Abstract

Background: New research fields to design social robots for older people are emerging. By providing support with communication and social interaction, these robots aim to increase quality of life. Because of the decline in functioning due to cognitive impairment in older people, social robots are regarded as promising, especially for people with dementia. Although study outcomes are hopeful, the quality of studies on the effectiveness of social robots for the elderly is still low due to many methodological limitations.

Objective: We aimed to review the methodologies used thus far in studies evaluating the feasibility, usability, efficacy, and effectiveness of social robots in clinical and social settings for elderly people, including persons with dementia.

Methods: Dedicated search strings were developed. Searches in MEDLINE (PubMed), Web of Science, PsycInfo, and CINAHL were performed on August 13, 2020.

Results: In the 33 included papers, 23 different social robots were investigated for their feasibility, usability, efficacy, and effectiveness. A total of 8 (24.2%) studies included elderly persons in the community, 9 (27.3%) included long-term care facility residents, and 16 (48.5%) included people with dementia. Most of the studies had a single aim, of which 7 (21.2%) focused on efficacy and 7 (21.2%) focused on effectiveness. Moreover, forms of randomized controlled trials were the most applied designs. Feasibility and usability were often studied together in mixed methods or experimental designs and were most often studied in individual interventions. Feasibility was often assessed with the Unified Theory of the Acceptance and Use of Technology model. Efficacy and effectiveness studies used a range of psychosocial and cognitive outcome measures. However, the included studies failed to find significant improvements in quality of life, depression, and cognition.

Conclusions: This study identified several shortcomings in methodologies used to evaluate social robots, resulting in ambivalent study findings. To improve the quality of these types of studies, efficacy/effectiveness studies will benefit from appropriate randomized controlled trial designs with large sample sizes and individual intervention sessions. Experimental designs might work best for feasibility and usability studies. For each of the 3 goals (efficacy/effectiveness, feasibility, and usability) we also recommend a mixed method of data collection. Multiple interaction sessions running for at least 1 month might aid researchers in drawing significant results and prove the real long-term impact of social robots.

aged; dementia; social robots; pet-bots; community settings; long-term care; methods; scoping review

Introduction

In the next few decades, we expect the global population to age due to a combination of high life expectancy, low birth rates, and the baby boomer generation entering their senior years. By 2030, 33% of the population in Western Europe will be over 60 years of age [1]. Dementia is one of the most common neurodegenerative diseases that affects 50 million older people around the world, and it is projected to reach 155 million in 2050 [2].

Dementia is characterized by deterioration in memory, cognition, behavior, and ability to perform everyday activities [3]. It is estimated that approximately one-third of people with dementia live alone [4]. They experience unmet needs because of living alone and are at a higher risk of faster deterioration. In addition, people with dementia who live alone are considered at a higher risk of medication use problems, falls and injuries, inadequate self-care, trouble with activities of daily living, and reduced social networks [5-8].

In the past decades, technological advances coincided with the great health challenge of aging societies [9]. New research fields in assistive technology are dedicated to designing social robots for older adults with or without cognitive impairment to promote their quality of life (QoL) through communication and social interactions [10]. Social robots are intended to provide and facilitate social contact, psychosocial and cognitive stimulation, and have the potential to support elderly people to maintain their autonomy and independence and enhance their well-being [11].

Socially assistive robots (SARs) can be grouped into 2 main categories based on their feature and function: (1) service robots, and (2) companion robots [12]. The main task of these robots is to establish any form of interaction and communication. This function can be performed by SARs in multiple manners, such as through touch sensors, cameras, (robotic) body movements, tablet interfaces, and sound and speech systems. Within the subgroup of the companion robots, humanoid robots like Pepper and Nao provide users with advanced applications that provide leisure activities (music, photos, and games), cognitive and physical stimulation activities, and assistance with mental or physical tasks. Pet robots, such as PARO, AIBO, and NeCoro as substitutes for pets and companion animals are intended to provide emotional and physiological stimulation, have calming effects, and lead to mood improvements [13].

For the successful implementation and large-scale uptake of social robots or any other psychosocial intervention, their feasibility, usability, and cost-effectiveness should be perceived as good by the end users (people with dementia and healthy older adults), clinicians, and other stakeholders (eg, health care insurers and policy makers). The Monitoring and Evaluating Digital Health Interventions framework recommends evaluating 4 factors to integrate and implement a digital health intervention: (1) feasibility, to assesses whether the digital health system works as intended in a given context; (2) usability, to assess whether the digital health system can be used as intended by users; (3) efficacy, to assess whether the digital health intervention can achieve the intended results in a research (controlled) setting, and (4) effectiveness, to assess whether the digital health intervention can achieve the intended results in a nonresearch (uncontrolled) setting [14].

Despite the rising interest in social robots after the COVID-19 pandemic, there is limited evidence on the effectiveness of social robots in elderly care. The methodological quality of studies on the effectiveness of social robots in elderly adults is still low, and inappropriate study designs, samples, form, duration of interventions, and data collection methods have affected the strength of study outcomes [12].

Currently, there is no state-of-the-art proof of concept for study designs to evaluate the use of social robots for elderly people. Since the degenerative nature of dementia can cause methodological challenges, specific attention should be paid to studies that include people with dementia. To determine what the appropriate research methods are to study feasibility, usability, efficacy, and effectiveness, this article aims to review the methodologies used thus far in studies with social robots in clinical and social settings with elderly people to pave the way for future researchers in this field.

Methods

Protocol Registration

The protocol of this scoping review was registered in Open Science Framework (OSF) [15].

Search Strategy

Searches were conducted on August 13, 2020, in MEDLINE (PubMed), Web of Science, PsycInfo, and CINAHL databases. No time window was applied. Three search strings covering the topics “social robots,” “community setting,” and “elderly people” were constructed. For each database, reverent subject headings were adapted. For MEDLINE, we used the following strings and keywords: ((robotics[MeSH Terms] OR robot*)) AND ((humanoid OR companion OR social* OR “socially assistive” OR interact* OR android)), (((((((aging[MeSH Terms]) OR (aged[MeSH Terms])) OR (elderly[MeSH Terms])) OR (vulnerable population[MeSH Terms])) OR (senior)) OR (ageing)) OR (geriatric)) OR (old*), and (((((community health service[MeSH Terms]) OR (social support[MeSH Terms])) OR (residential facilities[MeSH Terms])) OR (independent living[MeSH Terms])) OR (social support[MeSH Major Topic])) OR (“community dwelling” OR “home dwelling” OR “care home” OR “in-home” OR “at home” OR “home-based” OR “home setting” OR “nursing home” OR home).

Selection Criteria

Publications potentially eligible for inclusion had to study a social robot that was physically embedded in an experimental or clinical study in people aged 65 or above. Studies were excluded if they were (1) conducted in an acute care setting;

(2) conference abstracts, case studies, dissertations, books, or review papers; (3) published in a language other than English or Spanish; (4) solely reporting a robot design, development process, or theoretical models (5) stakeholder opinions on robots without any interaction; (6) involved in the implementation of new hardware or software or an assessment tool on a robot (such as assessing a fall detection sensor); and (7) involving telepresence robots with only video call features.

Selection Procedure

After the removal of duplicates, 2 reviewers (authors AM and MM) independently applied the inclusion and exclusion criteria in 3 steps, starting with screening titles, abstracts, and then full texts. The selections were compared, and in case of disagreement, discussed by the 2 reviewers. In cases where no consensus could be reached, a third reviewer was consulted (author HR).

Data Extraction

The literature was mapped according to the following areas of interest: author and country, robot name, the aim of the robot, aim of the study, type of outcome measure, study design, study sample, study setting, methodology of data collection, interaction scenario, relevant outcome measures, measurement instruments, results, and reported limitations of the study. Information was synthesized descriptively, and findings were narratively summarized according to the areas of interest.

The quality of the included articles was appraised independently by 2 authors (AM and MM), through the quality assessment of digital health interventions within the Monitoring and Evaluating Digital Health Interventions framework established by the World Health Organization (WHO) [14]. The tool includes a list of methodological study criteria comprising (1) 23 essential criteria for all types of studies and (2) essential criteria for qualitative and quantitative studies (3 criteria each). The extent to which criteria were met by studies was rated by 3 independent researchers on a 3-point scale (0= poor, 1= fair, 2= good). We calculated the percentage of agreement between the ratings (Multimedia Appendix 1). We also applied this framework to categorize the studies according to their aims in 4 categories: (1) feasibility, (2) usability, (3) efficacy, and (4) effectiveness.

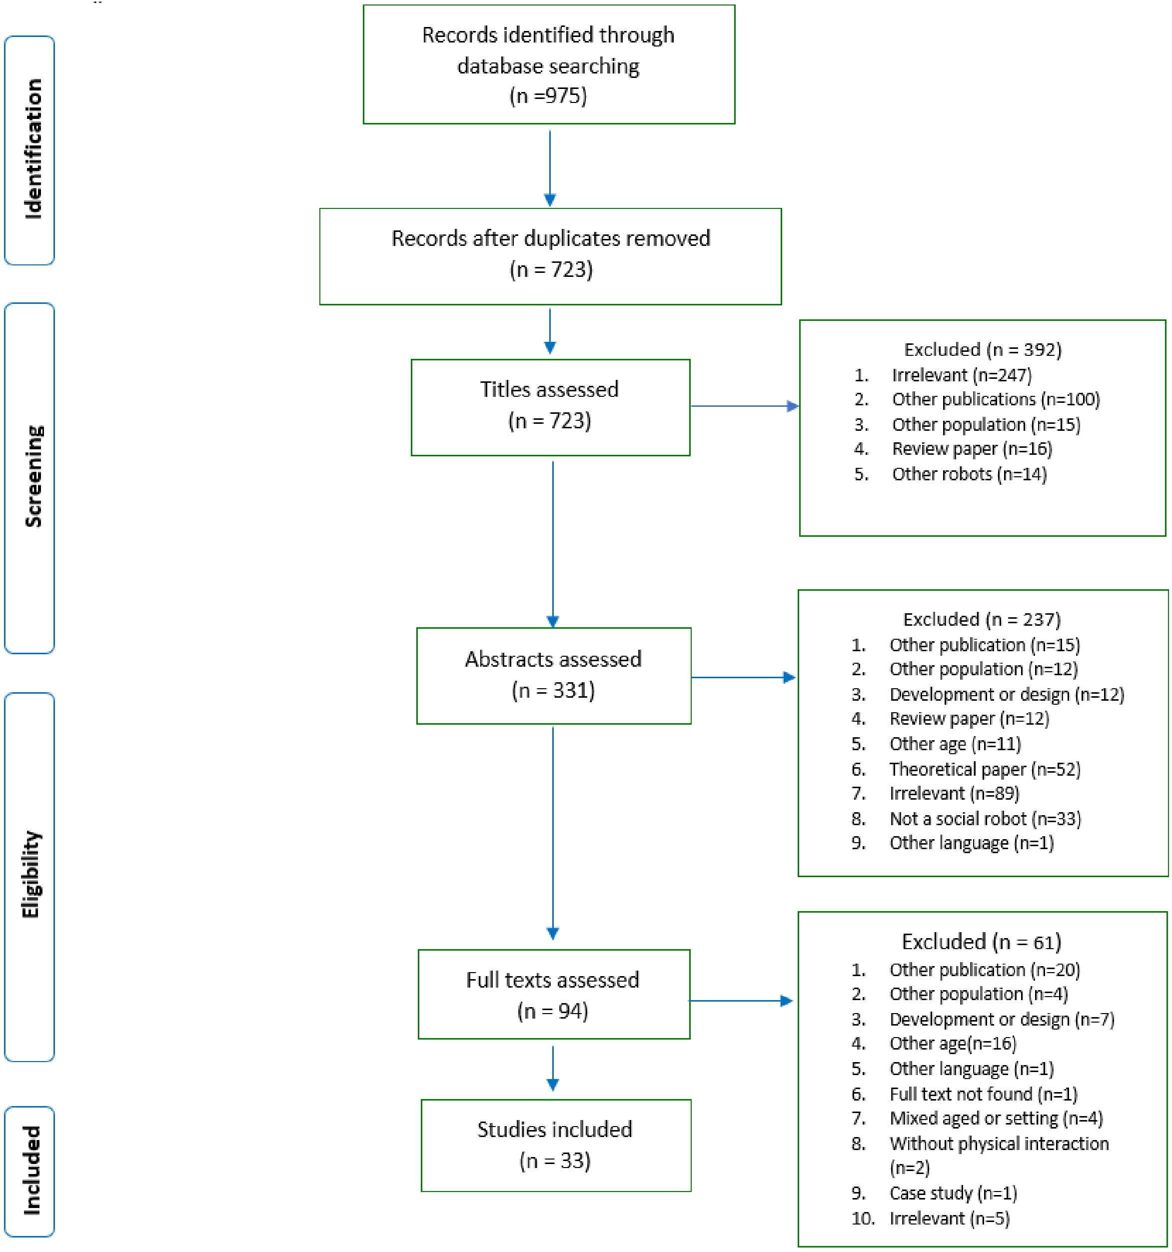
Results

General Findings

The search resulted in a total of 723 individual publications. After the screening process, 33 articles met the selection criteria (Figure 1). In 33 papers [11,16-45], 23 different social robots were evaluated among elderly adults and people with dementia in 13 different countries. Moreover, 19 studies specifically evaluated either feasibility, usability, efficacy, or effectiveness and were considered as single aim studies. The remaining studies (n=14) had multiple aims, evaluating 2 or 3 of the aforementioned study aims. Overall, feasibility was studied in 17 (51.5%) studies, usability in 13 (39.3%), effectiveness in 12 (36.3%), and efficacy in 10 (30.3%).

The quality appraisal identified that primary and secondary outcomes were clearly defined in all studies. Additionally, the methods of data collection were described well, but the eligibility of the participants was not reported in 12 (36.4%) papers. Moreover, 12 out of 33 (36.4%) papers did not present a clear description of the study design. Multimedia Appendices 2 and 3 show a summary of the characteristics, methodologies, and outcomes of the included studies.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for literature search.



Robots

Of the 23 different social robots, PARO (n=10, 30.3%), Nao (n=5, 15.1%), AIBO (n=2, 6%), and Hobbit (n=4, 12.1%) were the most often investigated.

Participants and Settings

Of the 33 identified studies, 16 (48.4%) focused on people with dementia [11,18,23,24,27,29-35,38,39,43,44], 9 (27.3%) were performed in samples of residents of long-term care facilities whose cognitive status was not mentioned [17,20,22,26,28,36,40,41,45], and the remaining 8 (24.2%) focused on elderly people living in the community whose cognitive status was also not clearly revealed [16,19,22,25,37,42,46,47]. Moreover, 4 (12.1%) studies additionally recruited care staff [22,24,26,38]. The age range of older adults was 65-98 years. Of the included studies, 3 (9.1%) did not report the number of participants [17,20,26]. The sample sizes used in the studies ranged from 5 to 139.

The social robots were studied in long-term facilities (n=17, 51.5%), private households (n=8, 24.2%), and laboratory settings (n=4, 12.1%). Additional settings were based in a care organization (n=1, 3%), a daycare center for dementia (n=1, 3%), and a health service facility (n=1, 3%). Four (12.1%) studies investigated the robots in 2 different settings [22,33,43,46].

Study Aims, Designs, and Outcome Measures

Single Aim Studies

Of the included studies, 3 (9.1%) focused solely on feasibility, using quasi-experimental designs [22,27,46], and 1 (3%) explicitly focused on usability in a private home setting [37]. Additionally, 7 (21.2%) studies aimed at studying efficacy [31-35,38,44], of which 2 (28.5%) applied a form of randomized controlled trial (RCT) design, 1 (14.3%) randomized crossover design, 1 (14.3%) pretest-posttest design, and the other 3 (42.8%) a form of quasi-experimental design. The effectiveness of the robots was explicitly studied in 8 (24.2%) articles [17,20,24,36,40,41,43,45] using randomized designs, with 1 (12.5%) RCT, 2 (25%) blocked RCTs, 2 (25%) quasi-experimental designs, 1 (12.5%) pretest-posttest design, 1 (12.5%) cross-sectional, and 1 (12.5%) qualitative study. The impact of robots was evaluated on QoL (n=6, 18.2%), mood and depression (n=6, 18.2%), behavioral (n=6, 18.2%) and neuropsychiatric symptoms (n=2, 6.1%), emotions and affect (n=5, 15.2%), cognition (n=4, 12,1%), engagement (n=8, 24.2%), participation and social interaction (n=8, 24.2%), care burden (n=1, 3%), loneliness (n=1, 3%), and physiological indicators (n=3, 9.1%). The sample size for the 22 studies with effectiveness/efficacy aims ranged from 11 to 139 participants, and 7 (31.8%) of these studies included samples of over 40 participants.

Multiple Aim Studies

A total of 14 (42.4%) studies had multiple aims. Of these, 7 (50%) focused on feasibility and usability [11,16,19,22,25,28,44], of which 3 (42.9%) applied a mixed methods design, and the remaining 4 (57.1%) applied either an experimental design or a field trial. Meanwhile, 3 (9.1%) focused on feasibility, usability, and effectiveness, and all applied a mixed methods design [26,29,39]. Additionally, 1 (3%) study investigated feasibility and efficacy and applied an experimental design [30], 1 (3%) focused on feasibility, usability, and efficacy using a pretest-posttest design [18], and 1 (3%) assessed the feasibility and effectiveness of the robot, applying a nonrandomized controlled trial design [22].

Study Aims and Settings

Only 5 (27.8%) of the 18 studies aiming to evaluate feasibility and/or usability were performed in nursing home settings; 5 (27.8%) were performed in laboratory settings, and the remaining 8 (44.4%) were performed in private households. In 7 (38.9%) of the 18 studies, people with dementia and those with cognitive impairment were included. In the remaining 11 (61.1%) studies, the cognitive status of the participants was not clearly indicated.

Of the 22 (66.7%) studies that focused on efficacy or effectiveness, all but 4 (81.8%) [29,33,39,47] were performed in long-term care settings. These 4 (18.2%) were performed in private households and a daycare facility. Of these studies, 13 (59.1%) included cognitively impaired samples, only 1 (4.5%) study included community-dwelling elderly persons without disclosing their cognitive status, and the remaining 8 (36.4%) included long-term care residents.

Study Interventions

Interaction between study participants and social robots was mostly investigated during individual sessions (n=18, 54.5%). In 12 (36.4%) studies, interactions were studied in group sessions. Only 3 (9.1%) studies applied both individual and group interactions [11,20,33], while 1 (3%) demonstrated the task performance of the robot without any close interaction with study participants [19]. Feasibility and/or usability (n=11, 33.3%) were mostly studied in individual settings (n = 8, 72.7%); 1 (9.1%) study was performed in a group, and 1 (9.1%) was applied to both individual and group settings. Individual (n=7, 21.2%) and group settings (n=6, 18.2%) were used most often to study efficacy and effectiveness (n=15, 45.5%); 2 (6.1%) studies applied the intervention individually and in a group. In studies with multiple aims, 4 (28.6%) individual and 2 (14.3%) group setting interventions were found. In 2 (6.1%) studies, social robots were available in the residents' lounge in nursing homes, and participants were free to interact with the social robots during scheduled time slots [22,45]. In 8 (24.2%) studies, the robots were installed in participants' private homes for a duration of 5 days to 3 months [16,27,29,33,37,39,44,47].

A total of 9 (27.3%) studies executed 1 or 2 interactive sessions [11,19,22-24,28,30,32,34], of which 6 (66.7%) investigated the usability and feasibility of the robot, 1 (11.1%) investigated effectiveness, and 2 (22.2%) investigated efficacy. Most of the studies conducted more than 2 interactive sessions: 5 (15.2%) studied feasibility and/or usability, 12 (36.4%) studied efficacy or effectiveness, and 8 (24.2%) were multiple aim studies. The interactive sessions ran from 10 to 90 minutes a day for a maximum of 4 months.

Data Collection

We identified 4 methods of data collection: (1) questionnaires (n=26, 78.8%), (2) observations (physical and videotape) (n=19, 57.6%), (3) interviews (n=13, 39.4%), and physiological measurements (n=3, 9.1%). Figures 2 and 3 show the data collection methods and the responsible administrator of data for the identified data collection methods, respectively.

Figure 2. Used methods of data collection for single and multiple aim studies.

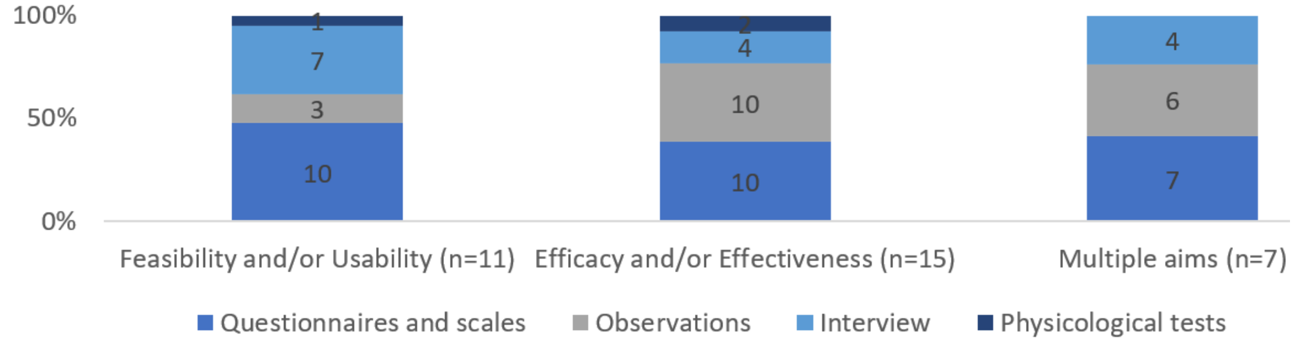


Figure 3. Responsible administrator of data for identified methods of data collection.

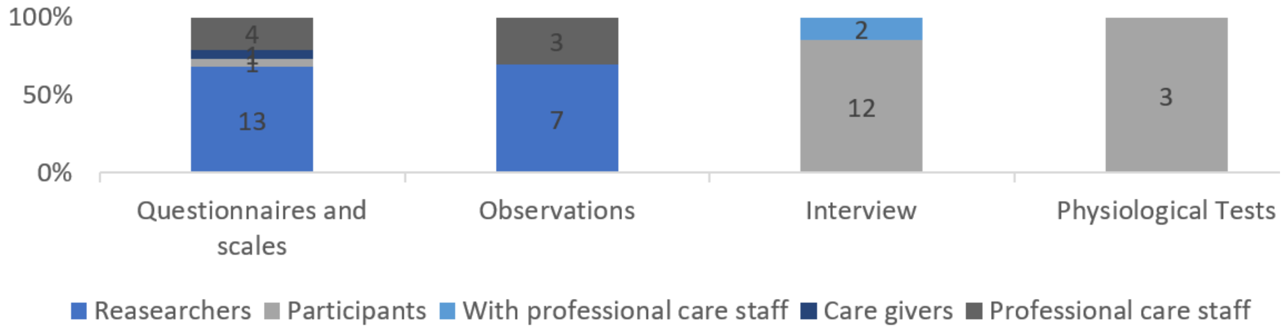

Measurement Instruments

Outcomes regarding feasibility were assessed with the Unified Theory of the Acceptance and Use of Technology (UTAUT) model adapted by Heerink [11,19,23,29,30,46,48], the Robot User Acceptance Scale, the Robot Attitude Scale, the Mind Perception Scale [21,47], and the Negative Attitudes Toward Robots Scale [16,37]. Of the included studies, 5 (15.2%) utilized questionnaires regarding robot functions and acceptance that were specifically developed for the study [19,22,23,25,46].

Studies exploring usability applied the System Usability Scale [22,25,28], a modification of the Usefulness, Satisfaction, and Ease of Use [26] scale, and the Technology Usage Inventory [39]. Two (6.1%) qualitative studies performed conversation and video analysis [27,28] to extract statements on acceptability and usability.

Efficacy and effectiveness outcomes were evaluated by a wide range of neuropsychosocial measurement instruments: (1) mood: Geriatric Depression Screening [49], the Cornell Scale For Depression in Dementia [50], Apparent Emotion Rating Instrument [51], University of California, Los Angeles (UCLA) Loneliness Scale [52], Observed Emotion Rating Scale [53]; (2) cognition: Montreal Cognitive Assessment [54], Mini-Mental State Examination [55]; (3) QoL: QoL Alzheimer Disease, Dementia QoL Questionnaire [56], QoL in Late-Stage Dementia [57]; (4) behavior: Neuropsychiatric Inventory [58], Gottfries-Bråne-Steen Scale [59], Apathy Evaluation Scale [60], Cohen-Mansfield Agitation Inventory [61], Apathy Inventory [62], Apathy Scale for Institutionalized People With Dementia Nursing Home Version [63]; (5) Participation and Interaction: Activity Participation Scale [40], and Assessments of Communication and Interaction Skills [64].

Among the studies applying questionnaires, 5 (19.2%) indirectly collected data via care staff and informal caregivers, and 13 (50%) directly collected data via the researchers.

Study Outcomes

Concerning social robots' feasibility outcomes, almost all studies (n=16, 94.1%) deemed social robots acceptable. Nevertheless, 1 (5.9%) study reported mixed results on acceptability by care staff [22], and 1 (5.9%) did not find any significant results on quantitative measurements for acceptability, but qualitative results were positive [16]. In 3 (17.6%) studies, the perceived agency [21,47] and perceived enjoyment [46] were found to decrease over time.

The reported usability (n=12, 36.4%) was overall positive, except in 2 (16.7%) studies in which the usability was negatively affected by technical issues or lack of robustness of the robots [28,37]. Only 3 (9.1%) studies assessed affordability for Hobbit and Nao, in which the participants did not consider the social robots affordable and were skeptical of buying them [25,28,37].

Most of the findings endorse the use of social robots by older adults. Improvements were mostly found in emotion and mood [20,31,33-35,38,44], engagement [24,29,30], and participation and social interaction [20,31-33,40,45]. Increased job satisfaction of staff [22], self-report pain reduction [38], and improved global psychiatric symptoms [43] were the other positive study outcomes. There were findings of reduced challenging behavior [20,31,34], sense of loneliness [17], and stress levels [45]. However, dementia symptoms like agitation and other problematic symptoms did not improve in 1 (3%) study [33].

Meanwhile, 4 (12.1%) studies did not find a significant impact on QoL [19,21,43,47]. Only 1 (3%) study found a moderate-to-large positive effect on QoL of people with dementia [35]. Social robot interventions also failed to significantly improve depression [18,21,43,47], perceived social support [18], medication adherence [47], and cognition [24]. There were mixed results regarding physiological measures, such as urine tests measuring stress levels and blood pressure [33,45]. No author declared a proven negative effect of social robots on older adults.

Reported Study Limitations

Of the 33 studies, 7 (21.2%) did not report any study limitations [16,17,23,25,30,42,46]. A wide range of limitations was reported, and the most common barrier considered in 17 (51.5%) studies was the small sample size, which was mostly reported for efficacy and effectiveness studies. In the feasibility and/or usability studies, the limitations were mainly attributed to technical problems or interaction difficulties. The use of unvalidated questionnaires, homogeneity in the sex of the study sample, inadequate observation, and short duration of interventions were reported as other limitations in general.

Quality Appraisal

The inter-rater agreement for the quality appraisal was 86.1%. Reports of the description of study design, bias, and enrollment procedure were mostly rated as "fair." In most of the articles, the sampling methods, confounding factors, missing data in quantitative studies, and reflexivity of data interpretation in qualitative studies were poorly reported. Other criteria were mostly rated as "good" (Multimedia Appendix 1). The quality appraisal revealed unclear descriptions or insufficient details in 5 (15.2%) studies, especially those in disciplines other than health research [25,30,42,44,45].

Discussion

Principal Findings

The results of this scoping review revealed a variety of applied study methods in studies with social robots concerning study design, sample size, study setting, method of data collection, interaction scenario (the sequence, duration, and setting of the intervention), outcome measures, measurement instruments, study results, and reported limitations. Feasibility and usability were mainly studied on preprototype social robots in laboratory settings. Considering the relatively short history of the use of social robots in psychosocial interventions, it is crucial to determine the main features and functions of the robots to be considered in the design and development phase. Hence, usability, feasibility, and implementation should be strategic research aims. Fully developed robots such as PARO were evaluated in terms of effectiveness in real-world settings. Most of the identified studies aimed to determine the neuropsychosocial impact of social robots on older adults.

For the studies that explicitly fall within a feasibility and/or usability evaluation, researchers applied experimental, mixed method, and field trial designs, mostly applied outside nursing home care settings. This might imply that feasibility and/or usability for persons that are more severely cognitively impaired are currently understudied. Most of the studies verified the acceptability and usability of the robots within single or multiple interactive sessions in individual or group settings, and all these studies reported positive outcomes in varying degrees on the feasibility and/or usability of the social robots. The quantitative and qualitative data were collected mostly through questionnaires and interviews and a few by direct observation. Regarding this point, researchers should consider using the direct observational methodology to capture main factors of the interaction and emotional relationships fostered by robot use. Within the questionnaires and interview questions based on the UTAUT model, some concepts such as trust, anxiety, perceived enjoyment, and social support can change over time [37,46,47]. Therefore, longer use of the robots might reveal these changes and reduce the novelty effect over time [46].

Overall, efficacy and effectiveness studies were conducted on study populations either with cognitive impairment or residing in long-term care facilities. The studies with significant results [17,24,29-31,34-36,45] mostly employed experimental designs including RCTs and quasi-experimental designs with larger sample sizes and longer intervention periods compared to studies showing slight or no improvements. RCTs are likely to be the most appropriate design and a gold standard to confidently demonstrate that a specific intervention has resulted in a change in a process or a health outcome [14]. Biased assessment of outcomes and any confounding effects can be avoidable by large-scale RCTs. However, due to the degenerative character of dementia and personal differences in capacities of people with dementia, difficulties in randomizing subjects often arise [14]. Additionally, when using long study periods, the dropout rate might be high, as participants' cognitive deterioration can hinder their continued participation in the study. On the other hand, when it is not feasible or ethical to conduct an RCT, a quasi-experimental design may serve best for collecting quantitative data. We also recommend randomized controlled block designs in the case of heterogeneous study samples. When, for instance, including people with dementia in studies with long intervention periods, the dementia levels alter. With a randomized controlled block design, some variables in different blocks can be controlled for, or comparable approaches can be applied within the blocks.

Studies targeting the efficacy and effectiveness of the robots delivered interventions diverged in format, duration, dosage, and location. Two (6.1%) studies [32,38] highlighted a need for individual intervention sessions tailored to users' preferences and capacities, and the findings of another study confirmed this approach [65]. Additionally, individualized sessions could omit confounding factors by reducing the chance of interactions with the facilitator or other participants [66]. Group interventions may lower the odds of interaction between potential users and the robot, potentially lowering the effect of the intervention, especially when the intervention is delivered in a noisy setting with many participants [18]. The issues of small sample sizes and short interactions were considered major limitations in studies that failed to find significant results, and they are considered the toughest challenges for researchers in this field [66,67]. These limitations are often cojoined with the study setting. In nursing homes, a larger number of residents are often enrolled in a clinical trial, and the robots are not personalized but must be shared by the entire group. Whereas in private homes, studies are conducted with individuals or dyads, which creates better possibilities for personalization of the robot. Overall, the personalization of the intervention and alleviation of loneliness are 2 advantages of home-based clinical trials. However, there are some challenges to these types of studies, such as the need for several robots, implementation difficulty, and personalization, but it is nevertheless a step in the right direction. We observe a paradox, in that new or experimental robots are employed in research with low numbers of participants, whereas commercially available robots are tested on large study samples. Commercialization allows for better testing and evaluation, which is logical from an economical perspective. However, we urge that before robots are marketed, developers should study the feasibility and usability appropriately in the target group, as well as the effectiveness in a substantial study sample with sufficient power. After bringing the robot to the market, producers should continue to invest in studies to improve their product to tailor it optimally to their users. This should be a joined mission of producers and policy makers to improve the sustainability of health care systems.

Apart from the aforementioned limitations of the studies, some weak aspects of the study designs led to failure of the social robots' impacts. For instance, a mismatch between the studied construct and the main aim of the robot may lead to the poor conclusion that the robot is not efficient. An example of this is the studies on PARO that failed to demonstrate significant results for cognition, as PARO is not developed to stimulate cognitive functioning [31,33,41,43]. Additionally, to capture significant results in constructs such as cognition, QoL, and depression, a long intervention period is necessary because these are constructs that do not change very quickly. In studies with people with dementia, it might also be useful to study stability of these constructs instead of improvement, since it is inherent to the disease that these constructs deteriorate over time. Regarding the broad concept of QoL ranging from physical health to psychological state and social relationships, the application of a suitable QoL measurement instrument that corresponds to the robot's aim should be taken into account.

Implications For Efficacy and Effectiveness Studies

Appropriate RCTs with large sample sizes and individual interaction sessions running for longer than 1 month would serve best for such studies to draw relatively robust and reliable results.

Implications For Feasibility and Usability Studies

The study methods are similar for both aims, so researchers could apply the same design. Experimental designs with mixed methods of data collection are recommended for these studies. Multiple interaction sessions might reveal the changes in feasibility and usability.

Implication For Studies With Multiple Aims

We recommend performing separate studies for multiple aims since the study designs for each aim are comparable.

We gathered further practical recommendations through which future work may address existing shortcomings (Table 1). Regarding the mixed methods of data collection, studies suggest a combination of qualitative and quantitative methods for data collection, which will enable the researcher to capture different details in users' responses and address different aspects of the research question. A mixed methods approach was helpful in studies that could not derive positive results from quantitative data but did from qualitative data [16]. Regarding the difficulties of recruiting many users in case of availability of just a few robots, these mixed methods should be mandatory. Even though we did not find any negative results regarding the intervention dosage, there are shreds of evidence of highly intense intervention resulting in negative effects or exhaustion [18]. Hence, the dose response for specific measures remain an open question for future researchers.

Table 1. Further implications and recommendations for future studies.

Area of consideration	Type of study	Recommendation
Participant and setting	Efficacy/effectiveness	• Gender homogeneity • Different levels of dementia • Realistic environments
Intervention and data collection	Efficacy/effectiveness	• Multiple intervention sessions for longer than 1 month
	Feasibility/usability	• Initialization phase before trial
	All types of studies	• Well-trained observers and professionals • Tailored interventions • Include an intervention facilitator apart from an observer • Consistent observations • Standardized and validated measurement instruments • A client-centered approach to intervention design • A combination of qualitative and quantitative methods of data collection • Observational study when including people with severe dementia
Gap in the existing literature to be filled	Efficacy/effectiveness	• Best response-dosage of intervention for particular measure and participant condition • Characteristics of subjects who benefit most from the social robots

Limitations and Strengths

Although the use of social robots is promising to support people with dementia, we did not include dementia specifically in the search strings, since this scoping review focused on elderly people in general. However, we believe that our search captured most of the studies executed in the field of dementia because many of the identified studies included people with dementia in either mixed or specific study samples. However, some relevant studies on elderly people with dementia may be missing in this review, as well as may studies that are only traceable in databases that were not taken into account in this review. The searches were conducted in scientific databases deemed the most viable to retrieve valid and reliable results for this scoping review. The exclusion of studies focusing only on the development phase of social robots can be considered a limitation of this study. Some information on the evaluation of the feasibility and usability executed in the development stage might have been missed. In addition, studies on telepresence robots were excluded due to their relatively simple features. Compared to pet robots and humanoid robots, telepresence robots are limited in interactions with users, which occur merely through a touch screen, making use of visual and audio stimuli but omitting other sensory stimulation. Although mainly used for medical visits, some telepresence robots might support social functioning. Information on studies performed on these robots might have been missed.

