COVID-19 vaccines in the United States by using topic modeling. Kwok et al [13] analyzed tweets from Australian users by using topic modeling and sentiment analysis. Griffith et al [14] conducted content analysis on tweets from Canada, posted between December 10 and December 23, 2020, and identified reasons underlying vaccine hesitancy among Twitter users in Canada. Although prior research investigated public attitudes toward COVID-19 vaccination, to our knowledge, there has not been much research examining public sentiments toward COVID-19 vaccination over an extended period following the start of vaccine rollout. In addition, no prior work has investigated the most influential tweets.

In this paper, we investigate Twitter users' attitudes toward COVID-19 vaccination in Canada from December 2020 to May 2021. More specifically, we examined sentiments toward certain aspects related to COVID-19 vaccination, which were chosen by our public health domain experts, and show how those sentiments change over time. In addition, we observe what the most retweeted or liked tweets discuss and how their sentiments are. For these analyses, we use weakly supervised aspect-based sentiment analysis (ABSA) [15], a natural language processing technique that allows identifying sentiments for aspects. Our findings could inform the design and implementation of public health interventions to promote vaccination, toward the goal of ending the pandemic.

Methods

Methods Overview

The overview of our process is displayed in Figure 1. We first selected COVID-19 vaccination-related tweets and then preprocessed them. Then, based on these tweets, we performed weakly supervised ABSA.

Figure 1. Study overview.

Data and Preprocessing

We used a public Twitter data set about the COVID-19 pandemic, which was curated by Chen et al [16], using numerous COVID-19–related case-insensitive keywords such as “coronavirus,” “COVID-19,” and “pandemic.” Data collection started on January 28, 2020 (tweets from January 21, 2020), and is still ongoing. For the analysis in this paper, we collected tweets from December 2020 to May 2021, which spans from the beginning of vaccine rollout in Canada to the present.

From the data set, we extracted tweets originating in Canada and written in English by using tweet metadata and the spacy-langdetect toolkit (version 0.1.2) [17]. In addition, to focus on COVID-19 vaccination, we selected vaccine-related tweets using keywords (eg, “vaccine,” “vaccination,” “immunity,” “immune,” “rollout,” “mrna,” and “side effect”) defined by our domain experts. Our experts selected these keywords on the basis of public questions they received at the British Columbia Centre for Disease Control, which is responsible for vaccine programs and vaccine promotion. The original COVID-19 data set collected by Chen et al [16] contains 678,456,379 tweets for December 2020 to May 2021. Among them, the number of English tweets in Canada was 193,071. Of these, the number of the tweets that contain our search keywords was 21,821. As a result, 21,821 tweets were used for analysis. Among these, 10,202 tweets were original tweets, 6664 tweets were retweets or quoted tweets, 4955 tweets were replies to other tweets, and 112 tweets were both replies and quoted tweets. Of note, a quoted tweet is a type of retweet that contains an additional comment of the user. To remove tweet-specific keywords and URLs, we used the tweet-preprocessor toolkit (version 0.5.0) [18]. We did not remove hashtags and mentions because they are often part of a sentence, and could be informative for our work.

ABSA

We used ABSApp [19], a weakly supervised ABSA human-in-the-loop system, which enables public health domain experts to modify aspect and opinion terms that were automatically extracted from the corpus by the system. More

specifically, ABSApp automatically extracts both aspect and opinion terms from the data set without any manual labeling as the initial step and then allows humans to revise these terms. Then, based on these terms, the system automatically infers sentiment appearing in the data toward the aspect terms (Figure 1). In comparison to this weakly supervised ABSA system, a supervised method uses human labeled data and an unsupervised method does not use human efforts at all.

The aspect terms represent aspects we want to compute sentiment for, such as “pfizer” or “side effects.” The opinion terms are those that can be used for inference of sentiment; for example, “sore” for a negative sentiment and “immune” for a positive sentiment. The aspect and opinion terms can be domain-specific; hence, it is important to allow domain experts to edit them rather than just using automatically extracted general terms. These modified aspect and opinion terms were used for inference of sentiments for aspects.

To extract aspect and opinion terms in an unsupervised way using the ABSApp system first, we used 9239 tweets from December 2020 to February 2021. We used only the subset of the data for computational efficiency. The original study by Pereg et al [19] extracted terms from 75% of 2 data sets that consist of 5841 and 3614 sentences, respectively, which were much smaller than our data used for term extraction. Previous work [20] showed experimental results suggesting that increasing amounts of data beyond a certain point are unlikely to significantly increase the number of aspect terms when using ABSApp. In addition, opinion terms are not expected to differ much between February 2021 and May 2021 as they are the terms that indicate the sentiment of the tweets. The system automatically extracted 108 aspect terms and 6793 opinion terms.

Automatically extracted terms were manually reviewed and edited by 2 public health experts. Each expert reviewed and edited the whole list of aspect terms and opinion terms separately. The discrepancies in edits were addressed differently for the aspect terms and the opinion terms. For the aspect terms, we did not discard differences and selected all terms including discrepancies because an aspect term could be meaningful if at

least one expert found it useful. For the opinion terms, we excluded the terms that did not agree because those opinion terms would not be a strong indicator of a sentiment if the experts did not agree. This manual edition process resulted in 170 aspect terms and 6775 opinion terms, and they were used for the sentiment inference step. Among the aspect terms, our experts selected 20 key aspects more relevant to COVID-19 vaccination, for which we report results in this paper.

In addition, we investigated most liked or retweeted tweets to determine what they discuss and which sentiment they convey. We first identified original tweets that were not retweets, quoted tweets, or replies to other tweets. Tweet metadata such as *retweeted_status*, *is_quote_status*, and *in_reply_to_status_id* were used. Then, we sorted the original tweets by their *retweet_count* and *favorite_count* (Twitter changed the “favorite” button to a “like” button; hence, hereinafter, we have used these two terms interchangeably). To observe the discourse in the top-ranked original tweets, we computed the frequency

of nouns appearing in the tweets. For this computation, we first tokenized preprocessed tweets that did not contain tweet-specific keywords, URLs, and hashtags, and tagged part-of-speech. For both tokenization and part-of-speech tagging, the spacy toolkit (version 2.1.8) [21] was used. Scripts for preprocessing and analysis are available on the internet [22].

Results

Figure 2 shows the most frequently appearing aspect terms that were automatically extracted by the system. “vaccines” and “covid” were the most common aspects, probably because they were used for filtering out non-vaccine-related tweets during the data collection. The other words describe the discussion in this data set. People discussed aspects such as “hope,” “people,” “friends,” “world,” “deaths,” and “delay” together with COVID-19 vaccines. The less meaningful aspects (eg, “ones”) are included as these aspects were automatically extracted without any manual intervention.

Figure 2. Most frequently appearing aspects in the data, extracted automatically by the system.

The sentiment outcomes of the aspects most relevant to COVID-19 vaccines, which were selected by public health experts, are shown in Figure 3. Overall, the sentiment toward “vaccines,” “vaccination,” and specific vaccine brands such as “pfizer” and “moderna” show similar levels of positive and negative sentiments. A more negative sentiment was observed with “vaccine distribution,” “side effects,” “allergy,” “reactions,” and “anti-vaxxer.” A more positive sentiment was observed toward “vaccination campaign,” “vaccine candidates,” and “immune response.”