Our study is the first scoping review on the methodologies for studying social robots in elderly people and people with dementia. The existing reviews on this topic mostly focus on design, use, effectiveness, facilitators, and barriers to the implementation of social robots [12,66,67,68-73]. This study might support future researchers to design a research study on social robots in elderly adults and answer some study design queries.

Conclusions

This review narratively synthesizes information on the methodology of studying social robots in elderly adults and people with dementia. Relevant recommendations were formulated, directed for studies with specific aims that may aid future researchers in developing adequate study designs to evaluate social robots, allowing for more reliable information on study outcomes. Our research leads us to the conclusion that more studies with large sample sizes are needed on the effectiveness of social robots in private households of elderly adults and people with dementia to demonstrate the actual usefulness of social robots on delaying institutionalization by improving QoL, cognition, and social contact, and counteracting loneliness. Most of the identified studies focused on usability, and the robots appeared to be favorably accepted in most cases. It is time to encourage investigations in private homes to supplement existing knowledge about the effectiveness of robots and personalization of their functions. We expect that additional research will corroborate the impact of social robots on loneliness, mood, QoL, and social health in people with dementia and the elderly.

Acknowledgments

This research was carried out as part of the Marie Curie Innovative Training Network (ITN) action, H2020-MSCA-ITN-2018, under grant agreement number 813196.

Conflicts of Interest

MFM has participated in clinical trials with Lundbeck, Acadia, Janssen, Otsuka, Angellini, Oxygen, Roche, Servier, Boehringer Ingelheim, and Gw Research Limited.

Abstract

Background: An increasing number of patients expect and want to play a greater role in their treatment and care decisions. This emphasizes the need to adopt collaborative health care practices, which implies collaboration among interprofessional health care teams and patients, their families, caregivers, and communities. In recent years, digital health technologies that support self-care and collaboration between the community and health care providers (ie, participatory health technologies) have received increasing attention. However, knowledge regarding the features of such technologies that support effective patient-professional partnerships is still limited.

Objective: This study aimed to map and assess published studies on participatory health technologies intended to support partnerships among patients, caregivers, and health care professionals in chronic care, focusing specifically on identifying the main features of these technologies.

Methods: A scoping review covering scientific publications in English between January 2008 and December 2020 was performed. We searched PubMed and Web of Science databases. Peer-reviewed qualitative, quantitative, and mixed methods studies that evaluated digital health technologies for patient-professional partnerships in chronic care settings were included. The data were charted and analyzed thematically. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist was used.

Results: This review included 32 studies, reported in 34 papers. The topic of participatory health technologies experienced a slightly increasing trend across publication years, with most papers originating from the United States and Norway. Diabetes and cardiovascular diseases were the most common conditions addressed. Of the 32 studies, 12 (38%) evaluated the influence of participatory health technologies on partnerships, mostly with positive outcomes, although we also identified how partnership relationships and the nature of collaborative work could be challenged when the roles and expectations between users were unclear. Six common features of participatory health technologies were identified: patient-professional communication, self-monitoring, tailored self-care support, self-care education, care planning, and community forums for peer-to-peer interactions.

Conclusions: Our findings emphasize the importance of clarifying mutual expectations and carefully considering the implications that the introduction of participatory health technologies may have on the work of patients and health care professionals, both individually and in collaboration. A knowledge gap remains regarding the use of participatory health technologies to effectively support patient-professional partnerships in chronic care management.

Introduction

Chronic Care Model

Changes in demographics, disease panorama, and medical technology enabling early diagnoses and effective treatments have led to chronic diseases dominating the disease burden, accounting for alarming increases in health care use and costs [1]. Thirty years ago, Wagner et al [2,3] proposed the chronic care model (CCM), which called for a system of care that goes beyond health care provision by mobilizing supporting resources in the community. The model foresaw that the design and organization of service delivery would need to be adjusted to what was required and made possible by viewing chronic care as a system. Clinical information systems have been identified as important assets, particularly for decision support. In addition, self-management support for *informed and activated patients* has been emphasized [3]. Over the years, the CCM has inspired much of the development of chronic care management, as individuals with chronic conditions need services and support from several providers. Research has shown that more patients expect and want to play greater roles in decisions about their treatment and care and perform self-care more effectively [4-6]. Nevertheless, the transformation of health care practices into effective chronic care systems remains challenging [7].

Collaborative Care Partnerships

The reference to *informed and activated patients* indicates that care arrangements according to the CCM are professionally driven, with health care professionals providing information and guidance to patients [3]. In contrast, patient-centered and person-centered care initiatives, launched at the start of the new millennium, highlighted the need to place patients at the center of their care and to make space for patient preferences in care planning, accomplished through a shared decision-making process [8]. This shift in care philosophy undoubtedly paved the way for patients with chronic conditions to be active rather than activated, which matched the aims of empowering patients and promoting equality in the patient-provider relationship. These movements emphasize the need to adopt collaborative health care practices, which implies collaboration between an interprofessional health care team and patients, their families, caregivers, and communities [9].

Central to this form of collaboration is the acknowledgment of patients as experts in their “experience, feelings, fears, hopes, and desires” [10]. Patient participation in co-design and *slow coproduction* helps strengthen their voices in the design of care services and can lead to improved patient experiences [11]. There is also evidence that when patients express what is important to them and have active roles in designing care, outcomes, including clinical outcomes, will improve [12]. In addition, several randomized controlled trials have shown that engaging patients in symptom monitoring, usually by applying digital technologies, has a positive effect on patient outcomes [13,14]. Symptoms are important not only to alert and guide the diagnostic workup but also to measure treatment effects (especially in severe illnesses) [15]. As patient-professional partnerships based on mutual respect for professional and experiential knowledge can strengthen patients in their self-management and shared decision-making with health care professionals, ultimately leading to improved clinical outcomes, it is worthwhile to study how such a collaborative care partnership can be enhanced.

Participatory Health Technologies

Digital health technologies delivered in real time and in real-world settings offer opportunities to support such partnerships. Participatory health informatics, which emerged as a field around 2008, concerns the use of “information technology as provided through the web, smartphones, or wearables to increase participation of individuals in their care process, and to enable them in self-care and decision-making” [16]. For example, web-based social health networks such as PatientsLikeMe [17] have become powerful tools for patients to share their experiences and learn from each other. Technologies for community support marked the beginning of participatory health technologies, and interest has been increasing in technologies supporting self-care and patient-professional partnerships, which was the focus of this study. In particular, the use of text-based patient-professional communication tools has increased over the past decade [18], supporting self-management and contributing to increased patient participation [19]. Although the use of mobile health apps generally has a positive influence on patient-professional relationships, health care professionals may still be reluctant to use them [20]. In addition, despite these apps’ potential to improve health care delivery to people with chronic conditions, their effects on health outcomes have been found to be inconsistent [19,21]. Thus, there is a need to gain more knowledge about the mechanisms that contribute to effective patient-professional partnerships. Therefore, this study aimed to map and assess published studies on participatory health technologies intended to support partnerships between patients, caregivers, and health care professionals in chronic care, focusing specifically on identifying the main features of these technologies.

Methods

Study Design

A scoping review was considered relevant as our aim was to examine the size, scope, and nature of the available literature on our phenomenon of interest and summarize existing research findings [22]. The review was performed in 5 stages, guided by the Arksey and O’Malley framework [23,24]. A review protocol (available on request) was developed beforehand and continuously updated to ensure consistency and reproducibility. The review team covered multiple areas of relevant expertise, including health informatics, health services research, medical technology management, and medicine. A list of experts in the domains of health care, patient self-care, and digital health was established to be contacted if expert advice was needed. For example, we sought and obtained input on the practical relevance of our research questions.

Stage 1: Identifying the Research Question

The scoping review question was specified by considering the population, intervention, comparison, and outcome [25]. The population of interest was broadly limited to people living with chronic illnesses; the intervention of interest was specified in detail, focusing on digital health technologies that enable partnerships between patients, caregivers, and health care professionals (ie, participatory health technologies). No comparison method was specified, and we aimed to identify all types of outcomes explored in previous studies. We posed the following overarching research question: what is known from the existing literature about participatory health technologies that intend to support partnerships between patients, caregivers, and health care professionals in chronic care? More specific research questions were posed in line with our aim:

- The context of use: At which levels of care are the participatory health technologies used? For which types of chronic conditions are participatory health technologies used? Who are the users of participatory health technologies?
- Evaluation: What study designs are used and what outcomes are measured and reported?
- Features supporting partnerships: What are the main features of participatory health technologies? How do the different features influence partnerships?

Stage 2: Identifying Relevant Studies

The search strategy was developed in consultation with the Karolinska Institutet University Library, following the Peer Review of Electronic Search Strategies guidelines [26]. Search terms were designed to capture papers related to three key concepts: (1) digital health technologies, (2) partnerships between patients, caregivers, and health care professionals, and (3) chronic care management. Searches were performed using the bibliographic databases PubMed and Web of Science, which were considered most relevant in relation to our aim. First, we identified synonymous terms for each key concept and combined them into a search phrase using the Boolean operator OR. We also identified and used relevant Medical Subject Heading terms in PubMed. We then combined the search phrases for the 3 concepts using the Boolean operator AND. The exact search phrases for the 2 databases are presented in Multimedia Appendix 1. Our searches were performed on November 21, 2017, and updated on December 14, 2020. The search results were filtered by language and time span, covering papers in English and Swedish published between January 2008 and December 14, 2020.

Stage 3: Study Selection

The inclusion and exclusion criteria are listed in Table 1. The period of inclusion, from 2008 to 2020, was motivated by the emergence of the term *participatory health informatics* in 2008 [16]. Screening was performed using the open-source platform Rayyan [27]. We specified the labels to be used as reasons for exclusion in the screening process if the inclusion criteria were not met. At the beginning of the screening process, the inclusion criteria were piloted and refined in several iterations until a consensus was reached among all authors. The first screening was performed in late 2017 and early 2018 by EE and MÅW with support from MD, ST, ÅR, and CW; titles and abstracts for each study were screened by at least two of these researchers (blinded). Conflicts were resolved through discussion and, if necessary, by involving the research team. The second screening, following an updated search, was performed in early 2021 by CW and MB who both screened all titles and abstracts and resolved conflicts through discussion. They also screened the reference lists of the included studies to identify additional relevant publications.

Table 1. Inclusion and exclusion criteria.

Criteria	Inclusion	Exclusion
Type of studies	Qualitative, quantitative, and mixed methods studies on the phenomenon published in peer-reviewed journals	Letters, commentaries, editorials, conference abstracts, doctoral theses, or any type of review
Period	January 1, 2008, until December 14, 2020	Before January 1, 2008, and after December 14, 2020
Language	English and Swedish	All other languages
Type of participants	Patients with chronic conditions, defined as a health condition that lasts at least 3 months	Patients who do not have chronic conditions
Phenomenon of interest	Studies that meet all 3 criteria listed below	Studies that do not meet all the 3 criteria listed below
Digital health technology	A digital health technology is defined as software intended for use for *preventive, promotive, curative, rehabilitative, assistive, or palliative care*; this includes categories such as eHealth or mobile health, wearable devices, and telehealth services; the digital health technology should enable processing and exchange of health information between end users using the *internet*	Nondigital services or digital services not specifically intended for medical use; for example, WhatsApp, email, telephone, and SMS text messages are technologies that are not primarily intended for the abovementioned purposes and were thus excluded
Partnership	The digital health technology intends to support collaboration and enables interaction between at least two types of users: patients or caregivers, and health care professionals or allied professionals (eg, pharmacists)	Digital health services for peer-to-peer collaboration between patients or caregivers only, or tools for team collaboration among staff, without patient or caregiver involvement, were excluded; tools that only intended to support self-care or treatment adherence were also excluded
Evaluation	Evaluation results testing the digital health technology in chronic care need to be available	Studies that merely describe the design and development of digital health technologies; evaluation that has not been performed in a real-world setting (eg, heuristic evaluation by experts)

Stage 4: Charting the Data

A data extraction sheet was developed containing bibliometric variables (author, country based on corresponding author affiliation, title, year, and journal), descriptive study variables (study aim, study design, and sample size), and variables based on the research questions (chronic condition, level of care, name and description of the participatory health technology, outcome measures, and evaluation results). All authors were involved in testing and refining the data extraction sheet with a selection of papers. A total of 2 authors per paper extracted and compared these to calibrate the variable definitions and our shared understanding thereof. Thereafter, CW and MB performed the remaining extractions for all the papers.

Stage 5: Collating, Summarizing, and Reporting Results

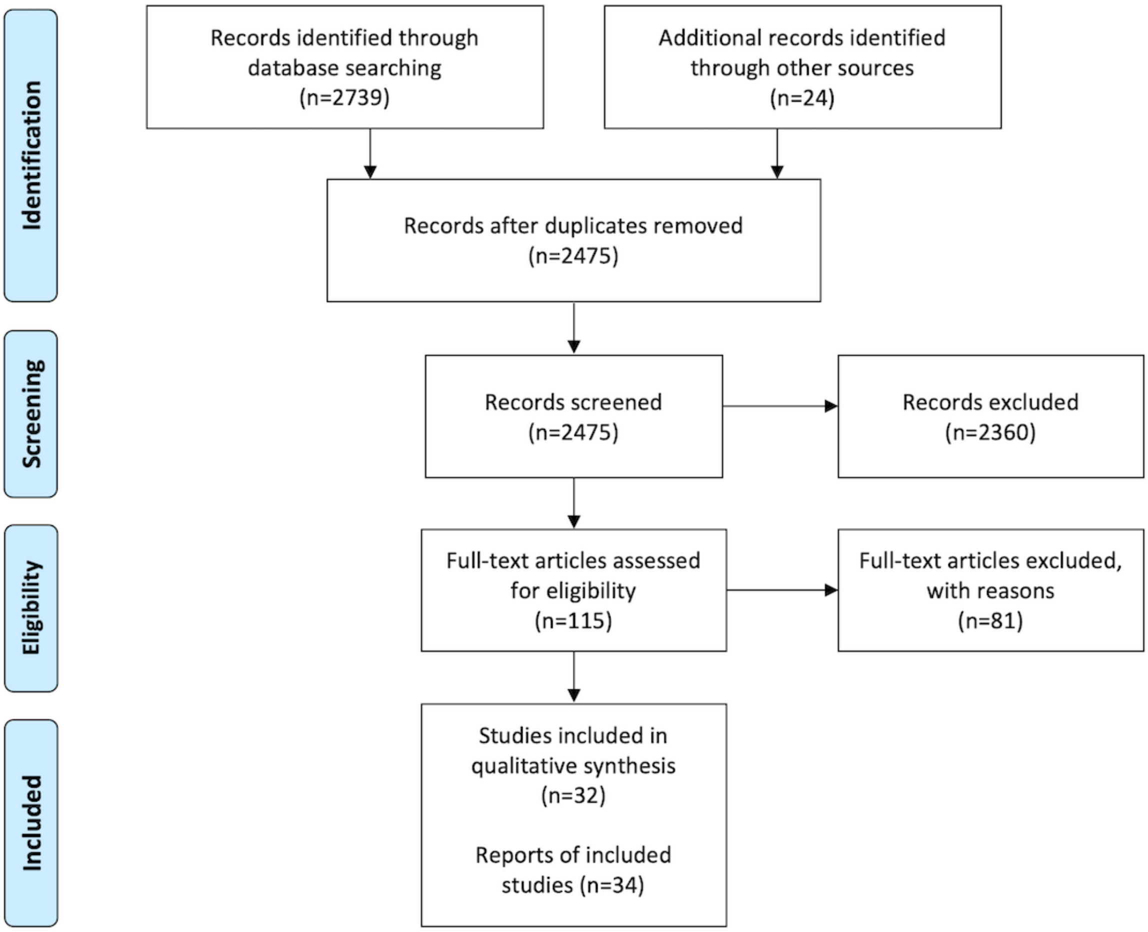
Charted data were condensed and grouped into categories that enabled the classification of the studies based on their study aims, study designs, chronic conditions, outcome measures, and evaluation results. The charted text describing the participatory health technology features and their influences on partnerships was extensive and was, therefore, analyzed separately using a qualitative content analysis process [28]. The charted text was abstracted through text condensation and categorization, which was performed by CW and discussed with MB. Meaning units were identified and coded inductively using a Microsoft Excel spreadsheet. Thereafter, all codes were transferred to the open source FreeMind mind-mapping software [29], where they were grouped into categories and subcategories. After categorizing all charted data, we used the statistical software R (R Foundation for Statistical Computing) [30] to explore descriptive statistics and the ggplot2 package [31] to produce visualizations. We first present a descriptive numerical summary of the included papers and then present an inductive categorization of the main participatory health technology features, supported by illustrative examples. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist for scoping reviews was used for reporting.

Results

Study Selection

Database and manual searches yielded 2763 records (Figure 1); after removing duplicates, the titles and abstracts of 2475 (89.58%) records were screened, and 2360 (85.41%) records that did not meet the inclusion criteria were removed. We read the full texts of 115 papers and excluded 81 (70.4%) for the following reasons: not partnerships (n=67, 58.3%), not digital health technologies (n=11, 9.6%), not used in care (n=1, 0.9%), not evaluated (n=1, 0.9%), and not original research (n=1, 0.9%). The remaining 34 papers, reporting on 32 studies of 30 participatory health technologies, were included in the qualitative synthesis. The characteristics of individual papers are presented in Multimedia Appendix 2 [32-65]. In our presentation of study characteristics, data were consolidated from publications reporting on the e-BP study [33,34] and the MyCyFAPP study [43,44].

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow chart.

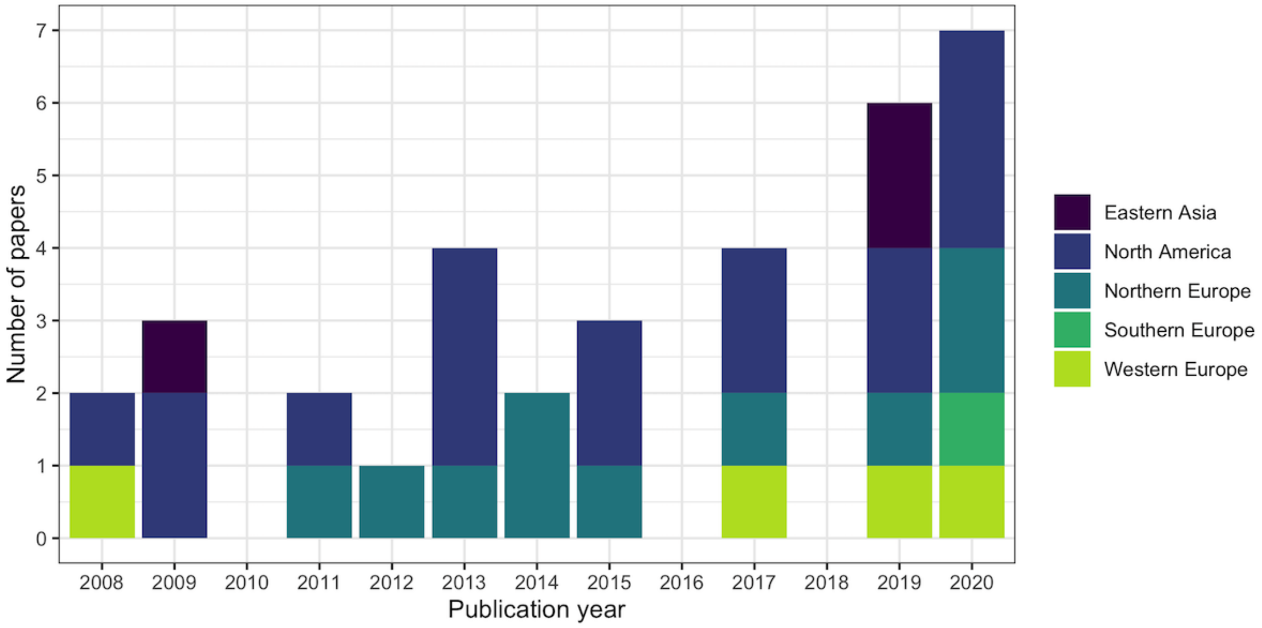


Study Characteristics

Publication Details

The topic of participatory health technologies experienced a slightly increasing trend across the publication years, with most papers being published in the past 2 years of the review period (Figure 2). The papers originated from the United States (15/34, 44%), Norway (7/34, 21%), and China (2/34, 6%), and a single (1/34, 3%) paper each from the following countries: Canada, Denmark, Sweden, the United Kingdom, the Netherlands, Germany, Austria, Switzerland, Spain, and South Korea. They were published in 21 journals, most commonly the *Journal of Medical Internet Research* (5/34, 15%), *JMIR mHealth and uHealth* (5/34, 15%), *Telemedicine and eHealth* (3/34, 9%), and the *International Journal of Medical Informatics* (3/34, 9%).

Figure 2. Number of included papers by year and world region.



Context of Use

The studies were conducted in primary care (18/32, 56%), secondary care (18/32, 56%), and tertiary care (7/32, 22%; Table 2). Approximately one-third (10/32, 31%) of the studies were set across levels of care, and some (3/32, 9%) additionally involved home care, social services, or school health services. Most studies addressed diabetes (8/32, 24%), followed by cardiovascular disease (6/32, 19%). The participatory health technologies were deployed almost exclusively as web applications or websites for health care professionals, whereas mobile deployment was common for patient users (14/32, 44%).

In some studies, participatory health technologies were integrated into electronic health record systems or personal health records [32-38]. In addition to interactions between patients and health care professionals, participatory health technologies supported collaboration with allied professionals [33,34,36,39] or technical staff [40,41]. Caregivers were identified as users in some studies in which the patients were children [37,42-45], cognitively impaired [46], or in palliative care [47]. We identified 3% (1/32) of studies in which patients who did not meet these criteria had the option to invite their families and friends to be users of participatory health technology [48].

Evaluation

Of the 32 studies, 13 (41%) were effect studies of participatory health technology use in clinical practice, 8 (25%) were feasibility studies, 7 (22%) explored user experiences, and 4 (13%) reported on the design and implementation of participatory health technologies (Table 3). The study designs included randomized clinical trials (11/32, 34%), quantitative evaluations (8/32, 25%), qualitative evaluations (7/32, 22%), and mixed methods evaluations (6/32, 19%). Of the 32 studies, the sample size was as high as 50 in 11 (34%) studies, 50 to 200 in 14 (44%) studies, and >200 in 7 (22%) studies. The studies evaluated the effects of participatory health technologies on clinical outcomes, including health, well-being, quality of life (17/32, 53%), user experiences (12/32, 38%), and self-management (7/32, 22%). Approximately one-third (12/32, 38%) of studies evaluated effects on partnerships by describing the content, experiences, and nature of collaboration [39,48,51,56]; the distribution of tasks and responsibilities [42]; patient-professional relationships [51,54]; engagements of patients and family caregivers [41,45,46]; and the perceived quality of collaborations [45,46]. Other effects that were evaluated included access to care and waiting times [49], continuity of care [47], and health care costs [34,52]. Most studies reported positive outcomes (22/32, 69%), although they were minor or temporary in some cases [35,62]. A few studies reported mixed results (5/32, 15%) or no change (3/32, 9%).

Qualitative Synthesis of Participatory Health Technology Features and Their Influences on Partnerships

Overview of Features

We identified six main participatory health technology features for enabling partnerships between patients and health care professionals: (1) communication, (2) self-monitoring, (3) tailored self-care support, (4) self-care education, (5) care planning, and (6) community forum (Table 4). Most studies described a combination of these features, often involving the first 3 (Figure 3 [32-65]). In the following sections, we describe the 6 features and their influences on patient-professional partnerships that were discussed in the studies.

Table 4. Thematic analysis of participatory health technology features.

Themes (features)	References
Communication	
Asynchronous message exchange	[32-36,38,40-44,46-49,52-57,60-63]
Audio or video communication	[32,39,48,52]
Unspecified	[65]
Self-monitoring	
Self-measurements of health parameters	[33-36,52,53,57,59,61,65]
Self-assessment of symptoms or problems	[32,37,39,43-45,50,58,62,63]
Self-reported health status or activity	[32,35,38,40,41,44,45,48,50,54-56,59-61,64,65]
Self-reported medication adherence or side effects	[32,35,38,40,44,64]
Diary for personal notes	[48,55,63]
Tailored self-care support	
Personalized goals	[34-37,44,51,55,64]
Medication management	[32-34,36,39,41,49,56,64,65]
Individual feedback	[35,50,51,55,64]
Tailored recommendations	[33-35,37,43-45,49,52,57,62,63]

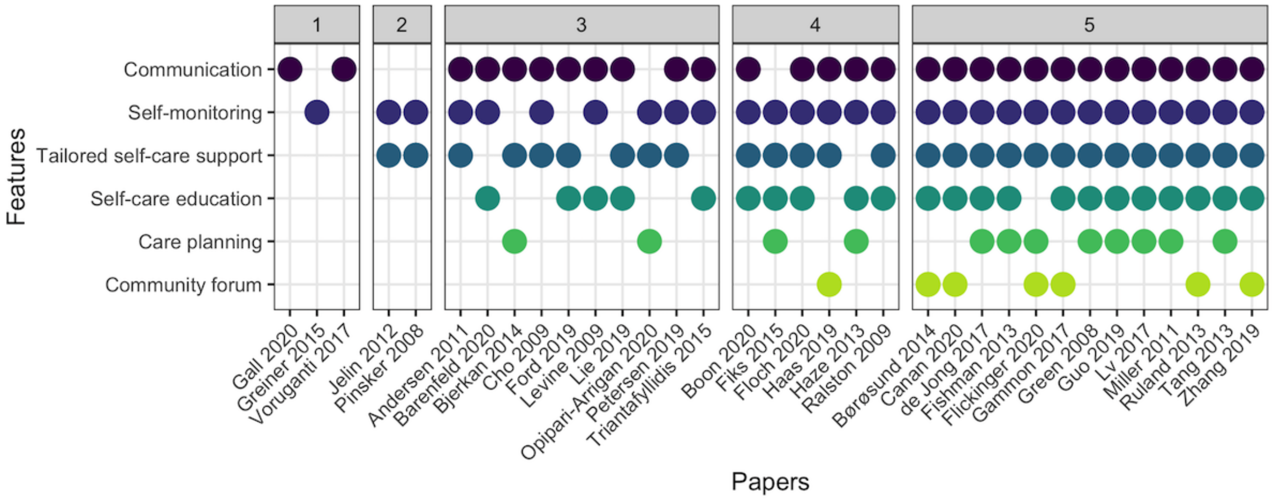
Figure 3. Illustration of identified participatory health technology features in each of the included papers, grouped by the total number of features (ranging from 1 to 5) [32-65].



Communication

Support for patient-professional communication was a central participatory health technology feature described in 84% (27/32) of studies. Most commonly, communication was facilitated through asynchronous text-based information exchanges between users; however, some studies also implemented audio- or video-based communication. In some studies, team-based communication between multiple users (including patients, caregivers, care team members, and allied health professionals) was also supported, enabling patients and caregivers to communicate with multiple care team members and care team members to interact with each other [46,47,49]. This communication feature contributed to rapport building [40] and improved patient-professional relationships among young and adult patients [44,54,60]. In a study of teenagers living with asthma, health care professionals reported that written communication could lead to more honest and elaborate responses among patients who may be less talkative in face-to-face encounters [54]. Meanwhile, a study that evaluated e-consultations for diabetes self-management support found that asynchronous communication could make patient-nurse relationships more fragile because of the risk of misunderstandings, suggesting that the best option may be a combination of written and face-to-face interactions [51]. Most studies did not describe any constraints in content, time, or word limits for message exchanges. Although one of the studies reported that health care professionals did not experience answering messages as too time consuming [63], other studies reported that tighter communication and follow-up of patients led to greater workloads for health care professionals between consultations [44] and could blur the boundaries between their private and work lives [56]. Various engagements with participatory health technologies among health care professionals and patients led to frustration when expectations were not met, for example, when messages were not answered [42,56].

Self-monitoring

Self-monitoring was also a central feature found in nearly all studies (27/32, 84%). It comprised the use of self-measurement devices to register and report health data, such as blood pressures [33,34,36,61,64], blood glucose levels [35,53,57,64,65], or physical activity [36,52]; self-assessments of symptoms or problems; self-reported health statuses or activities; self-reported medication adherence or side effects; and diaries for personal notes. When health parameters were not measured using external devices, self-monitoring was mostly facilitated through structured data input based on predefined forms. Several benefits regarding patient-provider partnerships were identified: increased patient motivation [50,59], higher perceptions of being recognized and respected by health care professionals [48], and more efficient consultations because of less time being spent on collecting and explaining data [44]. By providing contextual information and their own interpretations of self-monitored data, patients could participate as diagnostic agents in clinical assessments [39].

Tailored Self-care Support

The features for providing tailored self-care support were identified in 78% (25/32) of studies. This entailed support for setting and monitoring the progression toward personalized goals, medication management (eg, personal medication lists and managing refills), individual feedback, tailored recommendations, and alerts and reminders. Health care professionals provided individual feedback to patients on the basis of clinical variables or reported self-assessments and reflections [35,50,51,55,64]. In addition to feedback, tailored recommendations were often provided regarding therapy adjustments, symptom management, self-management activities, self-monitoring, and topics to discuss with clinicians. Recommendations were either automatically generated based on patients' reported data [37,43-45,52,62,63] or individually tailored by health care professionals [34,35,49,57]. The provision of feedback contributed to the development of good relationships and made patients feel understood and addressed, although feedback could also be experienced as challenging for patients [50]. Motivational messages could be both appreciated and experienced as annoying [44]. Alerts were provided to draw attention to patients and health care professionals, generally based on predefined threshold values for clinical parameters [32,36,45,60,64]. In some cases, alerts were also used to inform health care professionals about patients' activities or engagement with participatory health technologies [42,52]. Reminders were used to support medication adherence [41], prompt patients to upload self-monitoring data [37,57,58,64], or remind them of clinical examinations or appointments [38].

Self-care Education

Features for providing self-care education were described in almost two-thirds of the studies (20/32, 62%). Educational material was integrated into the participatory health technologies or provided through links to external sources and often covered both disease-specific information and lifestyle topics, such as nutrition, health and wellness, or smoking cessation [41,43,44,60]. Where educational material was embedded in participatory health technology, contents could be adapted specifically to the target group. For example, in a study of patients with diabetes [53], educational material was adapted to be culturally appropriate to the target group of native communities. Self-care education was sometimes delivered through video clips [35,37,54,61] or could include a toolbox of resources, such as recommended activities, good-to-know texts, and workbooks [56]. Several studies reported improvements in self-management knowledge and self-efficacy [32,43,44,60].

Care Planning

Approximately one-third (11/32, 34%) of the studies described features for participatory health technology–supported care planning. This involved access to planned activities or personal health plans and support for scheduling appointments or planning care visits. In preparation for care visits, patients had opportunities to identify goals, questions, or problems to discuss with their clinicians and provide information about their disease activity by filling in structured data forms [45,58,60]. A study of pediatric patients [45] found that visits and collaborations improved through this preparation. Another study identified shifts in roles and sometimes power transitions from health care professionals to patients and caregivers as they took more responsibility for care planning [42].

Community Forum

Web-based community forums for peer-to-peer interactions with other patients were provided in some studies (7/32, 22%). This functionality appeared in studies published in 2013 or later and only in participatory health technologies that had several other features as well. In most cases (5/7, 71%), the community forums enabled patients to write questions and comments anonymously to protect their integrity. In 43% (3/7) of studies, community forums were monitored by health care professionals who could contribute with answers to posted questions. In a community mental care setting, it was reported that peer support initially established through an anonymous community forum could develop into friendships when combined with café gatherings where service users could meet in real life [56]. Several studies found that patients would visit the web-based community forums to read others' posts more often than to post something themselves [41,56,62].

Discussion

Principal Findings

This scoping review identified and described the characteristics of participatory health technologies supporting patient-professional partnerships in chronic care management evaluated in 32 studies and published in 34 papers. These papers originated almost exclusively from North America and Europe and were published in a variety of journals, mainly in the fields of biomedical informatics or information science but also in the fields of health services research, medicine, and nursing. This reflects the multidisciplinary nature of participatory health informatics in chronic care management. The slight increase in the publication trends may suggest an increasing interest in digital services for participatory medicine in recent years. Notably, the included papers represented high variation in terms of the chronic conditions addressed, the levels of care where the participatory health technologies were used, the study designs, and the sample sizes. Nevertheless, 6 common participatory health technology features could be identified. Most participatory health technologies had features to support patient-professional communication, self-monitoring, and tailored self-care support. More than half of the studies described self-care education features, and approximately one-third discussed features to support care planning. In more recently published studies, the facilitation of peer support through web-based community forums emerged as a new feature. The engagement of caregivers as participatory health technology users was also more common in recent studies, possibly indicating a shift from focusing merely on the patient-professional dyad to a system view of collaborative care, acknowledging the involvement of more stakeholders. Most studies reported positive outcomes, although there were mixed results, highlighting the importance of tailoring participatory health technology implementation and use to individuals' needs and preferences.

Comparison With Prior Work

Our thematic analysis focused on identifying common participatory health technology features and describing the identified influences on patient-professional partnerships. In the following sections, we discuss 3 observations made when interpreting our findings, namely, how participatory health technologies influence roles and relationships, the changing nature of chronic care work, and a shift from intermediation to apomediation.

Changing Roles and Relationships

Overall, our findings are in line with previous studies indicating that the use of eHealth interventions can positively influence patient-professional communication and relationships [20] and also challenge these because of undefined or changed roles [66]. As a previous review has shown [20], the positive influences of participatory health technologies on patient-professional relationships depend on participating actors who meet the expectations and rules of minimal engagement. This was clearly seen in some studies in mental care [42,56], where variation in patient or professional engagement with participatory health technologies could lead to either enhanced or challenged relationships. One of these studies highlighted that health care professionals may need to communicate their personal boundaries to patients; for example, they would only check messages on certain weekdays [56]. However, these kinds of social interaction norms have rarely been made explicit in studies where asynchronous interactions were not structured or constrained, which could lead to a blurring of the boundaries that define the contents, extents, and times of interactions [67,68]. The ethical implications of digital patient-professional communication can be complex and require organizational guidelines to promote good practices in the use of digital communication [67]. Role uncertainty may affect both staff and patients [69], suggesting that the introduction of participatory health technology features that enable unlimited asynchronous interactions or task shifting (eg, the patient takes on tasks traditionally performed by health care professionals) should also involve mutual agreements on the distribution of tasks, roles, and responsibilities between patients and professionals.

Changing Nature of Collaborative Chronic Care Work

In addition to communication support, the most common participatory health technology features we identified were self-monitoring and tailored self-care support, which is comparable with the results of a recent scoping review focusing on the features of web portals for telerehabilitation [70]. These 3 features were often combined, and they have the potential to profoundly influence the nature of collaborative work among patients, caregivers, and health care professionals. Through self-monitoring and self-care, patients take over tasks that were previously performed by health care staff (eg, measuring of vital parameters) or not performed at all (eg, continuous collection of health parameters between consultations). As described in one of the papers in our review [44], patients' self-monitoring also influenced the work of health care professionals in several ways. Consultations could become more efficient as data were collected in real time and made available to both patients and health care professionals before consultations. In contrast, health care professionals had to spend more time between visits responding to questions or providing feedback to their patients (ie, communication and tailored self-care support). This indicates that health care professionals' workloads may increase in some areas but decrease in others, with implications for how their work is organized. Workloads, workflow disruptions, and alignment with clinical processes are among the most common barriers to the adoption of eHealth services [66]. Another study found that when patients' transmission of data replaced physical meetings, the patients could become passively disengaged, resulting in poorer collaborations [39]. Enabling patients to provide contextual information in addition to automated self-measurements contributed to reintroducing them as collaborative partners in diagnostic interpretation; however, the authors questioned whether this could really be labeled as collaboration or merely the transmission of more data. This study clearly problematized the potential issues when self-monitoring merely replaced previous collaborative work. When self-measured data are not interpreted in collaboration with the patient, the partnership may be harmed rather than improved.

Features for care planning provided another example in which the nature of collaborative work could change. For example, care planning enabled patients to influence the agenda for care visits by communicating their personal goals and the questions they wanted to address. One of the studies described a power transition, as patients took more responsibility for their care plans [42]. Altogether, these findings emphasize that the potential implications of participatory health technologies on the nature of collaborative work need to be carefully considered when introducing eHealth services that influence the work of patients and health care professionals in chronic care management.

Moving From Intermediation to Apomediation

With the rise of web-based technologies, referred to as Web 2.0, and similarly, Medicine 2.0, the terms intermediation, disintermediation, and apomediation were introduced [71,72]. Intermediation refers to the selection and delivery of "relevant" health information by an intermediary (eg, health care professionals or a web portal vetted by experts). For example, self-care education and self-care support features that were quite common in this review may be understood as methods of intermediation. By providing patients with relevant self-care information, health care professionals can shift away from the paternalistic model of physician-patient relationships to an interpretive model, where they take on roles as counselors or advisers in individuals' self-care [73]. The provision of self-care education was associated with increased knowledge and self-efficacy, which are resources that individuals can draw on to build their capacities for self-management [74]. It has been suggested that the more knowledgeable and self-efficacious patients become, the less they want to rely on experts (ie, disintermediation), preferring guidance from peers who "stand by" rather than "in between" patients and the knowledge they seek (ie, apomediation) [71]. An example of apomediation is web-based social health networks, which have been integrated as components in the eHealth-enhanced CCM [75]. Although web-based communities marked the beginning of participatory health informatics [16], the integration of social networking features in participatory health technologies intended for patient-professional interactions emerged as a new trend in this study. Our results illustrate that the 3 different types of participatory health technologies that have been previously distinguished (ie, Web 2.0, self-care support, and tools supporting health care provision) are being increasingly combined in multimodal services. This suggests that participatory health technologies may indeed enable a shift toward a more collaborative and networked approach to participatory medicine beyond the patient-professional dyad. We have identified several features to support partnerships in chronic care management; however, the processes of how patient knowledge is shaped and integrated in shared decision-making are still poorly characterized [76]. Future research may reveal how knowledge from web-based health communities, patients, caregivers, and health care professionals can be effectively combined to support patients in their individual self-care and drive quality improvement and collective organizational learning.

Strengths and Limitations

This scoping review has several strengths, including the inclusion of all types of study designs to obtain findings assessed using different methods, a screening method involving multiple researchers, and a qualitative synthesis contributing to new knowledge. The included studies covered various chronic conditions, clinical settings, and study designs. Our search strategy limited the review to papers published in English and Swedish between 2008 and 2020, implying that we may have missed important studies published earlier and in different languages. Furthermore, the inclusion criteria restricted the studies to those that reported the use of software specifically intended for clinical use (ie, excluding the use of email, SMS text messages, or nondigitally supported means of partnership) and had been evaluated in clinical practice. Nevertheless, our findings add new knowledge that contributes to describing the scope and nature of participatory health technology features to support patient-professional partnerships. Only 38% (12/32) of studies evaluated the effects on partnerships, which suggests that a knowledge gap remains regarding the influence of participatory health technologies on the nature of partnerships and how to support collaborative health care practices effectively. As most studies reported positive results, there may also be a publication bias, given that studies of failed eHealth interventions are published less frequently [77].

Conclusions

This scoping review identified participatory health technologies evaluated in studies intending to support partnerships between patients and caregivers and health care professionals in chronic care and qualitatively analyzed the main features of these technologies. A total of 6 common features were identified: patient-professional communication, self-monitoring, tailored self-care support, self-care education, care planning support, and community forums for peer-to-peer interactions. The integration of social networking features for community support in health technologies intended for patient-professional interactions is an emerging trend, which suggests a shift toward a more collaborative and networked approach to participatory medicine beyond the patient-professional dyad. The studies in this review mainly reported positive outcomes; however, we also identified how partnership relationships and the nature of collaborative work could be challenged when roles and expectations between users were unclear. This emphasizes the importance of clarifying mutual expectations and carefully considering the implications that the introduction of participatory health technologies may have on the work of patients and health care professionals, individually and in collaboration. Future research should further explore the mechanisms by which participatory health technologies contribute to the shaping and use of collaborative knowledge to benefit individual patients, patient populations, and organizational learning.

Acknowledgments

The research was funded by the Swedish Research Council for Health, Working Life, and Welfare (Forte) (grants number 2014-4238 and 2017-01451), the latter funding CW. The APC and Marie Dahlberg were additionally funded by the Kamprad Family Foundation for Entrepreneurship, Research, and Charity (grant number 20170012).

Authors' Contributions

CW contributed to conceptualization; methodology; formal analysis; investigation; data curation; writing, reviewing, and editing; and visualization, supervision, project administration, and funding acquisition. MÅW contributed to conceptualization, methodology, investigation, data curation, and reviewing and editing. MD, ÅR, and ST contributed to conceptualization, methodology, investigation, and reviewing and editing. EE contributed to conceptualization, methodology, investigation, data curation, reviewing and editing, supervision, and project administration. MB contributed to conceptualization; investigation; writing of the original draft, reviewing, and editing; supervision; project administration; and funding acquisition. All the authors have read and agreed to the published version of the manuscript.

Conflicts of Interest

MÅW was at the time of the study part-time employed by Philips. However, the company had no influence or financial interests related to the manuscript.

Abstract

Background: Social media tools have provided health researchers with the opportunity to engage with communities and groups in a nonconventional manner to recruit participants for health research. Using social media to advertise research opportunities and recruit participants facilitates accessibility to participants from broad geographical areas and diverse populations. However, little guidance is provided by ethics review boards for researchers to effectively use this recruitment method in their research.

Objective: This study sought to explore the literature on the use of social media for participant recruitment for research studies and identify the best practices for recruiting participants using this method.

Methods: An integrative review approach was used to synthesize the literature. A total of 5 health sciences databases, namely, EMBASE (Ovid), MEDLINE (Ovid and EBSCOhost), PsycINFO (Ovid), Scopus (Elsevier), and CINAHL Plus with Full Text (EBSCOhost), were searched using predefined keywords and inclusion and exclusion criteria. The initial search was conducted in October 2020 and was updated in February 2022. Descriptive and content analyses were applied to synthesize the results, and the findings are presented in a narrative and tabular format.

Results: A total of 96 records were included in this review, 83 (86%) from the initial search and 13 (14%) from the updated search. The publication year ranged between 2011 and 2022, with most publications (63/96, 66%) being from the United States. Regarding recruitment strategy, 45% (43/96) of the studies exclusively used social media, whereas 51% (49/96) used social media in conjunction with other strategies. The remaining 4% (4/96) provided guidelines and recommendations for social media recruitment. Notably, 38% (36/96) of these studies involved hard-to-reach populations. The findings also revealed that the use of social media is a cost-effective and efficient strategy for recruiting research participants. Despite the expanded use across different populations, there is limited participation of older adults in social media recruitment.

Conclusions: This review provides important insights into the current use of social media for health research participant recruitment. Ethics boards and research support services in academic institutions are encouraged to explicitly provide researchers with guidelines on the use of social media for health research participant recruitment. A preliminary guideline prepared based on the findings of this review is proposed to spark further development in this area.

Introduction

Background

In this digital age, advancements in technology have created opportunities for researchers to use new techniques to recruit research participants. For health researchers, technological innovations present an opportunity to use digital platforms such as social media, the internet, web applications, multimedia, and smartphones to effectively and efficiently engage the community for research recruitment [1]. These digital platforms provide an additional source for participant recruitment for health research studies [2]. Within health sciences, social media is being quickly adopted because of its increased use as a method of communication with the public [3]. For many researchers, recruiting participants for trials can be a daunting task that can result in study delays or the termination of trials [4]. Less than one-third of trials reach their original target within a specified time frame, and approximately one-third required extension [5]. Hence, reaching targeted participants through social media platforms provides an important avenue for facilitating researchers' work.

Social media refers to a group of internet-based communication services through which users create and participate in web-based exchanges, contribute user-created content such as videos, or join web-based communities to share information and ideas [6]. The trends and patterns of social engagement worldwide help provide researchers, policy makers, and other stakeholders with an overview of the different social media applications that users are engaged with [7] and how these tools could potentially be used to leverage health research. With a global population of 7.8 billion inhabitants [8], internet users stand at 4.54 billion, representing a 59% penetration rate, and active social media users at 3.80 billion, representing 49% [9,10]. Active social media platforms users include Facebook (63%), YouTube (61%), WhatsApp (48%), Facebook Messenger (38%), Instagram (36%), Twitter (23%), and Snapchat (13%) [9,11]. Social media provides an appropriate medium for user connection and communication, information collection and dissemination, knowledge sharing, discussion, and collaboration with communities for professional networking and business purposes [12-14].

Despite the numerous benefits and opportunities associated with social media, its use in the recruitment of research participants is still evolving. Health researchers using digital platforms for research participant recruitment encounter challenges such as efficiency, cost, information reliability, informed consent, confidentiality, privacy-related concerns [15], internet accessibility, information overload, informed consent, and interaction quality [12,13]. In traditional recruitment methods, researchers often face costs associated with personnel and resources, administrative changes, time-consuming recruitment processes, recruitment bias, and population homogeneity [16-20]. Cost plays an essential part in the success of a research process as a higher fraction of the cost is allocated to participant recruitment [21]. The cost involved in research studies varies and is dependent on certain factors such as the targeted population, geographical location, and type of recruitment approach [18]. To overcome the challenges associated with the cost of participant recruitment, researchers need metrics to determine the cost of recruitment.

To access social media, users are required to create a profile that requires certain mandatory information such as first name and last name, email address, or mobile phone number [22]. Although interested social media users willingly provide these data, they are often unknowingly signing away their privacy, which increases the possibility of privacy breaches [23]. Although research ethics boards (REBs) require removing identifying information of research participants from data using unique identifiers, such guidelines are rendered ineffective in the context of social media data as participants' relational links are predictive of their attributes [24]. Nonetheless, Narayanan and Shmatikov [25] stated that such anonymization of participants' data might be insufficient to protect social media networks' privacy.

Researchers need guidance to navigate the ethical and logistical issues associated with using social platforms as a recruitment tool other than the "Terms and Conditions" stated by the application software providers [26]. Therefore, researchers often turn to ethics boards within their institutions for guidance on social media and internet recruitment; however, this information is not always readily available. To determine this, we reviewed the REBs of the top 10 higher education institutions in Canada to identify any standard ethical guidelines currently being used or recommended for using social media tools to recruit participants for research studies beyond adopting the Tri-Council Policy Statement on research. We used the QS World University Ranking criteria, which determine universities' rankings worldwide based on 6 metrics [27]. This strategy was deemed appropriate as these universities are known for their high-impact research productivity. The results revealed that only 3 universities had guidelines available on social media use in research studies, which further supported the need for this integrative review (Multimedia Appendix 1). A standard protocol that could be adopted by postsecondary institutions, research organizations, and researchers could help mitigate the pitfalls researchers encounter during participant recruitment for research via social media applications. Such protocols may facilitate the research process, expedite data collection, and ensure that digital research recruitment practices protect participants' data and rights.

Regarding the published literature, only 1 review [15] examined the evidence of cost, effectiveness, and the characteristics of participants recruited through Facebook compared with other web-based, social media, and traditional recruitment methods for adult health research. Little is known about the use of other social media platforms for participant recruitment in health research. Therefore, this study was warranted to address these gaps in the literature.

Objectives and Research Questions

This review sought to examine the evidence available on all the applications identified as social media tools and identify the best practices to facilitate participant recruitment through these tools. We addressed the following research questions:

1. What are the different social media tools commonly used by health science researchers for recruiting research participants and in what populations?
2. What is the proportion of nursing researchers who use social media platforms for recruitment?
3. What are the benefits and challenges of using social media to recruit research participants?
4. What are the best practices and ethical considerations for using social media tools to recruit research participants?

Methods

Overview

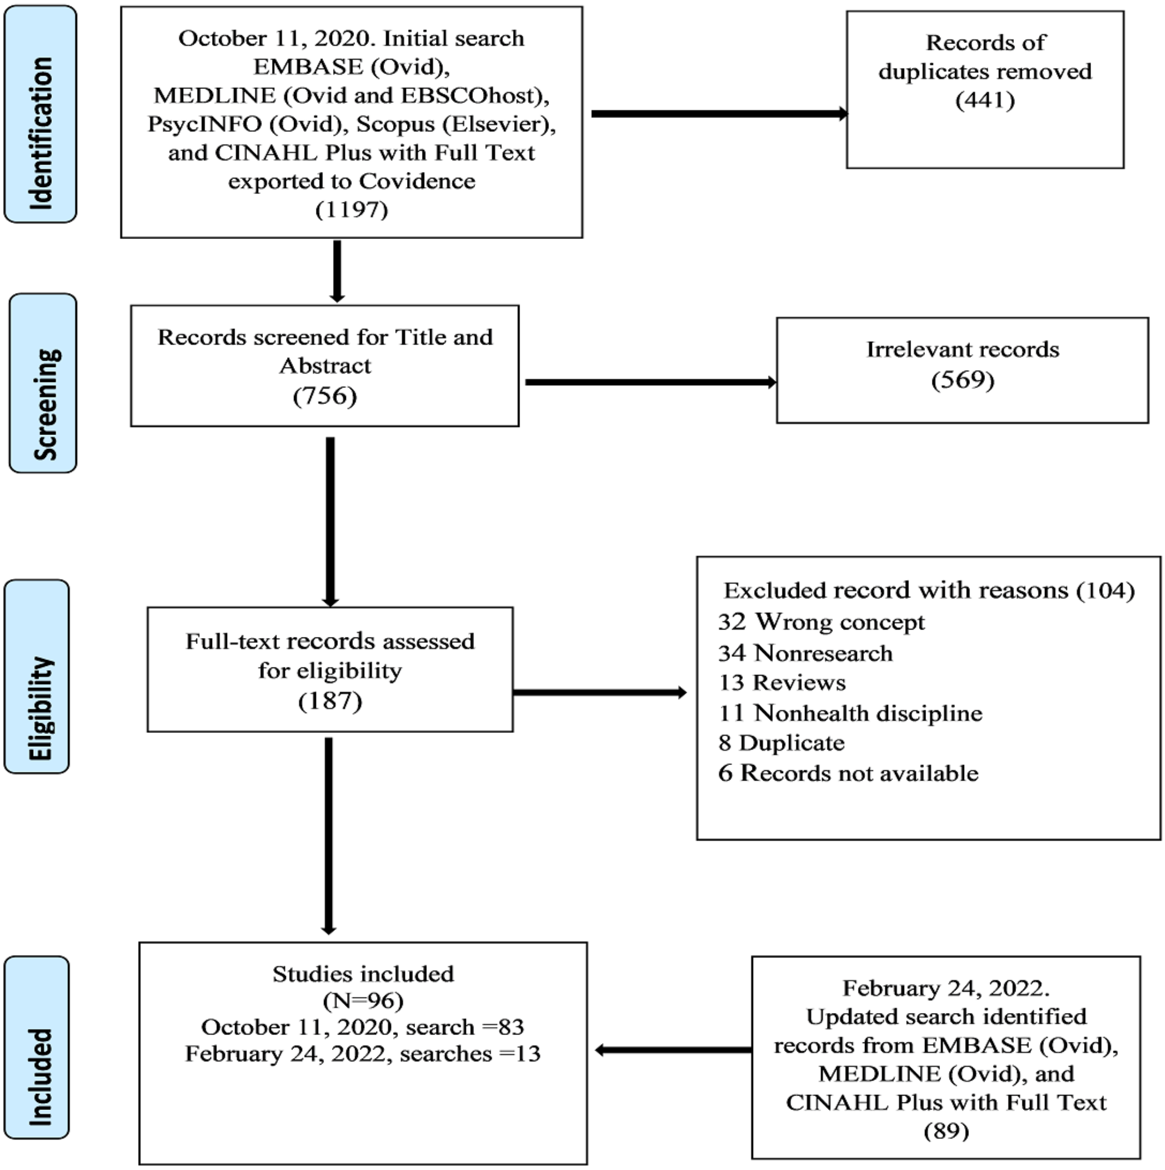
An integrative review guided by the Whittemore and Knafl [28] framework was conducted. This review type allows for the inclusion of diverse research methodologies and data sources to understand and generate new knowledge on the phenomenon of interest [28,29]. A comprehensive search strategy was formulated in consultation with a health science librarian. The initial search was conducted on October 11, 2020, and updated on February 24, 2022, in the EMBASE (Ovid), MEDLINE (Ovid and EBSCOhost), PsycINFO (Ovid), Scopus (Elsevier), and CINAHL Plus with Full Text (EBSCOhost) databases using a search strategy of keywords and subject headings through an iterative process (Multimedia Appendix 2). The criteria for eligibility were (1) all types of published research on primary and secondary studies, including qualitative, quantitative, and mixed methods; (2) discussion papers, white papers, reports, brief reports, specific guidelines, conference proceedings, dissertations, and published manuscripts that reported on social media use; (3) research reports published between January 2000 and February 2022; and (4) research reports that focused on research participant recruitment and advertisements on social media platforms, including all types of populations and health sciences disciplines, and (5) all geographical locations. The following articles were excluded: (1) non–English-language articles; (2) unpublished manuscripts and non–peer-reviewed publications such as descriptive papers, editorial papers, opinion papers, letters, book reviews, and article reviews; (3) review articles (scoping, integrative, narrative, and systematic) already published on the topic; and (4) all non–health sciences articles. The time frame for the published reports was chosen to capture the contemporary views that reflect the trends and popularity of digital platforms in participant recruitment.

Data Evaluation and Analysis

Records from the databases (initial search N=1197) were retrieved and imported into the Covidence Management Software for data screening and extraction. Overall, 2 reviewers (EMD and MK) independently conducted the screening process in Covidence, screening titles and abstracts, followed by full-text screening. All decisions made to either include or exclude records against the predetermined inclusion and exclusion criteria were documented. Where conflicts arose, the 2 reviewers consulted and resolved them through a voting process. We conducted another search on February 24, 2022, to update the results. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) Protocols template in Covidence was used to map out the screening process, and the results as shown in Figure 1.

The following details were extracted from the included records: name or names of the author or authors, year of publication, country of publication, study design, study population, total number recruited, total number of participants enrolled or recruited through social media, social media platform used, other recruitment strategies, type of advertisement (paid or not paid), incentives provided, whether the study was funded, limitations of social media reported by the authors, and duration of advertisement (Multimedia Appendix 3 [2,18,20,30-115]). The extracted data from these records were analyzed by identifying codes and categories to characterize emerging themes, patterns, trends, and relationships to aid in synthesizing the findings logically and coherently. In addition, descriptive statistics were applied where appropriate to describe and summarize the data pertinent to the distribution of research and other characteristics. The Critical Appraisal Skills Program [116] was used per the research methodology to appraise and evaluate each of the included studies critically to ensure the quality of the available evidence included in this review (Multimedia Appendix 4 [18,20,31,50,53,54,55,58,60,61,76,77,81,106,109,114]). The studies were assessed and rated as “low quality” or “moderate quality” based on their theoretical or methodological rigor [28]. Ethics approval was not required as this study did not involve human participants.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2009 flow diagram.



Results

Overview

In total, 1197 records were retrieved from the initial database search; in Covidence, 441 (36.8%) duplicate records were removed from the imported references, and a total of 756 (63.2%) records were moved for screening. In the first stage of screening, the titles and abstracts of each record were screened for full-text review. In the second stage of screening, 187 full-text studies were reviewed entirely and assessed for eligibility for inclusion or exclusion. For records that were not available in the full text, the Health Science Library was contacted to obtain those records. A total of 6 articles that reported on conference proceedings were retrieved but did not have any substantial information, as reported in the abstracts. Nonetheless, the full texts of these articles were requested through library services but could not be retrieved; thus, a decision was made to exclude them from the results. It should be noted that although the Covidence software automatically removes duplicates, there were instances of errors where some records were missed; therefore, removing these duplicates manually was warranted. Of the initial search, a total of 83 records were included. The updated search returned a total of 89 records. Of the 89 articles, after 11 (12%) duplicates were removed, a total of 78 (88%) articles were screened. A total of 23 articles underwent full-text review, of which 10 (43%) were excluded as they did not meet the inclusion criteria, and 13 (57%) articles were retained and included in the review. Finally, 96 records were included in the review. In total, 114 records were excluded (Multimedia Appendix 5).

Characteristics of Included Studies

The range of publication years of the articles included in the review was between 2011 and 2022 (Multimedia Appendix 3). Most publications were from the United States (63/96, 66%) and Australia (20/96, 21%). Besides that, they were from Canada (5/96, 5%), the Netherlands (2/96, 2%), and the United Kingdom (2/96, 2%). There was only one publication from each of the following countries: Taiwan, Ecuador, India, and Brazil. Out of the 96 included studies, 92 (96%) were papers reporting primary research and 4 (4%) were reports on using social media. The methodological approaches used were cross-sectional studies (38/96, 40%), web-based surveys (15/96, 16%), secondary data analysis (14/96, 15%), randomized controlled trials (10/96, 10%), reports (4/96, 4%), mixed methods studies (4/96, 4%), qualitative studies (3/96, 3%), cohort studies (3/96, 3%), clinical trials (3/96, 3%), quasi-experimental studies (1/96, 1%), and longitudinal studies (1/96, 1%).

Social Media Use by Nursing Researchers and Other Health Researchers

We were interested in determining the proportion of nursing researchers using social media; however, this was not easy to identify as researchers have published studies that have used social media for the recruitment of research participants in a variety of interdisciplinary journals. On the basis of the journal names where these articles were published, these researchers could be from any health discipline, including nursing, medicine, psychology, rehabilitation, nutrition, pharmacy, or public health. Of the 96 included studies, 71 (74%) were published in general health science journals or interdisciplinary journals [18,20,26,30-92,117-121], and 25 (26%) were published in nursing-related journals [2,93-115,122].

Social Media Tools Commonly Used by Health Researchers

Researchers used a variety of social media platforms to recruit participants, as reported in the included studies. Researchers either exclusively used social media (43/96, 45%) or social media in conjunction with other recruitment methods (49/96, 51%) to recruit participants (Multimedia Appendix 3). For studies that exclusively used social media, ≥1 social media platform was used simultaneously. Social media platforms included Facebook, Twitter, Craigslist, Instagram, YouTube, LinkedIn, Reddit, Snapchat, and Tumblr. For social media in conjunction with other recruitment strategies, researchers used the identified social media platforms in addition to blogs, social media, Grindr, and WhatsApp Messenger. It was noted that, at times, researchers used the term “social media” but did not specify the type of social media used. In both approaches, most participants relied on the use of Facebook for research recruitment.

Age Groups of Research Participants Recruited via Social Media

Although researchers used social media platforms for advertisement and recruitment of participants for research, they sometimes did not target specific populations. In addition, the age group distribution of these populations varied, and the definition of the age group differed depending on the study aims. To address this, initially, the range of age groups was specified as follows: children (aged <9 years), adolescents (aged 10-18 years), young adults (aged 19-35 years), middle-aged adults (aged 36-55 years), older adults (aged 56-64 years), and older adults aged ≥65 years. The included studies were then scanned against this categorization to identify which age group was most targeted for social media recruitment (Table 1).

Table 1. Age groups of research participants recruited via social media (N=92).

Age category	Participants, n (%)	Research studies
≥18 years	28 (30)	[30,31,33-35,40,48,50,52,57,58,70,73-76,78,79,81-83,90,94,97,108,111,112,114,115]
Age group: not specified	22 (24)	[2,32,36,39,56,66,68,86,89,92,93,96,98-101,103,105-107,110,119]
Two age categories	18 (20)	[20,38,41,42,46,47,49,53,55,58,61,63,64,72,84,87,95,102]
Age groups between 3 age categories	9 (10)	[37,44,54,62,67,77,80,85,117]
Age groups between 4 age categories	3 (3)	[60,71,91]
Age groups between 5 age categories	3 (3)	[65,69,113]
Adolescents	2 (2)	[18,120]
Age groups of ≥21 years	3 (3)	[52,88,109]
≥30 years	1 (1)	[51]
≥33 years	1 (1)	[104]
≥45 years	1 (1)	[45]
≥60 years	1 (1)	[43]
Age group of ≤9 years	0 (0)	—[a]

[a] Not available.

Populations Targeted in Social Media Recruitment and Their Characteristics

Researchers have targeted different populations in their research studies. Largely, there were many studies (46/96, 48%) that included the general population [2,18,20,31,32, 36,37,40,41, 43,46,47,49, 51,54,55, 58,60,63,64,65, 67,69,70,71,72,73,74,77, 79,80,84, 85,91,92,93,94, 104,106,108, 112,114,115, 119,120]. In addition, a significant proportion (36/96, 38%) of the included studies focused on recruiting hard-to-reach populations (Table 2). Hard-to-reach populations are groups that are socially disadvantaged and present a challenge to access for researchers because of ethnicity, low income, or health literacy [123,124]. In this review, these populations had addiction problems, unique medical disease conditions, or lifestyle choices or belonged to an ethnic minority group. A few studies applied social media recruitment to target health care professionals as research participants (10/96, 10%) [96,98,99,100,101,103,105,106,107,113].

Table 2. Hard-to-reach populations targeted in social media recruitment.

Population	Records
Addiction: smoking and alcohol	[30,35,37,38,44,48,50,52,81]
Medical disease conditions: survivor of cancer, autism spectrum disorder, Lynch syndrome, people living with HIV, asthma, obstructive pulmonary disease, depression, and kidney transplant recipient	[34,39,42,53,56,58,61,66,68,89,97,107,111]
Lifestyle: men who have sex with men	[33,57,78,82,83,90]
Ethnic minorities: low-income and racial minority	[45,62,75,76,86,88,95,102]

Cost-effectiveness, Efficacy, and Feasibility of Social Media in Comparison With Other Recruitment Methods

The costs of recruitment reported in all the included studies are presented in tabular form (Tables 3 and 4) to help ascertain how money was dispensed, as well as the cost-effectiveness of each recruitment strategy. However, it was noted that although some researchers included personnel costs, advertising costs, and other recruitment costs in the total cost, other researchers did not include these costs. Hence, researchers should use only this information as a guide. Few studies specifically compared social media effectiveness to other platforms with the goal of establishing cost-effectiveness, efficacy, and feasibility. In this review, 7% (7/96) of the included studies aimed to determine the effectiveness of social media compared with other recruitment strategies [39,51,52,58,70,74,106], and 9% (9/96) of studies that did not compare social media platforms with any other strategy [30,38,41,46,63,72,73,93,111] found social media as an effective recruitment strategy in both instances.

Few studies did not conclusively find social media to be cost-effective or efficient. The findings reported by these researchers differ because of the different populations targeted, scale of recruitment, and whether the research was funded. In their funded study, Moreno et al [18] found that in-person strategies yielded more participants in a geographic area at a lower cost than social media, and the cost per enrollee by social media was higher than that of traditional methods. In addition, Frandsen et al [48] suggested that Facebook was cost-effective in obtaining eligible participants at the initial stage of the recruitment process. The mailing of letters was cost-effective compared with Facebook, according to Waltman et al [106].

Best Practices and Strategies Used to Enhance Social Media Recruitment

Diverse advertisement strategies are adopted by researchers when recruiting research participants through social media platforms. Each social media platform advertisement differs in specification, advertisement content, word count, and design language [47]. In the included studies, researchers identified and used one or multiple paid, targeted advertisement campaigns with different themes to reach potential participants on various platforms within a specific advertisement duration. Some models of advertisement included the use of paid targeted advertisement [18,30,31, 37,39-44, 46-52,54, 58-60,63, 65,69-75, 77,78,80, 81,91,93, 95,102,109, 113,114,117,119,120]. In addition, some researchers used untargeted advertisements [38,62,111], untargeted but paid advertisements [45,74], "boosted" posts [94,106], posts [34,61,76,90,105,110,115], both advertisements and posts [55,57,64,68], tweets [79,104,108], targeted advertisements and posts [36], advertisements [56], blasts [33], paid and unpaid social media channels [32,35], and messengers [92] to strategically advertise and recruit their potential participants.

Another identified strategy was the use of cost-related model strategies to determine the cost of the advertisements. Researchers who are engaged with any social media platform to advertise and recruit participants are billed by cost per click, cost per thousand impressions, cost per view, or cost per action or per conversion [125]. With the cost per click model, researchers are billed when a potential participant clicks on the advertisement. This approach was one of the most preferred models for researchers in the included studies used for advertising. The cost per click model budget is set at a daily, weekly, or lifetime spending limit depending on the researcher's choice [18,30,33,38, 40,41,46, 47,48,51, 54,55,59, 60,64,69, 71,73,74, 75,77,80, 93,102, 111,126,129].

Researchers also noted considerations related to the display and design of an advertisement for a desktop application, which differed from that of a mobile app, and this affected how participants viewed and reacted to the recruitment advertisement. The displayed advertisements targeted either the user's browser or the newsfeed [91,117]. For Facebook, the advertisement is displayed on the user's web browser [58] or on the right-side panel of the Facebook newsfeed or placed directly in the newsfeed [47,55,65]. For Instagram, images are displayed in a linear format. Snapchat images are displayed using the story feature [47], and on Grindr, advertisements are displayed as pop-ups [57]. Therefore, cost is an influencing factor that determines the placement of the advertisement and the social media application of choice, thereby influencing the decisions that researchers make regarding recruitment.

Some researchers identified ethical challenges inherent to social media recruitment, such as privacy, confidentiality, and informed consent, and provided strategies to minimize the challenges for the researcher and the potential participant. The strategies offered and reported in the included studies included the use of a study-specific page for recruitment [2,51,76,78,82,91,94,107,112,113] and the use of secure landing sites or study webpages for data collection [35,43,48,50,58,75,106,118]. In addition to the strategies proposed by health researchers, there were 4 reports identified in the included studies that outlined guidelines and recommendations for social media recruitment (Table 5).

Table 5. Recommendations for best practices on social media recruitment.

Study	Study purpose or aim	Key findings	Recommendation
Curtis [118] (the United States)	To outline ethical challenges associated with social media recruitment	Social media platforms are challenged with issues of confidentiality, informed consent, and privacy issues.	Recruiting participants through secure landing sites; researchers regularly reviewing social media websites for regular updates; verifying participants' age through cross-checking with other information may provide solutions to the challenges; setting web-based quizzes to test participant competency; and providing a summary of the research study via email
Kamp et al [122] (the United States)	To examine and describe the challenges of the Facebook recruitment method and provide recommendations	The Facebook platform presents an inherent challenge with privacy, data security, and recruiting participants.	Researchers can implement a multifactor authentication process to access research data and regularly review the privacy settings and policies on social media sites
Gelinas et al [26] (United States)	To examine the norms governing social media recruitment and analyze the ethics of recruiting, and the implication of web-based communication	The foundational norms in research ethics include respect for persons, beneficence, and justice; however, in social media, the key norms governing social media recruitment include respect for privacy and researcher's transparency. The lack of regulatory guidance on ethics in social media recruitment poses a risk for ethical issues.	The authors proposed a checklist that researchers can use in social media recruitment
Bender et al [121] (Canada)	To develop a framework on ethics and privacy for social media and internet recruitment	The Privacy by Design framework evaluates the privacy strengths, thereby providing privacy protection in web-based recruitment.	Adhering to the Privacy by Design framework, which provides privacy-enhancing measures such as developing privacy notices, disabling comment features, or monitoring comments and removing identifiable information before it becomes public

Discussion

Principal Findings

Although we intentionally excluded 13 reviews from this study, 7 (54%) of them are discussed here against the findings of our review. The results from our review show an increased interest in using social media for research recruitment by researchers from different health disciplines in which social media strategies have fulfilled researchers' recruitment needs. Considering the wide range of publications, the scope of this literature review, and the social media applications examined in this review, it can be concluded that the use of social media is on the rise, as evidenced by the increase in the number of publications in the past few years. The different research methods identified in the included studies suggest increased use of social media for a variety of research methods. Notably, a few of the included studies recruited participants for clinical studies, with most recruiting participants for cross-sectional studies. Despite social media's reach within a broad geographic location, health researchers are still challenged with participant recruitment for clinical trials. This suggests that social media may be best suited for recruiting participants for noninterventional studies. Researchers recruiting for clinical trials may have to diversify their recruitment strategies to reach their recruitment goals until a comprehensive strategy to navigate social media platforms is established. This finding is similar to that of the review by Topolovec-Vranic and Natarajan [127], which found that only a few studies used social media to recruit participants for interventional studies as opposed to observational studies. Although the Topolovec-Vranic and Natarajan review [127] used a smaller number of studies to draw this conclusion, their findings are still significant, considering this review.

Researchers from different health disciplines, including nursing, medicine, public health, mental health, and pharmacy, have used social media for recruitment and have published their findings in a variety of journals. Some of these journals are discipline specific or interdisciplinary. This suggests different avenues for health researchers to publish their work. Within the nursing discipline, nurses are increasingly using social media for the recruitment of research studies, as published in multiple nursing and nonnursing journals. However, there are opportunities to continue promoting the use of social media among nurses for research and educational purposes.

On the basis of this review, researchers used different social media applications to advertise and recruit potential research participants. The preferred social media applications were Facebook, Instagram, Snapchat, LinkedIn, Twitter, Grindr, Reddit, Tumblr, WhatsApp, Craigslist, YouTube, and blogs to be used either solely to recruit or in conjunction with other recruitment strategies to achieve recruitment and study goals. Owing to its popularity among users and global penetration, Facebook was the most widely used application among researchers. Different social media applications enabled researchers to recruit participants with different demographics and characteristics. For instance, Facebook was used to recruit younger participants [77,113] and older individuals [67], whereas other researchers recruited young people through Tumblr [61]. This finding is similar to that of Arigo et al [128], who identified web-based platforms such as social networking sites (Facebook, Twitter, Instagram, Tumblr, and LinkedIn) as some of the common platforms that health researchers use to recruit research participants, including a diverse population for their research studies. In addition, researchers used multiple approaches and strategies to recruit participants. An approximately equal number of participants were recruited through social media alone or social media in conjunction with other strategies. This finding agrees with the general literature on the increasing acceptance of digital platforms for recruitment and with some health researchers using social media and traditional methods [129] for recruitment. In addition to the findings in this review, reviews conducted by some researchers [15,127,130-134], although focusing on only one social media application or using the term “social networking sites” broadly in their research, exclusively and comprehensively reported on a wide range of different social media applications used in research recruitment.