Figure 4 shows the change in sentiment over time toward “vaccination.” First, we observed that the discussion about vaccination increased drastically in March and peaked in mid-April. Thereafter, it decreased.

Tables 1 and 2 show the distribution of how many times the original tweets were retweeted and liked by other users,

respectively. As expected, large number of tweets were not retweeted or liked, while a small number of tweets had a large number of retweets and likes.

Figure 5 displays nouns that appeared in more than 5 tweets among the 100 most retweeted original tweets. These tweets were the same as the 100 most liked original tweets. In addition, Table 3 lists top 3 most liked and retweeted tweets. These data show that the most influential tweets were related to vaccine rollout, distribution, or administration and people’s hope and wish to end the pandemic situation.

Figure 6 shows the sentiment of 500 most liked tweets toward the key aspects selected by our public health experts. Compared to the sentiment of all the remaining tweets, these tweets show a significantly more positive sentiment overall about the key aspects ($P < .001$), especially vaccines ($P < .001$) and vaccination ($P = .009$), as revealed through chi-square analysis.

Figure 3. Results of aspect-based sentiment analysis. x-axis: selected aspects, y-axis (left): number of positive occurrences and number of negative occurrences in log scale; secondary y-axis (right): percentage of positive occurrences.

Figure 4. Sentiment changes over time for COVID-19 vaccination. Primary y-axis (left): number of total occurrences; secondary y-axis (right): percentage of positive occurrences.

Table 1. Frequency distribution of original tweets being retweeted.

Number of times a tweet is retweeted	Frequency (number of tweets)
0	7033
1-50	3040
51-100	50
101-200	46
201-2169	33

Table 2. Frequency distribution of original tweets being liked.

Number of times a tweet is liked	Frequency (number of tweets)
0	4804
1-50	4863
51-100	238
101-200	126
201-400	79
401-800	52
801-7304	40

Do you know why they haven't lifted the pandemic "emergency" yet? The first sentence on this pfizer website has an answer: none of the vaccines have been approved. They are only authorized for use in an "emergency". No emergency, no experimental vaccines.	4306	2169	256,484
We have a hyperinfectious Covid variant circulating in the community, a vaccine shortage and are just on the verge of restoring contact tracing. If we pursue a #COVIDzero strategy we can be out of this by March. If we don't we can forfeit our sacrifices & see a huge 3rd wave.	4169	1329	20,352
Vaccines sitting in freezers in Ontario: 985,132 Total vaccines administered today: 59,567	2926	1061	23,923
please stop playing games with our lives. Implement #PaidSickDays, ramp up vaccine administrations, and a real lockdown. Mockdown 3.0 isn't cutting it.			

Figure 6. Sentiment toward certain aspects observed in the 500 most influential (most liked) tweets (1: top 100 tweets, 2: 101st-200th, 3: 201st-300th, 4: 301st-400th, 5: 401st-500th, y-axis: number of tweets).

Discussion

Principal Findings

In this study, we examined sentiments expressed toward COVID-19 vaccination on Twitter in Canada from December 2020 to May 2021. Major aspects included risk, hope, deaths, and delay. Positive sentiments were expressed for “vaccination campaign,” “vaccine candidates,” and “immune response,” while negative sentiments were expressed for issues related vaccine distribution, adverse effects (safety), and antivaccination. As expected, there was a small number of tweets that were retweeted multiple times. Within this group, we found antivaccination tweets, which were retweeted multiple times to a large number of people. Tackling misinformation spread by this small number of posts could have a large impact on countering vaccine misinformation.

The aspect “risk” in our most frequent aspects (Figure 2) suggests that people who were concerned about the risk of COVID-19 considered vaccination a solution. There were also tweets about the risk of side effects of vaccination, but mostly

the conversations were centered around the risk of COVID-19 outweighing the risk of vaccination. This is aligned with prior work, which revealed that the safety category was ranked in the top 3 among 446 COVID-19 vaccine-hesitant tweets between March 10 and December 5, 2020 [10]. Survey data on vaccine acceptance also indicate an association between concerns about vaccine safety and a low intention to receive a COVID-19 vaccine [23-25]. A similar finding was observed in the study by Lyu et al [26], which showed that “trust” was the most dominant emotion in tweets from March 11, 2020, to January 31, 2021. This highlights the need to address safety concerns about vaccines to increase vaccine uptake. Other frequently discussed aspects “delay” and “hope” in our data indicate that people were worried about the delay in vaccine rollout in Canada but still considered vaccines as the option to end the pandemic. These aspects highlight frustration from twitter users in the delayed vaccine supply in Canada compared to those in the United States and in other countries.

Our results show that the largest segment of negative sentiment was toward vaccine adverse effects including “allergy,” “side

effects,” and “reactions” (Figure 3). This finding is similar to prior work that showed that the largest public concern about COVID-19 vaccines was safety. Eibensteiner et al [27] reported that 41.7% of Twitter users (n=3439) around the world were unsure about the safety of COVID-19 vaccines, in the polls conducted for 1 week in mid-February 2021. In addition, in the earlier analysis performed on manually coded tweets in Canada on December 18 and 23, 2020, a total of 48.3% (292/605) of tweets expressed concerns about the safety of vaccines [24,25]. These concerns are consistent with the public health focus as well as media attention to side effects including thrombosis and myocarditis (heart inflammation). This indicates the continued challenge for public health agencies to address concerns about vaccine safety and instill confidence about COVID-19 vaccines.

It is also interesting to note the lack of difference in sentiment toward the vaccine developed by pfizer versus that developed by AstraZeneca (Figure 3). This might suggest a more complex understanding of vaccination by Twitter users despite media attention toward people not wanting to be vaccinated with AstraZeneca’s vaccine in March 2021 [28,29]. The high attentiveness to dosing intervals after vaccination (Figure 3) further emphasizes the challenges of knowledge translation and science communication as evidence changes.

Our results (Figure 4) show that the discussion about vaccination gradually increased after vaccine rollout on December 14, 2020, and drastically decreased after mid-April 2021. This finding aligns with the deceleration in the uptake of the first vaccine dose [30,31]. This may indicate a shift of public attention away from vaccination and the need to bring back a focus on vaccination to enhance vaccine coverage.

The 500 most liked tweets showed more positive sentiments overall toward the key aspects outlined in Figure 6, especially toward vaccines and vaccination, compared to the sentiments from the remaining tweets. On closer inspection, the most liked or retweeted tweets (Table 3) showed an interesting dichotomy in Twitter users who reported a negative sentiment toward vaccines: the “anti-vaxxer” population that largely used negative sentiment as a means to discourage vaccination, and the “Covid Zero” population that also used negative sentiment, albeit to encourage vaccination, while also critiquing the public health response. This finding from the most influential tweets highlights the need for public health agencies to have a

multipronged approach to health messaging related to vaccine information and misinformation. In addition, given that the most liked or retweeted tweets have a very large circle of influence (eg, 256,484 followers), investigating these tweets is crucial to identifying and tackling misinformation and even tracking dissemination of positive information. For example, if such tweets could be flagged for public health agencies through a dashboard, the information or claim in them could be verified or refuted in official channels.