The different social media platforms used to target the different groups of populations such as the general population, hard-to-reach populations, and specialized populations, depended on the research aim. The hard-to-reach populations included people with addictions, sensitive health issues, ethnic groups, and poor and stigmatized populations [135]. Social media was found to be effective in reaching and recruiting hard-to-reach potential participants who were otherwise unreceptive to traditional recruitment methods because of their conditions and representations within their communities and society [50]. Researchers must weigh all available options to determine the best approach to proceed when recruiting from these populations.

The age group distribution of the research participants included in this review spanned different age categories. As shown in Table 1, the most targeted population from an age perspective was young adults. According to Kemp [10], the engagement of social media platforms among youth stands at 58% between the ages of 16 and 24 years. This is not surprising because of the acceptability of social media among youth who are considered technology savvy and their tendency to use social media regularly. As such, targeting such an age group for research studies can lead to increased participation. An observation of interest in this review is the low involvement of children and adolescents aged <18 years and older adults. Only 2% (2/96) of studies [18,120] involved adolescents between the ages of 13 and 14 years. As researchers require parental consent among the children and the adolescent group, research studies involving these groups are relatively limited. This finding is similar to that of Amon et al [130], who suggested that instead of focusing on adolescents who require parental consent, targeting parents or guardians of the intended group could help waive parental consent.

For older adults, the usability of social media platforms presents a challenge, such as platform design and content, as these platforms are tailored to the interests of the younger population [136]. Owing to the complex design, nature, and privacy-related concerns associated with social media platforms, older adults are more comfortable and familiar with traditional forms of recruitment than social-mediated platforms [137]. Other barriers encountered by older adults include intrapersonal, interpersonal, functional, and structural elements that hinder the use of social media platforms [138]. Although social media presents a challenge for recruitment in the older population, researchers can continue to explore traditional methods in such populations to offer an equal chance of participation in research studies. The trade-off between using traditional methods and social media for recruiting research participants is a complicated issue, requiring health researchers to weigh options and the benefits and risks to the participant and the research study, as well as more creative ways of engaging low participating groups.

There is a debate on the cost-effectiveness of social media in the literature. Some studies found the social media method to be cost-effective, whereas other studies disagree with this assertion [18,58]. In this review, the cost of other recruitment strategies compared with social media recruitment strategies was presented as part of this review to assist researchers in making an informed decision (Tables 3 and 4). In addition, in this review, the factors that influenced the cost associated with recruitment varied from one study to the next. Some researchers reported advertising, recruitment, and other administrative costs as the total cost, whereas others reported only aspects of social media advertisement and recruitment as the total cost. Owing to the inconsistency in cost reporting, having a standardized cost reporting system to maintain consistency would help to effectively determine whether social media recruitment is cost-effective. On the basis of the analysis of the cost-effectiveness of both social media and other recruitment strategies, this review found that social media was viewed by researchers as a cost-effective strategy. Although 28% (27/96) of studies in this review reported on the cost of social media compared with other recruitment methods, not all researchers found social media as a cost-effective method. Nonetheless, given that a large proportion of these studies found social media to be cost-effective, this review supports this conclusion. Compared with the previously published reviews by Reagan et al [15] and Topolovec-Vranic and Natarajan [127], this review provides additional insights and includes a broader range of studies. This review captured additional literature not included in the review by Reagan et al [15], which relied only on 18 articles, of which only 10 articles reported on cost. In the review by Topolovec-Vranic and Natarajan [127], the authors included 30 studies, of which 5 reported on cost-effectiveness, and 7 did not find social media to be a cost-effective method. The findings also revealed that the cost of recruitment for hard-to-reach populations differs from that for the general population. Juraschek et al [58] found that recruiting through Facebook advertisements for the African American population was costly; however, advertisements were effective in directing eligible participants to the website. Hence, researchers hoping to recruit research participants through social media must consider these factors to make decisive choices on the most suitable method for recruitment.

Best Practices for the Use of Social Media in Recruitment of Research Participants

Researchers are increasingly tapping into the available opportunities to use social media platforms for their research studies. However, there is a need for best practices to guide this process. To adequately explore and navigate social media platforms successfully for recruitment, adhering to best practices, including those of ethical considerations (informed consent, privacy, confidentiality, and transparency) that protect the researcher and participants, is of utmost importance [26,118,122]. In the review by Amon et al [130], the authors found that participants recruited on web-based platforms were subjected to the same ethical standards as though they were responding to a traditional recruitment method. In that regard, Gelinas et al [26] were of the view that REBs should standardize social media techniques by clarifying their similarity to traditional recruitment. Furthermore, the findings from the review also establish the need to take additional steps to make available informed consent through other means, where the potential participants are well informed with detailed information about the research study before participation. To curb and curtail the complexities and complicated nature of informed consent, the findings from this review support the recommendations suggested by Herbell and Zauszniewski [94] and Stokes et al [105] in their studies to make an information sheet in a downloadable version available for participants and send web-based consent forms to potential participants after meeting the eligibility criteria. To maintain the confidentiality of both researchers and participants, Shaver et al [71] suggested using anonymous surveys and directing interested participants through a survey link to a landing page for study information. Researchers are discouraged from directly recruiting participants on social media platforms but instead using the social media platform to advertise, as the confidentiality and privacy of participants' data cannot be guaranteed. To further ensure the provision of privacy, Bender et al [121] used privacy-enhancing measures aligned with the principles of Privacy by Design by disabling the comment feature, developing privacy notices for social media campaigns, sending disclaimers about the privacy risks of social media pages, and building privacy protection into the recruitment strategy. Although the tenets of the foundational principles were incorporated to avoid privacy-related issues, Bender et al [121] were of the view that the principles of transparency and user-centric options of Privacy by Design provide inadequate guidance on how to design privacy notices using these key principles.

In addition, some factors were identified to influence advertisements, such as advertisement targets, crafting of multiple advertisement campaigns with different wordings and themes, rotating and alternating advertisements, payment model, duration of the advertisement, and location of the advertisement on the social media platform. To favorably achieve the results of recruiting an increasing number of participants for research, researchers advertising on social media must strategically reach out to their participants. On the basis of the findings of this review, using an appealing image and simple and consistent language through both the text caption and image [69] influences and attracts participants to the study. Some social media platforms' advertising policies provide details on advertisement content, including the choice of words and counts and the duration of an advertisement on their platforms. The advertisement policies differ from platform to platform. Researchers must research any platform they wish to engage in, understand the policies, and adhere to them. In addition, working with REBs on social recruitment messages and strategies helps avoid ineffective strategies and enhance ethical conduct. Incorporating prescreening questions before allowing participants to enter details for study participation reduces the rate of ineligible participants and maximizes the reach and sample representativeness. Researchers can use these applications simultaneously because of the feasibility of incorporating social media platforms such as Instagram, Snapchat, and Facebook into a study without difficulty [47].

Implications

The findings from the review show the increasing accessibility and multifunctionality of social media platforms that could be leveraged to further support health science research. In fact, one of the benefits of social media for conducting research recruitment has been amplified during the COVID-19 pandemic because of the limitations to in-person recruitment, thus sustaining the continuity of research.

Generally, social media platforms provide avenues for a practical approach to reaching diverse, extensive, and targeted audiences [139] or populations, particularly those that are hard to reach. Further research may be needed to understand the barriers to and facilitators of older adults' engagement with social media platform recruitment.

Although different approaches to recruitment, advertisement, cost determination, and efficiency reporting can challenge novice researchers planning to use social media, there are ways of mitigating some of these challenges. For example, with the availability of funds and resources, researchers can benefit from hiring specialized companies or third-party service organizations to assist with the marketing and development of social media recruitment strategies and other innovative recruitment approaches targeting potential research participants. It is also recommended that these strategies be discussed and coordinated with the researcher's academic institution's REB to ensure no risks to participants.

The lack of explicit regulations by REBs to guide researchers continues to prevent the full exploration of social media platforms to support health science research. As such, stakeholders and collaborative efforts from research-based organizations, academia, researchers, think tanks, and student groups must partner to develop guidelines that reflect the use of social media in research studies. The different guidelines developed and published by researchers and academic institutions can provide a context for what is available. Therefore, based on our review, we propose a tentative description or guideline to guide researchers based on what we have synthesized from the literature included in this review (Multimedia Appendix 6). Ultimately, this guide could serve as a starting point to inform stakeholders in the development of a standardized protocol to guide health science researchers in the use of various social media platforms for research participant recruitment.

Finally, there are opportunities to advance health science education regarding social media use in general and its use for the recruitment of research participants. As students become technologically savvy, incorporating social media into their learning process will allow them to effectively engage with the platform. Schools can also provide guidelines on social media platforms on their websites to enhance learning about their applications in research processes. In addition, teaching students about best practices that support professional social media use and including social media applications as part of ethics training programs are also recommended.

Strengths and Limitations

The findings of this review offer a broad perspective on the use of social media platforms for participant recruitment by health researchers. A large number of studies were included for analysis in this review. The timelines for the included studies span >20 years and provide sufficient time to capture all studies published during the popularity of social media. This study comprehensively synthesized available literature from all health science disciplines. However, the review was limited to studies reported only in English.

Conclusions

The purpose of this integrative review was to explore the literature on recruiting participants for research studies through social media application tools and identify best practices to assist researchers in conducting research participant recruitment via social media tools. This integrative review expanded on the review by Reagan et al [15], which focused primarily on Facebook, by including other social media applications used by health researchers to recruit research participants, such as Facebook, Craigslist, Instagram, LinkedIn, Reddit, Tumblr, Twitter, and YouTube. Overall, the findings showed that social media is a suitable, viable, and cost-effective channel for recruiting research participants, despite some challenges associated with its use. Health researchers are increasingly embracing various social media platforms in their research to recruit participants from various age groups and diverse backgrounds; however, there is less use of social media to recruit older adults. Adhering to best practices when targeting various populations through social media advertisements is vitally important to protect participants' and researchers' rights and increase participation. REBs must proactively provide protocols and best practice guidelines that researchers can apply during the advertisement and recruitment of research participants.

Abstract

Background: The adoption and use of technology have significantly changed health care delivery. Patient experience has become a significant factor in the entire spectrum of patient-centered health care delivery. Digital health facilitates further improvement and empowerment of patient experiences. Therefore, the design of digital health is served by insights into the barriers to and facilitators of digital patient experience (PEx).

Objective: This study aimed to systematically review the influencing factors and design considerations of PEx in digital health from the literature and generate design guidelines for further improvement of PEx in digital health.

Methods: We performed an umbrella systematic review following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) methodology. We searched Scopus, PubMed, and Web of Science databases. Two rounds of small random sampling (20%) were independently reviewed by 2 reviewers who evaluated the eligibility of the articles against the selection criteria. Two-round interrater reliability was assessed using the Fleiss-Cohen coefficient ($k1=0.88$ and $k2=0.80$). Thematic analysis was applied to analyze the extracted data based on a small set of a priori categories.

Results: The search yielded 173 records, of which 45 (26%) were selected for data analysis. Findings and conclusions showed a great diversity; most studies presented a set of themes (19/45, 42%) or descriptive information only (16/45, 36%). The digital PEx–related influencing factors were classified into 9 categories: patient capability, patient opportunity, patient motivation, intervention technology, intervention functionality, intervention interaction design, organizational environment, physical environment, and social environment. These can have three types of impacts: positive, negative, or double edged. We captured 4 design constructs (personalization, information, navigation, and visualization) and 3 design methods (human-centered or user-centered design, co-design or participatory design, and inclusive design) as design considerations.

Conclusions: We propose the following definition for digital PEx: “Digital patient experience is the sum of all interactions affected by a patient’s behavioral determinants, framed by digital technologies, and shaped by organizational culture, that influence patient perceptions across the continuum of care channeling digital health.” In this study, we constructed a design and evaluation framework that contains 4 phases—define design, define evaluation, design ideation, and design evaluation—and 9 design guidelines to help digital health designers and developers address digital PEx throughout the entire design process. Finally, our review suggests 6 directions for future digital PEx–related research.

Introduction

Background

Recently, there has been a significant increase in the use of digital health technologies. In addition, many countries currently use digital health technologies to support health care service delivery to overcome the disruptions caused by the COVID-19 pandemic. These include web-based patient consultations and requesting pharmacy and medication refills [1]. Digital health offers care without the risk of exposure to the virus, especially for vulnerable patients such as older adults and patients with chronic diseases [2]. Before the COVID-19 pandemic, there was increasing recognition of the potential of digital health to improve the accessibility of health care in different clinical settings (eg, ambulatory care, acute care, and inpatient care) [3]. Digital health provides an opportunity to both reduce the costs of care and improve patient affordability [4,5], and previous research suggests that digital health has the potential to provide health prevention, consultation, treatment, and management [5-10]. With digital health solutions continuing to grow in both number and functionality, patient interest in digital health has rapidly increased, leading to an expanding reliance on digital health technologies [11].

As digital health has become a more familiar term, it has generated many definitions, and the concept has been expanded to encompass a much broader set of scientific concepts and technologies [12]. These include digital health applications, ecosystems and platforms [13], patient portals [14], mobile health apps [15], eHealth records, and appointment scheduling applications [16]. For the purposes of this study, we will use eHealth, mobile health, telemedicine, telehealth, virtual health, remote health, electronic consultations, and health information systems (HISs) as interchangeable terms for digital health.

Patient Experience in Digital Health

Digital health has the potential to improve patients' overall health care experience [17-19]. However, there is currently no common concept for describing patient experience (PEx) in digital health. Neither the general PEx nor user experience (UX) adequately reflects the experience of a patient using a digital service. For example, in a hospital setting, the environment's cleanliness, background noise, and even food provision could affect PEx [20]; however, these factors would not be expected to influence the experience of a patient using a digital service. Similarly, the fact that the system passes usability heuristics does not necessarily mean that the overall experience of a patient using digital health services is positive [21]. Therefore, it is vital to understand the experiences of individuals using digital health and how the design of new technologies can affect them [17,22,23].

The concept of (nondigital) PEx has many definitions in general health care practice and research. The Beryl Institute defines PEx as "the sum of all interactions, shaped by an organization's culture, that influence patient perceptions, across the continuum of care" [24]. Other definitions and studies note that the core elements of optimized PEx include access to appropriate care, patients' active participation in care, a good patient-physician relationship, reliable evidence-based care, comprehensible information, physical comfort, emotional support, involvement of family and friends, individualized approaches, responsiveness of services, and continuity of care [19,25-27]. These core elements of PEx help to recognize patients' priorities when receiving care and in providing patient-centered care. However, patients' priorities may differ for digital health, in which traditional face-to-face interaction is replaced by human to digital interface interaction. Therefore, to address patient priorities in digital health, it is essential to consider UX in the design of digital health [28]. In this study, we define UX as a person's perceptions and responses that result from the use or anticipated use of a product, system, or service [18,29]. Usable, useful, findable, accessible, credible, valuable, and desirable products are more likely to succeed in delivering a positive UX [30]. However, the full impact of digital health technologies on PEx or UX still remains unclear [31]; some products even result in negative effects such as increased patient anxiety [32]. Therefore, more insights into the barriers to and facilitators of individuals' experiences with digital health are required [33].

Objectives

The objectives of this paper were to systematically review (1) the factors that influence PEx in digital health and (2) the design considerations of PEx that are in digital health. The overall aim was to generate a design framework and guidelines for further improving PEx in digital health.

Methods

We performed an umbrella systematic review compiling evidence from multiple systematic reviews [34] on PEx and UX in digital health. This review was conducted according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) methodology, which is an evidence-based minimum set of items for reporting in systematic reviews and meta-analyses [35].

Digital PEx Working Definition

Throughout this study, we use the term digital PEx as a working definition to describe people's experiences in various digital health contexts. As the study progressed, the definition underwent several revisions, which resulted in a more inclusive final definition.

Search Strategy

We searched Scopus, PubMed, and Web of Science for studies published between January 1, 2000, and December 16, 2020. The search time window was limited to 2000 as the term digital health was first introduced by Frank [36] in 2000. To be inclusive, we used broad interchangeable search terms with varying combinations of digital health, PEx, and UX:

1. Category 1: "patient experience" OR "health experience" OR "user experience" OR "customer experience" OR "client experience"
2. Category 2: "ehealth" OR "e-health" OR "mhealth" OR "m-health" OR "telehealth" OR "tele-health" OR "digital health" OR "virtual health" OR "remote health" OR "telemedicine" OR "telemonitoring" OR "teleconsultation"

3. Category 3: “patient digital experience” OR “patient experience in digital health” OR “e-patient experience” OR “epatient experience” OR “online patient experience”

After combining categories 1, 2, and 3, limits were set to restrict studies to English-language literature reviews published in journals after 2000. The final search strategy was ([category 1 AND category 2] OR category 3) AND (DOCTYPE [review]) AND (PUBYEAR>2000) AND (LIMIT-TO [SRCTYPE, “journal”]) AND (LIMIT-TO [LANGUAGE, “English”]). Google Scholar was used as an additional database to manually search for additional related references based on the snowballing method during the review process.

Selection Criteria

Eligibility criteria were developed for title and abstract screening and refined for full-text screening. The following inclusion criteria were proposed by TW and GG and adjusted by MM and RG:

1. No duplicated articles
2. Full text available
3. English language
4. Only completed peer-reviewed journal articles
5. Only review articles
6. Related to digital health (ie, use of information and communication technology in health) and PEx, UX, or health care experience

Screening Process

The collected articles were included in the final analysis if they met all the inclusion criteria after a 2-stage screening process: first, a title and abstract review, followed by a full-text review. In the screening process, 2-round, small random samples (20%) were independently reviewed by 2 reviewers (TW and GG) who evaluated the eligibility of the articles against the selection criteria. The interrater reliability and clarity of the selection criteria were assessed using the Fleiss-Cohen coefficient until it reached the required strength (≥0.60). Uncertainties around paper inclusion and exclusion were resolved by discussions with the research team (TW, GG, MM, and RG) when necessary.

Data Extraction and Thematic Analysis

Articles meeting the eligibility criteria were imported into ATLAS.ti (Scientific Software Development GmbH; version 9.0.7; 1857) for data extraction. Data were extracted for the following aspects: (1) study characteristics, including authors, year of publication, research aims, review methods, target users, and digital health intervention (DHI) characteristics; (2) the overall impression of digital PEx (eg, the foci or types of findings regarding digital PEx); (3) influencing factors of digital PEx; and (4) design considerations for improving digital PEx.

We used the Braun and Clarke 6-phase thematic analysis method [37] to analyze the extracted data; these include (1) familiarization with the data, (2) generation of initial codes, (3) searching for themes among codes, (4) reviewing themes, (5) defining and naming themes, and (6) producing the final report (analytical themes). A total of 4 researchers participated in the review process. After data familiarization, a set of a priori categories was defined by TW and refined by all the coauthors (Table 1). The coding was based on the Performance of Routine Information System Management (PRISM) framework [38], which states that routine HIS performance is affected by the system’s inputs (ie, technical, behavioral [39], and organizational determinants) and progress. Please note that other elements of the framework (outputs, outcomes, and impact) are discussed in another study addressing the evaluation of digital PEx (work in progress).

Group discussions among the authors were used to reach an agreement on the produced a priori categories. TW quoted the relevant data across the included reviews, generated initial codes based on a priori categories, and then searched for themes among codes. Frequently used terms in the included reviews were used as inspiration to generate subsequent codes and themes. The latter process was independently and randomly validated by GG, MM, and RG.

Table 1. A priori categories of influencing factors of digital patient experience based on the Performance of Routine Information System Management framework [38].

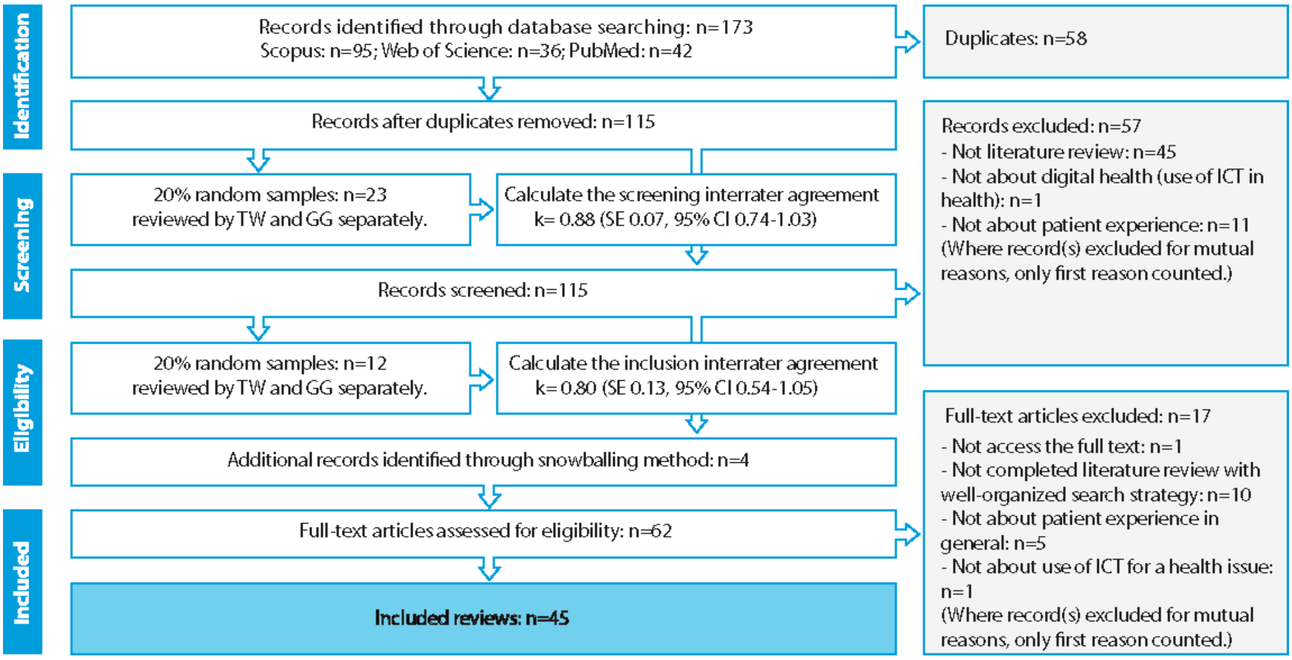
Determinants and a priori categories	Description
Behavioral determinants	
Patient capability	The individual’s psychological and physical capacity to engage in the concerned digital health activity
Patient opportunity	The individual’s internal conditions that enable or disrupt patients to engage in digital health
Patient motivation	The reflective and automatic brain processes that energize and direct patients’ goal setting and decision-making and their behaviors regarding using digital health
Technical determinants	
Intervention technology	The integration of telecommunications and computers, as well as necessary enterprise software, middleware, and storage and audiovisual software, which enables users to access, store, transmit, understand, and manipulate health information
Intervention functionality	The ability of digital health to work as expected to help users meet their health goals and needs
Intervention interaction design	The process of moving digital health from its existing state to a preferred state to optimize interactions between patients and digital health interventions
Organizational determinants	
Organizational environment	The management of the health service system, as affected by the rules, values, and practices of the involved people or community
Physical environment	The tangible surroundings (such as space, light, or sound) around patients, which affects their interactions with digital health
Social environment	The cultural environment (such as policy, business, or customs) that affect patients’ interactions with digital health

Results

Overview

Figure 1 shows the flow diagram of the systematic search. A total of 173 records were generated after the computer search; 58 (33.5%) duplicates were removed, and the titles and abstracts of 115 (66.5%) articles were reviewed. Subsequently, 53.9% (62/115) of full-text articles (including 4 additional records collected through snowballing) were reviewed for inclusion. Ultimately, 45 studies were included in the review for data extraction.

Figure 1. Study flow diagram. ICT: information and communications technology.



Study Characteristics

Embase, MEDLINE, PubMed, PsycINFO, CINAHL, and the Cochrane Library were the most common databases for the included reviews. Of these, 62% (28/45) were systematic review articles. The remainder included scoping reviews (6/45, 13%), literature reviews (3/45, 7%), integrative reviews (3/45, 7%), narrative reviews (2/45, 4%), comprehensive overviews (1/45, 2%), review of systematic reviews (1/45, 2%), and umbrella reviews (1/45, 2%). More than half of the included reviews (24/45, 53%) conducted quality assessments. The reviews included >1400 studies, which mainly or partially reported qualitative and quantitative analyses of PEx in digital health. The data analysis methods varied and included thematic analysis (8/45, 18%), meta-synthesis (5/45, 11%), meta-ethnography synthesis (2/45, 4%), taxonomy (1/45, 2%), hermeneutic synthesis (1/45, 2%), qualitative evidence synthesis (1/45, 2%), and state-of-the-art survey analysis (1/45, 2%).

Among the included reviews, some focused on specific populations, such as children (3/45, 7%), college students (1/45, 2%), younger people (1/45, 2%), adults (7/45, 16%), or older adults (4/45, 9%). Others either focused on the general population or did not mention the target population. The most common health issues across the included articles were chronic diseases (17/45, 38%), including chronic obstructive pulmonary disease, heart failure, cardiovascular disease, cancer, diabetes, and hypertension. Mental health problems (7/45, 16%), including depression, anxiety, psychological well-being, psychotic disorders, and schizophrenia, were the second most common health issues. The remainder either focused on other issues (8/45, 18%), including audiology, asthma, reproductive health, maternal health, newborn health, child health, adolescent health, surgery, postpartum, somatic diseases, or palliative care, or did not mention any specific health issues (14/45, 31%). Some papers (8/45, 18%) also provided multistakeholder perspectives, including health care professionals, providers, surgeons, clinicians, staff and organizations, implementers (such as health policy makers, clinicians, and researchers), and the participation of information technology.

The degree of detail provided about the interventions varied greatly across the studies. Phone-based apps, websites, handheld sensing devices, and ambient assisted living health care systems were common digital health deliveries. Interaction techniques included synchronous, asynchronous, and hybrid models. Diverse intervention platforms, systems, or functions were used to deliver various health care services, including supporting disease management (14/45, 31%); patient-to-physician communication or consultation (9/45, 20%); symptom monitoring (9/45, 20%); information transmission (4/45, 9%); health promotion activities (3/45, 7%); screening, diagnosis, or self-assessment (2/45, 4%); behavior changes (2/45, 4%); self-education (1/45, 2%); and decision-making (1/45, 2%). Multimedia Appendix 1 [28,40-83] provides detailed information regarding the characteristics of the included studies.

Overall Impression of Digital PEx

Our study revealed great diversity in the perspectives and definitions describing patients' experiences and characteristics when using digital health, presenting a variety of influencing factors and design considerations for digital PEx. The included studies showed different foci regarding digital PEx, including influencing factors (21/45, 47%) [28,40-59], digital health performance (19/45, 42%) [40-43,46,48,49,56,57,59-68], patient perceptions (9/45, 20%) [28,45,47,49,69-73], evaluation methods of digital health or digital PEx (8/45, 18%) [43,64,74-79], and design considerations (9/45, 20%) [48-50,53,54,59,80-82]. The findings and conclusions of the 45 reviews showed a great diversity. Most studies presented a set of themes (19/45, 42%) [28,44,45,48,49,51,54-57,59,62,69-73,76,79] or descriptions only (16/45, 36%) [40-42,46,47,58,60,61,63-67,74,75,83]. Other studies concluded with a theory-based description (5/45, 11%) [52,68,77,78,80], framework (4/45, 9%) [28,49,50,82], model (2/45, 4%) [53,69], method (2/45, 4%) [43,81], or checklist (1/45, 2%) [59]. Only a few studies transformed findings into design considerations (9/45, 20%) or visualized or structured their results into frameworks, models, checklists, or methods (9/45, 20%). Limited information was found on participant dropout reasons during the interventions [28,41,43,51,53,63,69,71]. The overall impression of the researchers on the DHIs was positive. In 51% (23/45) of reviews [41-44,48,49,52-54,57,59,61-63,65-69,72,73,77,80], the DHIs either showed promising results or at least results comparable with face-to-face health care services. Only 4% (2/45) of reviews [47,60] reported concrete evidence of the negative impact of current DHIs on digital PEx. In general, digital PEx was addressed because of the interactions between the DHIs and the patients involved and how the service was organized and carried out.

Influencing Factors of Digital PEx

An influencing factor is an aspect of the existing situation that influences other aspects of the situation, and it is formulated as an attribute of an element that is considered relevant and can be observed, measured, or assessed [84]. In this study, influencing factors refer to specific factors that lead to a positive or negative experience (digital PEx). Some factors have either positive or negative consistent and concrete impacts, whereas others have double-edged impacts; that is, impacts that are different per individual or change over time. Among the included papers, a common understanding of the potential influencing factors was captured from 3 aspects—behavioral, technical, and organizational determinants—following the categorization of the PRISM framework. These determinants were each classified into 3 categories, resulting in nine categories: patient capability, patient opportunity, patient motivation, intervention technology, intervention functionality, intervention interaction design, organizational environment, physical environment, and social environment. Multimedia Appendix 2 [28,40-83] presents an overview of the themes identified for each category, the influencing factors per theme (positive, negative, and double-edged), and references. Most factors appear to be related to technical determinants, followed by behavioral and organizational determinants. For *technical determinants*, we summarized 3 categories with 13 themes, containing 58 positive, 35 negative, and 13 double-edged factors. For example, DHIs with multiple behavioral change techniques appeared to be more effective [42,56,80] and reported higher patient satisfaction [54,57]. *Behavioral determinants* included 3 categories with 9 themes containing 11 positive, 21 negative, and 5 double-edged factors. For instance, some studies mentioned a lack of confidence in patients' own ability to use the technology [43,45,47,48,71,81], leading to a negative digital PEx. *Organizational determinants* were classified into 3 categories with 5 themes, including 13 positive and 23 negative factors. For example, unrealistic financial reimbursement and higher costs related to the internet or equipment were practical challenges of using digital health [47,48,51,55,56]. For the behavioral and organizational determinants, we collected more negative factors than positive factors. This is in contrast to the technical determinants, in which more positive factors were identified. Double-edged factors were less than both positive and negative factors for all the 3 determinants. Multimedia Appendix 3 [28,40-61,63-67,69-73,75-78,80-83] provides detailed information and examples.

Design Considerations of Digital PEx

Table 2 provides an overview of the identified themes for each design construct or method, related considerations, and references. To address the abovementioned influencing factors, several the included articles referred to *design constructs* (personalization, information, navigation, and visualization) [48,49,53,54,59,80] and *design methods* (ie, human-centered design [HCD] or user-centered design [UCD], co-design or participatory design, and inclusive design) [48-50,54,80-82], either as recommendations or implications for improving digital PEx from a design perspective. Notably, there was an overlap between design considerations and influencing factors. The former focuses on concluding possible design suggestions, recommendations, and implications proposed by the reviewed articles. The latter involves mapping the impacts of interaction design on digital PEx in different contexts; therefore, they refer to different themes and references. Generally, the *personalization construct* identifies patient profiles and tailors digital health according to patients' needs and preferences. The *information construct* addresses the source, language, presentation, content, and architecture of delivered health information. The *navigation construct* considers the interactive, delivered, and instructional elements of digital health to guide users to different areas of content within digital health. The *visualization construct* focuses on the aesthetics, attractiveness, visibility, and consistency of digital health appearance and interface. Furthermore, co-design and UCD or HCD were recommended as the most common methods for designing digital health, which involve multi-stakeholders and multi-disciplinaries in the design process to facilitate the designers' work, as designers need to understand end user needs and be aware of potential barriers to engaging in DHIs. Finally, *inclusive design* provides flexible design and is usable for a broader population. Notably, the design considerations identified in the included papers are not meant to be applied to every project; the implementation depends on the project's focus. Designers always need to balance project requirements (such as profits), user needs (such as privacy concerns), and policy regulations (such as data security). For example, peer-to-peer patient communication may not be appropriate for more sensitive health issues.

Table 2. Design considerations of digital patient experience.

Themes	Considerations	References
Design constructs		
Personalization		
Profiling	• Careful patient selection for digital health use • Assess specific metrics (eg, sociodemographic characteristics, basic health status, individual preferences, and habits) • Create an accurate patient profile	[53,59]
Tailoring	• Provide personalized information, tailored intervention content, and customized feedback (eg, predicted possible causes and consequences of a health problem and advice on the behavior under investigation) • Tailor the content to the user's needs and preferences • Tailor images, colors, text quantity, and font size and color to what users find appealing • Tailor multiple variables rather than a single variable • Align with end users' habitual routines	[49,54,59,80]
Autonomy	• Choose desirable and accessible forms of delivery • Choose when and how to receive reminders • Select or change personalized goals for future use throughout the time span of intervention • Select preferred styles (eg, color and font)	[59,80]
Information		
Content	• Provide comprehensive health information (eg, medical history, test results, and medication information) • Provide appropriate education and training on a health condition • Provide concise information (not overwhelm) • Provide evidence-based information from a credible source (eg, no advertisements and validated advice) • Appropriate encryption and digital health security (eg, password setting and privacy policy)	[48,53,54,59]
Communication	• Provide peer-to-peer communication through web-based forums and communities using instant messages • Access to professionals directly via email, SMS text message, or live chat • Share duties between health care staff	[53,54,59,80]
Functionality	• Rewards (eg, material incentives, intangible rewards, and messages of congratulations when a task is completed) • Reminders (eg, email messages, SMS text messages, words of the day, and pop-ups) for task completion • Reflective feedback, persuasive features, and gaming features (eg, knowledge quizzes and games) • Functional characteristics enable accurate and continuous self-management (eg, activity planning, activity tracking, self-monitoring, and diaries), person-centered care, and sustained behavior change • Appropriate dose of treatment	[48,49,53,54,59,80]
Navigation		
Forms of delivery	• Readily accessible and downloadable • Improve DHI[a] delivery (eg, change from a website to a mobile phone app) • Ability to print and email the information	[49,54]
User flows	• Minimum input (eg, voice commands) • Efficient access to information • Clarify what to do next • Provide search bar and menu bar • Tools and aids to help understand health information and complete health tasks	[48,59]

Themes	Considerations	References
Instruction and tutorials	• Guide users to a greater extent if the design is not self-explanatory • Provide more concrete, explicit, and context-sensitive instructions (eg, a virtual guided tour and extra internal links) • Adopt features from common (ie, familiarized) user interfaces (eg, the iPhone interface) • Provide appropriate education and training on digital health use	[54,80]
Visualization		
Message presentation	• Visualize continuous monitoring data (eg, present data as graphs and tables) • Provide a coherent presentation in terms of colors, pictures, and themes • Simple nontechnical language • Straightforward and concise text • Comprehensive descriptions of actionable message • Provide positive, nonauthoritarian, friendly, and nonjudgmental tone of voice • Multimedia messages (eg, text combined with relevant pictures or video) • Highlight information using various font styles, sizes, and colors	[59]
Interface aesthetic	• Show graphics (ie, visual aids) rather than (too much) text • Provide a pleasing color scheme (eg, bright colors) • Simple interface	[54,59,80]
Design methods		
Co-design and participatory design approaches		
Multistakeholder	• Involve end users and other stakeholders • Include the user at the beginning of the design process	[48,49,54]
Interdisciplinary	• An interdisciplinary approach to the development and implementation	[48,80,81]
User-centered design and human-centered design approaches		
Needs assessment	• Know the needs, capabilities, and environment of users through focus groups, surveys, interviews, and personas • Composing, preparing, and organizing content	[48,81,82]
Usability testing	• Gain early feedback from users through prototypes; benchmark testing, user testing, heuristic analysis, failure modes and effects analysis, and observations in other health care settings	[48,81,82]
Implementation	• Fit the technology to the person, not the person to the technology; pilot testing, task analysis, and reporting mechanism	[81,82]
Monitor and sustain	• Understanding work as imagined often differs from work as done; pre- and posttesting, contextual inquiry, and safety and hazard reporting	[82]
Inclusive design approaches		
Inclusive	• Provide a flexible design that is usable by people with no limitations, as well as by people with functional limitations related to disabilities or old age	[48,50]

[a] DHI: digital health intervention.

Design Implications

On the basis of our findings regarding influencing factors and design considerations for digital PEx, in this section, we define digital PEx and present design guidelines for the implementation of improving PEx in digital services.

Definition of Digital PEx

Our review reveals the absence of a commonly used concept for PEx in digital health. An increasing number of studies have been conducted on surveying PEx, satisfaction with, and expectations in varied digital health. With the growing academic interest in this topic and increasing efforts to address PEx in digital health design practice, a common concept with a concise definition will strengthen and align efforts overall. After reviewing the alignment of widely accepted concepts of PEx, UX, and DHIs with our generated influencing factors, we observed that many of our findings are included in the PEx definition offered by The Beryl Institute. Therefore, by including the sum of all interactions shaped by an organization’s culture, which influence patient perceptions across the continuum of care [33] along with the constructs of UX (people’s perceptions and responses [18,29]), DHIs (digital health technologies [13]), and the determinants (ie, technical, behavioral, and organizational determinants) identified in this review, we propose a concise, practical definition of digital PEx to guide the future design of digital health: "Digital patient experience is the sum of all interactions, affected by a patient's behavioral determinants, framed by digital technologies, and shaped by organizational culture, that influence patient perceptions across the continuum of care channeling digital health." Compared with the original definition of general PEx, this new definition underlines the digital part of health care delivery and includes 2 new determinants (technical and behavioral) that go beyond the organization's culture to clarify what can influence patient perceptions while traveling along a digital care pathway.

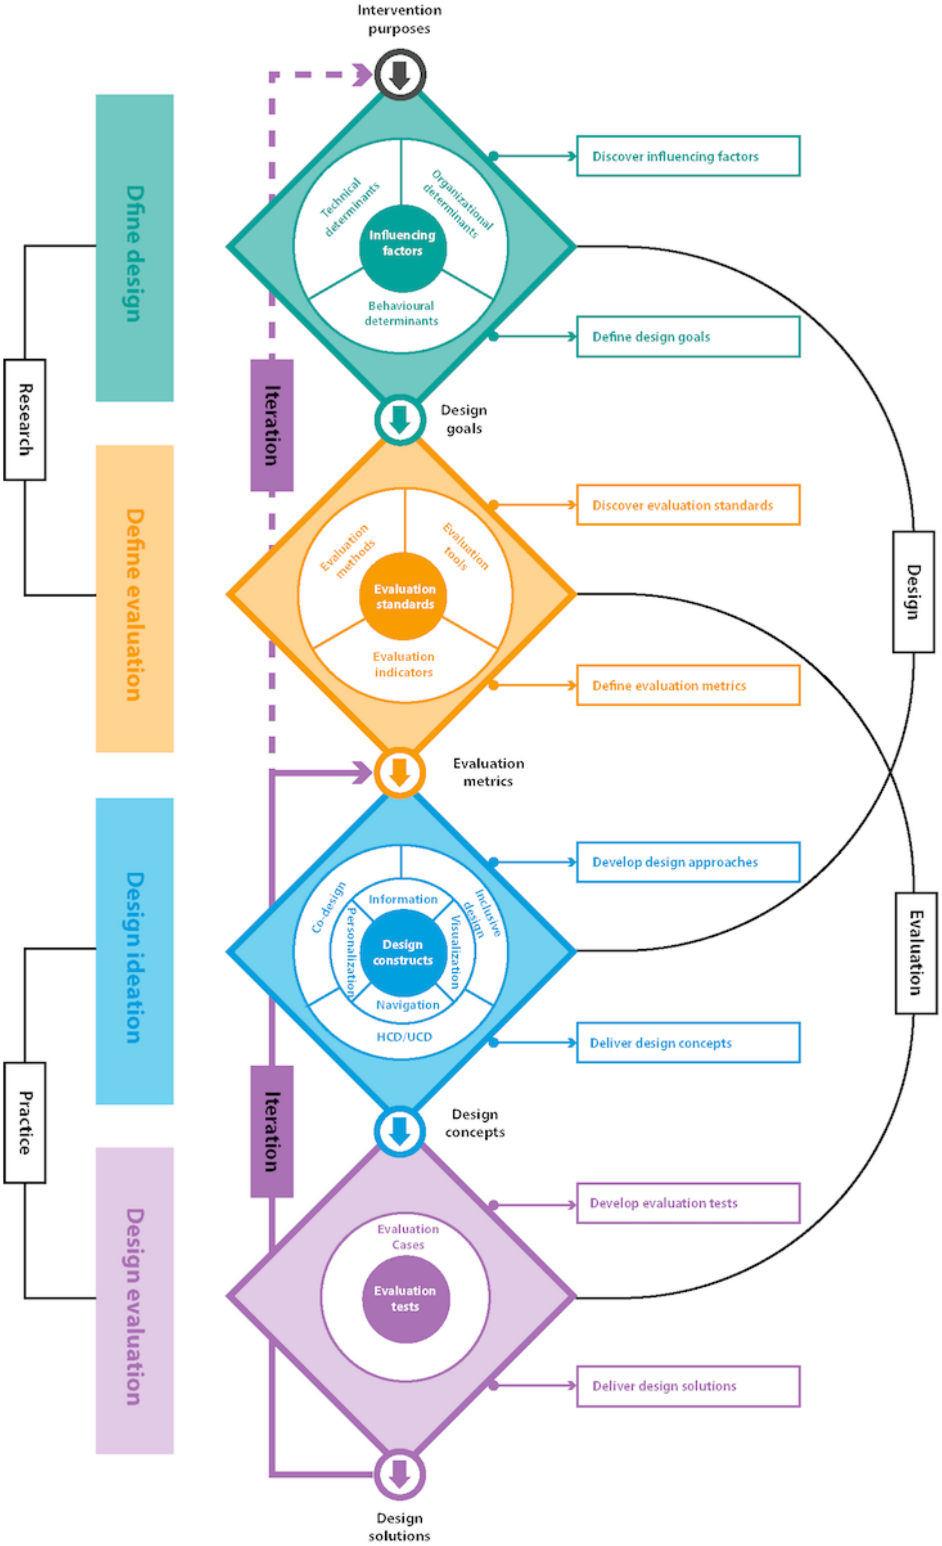
Design Guidelines for Improving Digital PEx

We developed a design and evaluation framework to help digital health designers or developers improve digital PEx in the design process (Figure 2). This framework was based on the findings of this umbrella review and was inspired by the double diamond model [85,86]. Our framework shows four phases: *define design, define evaluation, design ideation*, and *designevaluation*. The first and third phases focus on the design itself, and the second and fourth phases focus on design evaluation. In this study, we focus on explaining the first and third phases. In the first phase, designers must define the design goals by considering the factors that affect digital PEx. In this phase, we provided 3 determinants referring to 9 categories of influencing factors that have 3 types of impact on digital PEx (positive, negative, and double-edged) for designers to discover and explore. Designers can frame their design goals based on the intervention purposes and the selection of influencing factors. For example, if the purpose of the intervention is to improve patient eHealth literacy, designers need to pay more attention to patient capability and frame a design goal to develop suitable intervention functionality for improving patient capability. After defining the design goals, designers can move to the second phase, which is the *define evaluation* phase. In this phase, designers need to consider evaluation indicators (patient emotional, behavioral, and health outcomes) and evaluation methods (surveys and interviews) that are used to assess digital PEx. Detailed information regarding this phase will be discussed in a parallel study. Following this, we provide 4 design constructs (personalization, information, navigation, and visualization) and 3 design methods (ie, HCD or UCD, co-design, and inclusive design) for the design ideation phase. *Personalization* [41,54,56,57,59,69,81,87] refers to ascertaining user needs with design goals. It encompasses the design of intervention technology and functionality needs that meet the patients' ability, opportunity, and motivation to trigger behavior changes and promote health outcomes. *UCD/HCD* and *inclusive design* are valuable at this stage for the inclusion of patient perspectives. Driven by user needs and intervention goals, *information* includes content, communication, and functionality [54,59,81], and *navigation* comprises forms of delivery, user flows, instructions, and tutorials [54,59,80,81]. This relates to how relevant content presented in multimedia with a clear information architecture can attract patient attention and help them understand and complete tasks efficiently [88]. *Co-design* and *participatory design* are multidisciplinary collaborations that are necessary at these 2 stages. Finally, designers need to consider *visualization* [54,57,59,80,81], which determines the product look. The digital health interface can affect patients' first impressions when using DHIs. An attention-grabbing, simple, and consistent interface [59], layout (colors and images) [80], and message presentation [59] can all lead to positive UX. The design guidelines (Textbox 1) can be used at this stage to produce design concepts. In addition, this phase contains the digital health design workflow, challenges, and tips from a design practice perspective (which will be presented in an ongoing interview study). Finally, we ended up with this framework by introducing the design evaluation phase, in which designers need to develop tests (based on evaluation metrics) to evaluate design concepts. If the evaluation outcomes do not meet the evaluation standards, designers can return to the design ideation phase to adjust the design concepts or return to the first phase to reconsider the design goals.

Compared with the original double diamond model, our framework separates the evaluation part from the design part. This aligns with the design research methodology framework [84], which suggests generating success criteria after clarifying design research goals and before producing design support, formulating criteria for success is essential to be able to determine whether the results help achieve this aim. Therefore, we paid equal attention to design and evaluation. In addition, our framework provides detailed reference materials (such as 3 determinants) for each phase to provide designers with more practical support. Notably, in our framework, we retain some typical features of the double diamond model: the first 2 phases are research related, the last 2 phases are practice related, and each phase starts from divergence and ends at convergence.

On the basis of our findings on influencing factors and design considerations, we mapped the combinations of design constructs and design methods into 9 design guidelines to address different influencing factors (Textbox 1), which can be used to guide the design ideation process. Some of the design guidelines uncovered in this study have already been implemented, resulting in a positive digital PEx, such as the digital platform PatientsLikeMe, which aims to empower patients to navigate their health journeys together through peer support, personalized health insights, tailored digital health services, and patient-friendly clinical education [89]. One of the studies pointed out that patients can greatly benefit from using this platform as it improves patient health literacy, and its condition-specific customization may still further improve PEx [90], which aligns with our design guidelines on improving "patient capability" and providing "personalized information."

Figure 2. Digital patient experience design and evaluation framework. HCD: human-centered design; UCD: user-centered design.



Textbox 1. Design guidelines for improving digital patient experience.

Categories and design guidelines

- Patient capability
  - Identify patients' knowledge and skill levels by understanding their technology, language, and health literacy; consider their previous experience and current confidence level in using digital health; improve their actual literacy and correct their perceived inability; tailor design to their ability
- Patient opportunity
  - Profile patients' identity (eg, age, gender, economic status, and daily routines) and health status (eg, illness complexity, severity, and stability); consider patients' accessibility and affordance to digital health; tailor design to their individual opportunity
- Patient motivation
  - Recognize patients' mindset and perceived advantages and disadvantages; inform them of the potential benefits of using digital health; address their concerns and worries; understand their expectations and needs; tailor design to their preferences to trigger their motivation
- Intervention technology
  - Increase technical usability; ensure ease of use, ready to use, and timely feedback on digital health; select technical features (eg, data accessibility) and delivery media or devices (eg, device ownership) to meet patients' preferences and needs
- Intervention functionality
  - Strengthen theory-based interventions (eg, behavior change techniques and evidence-based interventions); improve intervention quality, considering privacy, security, and accuracy issues; provide regular and continuous social support combining both remote communication and real human contact; tailor health promotion and intervention structure to patients' needs and preferences
- Intervention interaction design
  - Provide personalized and consistent information, clear tutorials or technical support, and visualized data; allow patients to choose personalized interactive elements; follow human or user-centered design, co-design, and inclusive design methods; involve multi-stakeholders and multi-disciplines in the design process
- Organizational environment
  - Reduce equipment or service cost and time; improve health care providers' professional ability, communication skills, and service attitudes across the use of digital health; increase workflow transparency and clarify accountability; improve system integration and compatibility
- Physical environment
  - Provide a familiar, warm, and comfortable environment rather than cold and unfamiliar settings; reduce environmental distractions (eg, background noise or lighting)
- Social environment
  - Provide adequate support policies and legislation; develop plausible business cases

Discussion

Principal Findings

We systematically reviewed review articles on factors that influence digital PEx and considerations regarding how best to design digital PEx. The reviews varied greatly in type, including studies and data analysis methods, as well as in HIS, health issues, target patient groups, intervention content, and structure. Of the selected reviews, 62% (28/45) were systematic reviews, the rest were *other* types. These included qualitative, quantitative, and mixed methods studies. Thematic analysis and meta-analysis were the most common data analysis methods used in the reviews. We note that the studies described in the selected reviews were extremely heterogeneous, and information about interventions and digital PEx were often mixed and complex, making comparison difficult.

Our results are in line with the findings reported by previous authors [25,30,38] on the factors that affect PEx, UX, or the implementation of digital health. On the basis of the identified influencing factors and design considerations, we developed 9 design guidelines for improving digital PEx. Our findings reveal that among the selected reviews, only a few formulated design strategies or guidelines. This lack of design knowledge transformation makes it difficult for designers or developers to apply the findings directly. This aligns with the studies by Sakaguchi-Tang et al [48] and Søgaard Neilsen and Wilson [80]; the former indicated that the absence of specific design recommendations impairs the design of digital health, with the latter suggesting that there was a lack of understanding of the most beneficial design aspects for some specific digital health and how design principles can best be applied. Moreover, the use of UCD has been recommended in many studies to address

UX-relevant issues in digital health [3,80,91], which also supports our findings.

Digital PEx Versus General PEx and UX

We found a lack of a common term to describe PEx in digital health; UX (25/45, 56%) and PEx (17/45, 38%) were the most commonly used terms. Patient UX, patient perceptions, client experiences, patient empowerment, and user engagement were also used to describe similar concepts. Many reviews indicated that there was limited information about UX or PEx in varied digital health and underlined the need for a more holistic view of patient needs and priorities to better shape digital health design strategies and provide tailored digital health [28,40,42,45,60,74].

Influencing Factors Are More Complex Than Facilitators and Barriers

The information provided about digital PEx–influencing factors was complex and heterogeneous. Digital health is often treated as a whole, whereas digital PEx is affected by the additive effect of varying digital health factors. A single change in a factor may affect everything else. We found that without a concrete interaction context, factors could be regarded concurrently with facilitators or barriers. For example, regular contact with health care providers (HCPs) could be perceived to increase a sense of reassurance or perceived as a burden to patients' daily lives [28]; some patients experienced digital health as time consuming or an additional burden, whereas others experienced it as time saving or convenient [69]. Some influencing factors may have a soft or indirect influence on digital PEx [44,76]. For instance, users who are completely unaware of privacy or security risks may have excellent experience with digital health that fails to meet privacy or security requirements [76]. A lack of concrete solutions to address these barriers was mentioned [48]. It is likely that digital health cannot serve all populations equally well [71], which aligns with the results of a scoping review that investigated the inequities caused by the adoption of digital health technologies [92]. Some researchers indicated that older adults can also experience benefits by using digital health [53], whereas others suggested that telehealth is, at best, a partial solution for younger and fitter subpopulations [47,71]. Again, although some mentioned that patients preferred using personal devices [49,55,61,64], others noted the opposite [64].

Unclear Benefit From the Different Elements in Digital Health

It is likely that some patient groups benefit more than others from specific DHIs. For example, one of the reviews suggested that in telemedicine treatment for type 2 diabetes, behavioral change and continuous management were the keys to success [43]. However, it was unclear precisely which elements of digital health resulted in patients' satisfaction or dissatisfaction and how they could be addressed [83]. Moreover, we found limited data and even contradictory results on which factors affect digital PEx the most, which elements should be considered first when developing DHIs, and who benefits more from them. The latter is commonly mentioned [48,53,70], with some authors suggesting that patients with unstable chronic diseases might benefit the most [47,93]. However, another review indicated that even if patients are provided with the latest state-of-the-art technology at home, the intervention will not be beneficial if it remains unused [43]. Patients who are less activated are likely to have less positive experiences than those who are highly engaged [74].

Lack of Multiple Perspectives During the Design of Digital PEx

Clear communication between experts, designers, and patients regarding their understanding of digital PEx is required. Some reviews acknowledged the need for a multistakeholder perspective on digital PEx [55,69]. However, we found circumstances in which this was not possible. For example, in some cases, UCD for DHIs was conducted on nonpatient users either because of ethical reasons or relevant regulations [43], and in others, apps that are not specifically designed for patients with cancer were being used for this patient group [64]. HCPs are often isolated from the decision-making process to incorporate digital health into their current service provision [28]. Moreover, a lack of clinician perceptions of digital health use was also reported [40,54]. Furthermore, no studies focused on exploring designers' views, opinions, experiences, or values in addressing PEx or UX in the design of digital health. There was little information on whether experienced designers had worked with patients in their design process.

Over- or Underestimated Results

Some studies suggested that a lack of interest was the main reason for patients' refusal of digital health and that reasons for patient withdrawal were patients not wanting to use equipment, deteriorating health, and technical problems [94,95]. We need to gain better insights into the reasons for patients choosing not to engage in or withdraw from digital health, as these will significantly inform future DHI development and design [43,53,69]. However, it is likely that most studies only included patients who had already agreed to or were using digital health technologies; those who refused to use, withdrew from, or had no accessibility were excluded [28,51,63,69]. One of the reviews suggested that this would result in over- or underestimated results of DHIs' effects on digital PEx, as participants who completed the intervention may differ from those who did not [41]. Another review found that patients only reported positive themes associated with remote monitoring, which may indicate a selection bias [71].

Conflicts Between Benefits and Cost for Developing DHIs

The provision of digital health can reduce the treatment burden and better integrate care into patients' daily routines [69], which is consistent with our findings; we found that most reviews had a positive perspective of DHIs. However, in one of the reviews, it was suggested that although there was agreement among most professionals that health information technology can have a positive impact on PEx, when weighing the benefits against the potential cost, demonstrating this will be challenging [44,47]. Moreover, unnecessary high-frequency monitoring could result in a waste of health resources and an increased workload for HCPs [52]. Compared with existing health care services, the application of new technology needs to demonstrate clinical evidence of improved health conditions [43]. However, there were discordant findings in terms of the benefits of using DHIs. For example, there was no concrete evidence that telemedicine consultations were quicker than face-to-face consultations [40,57,68,83]. In another case, the impact of DHIs on health care use was not examined [57]. In conclusion, only user-friendly and quality-certified DHIs should be provided to patients [64]; health care organizations should not shift their focus from the basic and inexpensive strategies that affect patient care. Care is needed: new technology should not overwhelm the patient or ignore patient needs [44].

Limitations

First, when undertaking a review of review articles, some important details included in the original studies may have been lost, which increases the possibility of reporting bias. We also noted differences in the interpretation of terms and methods between the reviews. There is a lack of consistency in the terminology used to describe the functions of DHIs, HISs, or digital PEx itself. For example, in some cases, "eHealth" and "mHealth" were used as interchangeable terms [75], "persuasive technology" and "behavior change techniques" were presented as having a similar meaning [43], and "patient engagement" and "patient activation" were also regarded as being the same [74]. This inconsistent use of terms may impede knowledge translation and dissemination [57]. To counter this, we summarized the varied factors with unified descriptions to build a common understanding of the digital PEx–influencing factors.

Second, the intervention types and patient groups varied widely among the reviews, limiting meaningful comparisons between different studies. In addition, the digital health landscape is rapidly evolving, and the technology infrastructure is constantly shifting [41], as are the continuous updates of the UX design area. It is important to keep the influencing factors updated or adapted as the technology develops. Possibly, relevant original studies may have been excluded because of our focus on review papers. However, our approach to conducting an overarching review provides readers with a quick overview of the relevant digital PEx studies and a basis for further research.

Third, our umbrella review did not account for the multimodal relationships between subthemes or the potential overlap between subthemes within different domains. For example, different subthemes, such as "personalized design" in "interventions' interaction design" also interconnect with "interventions' technology" and "interventions' functionality." Moreover, our review process did not aim to address the question of whether some influencing factors are more important than others or how different aspects of DHIs influence them. This warrants further investigation as we suspect that differences may exist between the influencing factors, as some elements in digital health are more likely to increase or inhibit a positive digital PEx.

Finally, as we used qualitative thematic analysis to synthesize the findings and generate themes, the generated themes could have been influenced by the authors' previous research experiences and personal understanding. By asking other researchers to repeat the coding process, the resulting themes are likely to be different. However, to minimize the potential coding bias, the generation of categories was based on the PRISM framework; 4 researchers with different backgrounds, including design, medical, and human factors, were involved in the iterative coding process, group discussion, and independent and random validation, and existing theories were used.

Further Research

The goals of this umbrella review were to systematically review the influencing factors that affect digital PEx and the design considerations for improving digital PEx that are summarized in the existing literature. We must conclude that, currently, much remains unknown, and the topic of digital PEx is relatively new. We propose 6 directions that require further research. The first direction is to develop frameworks or models that translate digital PEx–related research findings into design practices or implications. For example, in this study, we used design guidelines and a design framework to summarize the findings. The second direction is to identify those who will benefit more from which elements in DHIs and which influencing factors could be addressed by combining design constructs and design methods. The third direction is to further examine how designers understand and address digital PEx in the digital health design process. To address this, we conducted a qualitative study on how designers address digital PEx in design practice. The fourth direction is to standardize evaluation indicators, methods, or tools for assessing digital PEx; we are currently evaluating digital PEx in a parallel study. The fifth direction is to quantify the balance between the benefits and costs of developing user-friendly and validated DHIs. The sixth direction is to identify participants' reasons for dropping out and their impact on the reported digital PEx–related results.

Conclusions

To the best of our knowledge, this is the first study to propose the term "digital patient experience" as a common phrase to describe PEx in digital health and define digital PEx by synthesizing the reported PEx or UX of varied DHIs from multiple reviews. Multimedia Appendix 4 shows more details about the structure of this study. In this review, information on influencing factors was identified and summarized into 9 categories (ie, patient capability, opportunity, motivation, intervention technology, functionality, interaction design, organizational, physical environment, and social environment). These categories were classified into positive, negative, and double-edged factors based on their positive, negative, and diverse impacts on digital PEx. Our review uncovered 4 design constructs (personalized, information, navigation, and visual design) and 3 common design methods (UCD or HCD, co-design, and inclusive design) as design considerations for addressing digital PEx. Finally, we proposed a design and evaluation framework and design guidelines to help digital health designers and developers address digital PEx throughout the entire design process.

Abstract

Background: Parkinson disease can impose substantial distress and costs on patients, their families and caregivers, and health care systems. To address these burdens for families and health care systems, there is a need to better support patient self-management. To achieve this, an overview of the current state of the literature on self-management is needed to identify what is being done, how well it is working, and what might be missing.

Objective: The aim of this scoping review was to provide an overview of the current body of research on self-management interventions for people with Parkinson disease and identify any knowledge gaps.

Methods: The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) and Population, Intervention, Comparator, Outcome, and Study type frameworks were used to structure the methodology of the review. Due to time and resource constraints, 1 reviewer systematically searched 4 databases (PubMed, Ovid, Scopus, and Web of Science) for the evaluations of self-management interventions for Parkinson disease published in English. The references were screened using the EndNote X9 citation management software, titles and abstracts were manually reviewed, and studies were selected for inclusion based on the eligibility criteria. Data were extracted into a pre-established form and synthesized in a descriptive analysis.

Results: There was variation among the studies on study design, sample size, intervention type, and outcomes measured. The randomized controlled trials had the strongest evidence of effectiveness: 5 out of 8 randomized controlled trials found a significant difference between groups favoring the intervention on their primary outcome, and the remaining 3 had significant effects on at least some of the secondary outcomes. The 2 interventions included in the review that targeted mental health outcomes both found significant changes over time, and the 3 algorithms evaluated performed well. The remaining studies examined patient perceptions, acceptability, and cost-effectiveness and found generally positive results.

Conclusions: This scoping review identified a wide variety of interventions designed to support various aspects of self-management for people with Parkinson disease. The studies all generally reported positive results, and although the strength of the evidence varied, it suggests that self-management interventions are promising for improving the care and outcomes of people with Parkinson disease. However, the research tended to focus on the motor aspects of Parkinson disease, with few nonmotor or holistic interventions, and there was a lack of evaluation of cost-effectiveness. This research will be important to providing self-management interventions that meet the varied and diverse needs of people with Parkinson disease and determining which interventions are worth promoting for widespread adoption.

Introduction

Background

Parkinson disease has a substantial impact on patients, their caregivers and families, and health care systems globally [1,2]. The United Kingdom's aging population is expected to nearly double the prevalence of Parkinson disease by 2065 [3]. The National Health Service (NHS) Long Term Plan has emphasized the need for supported self-management to improve patient outcomes and reduce the strain of an aging population on the health care system [4]. Self-management support interventions for chronic illnesses have been demonstrated to decrease health care use without negatively affecting patient health outcomes [5], but research is still needed on how they are used by and affect all users (including patients, caregivers, and health care professionals) [6]. The NHS has estimated that 25% to 40% of patients have low self-management knowledge, skills, and confidence (patient activation) [7]. A recent study focusing on people with Parkinson disease found that more than half of the patients rated themselves high on patient activation, whereas perceived self-management support was rated much lower [8].

Although Parkinson disease itself is not fatal, its complications and motor and nonmotor symptoms can have serious negative effects on the quality of life for both patients and care partners (CPs). The nonmotor symptoms of Parkinson disease are often undeclared in routine appointments [9] but can have severe negative effects on symptom burden and the quality of life [10,11]. For instance, it has been estimated that around half of the people with Parkinson disease have a mental health comorbidity [12]. Parkinson disease has a substantial impact on patients, their CPs and families, and health care systems [1,13,14]. Successful self-management is associated with improvements in chronic conditions and achieved by supported self-efficacy [15]. For all Parkinson disease symptoms, there are pharmacological and nonpharmacological approaches to management. Self-management interventions focus on the nonpharmacological approaches to symptoms by providing people with Parkinson disease and CPs with support to identify and monitor their symptoms and behavioral approaches to manage their symptoms [16,17].

Preliminary Literature Review

Previous systematic reviews have examined various aspects of support for people with Parkinson disease, particularly interventions that support a shift toward more home-based care, but none were identified that provided a comprehensive overview of self-management interventions. There are 2 recent systematic reviews that examined the use of digital technologies and wearables to monitor or support the care of people with Parkinson disease and provide a comprehensive and recent overview of the available technologies, what they are being used for, and how they are being evaluated [18,19]. A recent preprint review provided an overview of the trends in research in the use of mobile and wearable technology for Parkinson disease over the past decade and identified 4 main applications: assisting with diagnosis, monitoring and prognosis, predicting the outcomes of treatments, and therapy [20]. A scoping review conducted in 2018 summarized the literature about home-based rehabilitation interventions [21].

There were 2 reviews that focused specifically on self-management for people with Parkinson disease [22,23]. The first was a systematic review of the qualitative experience of self-management components by people with Parkinson disease and their carers [22]. This review identified 7 key aspects of self-management interventions for people with Parkinson disease: "(1) medication management, (2) physical exercise, (3) self-monitoring techniques, (4) psychological strategies, (5) maintaining independence, (6) encouraging social engagement, and (7) providing knowledge and information" [22]. However, it did not provide an overview or evaluation of the impact of the self-management interventions on health, behavioral, or other outcomes. The other review was an integrative literature review, which provided an overview of the characteristics of self-management support programs for people with Parkinson disease and their effectiveness [23]. It identified a wide variety of interventions, most of which were specific to Parkinson disease, but found limited evidence of their effectiveness. The review provided a good summary of the state of the field but was conducted in 2016 and did not examine the integration of digital technologies in self-management interventions.

Rationale

A search of the international prospective register of systematic reviews (PROSPERO) also did not find any relevant reviews on self-management and Parkinson disease in progress. A search for "parkinson AND (digital OR technolog*) AND (self-management OR home based care)" only retrieved 4 registrations: 1 focused on diabetes, and the others included a range of neurological conditions. A broader search for "parkinson AND self-management" identified 1 relevant registration—a systematic review and meta-analysis of self-management interventions in Parkinson disease. However, the registration is 2 years old (published on PROSPERO on April 15, 2019), has not been updated, and was not identified in a search for a published final article [24].

Given the rapid evolution of digital technology [25] and its growing role in health care [4], the state of the literature on self-management interventions has likely changed since the 2016 review was conducted, necessitating an updated overview that intentionally includes digital interventions, which are becoming a desired support for Parkinson disease care [26]. The variety of self-management aspects and applications identified in previous reviews indicates that an overview of the different types of self-management interventions and their potential impact is needed. The needs emphasized by the NHS Long Term Plan [4] for self-management and technology-enabled, personalized care demonstrate the potential for digital technology to help people with Parkinson disease and CPs improve their identification and management of Parkinson disease symptoms. Understanding the types of self-management interventions currently being developed and implemented will help inform the development of future, digitally enabled self-management interventions.

Objectives and Research Questions

The aim of this scoping review was to provide an overview of the current state of the field and the evidence of the effectiveness of self-management interventions for Parkinson disease and to identify any gaps. Specifically, the review asked, "What types of self-management interventions are available to support people with Parkinson disease, what outcomes do they target, and what evidence is there in the literature of their effectiveness?"

Methods

Search Strategy

The PRSIMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews; Multimedia Appendix 1 [27]) and Population, Intervention, Comparator, Outcome, and Studies (PICOS) frameworks were used to structure the review and develop the search strategy (see Table 1). Based on the PICOS, relevant Medical Subject Headings (MeSH) terms were identified from a preliminary search, and the search string was created using the following structure: Population (MeSH terms) AND Interventions (MeSH terms) AND Outcomes (MeSH terms). There was no limit on the publication date. The search was performed in 4 databases—PubMed, Ovid, Scopus, and Web of Science—using the University of Plymouth's search tool Primo. PubMed was chosen because it provides a good synthesis of biomedical literature, and the other search engines were selected because they capture a broad, multidisciplinary set of databases to ensure that no relevant literature was missed. Multimedia Appendix 2 provides a complete record of the specific search strings (modified slightly to fit the specific structure and requirements of each database) and the number of references retrieved. The database searches were performed on April 8, 2021.

Table 1. PICOS framework.

PICOS[a]	Detail	MeSH[b] terms used in search
Population	People with Parkinson disease and their carers	Parkinson Disease
Intervention	Self-management interventions for people with Parkinson disease	Self-Management OR Self-Care OR Home Nursing OR Delivery of Health Care, Integrated OR Telemedicine OR Mobile Applications OR Internet-based Interventions OR Internet of Things
Comparator	None or standard care	—[c]
Outcomes	• Primary outcome: self-management (with measures including, but not limited to, health outcomes, behaviors, perceived self-efficacy, quality of life, and use of health care services, etc) • Secondary outcomes: factors that could affect self-management (eg, demographics and disease factors, etc)	Self Efficacy OR Quality of Life OR Signs and Symptoms OR Health Behaviour OR Patient Admission OR Patient Readmission
Study types	Case-control studies, cohort studies, and RCTs[d]	—

[a] PICOS: Population, Intervention, Comparator, Outcome, Study type.

[b] MeSH: Medical Subject Headings.

[c] Not applicable.

[d] RCT: randomized controlled trial.

Inclusion Criteria

Studies were eligible for inclusion in the review if they evaluated a self-management intervention for people with Parkinson disease or their CPs. A broad definition of self-management interventions was used, so that an overview of the different types of intervention could be collected. Any intervention type (remote or in person) was eligible for inclusion if it aimed to help improve any elements of the patient self-management of Parkinson disease. Randomized controlled trials (RCTs), cohort studies, and case-control studies were eligible for inclusion. Studies published at any date were eligible for inclusion.

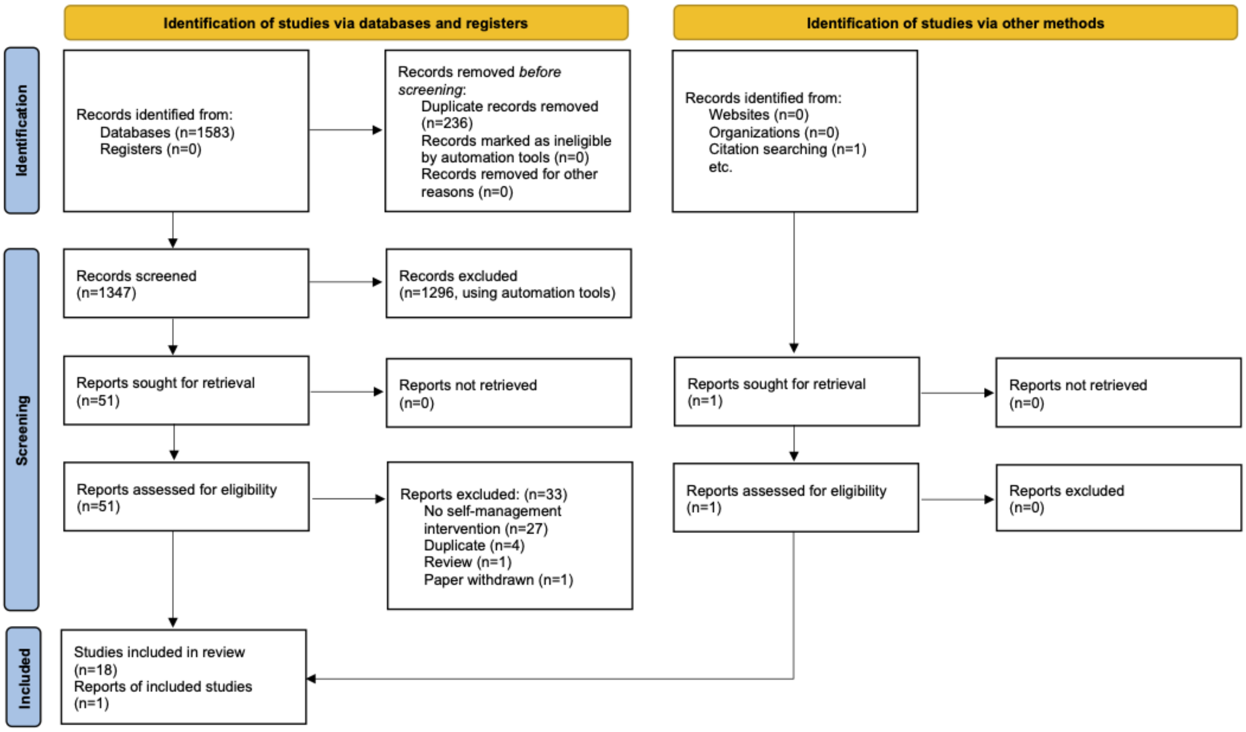
Exclusion Criteria

Studies were excluded if they did not include a self-management intervention for Parkinson disease or if they described an intervention without evaluating it. Protocols and reviews were also excluded. Studies that were published in languages other than English were also excluded, as the review team did not have the necessary resources to assess them.

Screening and Article Selection

The EndNote X9 citation management software (Clarivate) was used to store references, remove duplicates, and conduct the initial screening. The screening was done in several stages, using keywords based on the PICOS (see Multimedia Appendix 3). Next, 1 reviewer screened the remaining titles and abstracts (excluding articles with reasons) and conducted a full-text review to determine final eligibility (see Figure 1). The review team did not have the resources—in terms of time and budget—to have a second reviewer screen and extract data.