Limitations

This study highlights important trends in Twitter conversations, which may have crucial policy implications. However, the following limitations need to be considered when interpreting the results and when our pipeline is deployed in practice. First, the tweets we used might not be representative of the general population. Recently, it is reported that the largest age group in Twitter users is 30–49 years (44%) [32]. Second, it should be noted that specific cities might overrepresent Canada in our study according to previous work by Gore et al [33]. However, the Twitter data that meet our inclusion criteria are not sufficient for a city-level analysis, especially given that we carry out our analysis on the basis of aspects. The limitations we mention here exist not only for our study but also for most previous work, which used tweets for a certain period at a nationwide level.

Second, although the ABSApp approach for ABSA leverages manually edited domain-specific aspect and opinion terms to improve the accuracy of sentiment analysis, it is still premature to accurately capture the intricacy of human language, such as figurative languages. Nevertheless, these limitations are not particular to our study but rather inherent in all current state-of-the-art sentiment analysis tools and techniques as well.

Conclusions

Social media presents a convenient opportunity to assess public perception on a wide variety of issues, as part of the pandemic response. This study examined public sentiments toward COVID-19 vaccination on tweets over an extended period in Canada. In addition, we also investigated the most influential tweets. Our findings could inform public health agencies to design and implement interventions to promote vaccination, and approach the goal of ending the pandemic.

Authors' Contributions

HJ, ER, IR, GC, and NZJ contributed to the conception and design of the study. HJ performed data collection, preprocessing, and all analyses. ER and IR contributed to reviewing automatically generated aspect and opinion terms. GC, PA, and NZJ contributed to the discussion of statistical analysis. HJ wrote the first draft of the manuscript. ER contributed to sections of the manuscript. All authors contributed to manuscript revision, read, and approved the submitted version.

Abstract

Background: The spread of false and misleading health information on social media can cause individual and social harm. Research on debunking has shown that properly designed corrections can mitigate the impact of misinformation, but little is known about the impact of correction in the context of prolonged social media debates. For example, when a social media user takes to Facebook to make a false claim about a health-related practice and a health expert subsequently refutes the claim, the conversation rarely ends there. Often, the social media user proceeds by rebuking the critic and doubling down on the claim.

Objective: The aim of this study was to examine the impact of such extended back and forth between false claims and debunking attempts on observers' dispositions toward behavior that science favors. We tested competing predictions about the effect of extended exposure on people's attitudes and intentions toward masking in public during the early days of the COVID-19 pandemic and explored several psychological processes potentially underlying this effect.

Methods: A total of 500 US residents took part in an online experiment in October 2020. They reported on their attitudes and intentions toward wearing masks in public. They were then randomly assigned to one of four social media exposure conditions (misinformation only vs misinformation+correction vs misinformation+correction+rebuttal vs misinformation+correction+rebuttal+second correction), and reported their attitudes and intentions for a second time. They also indicated whether they would consider sharing the thread if they were to see it on social media and answered questions on potential mediators and covariates.

Results: Exposure to misinformation had a negative impact on attitudes and intentions toward masking ($\beta = -.35$, 95% CI $-.42$ to $-.29$; $P < .001$). Moreover, initial debunking of a false claim generally improved attitudes and intentions toward masking ($\beta = .35$, 95% CI $.16$ to $.54$; $P < .001$). However, this improvement was washed out by further exposure to false claims and debunking attempts ($\beta = -.53$, 95% CI $-.72$ to $-.34$; $P < .001$). The latter result is partially explained by a decrease in the perceived objectivity of truth. That is, extended exposure to false claims and debunking attempts appear to weaken the belief that there is an objectively correct answer to how people ought to behave in this situation, which in turn leads to less positive reactions toward masking as the prescribed behavior.

Conclusions: Health professionals and science advocates face an underappreciated challenge in attempting to debunk misinformation on social media. Although engaging in extended debates with science deniers and other purveyors of bunk appears necessary, more research is needed to address the unintended consequences of such engagement.

Introduction

Context

The internet in general and social media in particular have become important sources of information for many people seeking medical and health-related information. As of 2014, 72% of internet users in the United States reported having searched for health-related information online [1]. More recently, 49% of US adults reported obtaining at least some of their news about the COVID-19 vaccine on social media, and among those who regularly obtain news from social media, 61% rated social media as an important way of keeping up with news about COVID-19 vaccines [2]. Yet, content disseminated through social media sites such as Facebook, Twitter, or Reddit remains largely unregulated, and is replete with false and misleading information [3-8].

The widespread availability and consumption of false, inaccurate, or incomplete health information (herein referred to as “health misinformation”) is a serious problem that can cause individual and social harm by promoting erroneous beliefs about health and illness, leading to detrimental behavior [9,10]. For example, the persistent circulation of unfounded claims linking vaccination to autism has convinced many parents not to immunize their children, which has resulted in a significant rise in vaccine-preventable diseases and death [11]. Believing misinformation about COVID-19 has been linked to lower adoption of health protective behaviors [12] and greater consumption of harmful products [13]. Evidence also suggests that online disinformation campaigns on a global scale have played a key role in the notable drop in vaccination coverage over time [14].

Recognizing the potentially disastrous consequences of letting misinformation proliferate on social media, researchers from diverse fields have proposed a variety of countermeasures, including technological solutions aimed at limiting exposure to misinformation, educational interventions aimed at empowering people to recognize and deal with misinformation, as well as communication tools designed to help debunk and correct misinformation [15-19]. Importantly, health experts and health care professionals have been called upon to play an active role in correcting health misinformation when they encounter it on social media [20-27].

Elsewhere, a rich literature on debunking has shown that properly designed corrections can be effective at countering misinformation [28-31]. This research, however, has examined the issue mostly from a static perspective. In a typical study, participants are first exposed to misinformation. Subsequently, some participants receive a correction, and their responses are compared to a control group that received no correction or a comparison group that received an alternate correction varying in its content, source, or some other relevant attribute (eg, [27,32-36]). Although this paradigm allows for a clean test of the relative effectiveness of specific debunking interventions,

it oversimplifies the dynamic nature of social media conversations. For example, when a social media user takes to Facebook to make a false claim about a health-related practice, and a health expert subsequently refutes the claim, the conversation rarely ends there. Often, the social media user proceeds by rebuking the critic and doubling down on the claim.

Objectives

The aim of this study was to examine the impact of such extended back and forth between false claims and debunking attempts on observers’ dispositions toward behavior favored by science. The US Centers for Disease Control and Prevention (CDC) had been recommending mask wearing in public since April 2020. However, by the time of our study in October 2020, less than half of the states had issued a mandate for mask wearing in public [37], and misinformation regarding the safety and efficacy of masking had become rampant on social media [38].

In this study, we tested competing predictions about the effect of extended exposure on people’s attitudes and intentions toward masking in public and explored several psychological processes potentially underlying this effect.

On the one hand, properly debunking a false claim may have a lasting effect, such that when the purveyor of misinformation proceeds to rebuke the critic and double down on the false claim, observers’ attitudes toward masking would remain unaffected by the new round of misinformation. A detailed refutation that includes a clear explanation of why a claim is false and what is true instead [16,39] could have a persistent impact on observers’ attitudes because, in addition to arming them with facts, it undermines the credibility of the argument underlying the false claim [40]. Moreover, research on “prebunking” has shown that it is possible to inoculate individuals against misinformation before it is even encountered [41-43]. Extending the principle of prebunking to prolonged social media debates, one could surmise that witnessing a thorough refutation of a false claim early in the debate may inoculate people against later assertions of the false claim.

On the other hand, repeated exposure to misinformation and its rebuttal could create uncertainty about the very existence of true facts [4,44]. For example, in reference to President Donald Trump’s extensive record of making false and misleading claims, Lewandowski et al [44] quoted a 2017 editorial from the Bangor Daily News suggesting that one important consequence of the repeated falsehoods is that “A third of the population will say ‘clearly the White House is lying,’ a third will say ‘if Trump says it, it must be true,’ and the remaining third will say ‘gosh, I guess this is unknowable.’” A year later, former Director of National Intelligence, James Clapper [45], warned that “many Americans are questioning if facts are even knowable, as foreign adversaries and our national leaders continue to deny objective reality while advancing their own alternative facts.”

In the health domain, exposure to conflicting information about a wide range of topics, including mammography [46,47], nutrition [48,49], and the human papillomavirus vaccine [50], has been shown to increase confusion, uncertainty, and negative attitudes toward the health topic in question. Together, these results suggest that exposure to an extended back and forth between false claims and debunking attempts may generate doubt about the very existence of a nonsubjective true answer to a health-related question. This study specifically examined the discourse surrounding the question of whether wearing masks in public should be prescribed. Based on extant theory, we hypothesized that such discourse would weaken people's attitudes and intentions toward masking in public as the prescribed behavior.

In addition to testing these competing predictions, we explored the impact of extended exposure on people's intentions to share the social media threads. This has direct implications for understanding how misinformation spreads on social media.

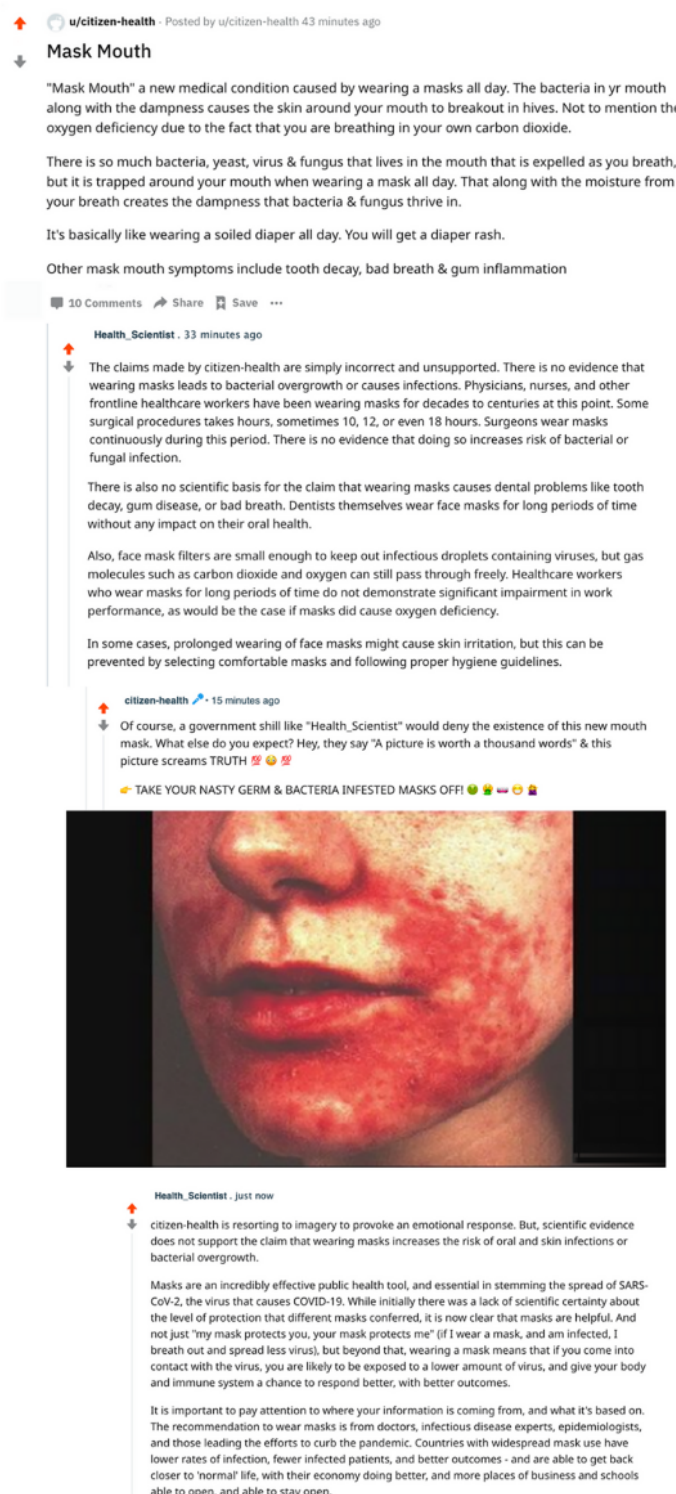

Methods

Participants and Procedure

Respondents were recruited from Prolific, a platform for recruiting online participants that explicitly caters to researchers. Prolific provides diverse and valid samples, and its data quality compares favorably with that of other online platforms such as MTurk [51,52]. US residents with an existing account on Prolific took part in the study on October 16, 2020, in exchange for monetary compensation.

Upon consenting in writing, participants answered questions about the relevance of various sources of health information, the impact of COVID-19 (including their perceived risk of infection), and reported on their attitudes and intentions toward wearing masks in public. They then completed a first attention check and were randomly assigned to one of four social media exposure conditions (misinformation only [M] vs misinformation+correction [MC] vs misinformation+correction+rebuttal [MCR] vs misinformation+correction+rebuttal+second correction [MCRC]). The attention check consisted of a statement at the end of a question asking participants to choose a specific answer to ensure they were reading the questions.

The social media content consisted of Reddit posts that were adapted from real social media posts and expert responses collected by the International Fact Checking Network [38], which are shown in full in Figure 1. Participants in the M condition reviewed a post by a user with the username *citizen-health* arguing that wearing face masks can cause a new disease called "mask mouth." Those in the MC condition saw the same post plus a correction from a user with the username *Health_Scientist*, pointing out that there is in fact no scientific evidence of any new disease caused by wearing face masks. Those in the MCR group saw a thread containing the previous two posts plus a second post from *citizen-health* rebuking *Health_Scientist* and doubling down on the original claim. Finally, those in the MCRC condition saw a thread containing the previous three posts plus a second correction from *Health_Scientist*.