Figure 1. PRIMSA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.



Data Extraction

The full texts of the included studies were reviewed, and the data were extracted by 1 reviewer based on a predetermined form (see Textbox 1). Given the anticipated variety of study types and aims, the specific outcomes to extract were not prespecified but included as data to be extracted.

Textbox 1. Article information and data extraction.

General study information

- Title
- Year of publication
- Sample size
- Population
- Method

Intervention

- Type of self-management intervention
- Description of self-management intervention

Evaluation

- Primary outcome
- Secondary outcomes
- Summary of reported results
- Evidence of effectiveness at achieving stated outcomes

Data Analysis and Synthesis

A descriptive analysis was used to summarize the data extracted from the studies and provide an overview of the state of the literature on self-management interventions for Parkinson disease. The implications of the findings are examined in the discussion.

Results

Included Studies

The database search retrieved 1583 references (see Multimedia Appendix 2). The EndNote X9 software was used to remove 236 duplicates, and the keyword search tool was used to screen out 1296 references (see Multimedia Appendix 3). The titles and abstracts of 51 studies were screened by 1 reviewer, and articles were excluded with reasons. Of these 51 articles, 19 were selected for the full-text review. Subsequently, 1 study was identified as a duplicate upon full-text review [28], and 1 study was a secondary data analysis of an RCT, so the original RCT was identified and included [29], resulting in a final set of 19 included studies. The reasons for exclusion in the full-text review stage are detailed in Figure 1. The table with the extracted data is included as Multimedia Appendix 4.

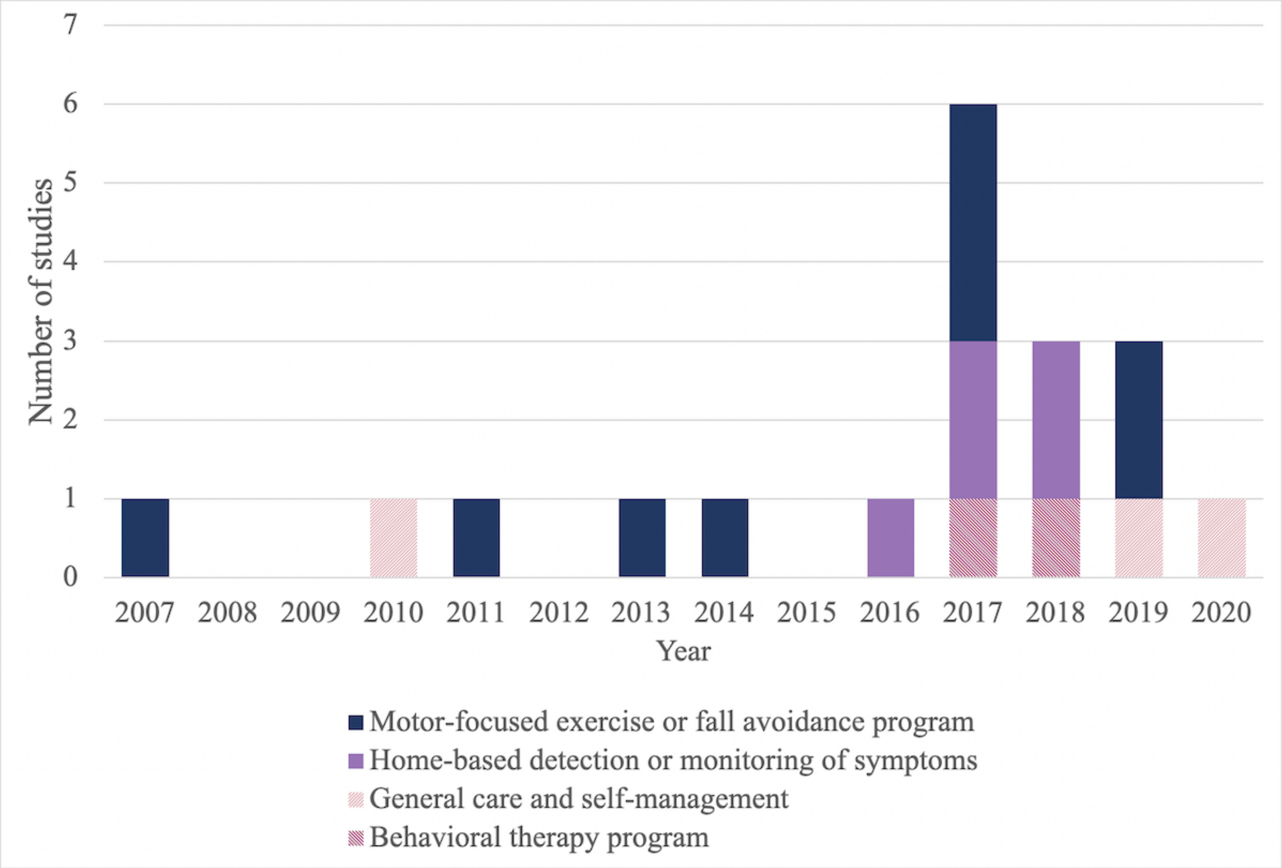
Study Characteristics

The largest proportion (8/19, 42% or 7/18, 39%, as 2 of the studies referred to the same trial) of the studies included in the review used an RCT methodology [29-36]. The remaining studies used a variety of study types, including 3 feasibility studies evaluating algorithms [37-39], 2 one-arm pre-post trials [40,41], 2 pilot studies [42,43], 2 mixed methods acceptability studies [44,45], a randomized case-control study [46], and a secondary data analysis of program adherence [47].

The studies also had a wide range of sample sizes, from 11 participants [42] to 474 participants [31]. All of the 8 studies with the largest sample sizes (greater than 100 participants) were RCTs [29-36].

The earliest study included in the review was published in 2007 [30] and the latest in 2020 [45], but two-thirds (13/19, 68%) of the studies were published in 2017 or later (see Figure 2).

Figure 2. Number of included studies by year and category of Parkinson disease self-management intervention. The intervention types included home-based detection or monitoring of symptoms [37-39,44,46], general care and self-management [29,35,45], behavioral therapy program [40,43], and motor-focused exercise or fall avoidance program [30-34,36,41,42,47]. Note that 2 of the papers included in general care and self-management relate to the same study [29,45].



Types of Interventions

A variety of different types of self-management intervention were described and evaluated by the included studies. The most common (9/19, 47%) type of intervention was home-based exercise or fall prevention programs [30-34,36,41,42,47]; within this category, two-thirds (6/9, 67%) were motor-related exercises or fall avoidance programs, and the remaining interventions were 1 that used sensor-based feedback [42], a community-based exercise program [32], and a handwriting program [33]. Several (5/19, 26%) interventions provided a means of home-based detection or monitoring of symptoms, which were also primarily focused on motor symptoms [37-39,44,46]. Of the remaining studies, 2 delivered behavioral therapy–type interventions to address mental health outcomes [40,43], 1 (addressed in 2 papers) delivered a nurse-led care management program [29,45], and 1 examined a rehabilitation program specifically focusing on self-management skills [35].

Evidence of Effectiveness

Summary

A variety of different outcome measures were used by the studies to evaluate the interventions, given their different aims and types. The strongest evidence of effectiveness came from the 8 RCTs [29-36]. In all, 5 of the 8 RCTs found significant evidence that the intervention was more effective than the control at achieving its respective primary outcome: a 2-minute walk [32], reducing fall rates [30], self-perceived performance of daily activities [34], motor score on the Movement Disorders Society–Unified Parkinson's Disease Rating Scale [36], and health-related quality of life [35]. The other 3 RCTs [29,31,33], a pre-post trial [41], and 1 of the pilot studies [42] found significant differences (between groups or over time) for some, but not all, of the outcomes measured.

Motor-Focused Program Outcomes

Several of the studies examined interventions that included sessions with physiotherapists or occupational therapists combined with independent practice aimed at preventing falls or improving physical activity function [30,31,34,41]. Of the 2 studies that focused specifically on fall prevention, 1 found a significantly reduced rate of falls in the intervention group compared to the control group [30]. The other study (PDSAFE personalized fall prevention program) did not find a significant difference in repeated falling between groups but did observe better balance, functional strength, and fall efficacy and reduced near-falls in the intervention group compared to the control group [31]. The remaining 2 studies focused on exercise; 1 found significant improvements in outcome expectations for exercise and time spent exercising and on the Unified Parkinson’s Disease Rating Scale and the Parkinson’s Disease Questionnaire-39 but not self-efficacy, outcome expectations for functional ability, depression, or timed chair rise scores [41], whereas the other found a significant difference on self-perceived performance in daily activity but not perceived capacity, daily activity performance, effect of fatigue, coping skills, mood, or quality of life measures [34].

There were 2 studies of motor-focused interventions that used digital technology to provide self-management support [36,42]. These studies found that a virtual reality home-trainer stationary cycle resulted in a significant difference between intervention and control groups on the Unified Parkinson’s Disease Rating Scale in favor of the intervention [36] and that a sensor-based auditory feedback device to improve stepping automaticity while dual-tasking had a significant difference for step automaticity but not for fear of falling, cognitive functioning, or self-reported gait freezing [42].

The remaining 2 studies of the motor-focused interventions delivered a community exercise intervention with aerobic and resistance training twice weekly, which found significant effects for 2-minute walk scores and the Unified Parkinson’s Disease Rating Scale over 12 months [32], and a control intervention focused on handwriting, which found some effect on self-reported difficulty [33].

Mental Health Outcomes

There were 2 studies that examined the impact of interventions on mental health outcomes related to Parkinson disease [40,43]. Both trials examined the effect of an intervention over time and found significant improvements with large effect sizes. One of the studies, which was pilot-testing a 10-week cognitive-behavioral telemedicine program (a self-help workbook combined with occasional telephone sessions), found a significant improvement in depression and anxiety over the 4-month study period [43]. The other study, which evaluated a 6-week telephone-based behavioral activation intervention, found a significant, medium-to-large effect size of the intervention on apathy (d=0.77), depression (d=0.70), and quality of life (d=0.50) [40].

Algorithm Evaluations

There were 2 studies that evaluated a classification algorithm by measuring area under the receiving operator curve (AUC) as their primary outcome. The AUC represents how well the model can differentiate between 2 conditions, with a general understanding that scores of 0.7-0.8 are acceptable, 0.8-0.9 are excellent, and 0.9 and higher are outstanding [48]. The first study found AUCs of 0.88 and 0.91 for the best models [37], and the other validated that the model performed similarly on data collected in clinic (AUC 0.83) as on data collected at home (AUC 0.76) [38]. A third study evaluating an algorithm reported that it compared favorably to similar systems and that it could replicate clinical decisions; however, the supervised machine learning process was based on the decisions of 1 neurologist, so the algorithm had learned to replicate those decisions [39]. The authors recognized this as a limitation of the study.

Patient Perceptions, Acceptability, and Usability

Of the 19 studies, 2 used mixed methods to examine the user perceptions of the interventions [44,45]. The first was a companion study to a multisite RCT of a nurse-led care management intervention for Parkinson disease [29]. The study found that after the intervention, people with Parkinson disease rated their medication self-management highly and found the nurse care managers to be helpful, although some usability issues with the program were reported by participants and nurse care managers. Likewise, the nurses found the program to be helpful, the Parkinson disease specialists found the nurse care manager’s role to be helpful, and both reported seeing improvements in the self-management of people with Parkinson disease [45].

The other study assessed the acceptability of a wrist-worn sensor [44]. Participants identified discomfort after long periods of use and problems with the strap; however, there was high compliance with wearing the sensor, and participants reported a preference for the sensor over symptom diaries [44].

Adherence

There was 1 article [47] that reported a secondary data analysis for 1 of the RCTs included in the review [30]. It examined the adherence of the 70 participants in the intervention group of the study to the home-based exercise program. Patients reported completing a high percentage (79%) of the recommended number of repetitions of their exercises. Adherence varied depending on participant characteristics; specifically, older age, worse physical condition, pain, anxiety, and depression were all associated with reduced adherence to the prescribed exercises [47].

Cost-effectiveness

Only 1 study focused on assessing cost-effectiveness [46]. Cubo et al [46] conducted a randomized, case-control study comparing home-based motor monitoring (using wireless motion sensors) with in-office monitoring. They reported that the home-based monitoring was cost-effective but found no significant differences between the groups for symptoms or quality of life [46].

Discussion

Summary of Findings

The studies included in the review varied widely in terms of the study and intervention types, the number of participants, and the outcomes assessed. Approximately two-thirds (13/19) of the studies included examined interventions that focused primarily on motor-related outcomes. Almost 40% (7/18) of the studies included were RCTs; these trials had the largest sample sizes (ranging from 105 to 474 participants) compared to the other study types (ranging from 11 to 82 participants).

The RCTs also had the strongest evidence of effectiveness for their interventions, with almost two-thirds (5/8) finding significant evidence of effectiveness for their primary outcome compared to the control group, and the remaining 3 studies finding significant evidence for some of their outcome variables. However, the non-RCT studies all had at least some evidence to support their intervention, including evidence of an effect of the intervention over time, good model fit, adherence, generally positive acceptability and user perceptions, or cost-effectiveness. However, several of these studies reported limitations in their design and emphasized the need for further investigations to address unanswered questions.

Limitations

A limitation of this scoping review is that only 1 researcher performed the article selection, data extraction, and data analysis. The PRISMA-ScR framework was used to guide the review [27] and ensure that the requirements for a scoping review were reported, but we could not prevent any potential bias due to the lack of validation from a second, independent reviewer.

Another potential source of selection bias is that no manual searches were conducted in the references of any of the included articles or reviews retrieved in the initial search. Due to time constraints, this search was not feasible but increases the possibility that relevant studies may not have been included in the review.

Meaning and Future Research

The volume of studies retrieved during the initial search and the variety of intervention types included in the review demonstrate the breadth of research on technological support and home-based care for Parkinson disease. The research into supporting self-management for people with Parkinson disease addressed several different aspects of management: home-based symptom monitoring that aimed to improve data collection and better inform health care professionals' care decisions; behavioral therapy that aimed to improve mental health; and independent, supervised, or community programs that aimed to increase mobility and strength, reduce the risk of falls, and improve the quality of life.

In addition to the variety of the research, this review identified some trends in the interventions being developed and evaluated to support self-management in people with Parkinson disease. The most prominent trend was the focus of the interventions on motor-related monitoring and care. This was an interesting observation, because the nonmotor symptoms of Parkinson disease can have a substantial impact on disease burden and the quality of life [49-52]. Only 2 of the reviewed interventions focused primarily on the mental health aspects of Parkinson disease [40,43]. Although some (6/17) of the other studies did include an assessment of at least one nonmotor symptom as a secondary outcome (most frequently depression) [29,31,34,36,41,46], there was a surprising lack of interventions that aimed to improve the self-management of nonmotor symptoms. Given the impact of nonmotor symptoms on people with Parkinson disease, this is an important gap that should be further investigated and addressed.

Another key area for future research would be the cost-effectiveness of self-management interventions. Only 1 of the included studies examined cost-effectiveness, which also identified a lack of the resources needed to conduct high-quality, cost-effectiveness evaluations (eg, the lack of a specific "cost-of-illness" questionnaire for people with Parkinson disease) [46]. This will be an important area to explore, as several of the interventions appeared to be resource-intensive, especially the interventions that involved home visits by therapists. Although there is likely to be an offset of costs if these interventions improve the quality of life, slow the deterioration of health, and reduce the need for expensive treatments, these interventions will need to be rigorously evaluated to demonstrate the potential benefit of their widespread adoption.

Conclusion

This scoping review aimed to examine and provide an overview of the state of the literature on self-management interventions for people with Parkinson disease. There is a large amount of research in this area, including several RCTs, that focus on a variety of types of self-management intervention. Most of the studies reported at least some evidence of effectiveness or positive effect of the intervention examined, with the best evidence of effectiveness coming from the RCTs. However, the majority of the studies reviewed focused on motor-related interventions and outcomes, with few interventions aimed at addressing the nonmotor aspects of Parkinson disease. There was also an apparent lack of consideration of the cost-effectiveness of the interventions. Further research will be needed to compare the potential health and economic benefits of implementing interventions to support self-management in people with Parkinson disease with the costs of delivering the interventions. Although some of the studies examined interventions that used digital technologies to monitor symptoms or provide feedback, many of the interventions had substantial in-person time commitments. Future investigations could compare the effectiveness of delivering interventions in person or through digital technologies to potentially improve the cost-effectiveness and availability of self-management support.

Acknowledgments

This research was supported by funding from Parkinson’s UK Non-Drug Approaches Award (grant H-2101) and the Centre for Health Technology at the University of Plymouth. The views expressed in the paper belong to the authors and do not necessarily reflect those of Parkinson’s UK or the University of Plymouth. The funding bodies were not involved in the study design, data collection or analysis, or the writing and decision to submit the article for publication.

Authors' Contributions

MMI and EM conceived the key research questions and scope. The scoping review was executed and drafted by MMI with revisions from CC and EM.

Conflicts of Interest

EM is the director of CM Digital Health Solutions Ltd (13570320). CC is the inventor of NMS Assist (a digital system to help people with Parkinson disease monitor and manage their nonmotor symptoms at home). CC receives salary from University Hospitals Plymouth National Health Service Trust and National Institute of Health and Care Research and has received advisory, consulting, or lecture fees from AbbVie, Bial, Scient, Orkyn, Abidetex, UCB, Pfizer, EverPharma, Lundbeck, Global Kinetics, Kyowa Kirin, Britannia, and Medscape and research funding from Parkinson’s UK, Edmond J Safra Foundation, National Institute of Health and Care Research, and Cure Parkinson's.

Abstract

Background: Motivational interviewing (MI) can increase health-promoting behaviors and decrease health-damaging behaviors. However, MI is often resource intensive, precluding its use with people with limited financial or time resources. Mobile health–based versions of MI interventions or technology-delivered adaptations of MI (TAMIs) might increase reach.

Objective: We aimed to understand the characteristics of existing TAMIs. We were particularly interested in the inclusion of people from marginalized sociodemographic groups, whether the TAMI addressed sociocontextual factors, and how behavioral and health outcomes were reported.

Methods: We employed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for scoping reviews to conduct our scoping review. We searched PubMed, CINAHL, and PsycInfo from January 1, 1996, to April 6, 2022, to identify studies that described interventions incorporating MI into a mobile or electronic health platform. For inclusion, the study was required to (1) describe methods/outcomes of an MI intervention, (2) feature an intervention delivered automatically via a mobile or electronic health platform, and (3) report a behavioral or health outcome. The exclusion criteria were (1) publication in a language other than English and (2) description of only in-person intervention delivery (ie, no TAMI). We charted results using Excel (Microsoft Corp).

Results: Thirty-four studies reported the use of TAMIs. Sample sizes ranged from 10 to 2069 participants aged 13 to 70 years. Most studies (n=27) directed interventions toward individuals engaging in behaviors that increased chronic disease risk. Most studies (n=22) oversampled individuals from marginalized sociodemographic groups, but few (n=3) were designed specifically with marginalized groups in mind. TAMIs used text messaging (n=8), web-based intervention (n=22), app + text messaging (n=1), and web-based intervention + text messaging (n=3) as delivery platforms. Of the 34 studies, 30 (88%) were randomized controlled trials reporting behavioral and health-related outcomes, 23 of which reported statistically significant improvements in targeted behaviors with TAMI use. TAMIs improved targeted health behaviors in the remaining 4 studies. Moreover, 11 (32%) studies assessed TAMI feasibility, acceptability, or satisfaction, and all rated TAMIs highly in this regard. Among 20 studies with a disproportionately high number of people from marginalized racial or ethnic groups compared with the general US population, 16 (80%) reported increased engagement in health behaviors or better health outcomes. However, no TAMIs included elements that addressed sociocontextual influences on behavior or health outcomes.

Conclusions: Our findings suggest that TAMIs may improve some health promotion and disease management behaviors. However, few TAMIs were designed specifically for people from marginalized sociodemographic groups, and none included elements to help address sociocontextual challenges. Research is needed to determine how TAMIs affect individual health outcomes and how to incorporate elements that address sociocontextual factors, and to identify the best practices for implementing TAMIs into clinical practice.

Introduction

Background

Chronic diseases, such as heart disease, cancer, and diabetes, are the leading causes of death in the United States, affecting 6 in 10 adults [1]. The risk of developing many chronic diseases and their corresponding complications, if diagnosed, can be reduced by avoiding the following 4 key health behaviors: tobacco use, poor nutrition, physical inactivity, and excessive alcohol use [1]. However, reducing these harmful behaviors can be exceptionally difficult. As a result, a multitude of interventions have been developed that attempt to facilitate health behavior change in these domains [2].

Using eHealth Technologies to Improve Health

The use of computing and internet technologies generally (eHealth), and smartphone and texting technologies specifically (mobile health [mHealth]), in health behavior change interventions has greatly increased over the past 3 decades [3]. These technologies can be effective tools for delivering health behavior interventions to diverse populations for a variety of behavior change goals. To illustrate, a systematic review of mobile apps and text messaging interventions demonstrated improvement across a variety of physical and mental health outcomes, including weight loss, smoking cessation, medication adherence, and depression and anxiety symptoms [4]. Similar findings were reported in a systematic review of text messaging health promotion interventions [5]. mHealth interventions may also be useful for facilitating self-management in patients with chronic diseases, such as improving medication adherence and control of chronic disease indicators like BMI, and activating and empowering patients [4-7].

mHealth technologies in particular have the potential to greatly improve health care access, improve delivery processes, and reduce chronic care costs [6], especially in areas that are medically underserved and underresourced, and in areas where internet access is limited to personal mobile phones [8]. mHealth technologies are widely accessible, popular across sociodemographic groups, and portable, and can facilitate timely interventions for patients [8,9]. These features are especially important for encouraging chronic disease prevention and management behaviors, which require timely and frequent reminders and interactions with patients that are impractical for health care practitioners to provide in office settings.

The accessibility of mHealth technologies may be especially important for people from sociodemographic groups that have been underserved, mistreated, or marginalized by biomedical research and practice (hereafter *marginalized*). For example, patients who live in rural areas face long travel and wait times, which may limit how often and for how long they can meet with their providers [10]. People from marginalized racial or ethnic groups face additional barriers, including medical distrust, which stems in large part from experiencing stigma, discrimination, and racism from health care systems and providers [11].

The effectiveness of eHealth and mHealth technologies for health promotion and management behaviors, combined with their availability and accessibility to the public, suggests that these platforms are effective tools for increasing the reach of interventions to greater numbers of individuals with sociocontextual challenges. However, the potential benefits of technology-delivered interventions may be offset by the fact that standard eHealth and mHealth technologies might not motivate patients in a way that fosters autonomy, which is critical to maintaining behavior change over time [12].

Motivational Interviewing and Its Use in eHealth Interventions

Motivational interviewing (MI) is a method of talking to people about changing their behavior [13]. The goal of MI is to increase intrinsic motivation and self-efficacy for engaging in health promoting behaviors using patient-centered yet directive communication techniques [14]. Specifically, MI counselors rely on reflexive listening, strategic questions, affirmations of character strengths, and statements emphasizing patients' decision-making autonomy to elicit "change talk" [15]. Change talk involves statements expressing patients' own desires, abilities, reasons, needs, and commitments to change their behavior while embodying "MI spirit," an empathetic, collaborative, and nonjudgmental demeanor. There is strong evidence supporting MI as a strategy to address barriers to effective health behavior counseling [16]. While health care professionals may attempt to persuade patients to adhere to recommended health behaviors, MI encourages personal decision-making about change and provides guidance and support about potential mechanisms of change [17,18]. During an MI session, a counselor uses the principles of the self-actualization theory and free choice to help individuals identify and work toward their goals[19,20]. MI can include health education and address sociocontextual factors that constrain an individual's choices. MI has been effective in promoting health behavior change for individuals with and without chronic diseases [21,22]. However, while MI offers many benefits to patients, its reach may be limited as employing trained counselors is expensive and training other health care providers may be time consuming and resource intensive.

Technology-delivered adaptations of MI (TAMIs) have been developed to combine the useful features of MI interventions (eg, promoting patient autonomy) with the benefits of mHealth interventions (eg, increase accessibility while limiting costs to patients and the health care system). Despite the complexity of developing TAMIs for intervention studies seeking to improve health behaviors, a 2016 systematic review reported that they are feasible to implement and well accepted by patients [23].

Objective and Research Questions

The objective of this research was to gain an understanding of the characteristics and outcomes of TAMIs that were not addressed in a previous review [23]. Specifically, we asked the following questions: (1) To what extent do TAMIs include individuals from marginalized sociodemographic groups? (2) How do TAMIs address sociocontextual influences on health (eg, the built environment and financial barriers)? (3) How do studies that report TAMIs describe their effects on behavioral and health outcomes?

This work is important for several reasons. First, the answers to the first 2 research questions (ie, including individuals from marginalized sociodemographic groups and addressing sociocontextual influences on health) have not been previously addressed, yet they are critical for expanding access of these potentially useful interventions to individuals and groups who have been socially marginalized or systematically and intentionally excluded from or underrepresented in biomedical research. Second, there have been many technological advancements made over the past 6 years that might shape the nature and effectiveness of TAMIs (eg, increased sophistication of tailoring interactions to participant responses) [24]. Although the previous review evaluated the effects of TAMIs on behavioral and psychological outcomes [23], examination of more modern interventions is informative considering rapidly emerging novel technologies.

We sought to map key concepts and knowledge gaps about TAMIs, including identifying the number of studies that include participants from underrepresented populations and the number of studies that address sociocontextual factors. Because these goals are more consistent with the goals of a scoping review than a systematic review [25], we conducted a scoping review.

Methods

We employed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for scoping reviews [26,27]. We did not preregister the review protocol.

JM and HP searched the PubMed, CINAHL, and PsycInfo databases for articles published from January 1, 1996, through April 6, 2022, that met the following inclusion criteria: (1) the publication described conducting an MI intervention, (2) the intervention was incorporated into an automated mobile or electronic health platform, and (3) the article reported behavioral or health outcomes.

The exclusion criteria were as follows: (1) the article was published in a language other than English and (2) the MI intervention was administered only in-person (ie, no mHealth or eHealth element).

We used the following search string to identify potentially eligible articles: ((“mHealth” OR (“m-Health”)) OR ((“text message”) OR (“text-message”) OR (“text messaging”) OR (“text-messaging”) OR (“ehealth”) OR (“e-health”) OR (“web-based”) OR (“electronic health”) OR (“technology-based”)) AND ((“motivational interviewing”) OR (“motivational interview”) OR (“intrinsic motivation”)) AND (“intervention”).

We reviewed the reference lists of identified articles and authors’ files for additional studies missed by the search criteria. HP reviewed abstracts and full-length articles. HP last searched the literature for articles to include in this review on April 6, 2022.

HP used Microsoft Excel (Microsoft Corp) to abstract the following data for each study: type of data collected (quantitative, qualitative, or mixed), study design, theoretical or conceptual model, study population, intervention target, eligibility criteria, intervention description, mHealth tool details, measures, sample size, sample characteristics, results, conclusions, and key limitations. Not all articles reported all data elements; we noted such instances as “NR” (not reported). The rows in the spreadsheet were individual articles, and the columns were individual data elements.

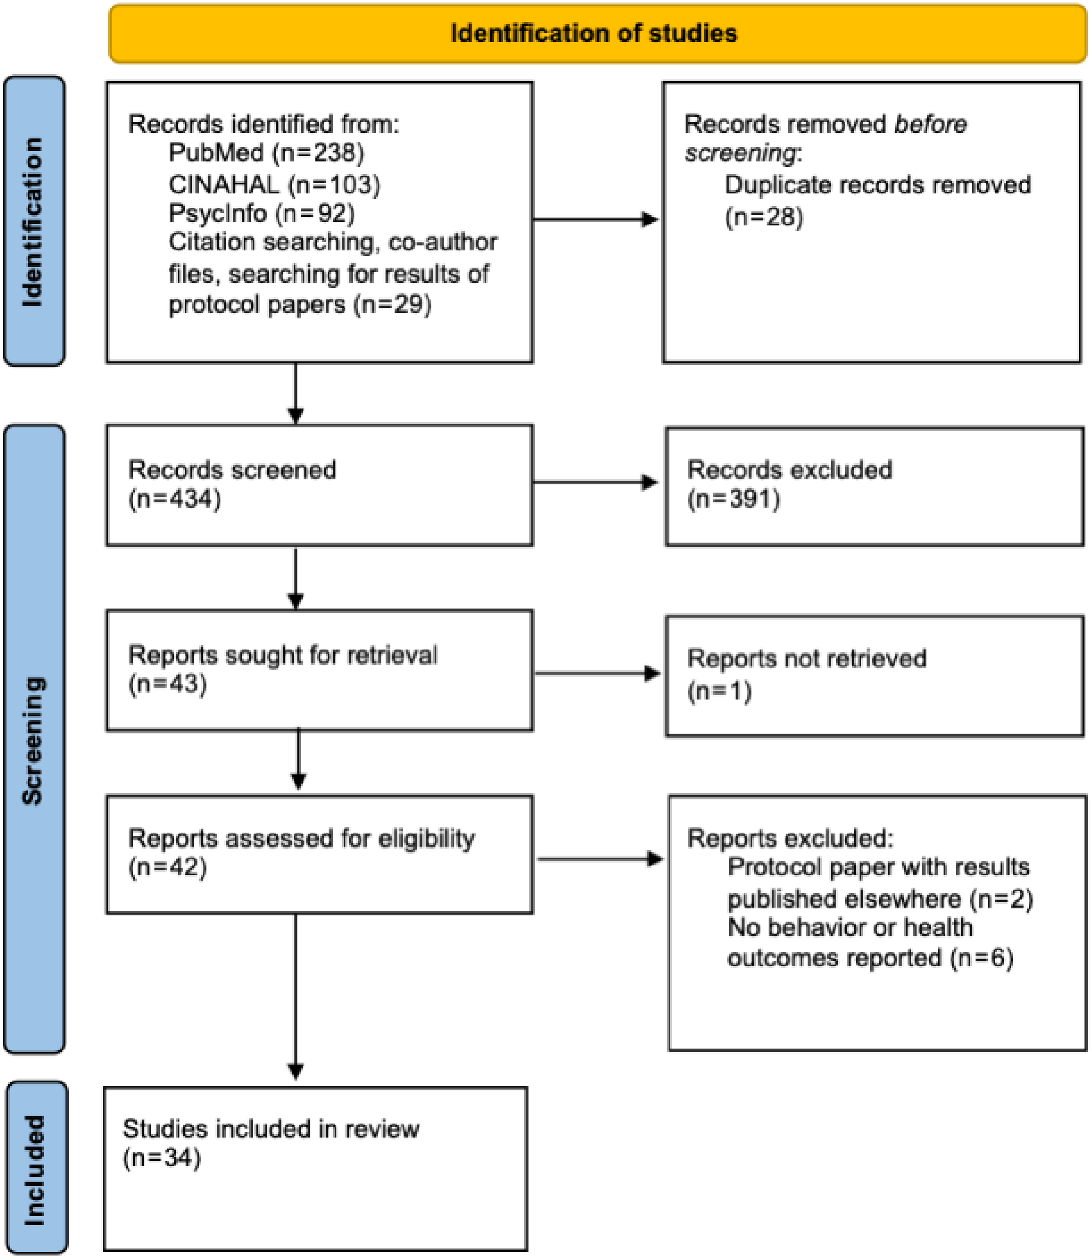
We have summarized the data using tables (Multimedia Appendix 1 and Multimedia Appendix 2) that are separated by the age category of participants (ie, younger than 18 years of age vs 18 years or older) and by the type of outcome (ie, behavioral vs health outcome). We have also described in the text the number and percentage of articles that had different methodological characteristics.

Results

Overview

We identified 34 studies reporting unique TAMIs (Figure 1). Most were conducted in the United States (n=22) [28-49]. Others were conducted in the Netherlands (n=4) [50-53], Switzerland (n=2) [54,55], Germany (n=1) [56], Korea (n=1) [57], Austria (n=1) [58], Canada (n=1) [59], and New Zealand (n=1) [60]. One study included participants from Germany, Sweden, Belgium, and the Czech Republic [61]. Detailed information about each study’s design, population, and outcomes is provided in Multimedia Appendix 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram [27] for the scoping review.



General Study Information

Conceptual Framework

Studies were based on a variety of conceptual frameworks. Of the 34 studies, 24 used only MI [28-32,34,35,37-39,41-44,46,47,49,51,53,54,56,59-61] and the remaining 10 used alternative frameworks in conjunction with MI [33,36,40,45,48,50,52,55,57,58] (Multimedia Appendix 1). The most commonly used conceptual framework other than MI was cognitive behavioral therapy (CBT; n=3) [45,50,55].

Study Design

The studies used a variety of designs. There were 30 randomized controlled trials (RCTs), 3 studies that used a nonrandomized pretest-posttest design with no control group [33,36,59], and 1 randomized experiment whose purpose was to refine the contents of the TAMI [58] (Multimedia Appendix 1). Control groups included active control (n=14) [29,31,34,35,37,39-41,43,45,47,53,54,57], treatment as usual (n=7) [28,30,42,44,48,49,60], wait list (n=5) [32,50,52,55,56], or no treatment (n=4) [38,46,51,61].

Study Population

The study populations among the selected studies varied widely (Multimedia Appendix 1). Studies ranged in size from 10 to 2069 participants (mean 341, median 136). Six studies included participants between 13 and 18 years of age. One study recruited from the general population [51], and 2 specifically recruited individuals with mental health diagnoses [31,32]. The 31 remaining studies focused on individuals who were engaging in behaviors that increased their risk of either developing new or exacerbating existing chronic health conditions.

Purpose

The purpose of the health behavior interventions fell into 2 broad categories (Multimedia Appendix 1). Twenty-seven interventions were designed to prevent disease among individuals in the general population or among those engaging in behaviors that put them at a higher risk of being diagnosed with a chronic disease [29-31,33,34,36,38-40,42-48,50-57,59-61]. The remaining 7 interventions were for encouraging chronic disease management [28,32,35,37,41,49,58].

Behaviors and Health Outcomes

Targeted health behaviors included the following: substance, alcohol, or tobacco use (n=24) [29-32,34,36,38-40,42-44,46-48,50,53-57,59-61]; diet or physical activity (n=2) [51,52]; treatment and medication adherence (n=4) [28,35,37,41]; mental health (n=1) [45]; and risky sexual behaviors (n=2) [33,47] (Multimedia Appendix 1). One study addressed both substance, alcohol, or tobacco use and risky sexual behaviors [47]. The most common chronic disease targeted for self-management interventions was diabetes (n=2) [28,35]. Targeted health outcomes included control of diabetes (n=2) [28,35], reduction of HIV viral load (n=1) [41], reduction in depressive symptoms (n=1) [45], reduction in BMI (n=1) [49], improvement in asthma symptoms (n=1) [37], and reduction in anorexia symptoms (n=1) [58].

Delivery

Most studies relied on text messaging or web-based tools to deliver their intervention (Multimedia Appendix 1). Eight used automated text messaging [28,33,38-40,46,49,60], 22 used a web-based intervention [30-32,34,35,41-44,47,48,50-59,61], 1 used an app combined with automated text messaging [36], and 3 used a web-based intervention and automated text messaging [29,37,45]. None used human-generated or chat bot–generated text messaging. Of the 25 studies that used a web-based intervention or a web-based intervention + text messaging, 8 used the Computerized Intervention Authorizing Software (CIAS; [62]) [29,30,34,35,37,41,42,47]. Studies with long-term engagement often used text message–based interventions.