Figure 1. Reddit posts for the misinformation+correction+rebuttal+second correction condition.

After reviewing the Reddit thread, participants completed a comprehension check assessing their comprehension of the position argued by *citizen-health*. They then indicated whether they would consider sharing the thread if they were to see it on social media, and reported their attitudes and intentions for a second time. They also answered questions on potential mediators and additional covariates. Mediators included perceptions of objectivity of truth, argument strength, and warmth and competence of the protagonists in the Reddit

exchange. Covariates included perceived COVID-19 risk, cognitive reflection, conspiracy mentality, and political orientation.

Ethical Considerations

The study was approved by the University of Calgary Conjoint Faculty Research Ethics Board (REB20-1178) and was conducted according to the principles expressed in the Declaration of Helsinki.

Measures

Attitudes were measured using three items (“Masking in public is necessary; good; beneficial”) rated on 7-point scales (1=*strongly disagree*, 7=*strongly agree*). Participants indicated their intention to wear a mask in public using a single item (“Over the next months, how often do you intend to wear a face mask when in public?”) also on a 7-point scale (1=*never*, 7=*all the time*). Since the attitude and intention measures were highly correlated, we combined them into a single index of disposition toward masking in public ($\alpha=.96$ preexposure and $\alpha=.97$ postexposure).

To measure perceived objectivity of truth, we asked respondents to consider the question “Should people wear masks in public?” and indicate the extent to which they think there is an objectively true answer to this question [53,54]. They reported their answers on a 7-point scale (1=*definitely no objective truth*, 7=*definitely an objective truth*).

Perceived argument strength was measured using five items adapted from Zhao et al [55]. A sample item is “The arguments of citizen-health are a convincing reason against masking in public” (1=*strongly disagree*, 7=*strongly agree*). The complete scale ($\alpha=.86$ for *citizen-health* and $\alpha=.94$ for *Health_Scientist*) is detailed in [Multimedia Appendix 1](#).

Participants rated the warmth and competence of both protagonists on 11-point bipolar scales adapted from previous research [40,56]. Perceived warmth was assessed using four items ($\alpha=.93$ for *citizen-health* and $\alpha=.96$ for *Health_Scientist*), including *unfriendly/friendly*, *cold/warm*, *irritable/good-natured*, *unsympathetic/sympathetic*. Perceived competence was assessed using six items ($\alpha=.97$ for *citizen-health* and $\alpha=.98$ for *Health_Scientist*), including *uninformed/informed*, *unqualified/qualified*, *unreliable/reliable*, *unbelievable/believable*, and *incompetent/competent*.

Respondents indicated the probability they will be infected with the coronavirus in the next 12 months on a sliding scale (0=0%, 100=100%), and rated how harmful it would be for their health if they were to become infected (1=*not at all*, 5=*extremely*). We computed a perceived COVID-19 risk score by multiplying the probability of infection by the perceived harm and dividing by 100.

Conspiracy mentality was measured using five items ($\alpha=.89$) rated on 7-point scales (1=*strongly disagree*, 7=*strongly agree*) adapted from Bruder et al [57]. A sample item is “Events which superficially seem to lack a connection are often the result of secret activities.”

We assessed cognitive reflection by combining the three items of Frederick’s [58] original Cognitive Reflection Test (CRT; eg, “A bat and a ball cost \$1.10 in total. The bat costs \$1.00 more than the ball. How much does the ball cost?”) with the four items of Thomson and Oppenheimer’s [59] nonnumeric CRT (eg, “If you’re running a race and you pass the person in second place, what place are you in?”). Answers were coded 1 for a correct answer and 0 for an incorrect answer. The final cognitive reflection score is the sum of all the correct answers.

The following two items ($r=0.89$) adapted from Schmid and Betsch [40] were used to measure political orientation: (1) If you think about your own political views, where would you classify your views on this scale? (1=*very conservative*, 7=*very liberal*), and (2) If you think about your own political identity, where would you classify your views on this scale? (1=*Republican*, 7=*Democrat*). Scores were reversed so that higher scores indicate political conservatism.

Participants rated their sharing intention on a single item: “If you were to see this post on social media, would you consider sharing it?” (1=*definitely not*, 5=*definitely yes*).

Statistical Analysis

Disposition Toward Masking in Public

Data analysis was performed using the statistical program R, version 4.0 [60], and the level of statistical significance was set at $\alpha=.05$. To answer our main research question, we examined how progressive exposure to false claims and debunking attempts affects people’s attitudes and intentions toward masking in public. Specifically, we tested whether a change in disposition toward masking in public varied from one exposure condition to the next.

Given the structure in our data (each participant provided two sets of ratings), we fit a linear mixed-effects model with disposition toward masking in public as the outcome variable; random intercepts for participants (ID); and fixed effects for exposure condition (contrast-coded using repeated contrasts), time of rating (contrast-coded using treatment contrast), and their interaction. We also added perceived COVID-19 risk, cognitive reflection, political orientation, and conspiracy mentality as mean-centered covariates in the model. The model was estimated using maximum likelihood. We compared this model’s goodness of fit to a second model that was identical but did not include the condition \times time interaction term. The likelihood ratio test indicated that model fit improved significantly when the interaction term was present ($\chi^2_3=33.71$, $P<.001$), thus suggesting a significant interaction.

The P values for the mixed-effects model with interaction were estimated via t tests using the Satterthwaite approximations to degrees of freedom. Effect sizes for the fixed effects are indicated by the standardized regression coefficients (β values) and their 95% CIs

Perceived Objectivity of Truth

Should people wear masks in public? We speculated that during extended debates, the reiteration of false information and rebuke of experts might shake people’s confidence, not only in the veracity of any answer to the question but also in the very existence of an objectively true answer. To test this idea, we performed an analysis of covariance (ANCOVA) on perceived objectivity of truth with exposure condition as the independent variable. Our model controlled for preexposure disposition toward masking in public, perceived COVID-19 risk, cognitive reflection, political orientation, and conspiracy mentality.

Perceived Argument Strength

To test whether exposure to extended debates influences perceptions of the strength of *citizen-health's* arguments, we performed an ANCOVA on perceived argument strength, with condition as the independent variable and controlling for the same set of covariates as indicated above.

Mediation Analysis

We examined whether multiple processes may underly the effect of exposure to misinformation and debunking attempts on the change in people's disposition toward masking in public. Specifically, we tested the idea that correcting the original false claim may improve disposition toward masking, in part, by undermining the strength of the arguments put forth by the misinformation purveyor. Yet, further exposure may generate some doubt about the very existence of an objectively true answer, which, in turn, may weaken people's attitudes and intentions toward masking.

We performed two parallel mediation analyses. The first focused on the difference between the MC and M conditions, whereas the second focused on the difference between the MCR and MC conditions. The mediation models included the change in

disposition toward masking in public as the dependent variable, exposure condition as the independent variable, perceived objectivity as the first mediator, and perceived argument strength as the second mediator. Change in disposition toward masking in public was computed by subtracting participants' initial disposition scores from their postexposure scores. The models were estimated using maximum likelihood with robust standard errors.

Results

Sample Characteristics

A total of 500 participants responded to the survey. Four participants failed the initial attention check and 17 failed the comprehension check. Of those, 6 were in the MC condition, 3 were in the MCR condition, and 8 were in the MCRC condition. After removing responses from participants who failed at least one attention check, we were left with a final sample of 479 participants. The sample's demographic characteristics are shown in Table 1. It is worth noting that including data from participants who failed the attention or comprehension checks did not materially change the size, direction, or statistical significance of the reported effects.

Table 1. Sample characteristics (N=479).

Characteristic	Value
Age (years), mean (SD)	32.1 (12.3)

Disposition Toward Masking in Public

Figure 2 shows the estimated marginal means and their 95% CIs. The means and SDs for all variables are presented in Table S1 of Multimedia Appendix 1. Prior to reviewing the Reddit threads, participants in all conditions reported similarly high dispositions toward masking in public. The estimated marginal means did not differ significantly between successive conditions, as shown in Table 2 (ie, P values for MC vs M, MCR vs MC, and MCRC vs MCR are all greater than .05). This confirmed that random assignment produced groups with equivalent baselines. The model statistics are summarized in Table 3. Furthermore, exposure to misinformation without any correction resulted in lower disposition toward masking in public (Time 2 in Table 2), while correcting false information improved disposition toward masking. Indeed, participants in the MC condition expressed more positive attitudes and intentions at time 2 than those in the M condition (Time 2: MC vs M in Table 2). Interestingly, the positive effect of correction seemed to vanish when the source of misinformation rebukes the correction

and doubles down on the false claim. Participants in the MCR condition reported significantly lower disposition scores than those in the MC condition (Time 2: MCR vs MC in Table 2). Perhaps even more concerning, a second round of corrections did not appear to effectively counter the impact of the rebuke and doubling down. Indeed, disposition toward masking in public did not differ significantly between participants in the MCRC and MCR conditions.

Although not our primary focus, it is worth noting that all four covariates had significant effects in the expected directions. Disposition toward masking in public was positively related to perceived COVID-19 risk and cognitive reflection (CRT). The latter is consistent with recent research showing CRT to be negatively correlated with the perceived accuracy of fake news, and positively correlated with the ability to discern fake news from real news [61]. Conversely, disposition toward masking in public was negatively related to conspiratorial thinking and political conservatism.

Figure 2. Estimated marginal means and 95% CIs for disposition toward masking in public across conditions and measurement times. M: misinformation-only experimental condition; MC: misinformation+correction experimental condition; MCR: misinformation+correction+rebutal experimental condition; MCRC: misinformation+correction+rebutal+second correction experimental condition.

Perceived Objectivity of Truth

The patterns in our data (see the estimated marginal means in Figure 3) lend support to the idea that reiteration of false

information and rebuttal of experts might weaken people's confidence in the very existence of an objectively true answer.

Figure 3. Estimated marginal means and 95% CIs for perceived objectivity of truth across conditions. M: misinformation-only experimental condition; MC: misinformation+correction experimental condition; MCR: misinformation+correction+rebuttal experimental condition; MCRC: misinformation+correction+rebuttal+second correction experimental condition.

We found a significant effect of condition ($F_{3,470}=16.96, P<.001, \eta_p^2=0.098$). Planned contrasts with Bonferroni correction for multiple tests revealed that people's perception of the objectivity of truth did not change significantly between the MC and M conditions (mean 6.18, SD 1.14 vs mean 5.91, SD 1.34, respectively; $t_{470}=0.53, P>.99, d=0.22, 95\% \text{ CI } -0.03 \text{ to } 0.47$). However, exposure to a second round of misinformation (MCR condition) resulted in appreciably lower perceptions of truth objectivity compared to those for the MC condition (mean 4.96, SD 1.88; $t_{470}=-6.01, P<.001, d=-0.79, 95\% \text{ CI } -1.05 \text{ to } -0.52$). Moreover, witnessing a second correction (MCRC condition) failed to improve perceptions of truth objectivity compared to the MCR condition (mean 5.31, SD 1.81; $t_{470}=1.74, P=.25, d=0.19, 95\% \text{ CI } -0.07 \text{ to } 0.44$). These results suggest that once undermined, perceived objectivity of truth may be difficult to restore.

With respect to the covariates, we found that initial disposition toward masking was positively related to perceived objectivity ($b=0.31, \text{ SE } 0.06; F_{1,470}=25.88, P<.001, \eta_p^2=0.05$), whereas political conservatism ($b=-0.17, \text{ SE } 0.04; F_{1,470}=14.48, P<.001, \eta_p^2=0.03$) and conspiracy mentality ($b=-0.12, \text{ SE } 0.05; F_{1,470}=5.06, P=.02, \eta_p^2=0.01$) were negatively related to perceived objectivity. The effects of cognitive reflection ($b=0.03, \text{ SE } 0.03; F_{1,470}=0.92, P=.34, \eta_p^2=0.002$) and perceived COVID-19 risk ($b=0.10, \text{ SE } 0.07; F_{1,470}=1.96, P=.16, \eta_p^2=0.004$) were not significant.

Figure 4. Estimated marginal means and 95% CIs for perceived argument strength across exposure conditions. M: misinformation-only experimental condition; MC: misinformation+correction experimental condition; MCR: misinformation+correction+rebuttal experimental condition; MCRC: misinformation+correction+rebuttal+second correction experimental condition.

As for the covariates, political conservatism ($b=0.14, \text{ SE } 0.04; F_{1,470}=14.03, P<.001, \eta_p^2=0.029$) and conspiracy mentality ($b=0.16, \text{ SE } 0.04; F_{1,470}=12.19, P<.001, \eta_p^2=0.025$) were positively related to perceived argument strength, whereas initial disposition to wearing masks ($b=-0.39, \text{ SE } 0.05; F_{1,470}=62.96, P<.001, \eta_p^2=0.118$) and cognitive reflection ($b=-0.05, \text{ SE } 0.03; F_{1,470}=4.13, P=.04, \eta_p^2=0.009$) were negatively related to perceived argument strength. Perceived COVID-19 risk ($b=0.08,$

Perceived Argument Strength

The previous analysis suggested that reduction in the perceived objectivity of truth only occurs following exposure to the second round of misinformation. Thus, perceived objectivity of truth cannot account for the observed changes in attitude and intention across the entire range of exposure conditions. In particular, it cannot account for the improvement in disposition toward masking following correction of the initial false claim. Therefore, we next examined whether perceptions of the strength of *citizen-health's* arguments may provide an alternative account.