CIAS is a mobile or web-based platform designed to create and launch behavioral health interventions, including those based on MI. CIAS includes an avatar that is capable of over 50 animated expressions and guides participants through questions, allowing the TAMI to more accurately mimic one-on-one conversations [29]. All 8 studies that used CIAS and 3 other studies included an avatar that interacted with participants and delivered the intervention [29,30,34,35,37,41-43,47,51,53]. In 1 study that included an avatar but did not use CIAS [51], participants could select either a male or female avatar whose appearance was designed based on focus group interviews asking the target population about how they believed a motivating and reliable avatar would look. The avatar communicated with speech movements and text displayed in balloons, and featured a limited number of nonverbal expressions. Although the avatar + intervention group did not show a significant improvement in the target outcome compared to the content-identical intervention without the avatar, the authors noted that the avatar had limited relational skills that may have precluded the development of a strong relationship with the user.

Inclusion of Individuals From Marginalized Populations

There was considerable variation in the extent to which studies included members of populations that have been marginalized (Multimedia Appendix 1). Among the 34 studies, 2 interventions were specifically designed for use by African American young people [35,37]. Moreover, 22 studies had samples that included an overrepresentation of people from marginalized sociodemographic groups in the general US population. Specifically, 14 studies recruited ≥22% African American participants [29,31,32,35,37-39,41-43,46-49], whereas African Americans represent 13.4% of the US population [63]. Five studies included ≥30% Hispanic/Latino participants [28,29,33,44,47], whereas 18.5% of the US population identifies as Hispanic/Latino [63]. One study reported that 50% of its participants identified with racial or ethnic groups other than white [34]. Three studies reported at least 67% of participants as having limited incomes [42,43,45], although TAMIs were not specifically designed for use by these populations. The remaining 14 studies had samples that either included fewer people from marginalized racial or ethnic groups than was representative in the US population or did not provide participants' racial and ethnic information.

Only 3 studies indicated an intent to develop content and interventions optimized for use by people from marginalized populations (Multimedia Appendix 1). Two studies described developing interventions with input from African American youth or adolescents [35,37]. However, neither of these studies commented on how the content of their interventions was adapted to fit the needs of African Americans. One study was designed to be culturally relevant, appropriate, accessible, and engaging (ie, for Māori people, New Zealand's indigenous population) [60].

Addressing Sociocontextual Influences on Health

No studies reported that their intervention was designed to accommodate challenging sociocontextual factors, such has having too little income to be able to afford products or services designed to improve health (eg, gym membership, fresh fruits, and vegetables).

Description of How TAMIs Affect Behavioral and Health Outcomes

Of the 34 studies, 30 were RCTs and reported outcomes, including alcohol consumption, tobacco use, hemoglobin A_{1c} levels, and human immunodeficiency virus viral load (see Multimedia Appendix 1 for a complete list). Of these 30 studies, 23 reported that the TAMI resulted in statistically significant improvements in the target behavioral and health outcomes [29,32,34,35,37-42,44-48,50,51,53,55-57,60,61] and the remaining 7 stated that the TAMI had no significant effect on behavior compared to the control group [28,30,31,43,49,52,54]. No RCTs reported that the TAMI resulted in worse outcomes compared to controls. The last 4 (out of 34) studies reporting behavioral and health outcomes used either a pretest-posttest design with no control group or a 1 group posttest only design [33,36,58,59]. All reported that the TAMI had a beneficial impact on promoting the desired health behavior. Eleven of the 34 studies examined feasibility, acceptability, or satisfaction, in addition to the behavioral or health outcomes [29,33,34,36,37,41,44,45,47,49,59]. All reported high participant ratings for these outcomes.

There were inconsistent reports about the value of adding CBT or other therapeutic components to an MI intervention. Some studies that reported combining MI and social determination theory (SDT) or MI and CBT did not achieve statistically significant increases in health behavior engagement compared to traditional web-based interventions [50,52,54]. One study reported that MI + CBT had a significant beneficial effect on alcohol consumption after 6 months [50]. Another study found that a web-based MI intervention with and without a trained psychologist coach was equally effective in decreasing the weekly standard units of alcohol at 6 weeks and 6 months compared to a wait-list control [56]. Two studies included in-person MI and reported a decrease in the number of drinking days in the TAMI group compared to the in-person MI and treatment as usual groups [44,48]. Finally, 1 study reported that adding an avatar to a web-based intervention did not significantly increase self-reported physical activity compared to the web-based intervention without an avatar [51], and the avatar did not create a stronger therapeutic relationship with participants.

Many studies noted that TAMIs could be useful in communities that have limited access to health care. Studies that focused on these communities or had many participants from these communities reported generally positive results, that is, the TAMI produced statistically significantly higher engagement in health promotion behaviors than the control treatment. Three studies designed specifically for underserved populations all reported that the TAMI intervention was more successful at promoting the desired target behavior than the control [35,37,60]. Specifically, 1 study noted that the intervention, which was designed specifically for the needs of Māori (New Zealand's indigenous population) and non-Māori Pacific audiences, was equally effective for both populations and across different age groups [60]. Of the 18 studies reporting behavioral or health outcomes in a large proportion of participants who were racial or ethnic minorities or had limited incomes, 15 showed increases in engagement in healthy behaviors or better health outcomes [29,32-35,37-39,41,42,44-47,60]. Studies designed specifically for underinvested communities reported more success in promoting behavior change compared to studies that were not designed specifically for underinvested communities.

Discussion

Principal Findings

This scoping review extends prior work [23] by examining the following: (1) to what extent have individuals from marginalized sociodemographic groups been included in research on TAMIs; (2) how TAMIs offset sociocontextual influences on health, such as challenges imposed by the built environment or economics; and (3) how TAMIs may affect behavioral and health outcomes. The 34 studies reviewed here suggest that TAMIs likely improve health promotion and disease management behaviors, and health outcomes. However, the diversity in study designs, populations, and target behavioral or health outcomes preclude a formal meta-analysis at this point in time. The impact of TAMIs on health may be stronger among marginalized sociodemographic groups, including people from racial and ethnic minority backgrounds and those with low incomes. Although TAMIs have generally led to improvements in health promotion behaviors compared to control conditions, to date, TAMIs have been developed for a limited scope of health behaviors, the inclusion of individuals from marginalized sociodemographic groups has been minimal, and their impact on sociocontextual factors is not well understood.

Twenty-three studies reviewed reported that TAMIs were associated with statistically significant improvements in health promotion and disease management behaviors. However, 10 studies combined MI with other therapeutic approaches, like CBT, or intervention elements, such as counselor-mediated chat, that prevented an assessment of the unique impact of the TAMI. It is important to understand how these various therapeutic frameworks affected the results to identify what is necessary for a successful eHealth intervention. An experiment using the multiphase optimization strategy (MOST) design would allow investigators to parse which combination of several intervention components yields the greatest benefit for patients [64].

With the advent of more sophisticated technologies, such as machine learning and artificial intelligence, there have been many technological advancements in recent years, including the development of avatars capable of more personalized interactions and greater relational skills [24]. In fact, study participants who interact with a human-like virtual character may feel stronger social relations compared to interacting only with a plain text-based interface [65]. Yet, no study has specifically examined whether avatars improve an intervention's target health behavior, despite calls [51] for future research to examine the effects of an avatar with more complex relational features. Such research may have implications for future uses of virtual reality, automated counseling or counselors, and other technological advancements for behavioral counseling, and offer a unique perspective on the importance of replicating human conversation in mHealth counseling technologies [66].

Scope of Health Behaviors and Outcomes Addressed by TAMIs

A majority of studies focused on substance, alcohol, or tobacco use (n=24), with the next most common behavioral targets being treatment or medication adherence (n=5) and diet or physical activity (n=2). This is consistent with the key health behaviors identified by the Centers for Disease Control and Prevention as being critical to promoting health and preventing chronic diseases [1]. However, there is potential to increase the scope of TAMI interventions. Health screenings can be critically important for detecting early disease in healthy populations and for preventing disease progression in populations with chronic health conditions [1,67]. For example, some studies screened for health metrics, such as BMI and hemoglobin A_{1c}, which are very important for preventive screening [28,49]. In addition, health screenings are particularly important for high-risk populations, such as the nearly 17 million cancer survivors living in the United States [68], many of whom are vulnerable to experiencing the late effects of toxic treatments [69] but who may not be aware of the need to be screened. TAMIs that promote screening behaviors, particularly among cancer survivors, should be designed and tested. Such interventions may be particularly impactful for survivors of childhood cancers, who experience significant premature morbidity and mortality [70].

Inclusion of Individuals From Populations That Have Been Marginalized

Few of the studies reviewed were intentionally designed for marginalized sociodemographic groups. Although 59% (20/34) of the studies reviewed included an overrepresentation of individuals from marginalized groups, only 2 studies [37,60] explicitly stated that they received input from the marginalized communities for which the intervention was designed (ie, African American [37], and Māori and non-Māori Pacific individuals [60]). Only 2 studies included over 67% of individuals with low incomes [43,45]. However, no study addressed other factors, such as socioeconomic status, age, and sexual or gender identity. This is important because many of the studies reviewed suggested that TAMIs have the potential to be particularly beneficial for marginalized communities. For example, a study involving an MI intervention that was culturally tailored for Hispanic/Latino participants reported that “nearly all participants (95%) said that understanding their culture was important to understanding their drinking behavior” [71]. This suggests that TAMIs that consider the unique interests and needs of marginalized populations may have a more beneficial and sustainable impact than standard MI [20]. In addition, MI may be highly efficacious in minority populations due to its autonomy supportive approach rather than the authoritarian approach, which can trigger feelings of stigmatization and marginalization, that is commonly found in behavior change interventions [72,73]. However, research is needed to confirm this hypothesis. It also suggests that further studies that are more inclusive of marginalized participants are needed, so that the benefits of MI for groups that are at the greatest risk of experiencing health disparities can be better evaluated and, if appropriate, translated into practice and policy change.

Address Strategies for Overcoming Sociocontextual Barriers

In the studies we identified, there was scant attention to sociocontextual factors that shape and constrain people’s ability to engage in health promotion behaviors outside of race and ethnicity. This dearth of research is concerning, because it represents a missed opportunity to understand the role of TAMIs in overcoming powerful barriers to health behavior change [74]. For example, a TAMI focused on improving dietary behavior among people with low incomes might be more effective if information and other resources are provided to enable people living in food deserts to access fresh fruits and vegetables more easily. Similarly, a TAMI might offer information about strategies for exercising safely to people who indicate that they live in a neighborhood that is not conducive to outdoor exercise and cannot afford a gym membership.

Comparison With Prior Work

A previous systematic review of TAMIs did not examine health outcomes or the potential relevance of TAMIs to people from marginalized or underserved sociodemographic groups [23]. Our research extends that work by evaluating these important characteristics. In addition, our findings indicating that TAMIs may be effective for improving health behaviors are consistent with the findings of previous reports [23].

Limitations

This review should be considered in light of the following limitations. First, our analysis may have been limited by publication bias. While we found that a majority of studies reported positive results, those with negative results might remain disproportionately unpublished. The identified studies were also quite heterogeneous in populations, interventions, and outcomes assessed, restricting the conclusions that can be drawn when considering the results in aggregate. In addition, similar to a 2016 systematic review [23], only 1 study included a counselor-mediated MI group, so we are unable to report the efficacy of TAMIs compared to traditional MI interventions [23]. However, reports that TAMIs produce more beneficial changes in health promotion and disease management behaviors compared to no treatment or treatment as usual are critical, because traditional MI interventions are very costly and difficult to disseminate widely.

Conclusions

MI has been largely successful in influencing positive behavioral change. Given the rapid increase in technological advancements in recent decades, TAMIs offer a low-cost and accessible platform to help patients improve their health. The results of this scoping review suggest that TAMIs are likely an effective way to promote positive behavioral change for the prevention and management of chronic diseases. TAMIs may hold particular promise for improving the health of marginalized communities, but few studies have described tailoring TAMIs in a culturally relevant, appropriate, or meaningful manner. In addition, no studies we reviewed addressed major sociocontextual factors that shape and constrain people’s ability to initiate and maintain changes in health behaviors. Studies that are more inclusive of communities that have been marginalized or underserved and that adequately address the sociocontextual factors shaping health could help reduce health disparities.

Abstract

Background: Prevalence of diabetes has steadily increased over the last few decades with 1.5 million deaths reported in 2012 alone. Traditionally, analyzing patients with diabetes has remained a largely invasive approach. Wearable devices (WDs) make use of sensors historically reserved for hospital settings. WDs coupled with artificial intelligence (AI) algorithms show promise to help understand and conclude meaningful information from the gathered data and provide advanced and clinically meaningful analytics.

Objective: This review aimed to provide an overview of AI-driven WD features for diabetes and their use in monitoring diabetes-related parameters.

Methods: We searched 7 of the most popular bibliographic databases using 3 groups of search terms related to diabetes, WDs, and AI. A 2-stage process was followed for study selection: reading abstracts and titles followed by full-text screening. Two reviewers independently performed study selection and data extraction, and disagreements were resolved by consensus. A narrative approach was used to synthesize the data.

Results: From an initial 3872 studies, we report the features from 37 studies post filtering according to our predefined inclusion criteria. Most of the studies targeted type 1 diabetes, type 2 diabetes, or both (21/37, 57%). Many studies (15/37, 41%) reported blood glucose as their main measurement. More than half of the studies (21/37, 57%) had the aim of estimation and prediction of glucose or glucose level monitoring. Over half of the reviewed studies looked at wrist-worn devices. Only 41% of the study devices were commercially available. We observed the use of multiple sensors with photoplethysmography sensors being most prevalent in 32% (12/37) of studies. Studies reported and compared >1 machine learning (ML) model with high levels of accuracy. Support vector machine was the most reported (13/37, 35%), followed by random forest (12/37, 32%).

Conclusions: This review is the most extensive work, to date, summarizing WDs that use ML for people with diabetes, and provides research direction to those wanting to further contribute to this emerging field. Given the advancements in WD technologies replacing the need for invasive hospital setting devices, we see great advancement potential in this domain. Further work is needed to validate the ML approaches on clinical data from WDs and provide meaningful analytics that could serve as data gathering, monitoring, prediction, classification, and recommendation devices in the context of diabetes.

diabetes; artificial intelligence; wearable devices; machine learning; mobile phone

Introduction

Background

Diabetes, also known as diabetes mellitus, is a metabolic disease characterized by elevated blood glucose levels, which can ultimately result in many complications such as heart attack, stroke, kidney failure, leg amputation, vision loss, and nerve damage [1]. As the world embarks on a centennial anniversary since the development of insulin to manage glucose levels of people with diabetes, we have seen remarkable advances during these 100 years, with improved life expectancy and quality of life [2]. Noncommunicable diseases such as metabolic syndrome and diabetes continue to be among the leading causes of disability and mortality [3]. The number of cases and their prevalence have steadily increased over the last few decades. According to the World Health Organization, 1.5 million people died in 2012 alone because of diabetes, with an additional 2.1 million deaths caused by a higher than optimal blood glucose level, resulting in increased risks of cardiovascular and other diseases. A total of 463 million people, globally, were affected by type 2 diabetes (T2D) mellitus in 2019. Furthermore, it is predicted that 700 million individuals would develop diabetes by 2045 [4]. Although the World Health Organization acknowledges that there is no one fixed solution and that a coordinated multicomponent intervention is needed, it outlines technology as one of the key stakeholders in reducing the impact of diabetes in addition to input from governments, health care providers, people with diabetes, civil society, food producers and manufacturers, and suppliers of medicine [1].

Despite the advancements in blood glucose monitoring techniques, the mainstream detection technology remains largely invasive. The commonly used home electronic glucometers involve people with diabetes invasively self-pricking to draw blood from fingertips, opening them up to infections as well as stress and pain caused by the procedure that is often expected multiple times a day.

The availability and advancements of smart devices, such as smartphones, have made the monitoring of diabetes-related features more accessible. Many studies have examined this much welcomed technology [5,6]. These normally require the use of an external attachable sensor, and monitoring is then delivered via an app or a separate continuous glucose monitoring (CGM) device, which can still be semi-invasive and require a connection range via Bluetooth or Wi-Fi signals. The use of completely noninvasive technology in the form of wearable devices (WDs) for regulating and monitoring glucose levels for people with diabetes is a fairly new concept and is in its infancy. Commercially available devices, such as smart watches and smart bands, can take measurements using sensors that researchers have reported on their usefulness in diabetes monitoring [7,8]. Such technologies can be affordable and easily accessible, and when used properly, can improve the quality of life of patients in a noninvasive manner. With their widespread commercial use and acceptance owing to their fashionable nature, globally researchers have a unique opportunity to provide medical care away from hospital settings and bulky invasive hardware in an affordable manner without requiring expert assistance. WDs have an increasing capacity, although not at the level of smartphones, to gather, store, transmit, and process data; the features can then be used for management, treatment, assessment, and sometimes even prediction. Furthermore, many WDs are normally connected via Wi-Fi or Bluetooth to external devices, such as a smartphone, where computationally expensive processing is performed for the simple purpose of storage or as a gateway to cloud spaces. Cloud storage can facilitate monitoring by clinicians without the need of hospitalization. Several useful sensors already exist incorporated into WDs similar to those of smartphones, including electrocardiogram (ECG), photoplethysmography, galvanic skin response, near infrared, and accelerometer sensors. WDs have additional advantages when it comes to sensing physiological signs, such as heart rate, ECG, and skin temperature. This is largely owing to their close contact with the wearer, which is of particular interest when monitoring diabetes-related metrics.

Artificial intelligence (AI) is a broader term that encompasses machine learning (ML). Technically, ML is a subset of AI, often loosely used interchangeable buzzwords. As a high-level definition, AI is anything related to making machines smarter (eg, computational search algorithms). ML, on the other hand, is an AI system that can self-learn via an algorithm, and as a result, such a system becomes smarter without human intervention over time (eg, classifying an outcome) [9]. Deep learning, on the other hand, is another branch of AI that attempts to mimic the human brain in terms of how it processes large amounts of data and has already shown success rates in areas such as diabetic retinopathy screening [10]. ML principles have been applied in clinical settings to build algorithms to support predictive models for the risk of development of diabetes [11]. AI has also been shown to provide useful management tools to deal with large amounts of data [12]. Owing to the large amount of data measurable through continuous monitoring via wearables, AI can be used to further analyze the acquired data. This can help to understand and draw meaningful information from the gathered data and provide advanced and clinically meaningful analytics. Many researchers have adapted existing WDs not originally intended for diabetes management and adapted the sensory information for use in diabetes-related metrics, and some have created prototypes especially designed for diabetes [13,14]. WDs are used for a variety of reasons, including monitoring, prevention, glucose estimation, diagnostics, classification, and prevention, but the number of studies that are reported are low in comparison with those that make use of smartphones for example. With the increased potential outreach of WDs globally, especially when combined with the ever-expanding field of AI-incorporating ML algorithms, the correct management of large amounts of data and processing with ML algorithms holds great potential for quality-of-life improvement in people with diabetes [15].

Research Problem and Aim

Many studies have been conducted on AI-based WDs for diabetes. Exploring the features of AI-based WDs reported in these studies is important for developers, patients, health care providers, and researchers to identify the recent advances and challenges in this area. Although several reviews were conducted in this area, (1) they were focused on smartphones and AI for diabetes [16-18], (2) they were focused on WDs in general rather than AI-based WDs [17,19], and (3) they did not summarize the features of AI-based WDs in a thorough manner [16-19]. Therefore, we aimed to explore the features of AI-based WDs for diabetes as reported in previous studies. We believe that this review will allow developers and researchers to advance further in this field by highlighting the gaps and opportunities.

Methods

Overview

This scoping review was carried out to satisfy this study's goals of exploring features of AI-driven wearable technologies for diabetes. In order to construct a complete scoping review, the *PRISMA-ScR* (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [20] was used as a guiding approach. The PRISMA-ScR checklist is shown in Multimedia Appendix 1.

Search Strategy

Search Sources

The article search for this review began by identifying all relevant studies using 7 electronic databases: MEDLINE, PsycINFO, EMBASE, IEEE Xplore, ACM Digital Library, Web of Science, and Google Scholar. We scanned the first 100 hits retrieved by searching Google Scholar. The reason being Google Scholar typically returns several items that are sorted by relevance to the search topic. Bibliographic collection was conducted from October 25 to October 30, 2021. The reference lists of the included articles were then searched for additional sources. We also checked relevant articles that cited the included studies using Google Scholar's "cited by" tool (forward reference list checking).

Search Terms

A number of different sets of keywords were designed to search databases depending on each database's search term limit; as IEEE and Google Scholar have term limits, search queries were truncated based on the required limit. We considered the research topics included in the database to complete our search queries. We combined *Diabetic* OR *Diabetes* keywords describing the relevant population (people with diabetes), with each kind of relevant intervention to wearables (*wearable** OR *smart watch** OR *smart** OR *smartwatch** OR *fitness band* OR flexible band* OR wristband* OR smart insole* OR bracelet**) and AI (*Artificial Intelligence OR Machine Learning OR Deep Learning OR Decision tree OR K-Nearest Neighbor* OR Support vector machine* OR Recurrent neural network* OR convolutional neural network* OR Artificial neural network* OR Naïve Bayes OR Naive Bayes OR Fuzzy Logic OR K-Means OR Random Forest OR LSTM OR autoencoder OR boltzmann machine OR deep belief network*). For example, the following search terms were applied in Google Scholar: (*Artificial Intelligence OR Machine Learning OR Deep Learning OR convolutional neural network* OR Artificial neural network*) AND (wearable* OR smart watch* OR smart*) AND (Diabetic OR Diabetes)*. All the databases had search time period criteria that were enabled and set with the search query from 2015 to present; in addition, the language checkbox in each database was set to English only. Full search terms for each electronic database searched are available in Multimedia Appendix 2.

Studies were chosen based on the criteria in Textbox 1. Peer-reviewed articles and published protocols were included only if they were related to wearables that could be used by an individual outside of a clinical setting. They also had to use AI for the purpose of diabetes and be classified as noninvasive. For full inclusion and exclusion criteria refer to Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

1. Publications that are in the English language.
2. Peer-reviewed articles including proposals.
3. Population with or suspected to have diabetes. No restrictions regarding their age, gender, and ethnicity.
4. Commercial, medical, or prototypes but with condition wearable device and uses artificial intelligence (AI).
5. Wearable usable by individual person not with help of clinical staff or plugged in to hospital setting.
6. Wearables using methods for diabetes analysis are to be noninvasive.

Exclusion criteria

1. Any study that does not contain AI as an intervention.
2. People with other diseases, health care providers, and caregivers as population.
3. Not a wearable device (example artificial implant or body infused).
4. Studies opting statistical measures only, for analysis of collected data.
5. Sensors or tracking devices infused inside a person's body.
6. Wearable devices that need professional sittings or hospital sittings.

Study Selection

This review's studies were selected in 2 steps. In the first stage, 2 reviewers (AA and SA) independently reviewed the titles and abstracts of all retrieved papers. In the second phase, the same reviewers individually read the whole texts of the papers included in the first step. Rayyan (Qatar Computing Research Institute, Hamad Bin Khalifa University) [21], a web-based tool developed for data management for systematic and scoping reviews, was used to upload all the articles acquired from databases in a Research Information Systems format; then, filtering and citations were managed. During the first and second steps of the selection process, any disagreements between the 2 reviewers were resolved through conversation and decisions were made based on consensus.

Data Extraction

AA and SA constructed the data extraction form, as shown in Multimedia Appendix 3. The data extraction technique was carried out independently by 2 reviewers (AA and SA), and any discrepancies were resolved by discussion and consensus. Microsoft Excel was used to record the data extracted.

Data Synthesis

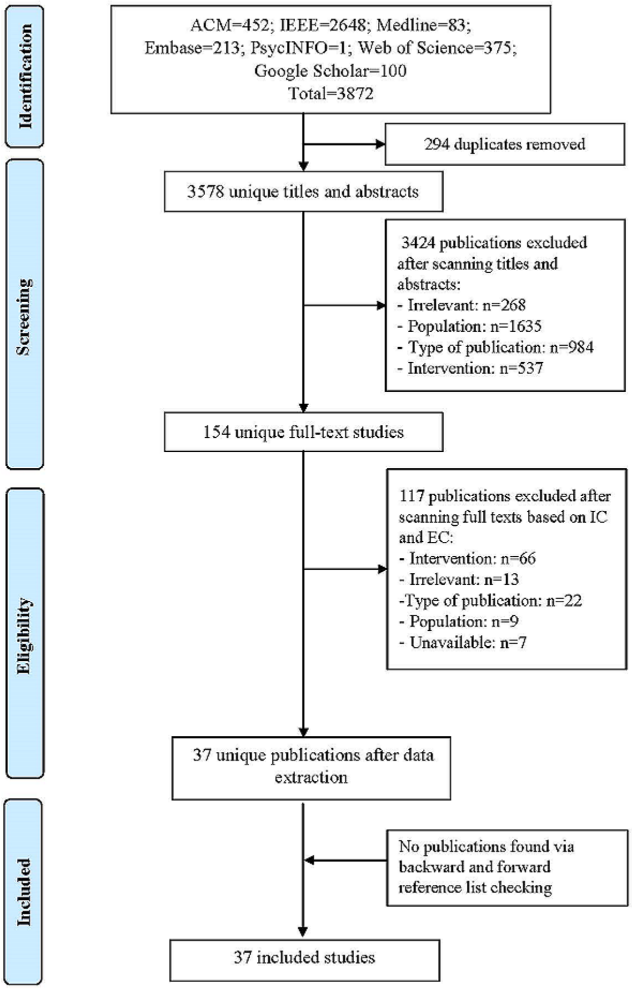
SA synthesized the extracted data using the narrative approach, aggregating the data using tables and text and nonstatistical techniques. For being more precise, we presented the search results followed by general features of the studies, finally describing characteristics of the WDs and AI technologies. We described the general features of WDs (eg, device placement, type, and operating system [OS]) and their technical features (ie, features of sensors, such as sensors used, sensing approach, and primary measurements). The AI features were addressed based on the models used, the evaluation metrics, and their applications.

Results

Search Results

Having searched 7 bibliographic databases, this study returned 3872 citations. As shown in Figure 1, a total of 294 duplicates were subsequently removed, leaving 3578 unique titles, and abstracts; publications that did not make use of AI technologies via WDs for diabetes management were considered irrelevant. Of these, we further excluded 3424 citations after screening their titles and abstracts. Of the remaining 154 references, 117 publications were excluded during the full-text screening. We were left with 37 studies, and this number remained unchanged even after performing backward and forward reference list checking. The synthesis included a total of 37 articles (Multimedia Appendix 4 [7,8,13,14,22-54]).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow chart of the study selection process. EC: exclusion criteria; IC: inclusion criteria.



General Description of Included Studies

Table 1 highlights the general features of the studies included. Many of the included studies (27/37, 73%) were published between 2019 and 2021, with the remaining 27% (10/37) published between 2016 and 2018. Most of the included studies were published in IEEE (21/37, 57%). A large proportion of the studies were authored by institutes in the United States (7/37, 19%), China (5/37, 14%), and India (5/37, 14%). A total of 26 of the 37 studies (70%) were journal articles, and the remainder were conference proceedings (11/37, 30%). Most of the studies targeted type 1 diabetes (T1D), T2D, or both (21/37, 57%), whereas 32% (12/37) did not specify the type of diabetes and mentioned diabetes in general. The remainder targeted prediabetes or a combination of T1D, T2D, and prediabetes (4/37, 11%). Features of each included study are shown in Multimedia Appendix 5.

[b] 1 study for each country.

[c] T1D: type 1 diabetes.

[d] T2D: type 2 diabetes.

Study Design Features

Table 2 outlines details about the studies associated with this review. More than half of the studies (21/37, 57%) had the aim of estimation and prediction of glucose (10/37, 27%) or glucose level monitoring (11/37, 30%). A couple of studies had multiple aims, and the remainder aimed to provide diabetes classification (4/37, 11%), diagnostic solutions (5/37, 14%), self-administration and monitoring (4/37, 11%), and prevention (2/37, 5%). Most of the studies did not mention anything about security (31/37, 84%); the remainder did specify security measures taken (6/37, 16%). Participants' demographics depicted most of them being adult (18/37, 49%) with both genders considered in equal proportional in most of the studies (10/37, 27%). Approximately 41% (15/37) of the studies used diverse populations by separating them into people with diabetes and people without diabetes. Study design features of each included study are shown in Multimedia Appendix 5.

Table 2. Study design features (n=37).

Features	Studies, n (%)	Study ID
Study aim		
Blood glucose estimation (predictions)	10 (27)	S3, S18, S19, S21, S23, S25, S27, S28, S32, S33, S37
Glucose level monitoring	10 (27)	S7-S11, S15, S20, S24, S26, S30
Diagnostic solution	5 (14)	S4, S29, S33, S34, S35
Diabetes classification	4 (11)	S12-S14, S17
Self-administration and monitoring	4 (11)	S1, S5, S6, S31
Prevention	2 (5)	S2, S16
Other disease predictions, detection, and monitoring (hypoglycemia and foot temperature)	2 (5)	S22, S36
Privacy and security		
Not mentioned	31 (84)	S1-S22, S24-S26, S29, S30, S34-S37
Mentioned	6 (16)	S23, S27, S28, S31, S32, S33
Data source		
Private	25 (68)	S2, S3, S5, S7, S8-S19, S21, S22, S24, S26, S29, S34-S37
Public	4 (11)	S1, S4, S6, S25
Not mentioned	2 (5)	S20, S30
Participant demographics		
Age group (years)[a]		
Children and young adults (≤18)	1 (3)	S8
Adult (19-65)	18 (49)	S2-S5, S8, S10, S13, S15, S16, S17, S19, S21, S22, S27, S29, S31, S33, S34
Older adult (>65)	6 (16)	S2, S4, S15, S21, S22, S33
Not mentioned	19 (51)	S1, S6, S7, S9, S11, S12, S14, S18, S20, S23-S26, S28, S30, S32, S35-S37
Gender		
Male	10 (27)	S2, S3, S5, S13, S15, S17, S18, S27, S29, S34
Female	10 (27)	S2, S3, S5, S13, S15, S17, S18, S27, S29, S34
Not mentioned	27 (73)	S1, S4, S6-S12, S14, S16, S19-S26, S28, S30-S33, S35-S37
Diabetes[b]		
Yes	14 (38)	S1, S4, S5-S7, S10, S12, S14, S15, S18, S19, S21, S27, S34, S36
No	15 (41)	S1, S5, S6, S8-S10, S12, S14, S18, S19, S27, S29, S31, S33, S36
Not mentioned	17 (46)	S2, S3, S11, S13, S16, S17, S20, S22-S26, S29, S30, S32, S35, S37

[a] Numbers do not add up as participants in some studies belong to more than one age group.

[b] Numbers do not add up as participants in some studies were diabetic and nondiabetic.

Features of WDs

General Features of Wearables

Table 3 highlights the general features of WDs; some studies used multiple devices. Only 41% (15/37) of the studies used commercially available WDs, whereas 59% (22/37) used prototypes. Most of the studies (22/37, 59%) included wrist-worn devices. In most of the studies, the device type was in the form of a wearable sensor (14/37, 38%), followed by smartwatch (8/37, 22%) and smart wristband (9/37, 24%). Only one study reported a smart sock and another reported smart clothes. Among the developed wearable technologies used, Empatica E4 was the most cited (6/37, 16%), followed by Glutrac (3/37, 8%). For OSs, most of the studies reported devices either directly or indirectly compatible with iPhone OS and Android OS 43% (16/37); OS was not mentioned in a large number of studies (11/37, 28%), and 8% (3/37) mentioned Android only and 5% (2/37) mentioned iPhone OS only. For gateway (ie, a hardware that acts as a “gate” between 2 networks or any device that enables traffic to flow in and out of the network), many of the studies did not mention any sort of gateway (17/37, 46%). Most of the studies that mentioned a gateway used a smartphone (16/37, 43%). Host devices (devices where the actual manipulation of collected data was performed, ie, processing) were used in many of the studies, the most popular being cloud-based (18/37, 49%), many did not report any use of a host device (8/37, 22%), and smart devices were mentioned in 16% (6/37) of studies. For the purpose of transferring data (mode of data transfer) from the WD, the majority of devices reported Bluetooth as the means of transfer (19/37, 51%); 19% (7/37) of studies did not mention the mode of transfer. A total of 16% (6/37) of studies reported the use of some form of internet connection as the mode of transfer (ie, Wi-Fi or mobile network). Features of WDs for each included study are shown in Multimedia Appendix 5.

[a] Numbers do not add up as some studies used more than one wearable device.

[b] Numbers do not add up as the WD in one study worked on 2 operating systems.

[c] iOS: iPhone operating system.

[d] OS: operating system.

[e] N/A: not applicable.

Technical Features of Wearables

Table 4 shows an overview of the technical features of the WDs associated with the studies in this review. Devices were often reported as having >1 device measure, and we reported these primary measures along with the measurements used for the respective studies. We observed that many studies reported blood glucose (15/37, 41%) followed by temperature (10/37, 27%), heart rate (9/37, 24%) and galvanic skin response (9/37, 24%) as their top primary device measures. Regarding the second feature shown in Table 4, the majority of the studies reported on blood glucose as the main measurement studied (27/37, 73%), followed by heart rate or variability (4/37, 11%).

Most of the studies (28/37, 76%) reported an opportunistic approach (ie, no input required from the participant) when obtaining data using the WDs, whereas the remaining (9/37, 24%) used a participatory approach (ie, input required from the participants). For sensing technologies, various sensors were used, either built-in to the WD or as wearable sensors, often reported as >1 sensor per device. We observed a large number of devices in the studies reviewed reporting photoplethysmography sensor use (12/37, 32%), while optical heart rate was only seen in 5% (2/37) of studies among some of the other less-reported sensors. Features of WDs for each included study are shown in Multimedia Appendix 5.

Table 4. Technical features of wearables (n=37).

Feature	Studies, n (%)	Study ID
Primary device measure[a]		
Blood glucose	15 (41)	S3, S8, S10, S15, S17-S22, S24, S26, S28, S30, S37
Physiological	2 (5)	S1, S10
Heart rate, heart rate variability, or interbeat interval of the heart	9 (24)	S6, S11, S14, S22, S23, S32-S35
Galvanic skin response	9 (24)	S12-S14, S23, S25, S27, S32, S34, S35
Blood volume pulse	6 (16)	S12-S14, S25, S27, S35
Acceleration	6 (16)	S12-S14, S25, S27, S35
Plantar pressure	5 (14)	S5, S9, S23, S29, S32, S33
Temperature (skin, foot, shoe, air, or ambient)	10 (27)	S12, S13, S16, S23, S25, S27, S32, S34-S36
Step count	2 (5)	S7, S16
Other (sedentary behaviors, pulse wave information, inertial data, weight, humidity, activity patterns, frequency of food intake and water, and ankle edema quantification)	8 (22)	S2, S4, S9, S16, S21, S23, S31, S32
Measurement studied[b]		
Blood glucose	27 (73)	S1, S3, S6-S8, S10-S28, S30, S33, S37
Plantar pressure	3 (8)	S5, S9, S29
Heart rate or heart rate variability	4 (11)	S28, S33, S34, S35
Other (sedentary behavior, pulse wave, edema, general diabetes symptoms, temperature, sleep quality, step counts, and GSR)	7 (19)	S2, S4, S31, S32, S34-S36
Sensing approach		
Opportunistic	28 (76)	S1, S2, S5, S7, S11-S14, S16-S29, S31-S33, S35-S37
Participatory	9 (24)	S3, S4, S6, S8-S10, S15, S30, S34
Sensing technology[c]		
Accelerometer	5 (14)	S2, S13, S14, S21, S27

Infrared thermopile	3 (8)	S13, S14, S27
Temperature sensor	6 (16)	S7, S16, S23, S24, S32, S36
Optical heart rate sensor	2 (5)	S23, S32
Vibration sensor and flex sensor	2 (5)	S23, S32
Motion sensor	2 (5)	S7, S31
Others (physiological sensors, pulse sensor, blood glucose level sensor, Raspberry Pi camera, humidity sensor, step count sensor, weight sensor, stretch sensor, and optical sensor)	6 (16)	S1, S4, S7, S8, S16, S31

[a] Numbers do not add up as WDs in many studies were used to measures many biomarkers.