Exposure condition had a significant impact on perceived argument strength ($F_{3,470}=8.21, P<.001, \eta_p^2=0.05$). Planned contrasts with Bonferroni correction for multiple tests revealed that *citizen-health's* arguments were perceived to be weaker in the MC condition than in the M condition (mean 1.95, SD 1.26 vs mean 2.75, SD 1.59, respectively; $t_{470}=-4.43, P<.001, d=-0.55, 95\% \text{ CI } -0.81 \text{ to } -0.30$). However, perceived argument strength remained low in the MCR condition and showed no difference from that in the MC condition (mean 2.12, SD 1.31; $t_{470}=0.34, P>.99, d=0.13, 95\% \text{ CI } -0.12 \text{ to } 0.39$). It also did not differ significantly between the MCRC condition and the MCR condition (mean 2.34, SD 1.30; $t_{470}=1.72, P=.26, d=0.17, 95\% \text{ CI } -0.09 \text{ to } 0.42$). The estimated marginal means are shown in Figure 4.

SE 0.06; $F_{1,470}=1.92, P=.17, \eta_p^2=0.004$) was unrelated to perceived argument strength.

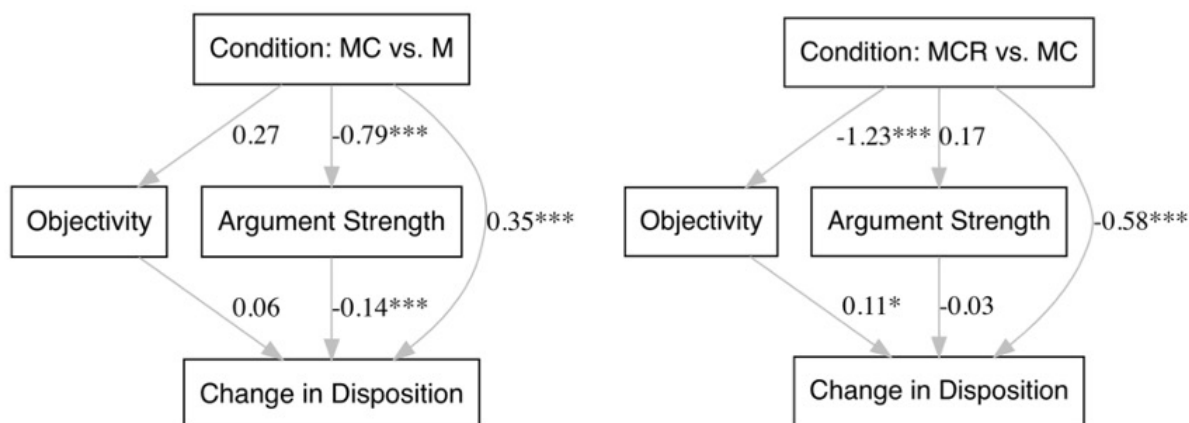

Mediation Analysis

When comparing the MC and M conditions, the effect of increased exposure on change in disposition toward masking in public was partially mediated by perceived argument strength (Figure 5). Indeed, both the indirect effect Condition through Argument Strength through Change in Disposition ($b=0.12, \text{ SE } 0.04, z=2.96; P=.01, 95\% \text{ CI } 0.04-0.19$) and the direct effect

Condition through Change in Disposition ($b=0.35$, SE 0.09, $z=3.90$; $P<.001$, 95% CI 0.17-0.52) were significant. However, the second indirect effect Condition through Objectivity through Change in Disposition was not significant ($b=0.02$, SE 0.02, $z=0.93$; $P=.35$, 95% CI -0.02 to 0.05). Moreover, a formal test

of the difference between the indirect effects confirmed that the indirect effect through Argument Strength was significantly larger than the indirect effect through Perceived Objectivity ($b=0.10$, SE 0.04, $z=2.84$; $P=.004$, 95% CI 0.03-0.17).

Figure 5. Objectivity and argument strength mediate the effect of exposure on change in disposition. Values are unstandardized coefficients (b values). M: misinformation-only experimental condition; MC: misinformation+correction experimental condition; MCR: misinformation+correction+rebuttal experimental condition. * $P<.05$, *** $P<.001$.

Conversely, when considering the MCR and MC conditions, perceived objectivity partially mediated the effect of exposure on change in disposition. The indirect effect Condition through Objectivity through Change in Disposition was statistically significant ($b=-0.14$, SE 0.07, $z=-2.09$; $P=.04$, 95% CI -0.27 to -0.01), as was the direct effect Condition through Change in Disposition ($b=-0.58$, SE 0.13, $z=-4.59$; $P<.001$, 95% CI -0.83 to -0.33). Moreover, the indirect effect Condition through Argument Strength through Change in Disposition was not significant ($b=-0.004$, SE 0.01, $z=-0.47$; $P=.64$, 95% CI -0.02 to 0.01), and the indirect effect through Perceived Objectivity was larger than the indirect effect through Argument Strength ($b=0.14$, SE 0.07, $z=2.00$; $P=.05$, 95% CI 0.003-0.27).

These results suggest that no single process can fully account for the observed patterns in the data. Although a decrease in perceived argument strength partially explains why seeing a correction following initial exposure to misinformation improves attitudes and intentions toward masking, this path accounted for only 24.0% of the total effect of seeing a correction on change in attitudes and intentions. Moreover, a decrease in the perceived objectivity of truth partially explains why exposure to a second round of misinformation that includes rebuttal of the correction and doubling down on the original false claim negatively impacts attitudes and intentions toward masking. However, this path accounted for only 19.4% of the total effect of further exposure to misinformation on change in disposition toward masking.

Given the significant direct effect of exposure on change in disposition and the modest proportion mediated in both cases,

it is likely that there are additional mediators that could contribute to understanding the dynamic effects of extended exposure to misinformation on people's attitudes and intentions toward behaviors favored by science.

Additional Analyses

We tested for other potential mediators, but found that increased exposure did not influence participants' perceptions of *citizen-health's* warmth ($F_{3,470}=1.73$, $P=.16$, $\eta_p^2=0.01$), *citizen-health's* competence ($F_{3,470}=0.92$, $P=.43$, $\eta_p^2=0.006$), *Health_Scientist's* warmth ($F_{2,349}=0.63$, $P=.53$, $\eta_p^2=0.004$), *Health_Scientist's* competence ($F_{2,349}=0.37$, $P=.69$, $\eta_p^2=0.002$), or strength of *Health_Scientist's* arguments ($F_{2,349}=1.39$, $P=.25$, $\eta_p^2=0.008$).

Finally, we analyzed participants' intention to share misinformation on social media (see Figure 6). Exposure had a significant effect on sharing intention ($F_{3,470}=6.24$, $P<.001$, $\eta_p^2=0.038$). Planned contrasts with Bonferroni correction for multiple comparisons showed a decrease in the intention to share the original posting after seeing a correction (MC mean 1.88, SD 1.15 vs M mean 2.48, SD 1.40; $t_{470}=-3.93$, $P<.001$, $d=-0.47$, 95% CI -0.72 to -0.21). Furthermore, there was no significant difference in sharing intention between the MCR and MC conditions (mean 2.03, SD 0.99; $t_{470}=0.86$, $P>.99$, $d=0.14$, 95% CI -0.11 to 0.39), or between the MCRC and MCR conditions (mean 1.96, SD 1.09; $t_{470}=-0.29$, $P>.99$, $d=-0.07$, 95% CI -0.32 to 0.19).

Figure 6. Marginal means and 95% CIs of intention to share across exposure conditions. M: misinformation-only experimental condition; MC: misinformation+correction experimental condition; MCR: misinformation+correction+rebuttal experimental condition; MCRC: misinformation+correction+rebuttal+second correction experimental condition.

Examining the covariates, we found that initial disposition to wearing masks ($b=-0.23$, SE 0.05; $F_{1,470}=23.76$, $P<.001$, $\eta_p^2=0.046$) and cognitive reflection ($b=-0.06$, SE 0.02; $F_{1,470}=6.32$, $P=.01$, $\eta_p^2=0.013$) were negatively associated with intention to share. Neither perceived COVID-19 risk ($b=0.06$, SE 0.05; $F_{1,470}=1.33$, $P=.25$, $\eta_p^2=0.003$) nor political orientation ($b=0.04$, SE 0.03; $F_{1,470}=1.55$, $P=.21$, $\eta_p^2=0.003$) or conspiracy mentality ($b=0.01$, SE 0.04; $F_{1,470}=0.03$, $P=.86$, $\eta_p^2=0.000$) was significantly related to sharing intentions.

These results indicate that people are more likely to share misinformation when its content is consistent with their existing beliefs about the issue. Importantly, they also suggest that correcting a false claim can reduce the extent of its spread on social media, and this effect seems resistant to further exposure to the same misinformation.

Discussion

Principal Findings

Past research from across a variety of domains has shown that debunking misinformation works. That is, well-crafted corrections delivered by trusted sources can positively impact beliefs, attitudes, and intentions toward behavior favored by science [26-36]. With the explosion of false and misleading health claims on social media, especially since the start of the COVID-19 pandemic [62,63], scientists, experts, and health care professionals have been called upon to increase their presence on social media and help combat this “infodemic” [20-27]. A recent study found that US physicians and nurses are generally willing to take on the task even if it comes with important challenges [64]. However, little is known about the impact of extended social media debates on observers’ attitudes and intentions toward the debated issue. In this study, we tested such an impact in the context of a debate about the safety and effectiveness of wearing face masks in public during the early days of the pandemic.

We found that exposure to misinformation has a negative impact on attitudes and intentions toward masking. This result is consistent with prior research finding that exposure to

misinformation negatively impacts attitudes and intentions toward behaviors favored by science [40].

Also in line with prior work [28-31], we found that initial debunking of a false claim generally improves attitudes and intentions toward masking. This effect is partially explained by a decrease in the perceived strength of the argument underlying the false claim. However, this improvement is washed out by further exposure to false claims and debunking attempts. The latter result is partially explained by a decrease in the perceived objectivity of truth. That is, extended exposure to false claims and debunking attempts appears to weaken the belief that there is a nonsubjective, correct answer to how people ought to behave in this situation, which in turn leads to less positive reactions toward masking as the prescribed behavior. Interestingly, exposure to contradictory information affects perceived truth objectivity in a nonlinear fashion. For instance, exposure to a false claim and its initial debunking does not weaken the belief that there is an objectively true answer. It appears that the level of exposure to contradictory information needs to reach a certain threshold before it affects perceived truth objectivity.

Finally, we found that people are more likely to share misinformation when its content is consistent with their existing beliefs. However, correcting misinformation reduces its likelihood of being shared on social media, and this effect persists even after multiple exposures. These results, while highlighting the value of debunking in combating the spread of misinformation on social media, suggest that, unlike attitudes, sharing intentions may be insensitive to extended exposure to a back and forth between misinformation and correction. This pattern may reflect a floor effect, in that people had expressed very low intentions to share corrected misinformation (mean of 1.89 on a 7-point scale). Exposure to further debate resulted in more negative attitudes toward masking, but did not impact sharing intentions because sharing intentions were already extremely low.

Comparison With Prior Work

Our findings have important implications for research on debunking misinformation. Extant literature has noted that even though corrections generally reduce people’s beliefs in false information, the misinformation often continues to influence

their thinking, a phenomenon known as the continued influence effect [65]. Once people process information that appears vaguely credible to them, it becomes difficult to retract it. A popular explanation of the continued influence effect assumes that people build mental models of the world and want their models to be complete. They are willing to accept false information if it allows them to build complete models. When that false information is later debunked, it creates a gap in their understanding of the world. Since people dislike gaps in their understanding and prefer their mental models to be complete, they continue to rely on information they know is false. [65,66].

Another explanation of the continued influence effect argues that attempts to correct misinformation often end up reinforcing it through repetition [67,68]. From this perspective, repeating misinformation when attempting to correct it makes it feel more familiar and fluent. By inadvertently increasing the ease with which misinformation is processed, correction attempts also increase the likelihood of it being accepted as true. Our study suggests yet another possible explanation of the stickiness of misinformation. In some situations, witnessing a heated debate with arguments for and against a controversial issue could undermine people's confidence in the existence of an objectively true answer, which may weaken their commitment to either side of the debate.

Limitations and Future Research

We set out to study the impact of exposure to extended debates on social media. However, our study was limited to a single platform (Reddit), and the debate was restricted to four exchanges between only two protagonists. This limits the generalizability of our findings. Interaction norms likely differ across social media platforms, which may impact how users interpret the conversation. Future research could attempt to replicate our findings using different social media platforms (eg, Facebook and Twitter), and examine the consequences of extending the debate to include more than two protagonists and more than four exchanges. Relatedly, although extended debates such as those described in this research are familiar to regular users of social media, we do not know how often they happen. Future research would benefit from quantifying the frequency of their occurrence and how it may vary across platforms.

A possible limitation of our experimental design is that the rebuke message included an image, whereas all other messages were strictly text-based. Thus, it is impossible to disentangle the impact of exposure to the rebuke message from the presence of an image. However, pinpointing which message element (image vs text) accounts for the effect of exposure was not a goal of this study. Instead, we sought to pit strong refutation against persuasive misinformation. We chose to include a graphic image in the rebuke message precisely because of its persuasive power.

Although the debunking messages used in this study were developed using recommended best practices, it is possible that different debunking techniques would have resulted in different outcomes. Future research would greatly benefit from manipulating features of the debunking argument as well as the source of debunking. For example, previous research has shown that debunking messages from anonymous social media users are more effective when they include a link to a trusted source such as the CDC [26]. Future research could test whether the positive impact of providing links to credible sources persists in the context of extended social media debates. Other features of debunking messages previously found to sometimes reduce misperceptions include the use of humor [69] and infographics [70]. However, whether such debunking techniques can be effective in the context of extended debates remains an open question.

Preemptively refuting misinformation or even just warning people that they might be misinformed has been shown to decrease later reliance on misinformation. Future research could test the effectiveness of such prebunking in the context of extended debates, where—to extend the biomedical analogy—the viral load is higher.

Conclusions

In sum, dynamic conversations present a heretofore underappreciated challenge faced by health professionals and science advocates attempting to debunk misinformation on social media. Engaging in extended debates with science deniers and other purveyors of bunk appears necessary, but more research is needed to address the unintended consequences of such engagement.