[b] Numbers do not add up as some studies used more than one measure.

[c] Numbers do not add up as WDs in most studies used more than one sensor.

Wearables Characteristics With Regard to Diabetes Measurements

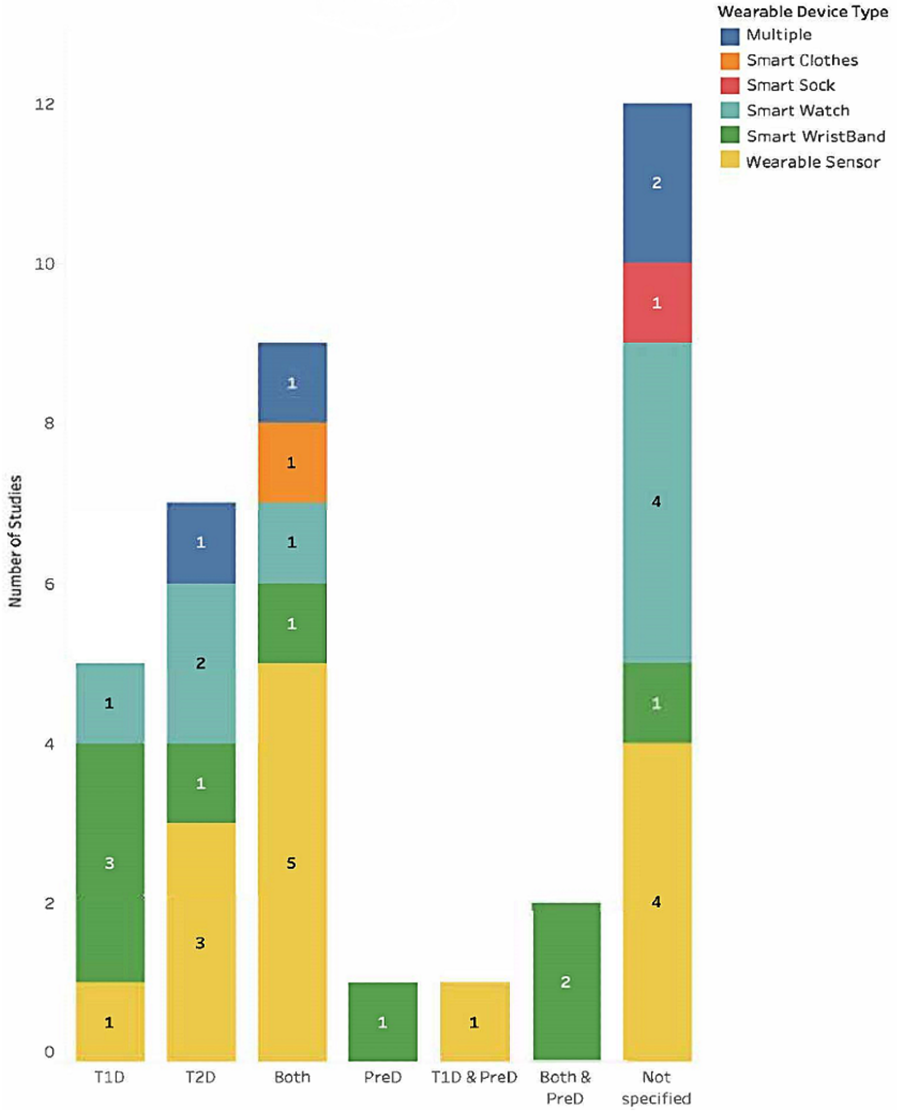
Wearable Technology Status Versus WD Type

Multimedia Appendix 6 further visualizes the data highlighting the WD type and whether they are commercial or prototypes. Wearable sensors were the most prominent as a prototype while smartwatches and smart wristbands were the most common as commercial.

Diabetes Types Versus WDs

Figure 2 shows the type of diabetes and number of studies related to each WD type. While most studies did not specify the type, T1D (as a smart wristband), T2D (as a wearable sensor), or both (as a wearable sensor or smartwatch) seem to be the most targeted types.

Figure 2. Diabetes type with regards to wearable device type. PreD: prediabetes; T1D: type 1 diabetes; T2D: type 2 diabetes.



AI and ML Technologies

For the purpose of this study, we categorized the ML algorithms into 4 categories (classification models, regression models, neural network–based models, and optimization algorithms) and those that were not clearly specified by the study authors were categorized as black boxes (ie, studies that mention they make use of ML or AI but do not specify any further details of algorithms used). Many ML technologies were reported that come under these headings (refer to Table 5 for a full list), and some studies reported and compared >1 model. Support vector machine (SVM) was the most reported (13/37, 35%), followed by random forest (12/37, 32%), k-nearest neighbor (7/37, 19%), Naive Bayes (5/37, 14%), and decision trees (4/37, 11%) among the most used models from classification models. From the regression models, only linear regression (2/37, 5%) was reported in a couple of studies, whereas all others were reported by single studies only. Artificial neural networks were reported in 14% (5/37) of the studies in neural network–based models, followed by long short-term memory (4/37, 11%), convolutional neural networks (3/37, 8%), and deep neural networks (3/37, 8%); these networks were used for both classification and regression purposes. Table 5 also highlights that the majority of the studies applied the AI and ML technologies for either the purpose of blood glucose level forecasting (12/37, 32%) or classifying the participants as normal, diabetic, or prediabetic

(12/37, 32%). Table 6 highlights some of the statistical measures used to evaluate the ML algorithms within the reported studies. Some studies used multiple statistical techniques for this purpose, among them were reports of accuracy (20/37, 54%) and sensitivity (9/37, 24%). While some studies did not mention which was the best ML model identified (6/37, 16%), random forest was reported as the best identified model (7/37, 19%), followed by SVM (6/37, 16%).

Table 5. Artificial intelligence (AI)– and machine learning (ML)–related features (n=37).

Features	Studies, n (%)	Study ID

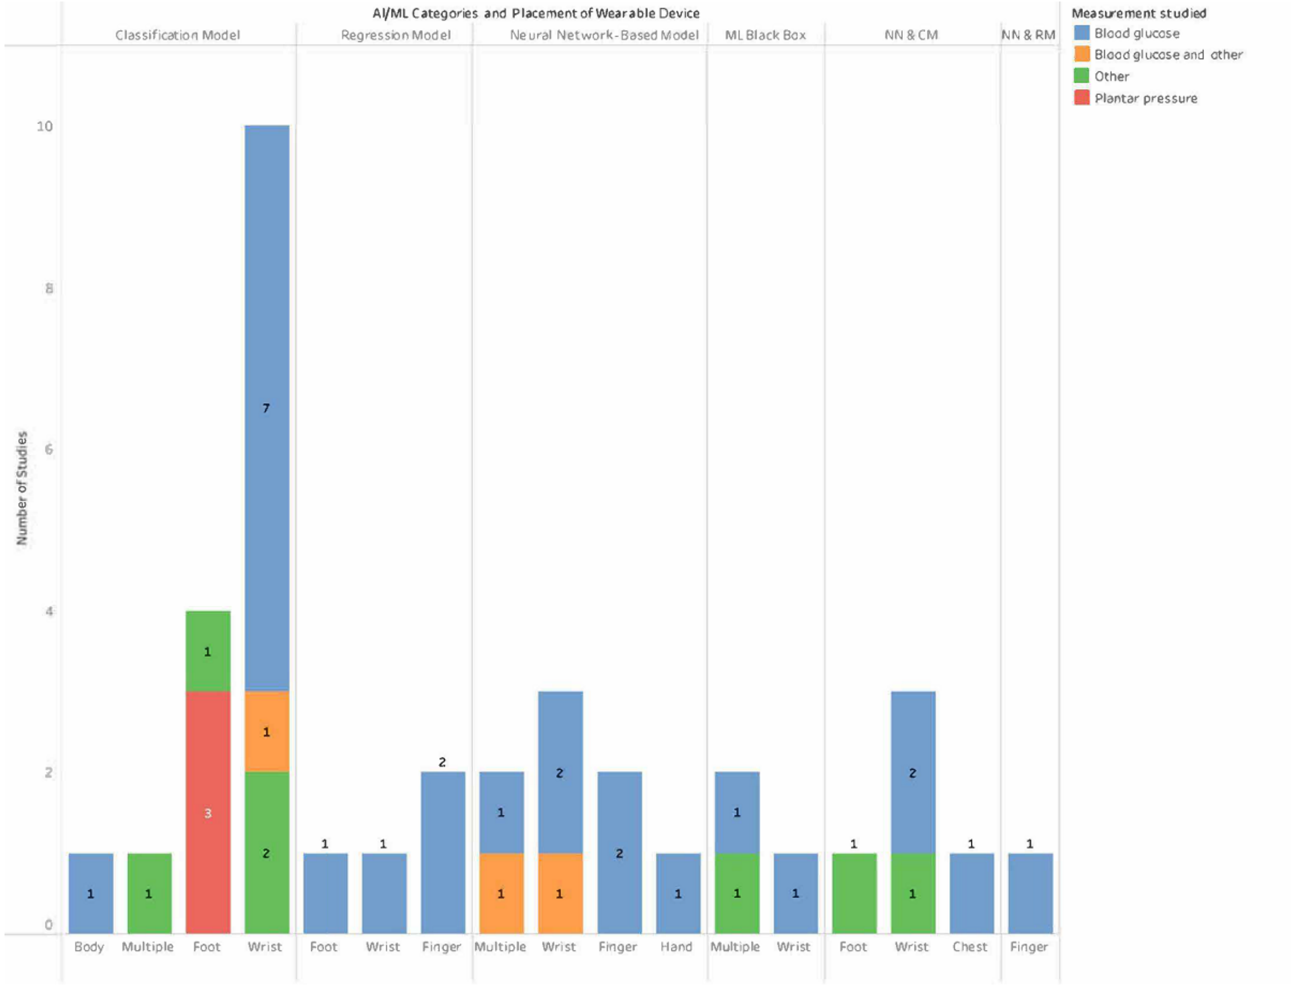
AI and ML Versus Wearables Versus Diabetes

Figure 3 shows the category of the ML algorithm used according to each WD placement and measurement. Most devices that made use of classification models among the wrist-worn devices were the most prominent. Neural network and regression model were the least used.

Figure 3. Artificial intelligence (AI) or machine learning (ML) models used with regard to wearable device placement and measurement studied. CM: classification model; NN: neural network; RM: regression model.



Discussion

Principal Findings

This was the first study of its kind to the best of our knowledge, considering the amount of features we were able to extract from each publication. The features extracted should give researchers insight not only into the technologies that are readily available commercially but also into what is possible in the future with studies we identified that developed prototypes. Our findings shed light on this emerging field, which is still in its infancy. This is further highlighted by the fact that 59% (22/37) of the studies that met our inclusion criteria were prototypes; we were only able to identify 41% as commercially available (as demonstrated in Multimedia Appendix 6) devices, of which only (7/15, 46%) studies performed some sort of ML classification on the extracted data directly from WDs, whereas (6/15, 40%) studies made use of neural network–based models with classification to make out of already collected data. Most of these measured blood glucose on wrist-worn devices and used a classification algorithm (Figure 3). Classification models were widely used (Figure 3) in the reviewed studies, largely owing to studies attempting to classify types of diabetes (T1D, T2D, etc). SVM and random forest were the most prevalent classifiers and exhibited the highest performance. SVM [55] is extensively used because of its superiority in generalization and nonlinear function fitting, and it also has a number of advantages when dealing with small-sample studies [56]. Furthermore, SVM is a binary classifier, and we observed that it is mostly used on blood glucose level data to determine levels for diabetes categorization. Aside from the accuracy for demonstrating efficacy, the Clarke Error Grid was the most commonly used performance metric, possibly because of its popularity as a performance metric for assessing blood glucose estimation. The grid was split into 5 zones, each with varied prediction accuracy between the estimated and reference blood glucose readings. The data fell within zone A, which pertains to precise glucose calculations, where each consecutive zone is thought to have progressively substantial erroneous estimations [57,58]. Most of the sensory data being collected especially when looking at commercially available devices, did not require any further or minimal input from the user, meaning the person with diabetes can get on with day-to-day tasks without having to worry about taking regular invasive finger pricks for monitoring glucose levels; for example, while still feeling that they are wearing a stylish item such as a smartwatch. We specifically examined studies after 2015, as previous studies related to the use of WDs found that most wearables were used in this range [59]. One of the reasons may be that Fitbit released its first device in 2009 and the Apple Watch followed in 2015; both these devices set the tone for WDs, and it is not surprising that 59% (22/37) from our review were wrist-worn. A total of 78% (29/37) of the devices were connected to either a gateway or host device, usually a smartphone (16/37, 43%) via either Bluetooth (19/37, 51%) or Wi-Fi or internet (6/37, 16%); this is likely owing to the fact that web-based data are now more affordable and the availability of low energy connectivity technology such as Bluetooth. This ability to connect has resulted in more analytics and data storage being possible on host devices than on smartphones or directly on the cloud (18/37, 49%) of studies in this review, compared with limited computing power on the WD itself. One of the limitations of this is that devices need continuous connections, which can be an issue, as reported data can be lost if the connection is not maintained for long periods [60]. We also observed that many devices used gateways or host devices, which we believe to be largely because of the limited computing power of WDs.

Strengths

This review was conducted according to the PRISMA-ScR; therefore, it can be considered a high standard. Two reviewers independently conducted the study selection and data extraction. We believe this to be the first of its kind study focusing on WDs targeting diabetes using AI approaches and were unable to identify previous scoping reviews in the literature that has as an exhaustive list of features extracted in this field. A combination of expert research computer scientists and research medical practitioners allowed us to explore the current technologies in depth and highlight gaps in the research community. The most popular databases in the health care and information technology fields were searched; furthermore, Google Scholar with forward and backward reference list checking allowed an exhaustive search of the literature, reducing the risk of publication bias.

Limitations

Only studies published between 2015 and 2021 in the English language were included. Furthermore, we did not use Medical Subject Headings terms in our search; therefore, we may have overlooked some relevant studies. We excluded devices that could be classified as WDs, such as electroencephalogram and ECG machines, which limited their use in hospital settings. As our focus was AI, we excluded any study of WDs and diabetes that had a statistical measurement not considered an AI approach. Although we included a large number of features and some effectiveness measures, we fall short of critically assessing the quality of each of the included studies—this goes beyond the scope of our review—and we hope to cover this in a full systematic review in the near future on the same topic.

Practical and Research Implications

WDs hold great potential for the self-monitoring of diabetes-related parameters, and their ability to be paired with a range of smart devices, including smartphones and general connectivity to clouds, allows the continuous collection of data from many biosensors that measure vitals and biosignals without user interference. The fact that they can be worn in a stylish and fashionable manner has potential for wider acceptance than other technologies, such as CGMs. Although many studies have used WDs for diabetes, we found that ML is still lacking in a sizable number of these studies. With the limited number of studies that reported the use of ML, we see great promise, largely owing to the accuracy levels of the ML algorithms reported in Table 6. Engineering and data science research experts need to come together and identify the most common sensors and technologies and study their effectiveness when combined with ML approaches. In addition, commercially available WDs are readily available and therefore sit in waiting for researchers to conduct studies and apply ML and report further in scientific journals to prove validity and instill consumer confidence. Most of the papers identified in this study used AI or ML algorithms for testing the validity of the system functioning rather than identifying the approaches that could be used for the development of such intelligent devices. More work needs to concentrate on applying known ML algorithms for the purpose of making more accurate diabetes-related measurement calculations. Currently, the number of commercial devices associated with studies are still very low, a quick search on retail sites such as Amazon reveals many commercial devices claiming diabetes-related measurements, which have still yet to be validated with related studies, and this is one area where researchers could get involved. Researchers need to make more use of purpose-shifted devices as they are lying in wait as opposed to creating prototypes and testing the effectiveness of the many commercially available devices. We encourage researchers to perform systematic reviews to assess the efficacy of AI-based and non–AI-based WDs compared with traditional medical devices. Some technologies that are classified as WDs such as CGMs are still classified as semi-invasive as they allow the embedding of a sensor partially into participants' skin, we feel for wider acceptance especially for home use products the technology really needs to move away from such sensors and more studies now need to focus on how measurements can be obtained from noninvasive sensors such as those available on commercial smart watches. Further work is also required on ML algorithms used for diabetes data that can be used on the WDs as opposed to on host devices, as this would reduce some issues reported such as loss of data owing to WD out of range with the host device, which will become easier with time as the technology advances and WD memories are no longer a limitation. We suspect there would be less reliance on host devices for some of the ML computations.

Another area for exploration is the use of the internet of things (IoT); in our search, we found a handful of studies making use of IoT. Most IoT papers describe the IoT architecture for diabetes management without specifying the sensors or WDs actually used or implemented, and do not go into much (if any) detail about any ML deployed. There are many opportunities in this domain; none of the studies were found to make good use of developed commercial technologies such as Alexa, Google Home, and Apple watches, which are readily available. The possibilities here are endless, using a combination of data gathered from sensors at the WDs with other patients and personal data in real-time with IoT. This brings along with its own caveats and the need to incorporate questions of privacy and data sovereignty arising from the mass data storage in cloud-based systems and the many interconnected devices and hospital datacenters; there are issues that need to be considered with the use of data and individual consent. There are also problems regarding the scope of an individual's consent to use their data, as well as potential accountability if the data are mishandled. There are dangers associated with AI algorithms and their misdiagnoses, dangerous advice, or recommendations that do not correspond to the required standard of care. Data security breaches or the reidentification of previously deidentified data may have unintended repercussions. Furthermore, other ethical issues need to be considered, such as accessibility, although commercial WDs that are easily and cheaply available may not be affordable for the masses in low-income countries. A multidisciplinary effort is required, including but not limited to engineers, medical practitioners, and legal experts.

Conclusions

We investigated and reported the current state of WDs and their features for the purpose of diabetes that use ML approaches. Considering the availability of consumer-grade biosensors, we see great advancement potential in this domain, replacing hospital setting, invasive devices, especially when it comes to monitoring glucose levels. Further clinically significant studies are needed to instill confidence and validate WD use as well as the application of ML algorithms on WD data. Researchers and those wanting to develop AI-based WDs can use our review to understand where the gaps are in this emerging field. We encourage readers to use more data and delve deeper into the studies we have identified in order to establish, validate, and repeat studies that showed high accuracy. There is still much work needed, and we feel our review has provided the most extensive work so far summarizing WDs that use ML for people with diabetes to date. Finally, researchers will also benefit from our study as they can embark on longer and better populated systematic studies scrutinizing the benefits of WDs as data gathering, monitoring, prediction, classification, and recommendation devices in the context of diabetes. We envisage several follow-up studies, starting with a full systematic review from our own group.

Abstract

Background: Pregnancy and the postnatal period can be a time of increased psychological distress, which can be detrimental to both the mother and the developing child. Digital interventions are cost-effective and accessible tools to support positive mental health in women during the perinatal period. Although studies report efficacy, a key concern regarding web-based interventions is the lack of engagement leading to drop out, lack of participation, or reduced potential intervention benefits.

Objective: This systematic review aimed to understand the reporting and levels of engagement in studies of digital psychological mental health or well-being interventions administered during the perinatal period. Specific objectives were to understand how studies report engagement across 4 domains specified in the Connect, Attend, Participate, and Enact (CAPE) model, make recommendations on best practices to report engagement in digital mental health interventions (DMHIs), and understand levels of engagement in intervention studies in this area. To maximize the utility of this systematic review, we intended to develop practical tools for public health use: to develop a logic model to reference the theory of change, evaluate the studies using the CAPE framework, and develop a guide for future data collection to enable consistent reporting in digital interventions.

Methods: This systematic review used the Cochrane Synthesis Without Meta-analysis reporting guidelines. This study aimed to identify studies reporting DMHIs delivered during the perinatal period in women with subclinical mood symptoms. A systematic database search was used to identify relevant papers using the Ovid Platform for MEDLINE, PsycINFO, EMBASE, Scopus, Web of Science, and Medical Subject Headings on Demand for all English-language articles published in the past 10 years.

Results: Searches generated a database of 3473 potentially eligible studies, with a final selection of 16 (0.46%) studies grouped by study design. Participant engagement was evaluated using the CAPE framework and comparable variables were described. All studies reported at least one engagement metric. However, the measures used were inconsistent, which may have contributed to the wide-ranging results. There was insufficient reporting for enactment (ie, participants' real-world use of intervention skills), with only 38% (6/16) of studies clearly recording longer-term practice through postintervention interviews. The logic model proposes ways of conceptualizing and reporting engagement details in DMHIs more consistently in the future.

Conclusions: The perinatal period is the optimal time to intervene with strength-based digital tools to build positive mental health. Despite the growing number of studies on digital interventions, few robustly explore engagement, and there is limited evidence of long-term skill use beyond the intervention period. Our results indicate variability in the reporting of both short- and long-term participant engagement behaviors, and we recommend the adoption of standardized reporting metrics in future digital interventions.

digital interventions; perinatal; mental health; well-being; logic model; systematic review; mobile phone

Introduction

The Importance of the Perinatal Period

Pregnancy, delivery, and the postnatal period can be times of increased psychological distress (stress, anxiety, or depression) [1], and up to 20% of women experience depression during the perinatal period [2,3]. There is considerable evidence that psychological distress during this period has detrimental effects on maternal health and can have long-term deleterious effects on the child [4-7], as recognized as part of the Developmental Origins of Health and Disease paradigm [8,9]. In particular, there is growing evidence of intergenerational transmission of poor mental health in utero and the first years of life through these pathways [10]. Therefore, cost-effective, accessible interventions that support lasting positive mental health while also preventing symptoms of mental health problems are of critical importance for public health. Mental health interventions to promote well-being have the potential to not only improve women's outcomes but also minimize the risk of negative health effect transmission to the next generation.

Health promotion strategies aim to enable optimal health and skills to cope with adversity in well subclinical populations. Therefore, it is important that efforts are made not only to deal with illness but also to develop individuals' emotional skills that can be applied in everyday life [11]. Psychological interventions aimed at perinatal women have also been shown to be effective when delivered digitally [12]. Digital interventions—that is, computer- or web-based interventions—can be delivered offline or on the web via a computer, tablet, or smartphone. In this format, interventions can be accessed by numerous people across wide geographical regions in a cost-effective and flexible manner [13]. Web-based interventions may be particularly useful in the perinatal period, given the accessibility issues faced by this population and as many pregnant women search the internet for health information [14,15]. Furthermore, these interventions may help overcome numerous barriers that exist for women who attempt to access traditional perinatal well-being, psychological distress prevention, or treatment programs, especially challenges in navigating psychosocial care systems [13]. Widespread restrictions imposed because of the COVID-19 pandemic have generated additional barriers to accessing mental health and well-being information and services [16].

Digital Mental Health Interventions

Although a recent systematic review provided preliminary evidence that web-based interventions can be a promising and advisable form of intervention during the prenatal period [13], there is a paucity of evidence on the long-term effectiveness of these programs [17]. There are many issues affecting digital mental health intervention (DMHI) implementation, such as availability issues, lack of promotion by health care providers, and lack of long-term outcome data; ultimately, program engagement is key. Low uptake of effective, evidence-based programs could diminish women's and infants' opportunities to enhance their well-being, limiting equitable public health benefits.

Dropout from the intervention and loss to follow-up reduces the treatment effect [18]. Although it has been argued that various strategies, including email prompts, SMS text messages, and *homework* are ways of helping participants develop intervention skills that can be applied, practiced, and sustained [19], it is unclear how frequently studies of DMHIs use or evaluate these strategies. Despite studies demonstrating intervention efficacy for those that remain in the study, we argue that it is just as salient to measure engagement as a benchmark of effectiveness. Web-based interventions provide tools to learn more about participant engagement and, furthermore, how it relates to retention and intervention outcomes, both in the short and the long term. This information can be used to understand the dynamics of engagement [18] and how to strengthen these characteristics in intervention development and delivery.

Assessing Engagement

It is widely accepted that the full benefit of many effective treatments can be achieved only if the prescribed regime is followed reasonably closely [20]. Recent reviews [21,22] have consistently highlighted these challenges with regard to low engagement and retention rates, particularly for digital programs that often experience poor reach and uptake [13]. Sustained engagement is a complex process that has been identified as a crucial factor in intervention success [23]. However, there is a lack of systematic methodologies to assess engagement, particularly in real-world contexts. Comparing program engagement across research studies is difficult because of the wide range of strategies applied to evaluate engagement outcomes [22,24]. Accordingly, applying structured processes to assess engagement can make comparisons more meaningful.

One of the frameworks for evaluating engagement in face-to-face programs, which can be adapted to web-based programs, is the Connect, Attend, Participate, and Enact (CAPE) model [25]. The CAPE model identifies and defines 4 aspects of engagement at various stages of intervention. First, *connect* pertains to how many people express interest in engaging in an intervention out of those eligible. Second, *attend* refers to continuous presence, such as the number of intervention sessions a participant completes. Third, *participate* is the degree to which participants actively engage with the content of the intervention, such as completing intervention tasks and remaining in the program. The final component, *enact*, refers to the participant making use of intervention strategies or knowledge as part of their daily life. Although this was developed to guide face-to-face parenting program engagement research, it can be readily applied to understanding and measuring digital intervention engagement in a research context.

Objectives

At a time when public resources are strained, policy makers and program administrators are looking to invest in effective, engaging prevention programs supported by scientific evidence and delivering long-term benefits. Intervention engagement must be foremost among these considerations, as this will ultimately determine the degree to which the target population takes up and benefits from the intervention when implemented in the community. Systematic reviews are an influential decision-making tool as they summarize a body of scientific research; identify implications for policy and practice [26,27]; and can be used to guide investment decisions, particularly for complex problems, such as poor intergenerational mental health.

This systematic review aimed to understand the reporting and levels of engagement in studies of web-based psychological mental health or well-being interventions administered in the perinatal period to women with subclinical mood symptoms.

Specifically, we aimed to (1) understand how studies report engagement, with engagement defined as containing the 4 steps in the CAPE model; (2) make recommendations on best practices to report engagement in DMHIs based on this; and (3) understand levels of engagement in intervention studies in this area.

To maximize the utility of this systematic review, we intended to develop practical tools for future public health use: to develop a logic model from the literature to reference the theory of change, evaluate the studies using the CAPE framework, and develop a guide for future data collection to enable consistent engagement reporting in web-based (and offline) interventions.

Methods

The methods used in this systematic review combine standard rigorous and transparent review methods using the Cochrane Synthesis Without Meta-analysis (SWiM) reporting guidelines [28] in conjunction with the development of a logic model to understand the theory of change.

Search Strategy

The review question, search strategy, inclusion criteria, and methods were registered in PROSPERO (International Prospective Register of Systematic Reviews; approval number CRD42020162283). The research question was as follows: what is known about engagement in digital mental health and well-being programs for women in the perinatal period? A systematic database search was conducted to identify papers relevant to the aims of this review. The initial search was performed by the first reviewer (JAD), using the Ovid Platform for MEDLINE, PsycINFO, EMBASE on the EBSCO Platform, Scopus, Web of Science, and Medical Subject Headings on Demand for all English-language articles published in the past 10 years (ie, from January 1, 2010, to May 29, 2020). Keywords and index terms identified as relevant in the search strategy were used and individual search criteria were developed for each database. All the database search strategies are provided in Multimedia Appendix 1. The impact of the COVID-19 pandemic delayed this publication; therefore, a subsequent rapid review was undertaken in May 2022 and performed in Google Scholar Advanced search to elicit any further publications since June 2020.

Identification of Studies and Eligibility Criteria

The search strategy aimed to identify studies reporting on engagement and retention in digital mental health and well-being programs for women during and after pregnancy. Clear inclusion and exclusion criteria were developed using the Population, Intervention, Comparison, Outcomes, and Study framework to guide the inclusion criteria for participants, intervention or phenomena of interest, comparators, outcomes, study design, and context (Textbox 1).

Textbox 1. Inclusion and exclusion criteria (based on the Population, Intervention, Comparison, Outcomes, and Study framework).

Inclusion criteria

- Participants
  - Childbearing individuals in the perinatal period (ie, from conception to the first year of the infant's life)
  - Studies focusing predominantly on the childbearing individual but can include partners
  - Studies that include childbearing individuals at moderate risk for psychological distress (ie, with Edinburgh Postnatal Depression Scale score ≤12)
  - Studies that include women at risk of postnatal depression with a history of depression or anxiety (ie, early intervention)
- Intervention
  - Any minimal contact digital interventions provided in the perinatal period aiming to reduce mild to moderate psychological distress or promote psychological well-being (ie, minimal contact as defined by a maximum of <1 hour of direct contact each week)
- Comparators
  - Studies with any form of comparator were considered
- Outcomes
  - None; although the focus of the review was on engagement outcomes, we included any studies of interventions meeting the above criteria to determine the proportion that reported engagement outcomes
- Study design
  - Quantitative (eg, randomized controlled trials, quasi-experimental studies, cohort studies, descriptive studies), and qualitative studies

Exclusion criteria

- Participants
  - Studies considering programs before conception and those specifically targeting the child
  - Studies focusing predominantly on the partner or father
  - Studies that include women at high risk for psychological distress (ie, with Edinburgh Postnatal Depression Scale score ≥13)
- Intervention
  - Interventions with a primary focus other than mental health or well-being (eg, parenting self-efficacy)
  - Interventions delivered face to face or as telehealth or telephone coaching

Selected Studies

All papers that appeared eligible based on their title and abstract were retrieved for screening. The first author (JAD) reviewed the titles and abstracts of all papers, assessed eligibility, and noted any reasons for exclusion. Full-text articles were assessed for eligibility and reviewed independently by both the first author (JAD) and third author (LYG). Once the third author (LYG) had reviewed the papers, any discrepancies were resolved through team discussion. The reference lists of the included studies were examined to identify additional relevant papers.

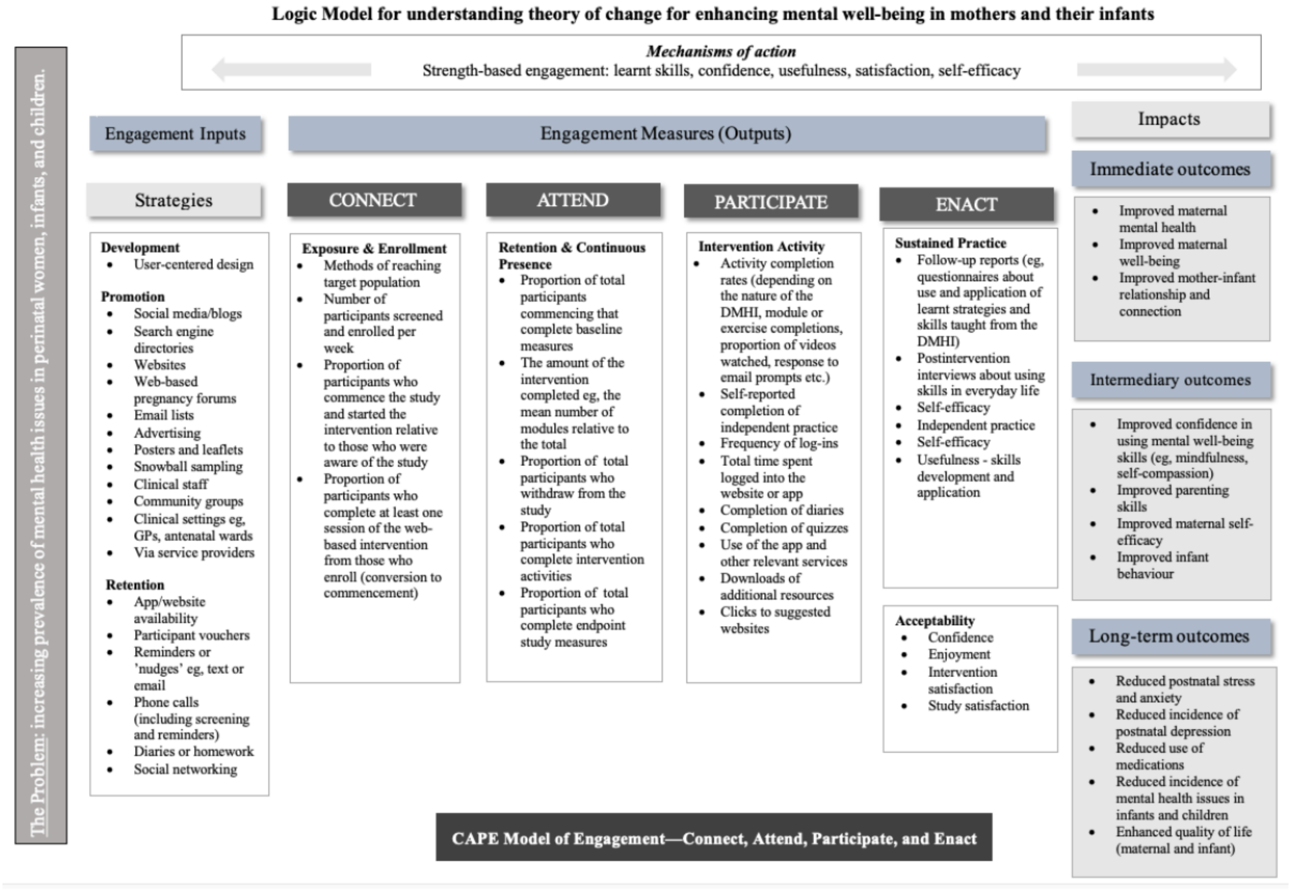
Coding of Study Characteristics and Data Extraction

Key article characteristics were recorded using a Microsoft Excel (version 2020) data extraction table developed for this review. These characteristics included general information about the study, such as the country and author, along with specific information about the study design, comparators, and intervention type. Coding of the study characteristics enabled us to group the studies as part of our synthesis. As our primary aim was to understand the engagement of the study population, we characterized the assessment time points, engagement measures, and reporting of attrition and adherence. Data relevant to engagement were extracted using the CAPE framework; this included variables for recruitment, retention, attrition, and follow-up time points. A framework analysis methodology [29] was used to determine which variables should be included in each step of the CAPE framework.

Development of Logic Model

Logic models can help conceptualize a complex review question and specify analytic links to test the plausibility that a program works as intended [26]. Logic models typically illustrate the chain of reasoning underpinning how interventions lead to immediate (or short-term) outcomes and then to longer-term outcomes and impacts [30]. A key part of the model is detailing the mechanisms of change within the pathway and the moderating and mediating factors that may be associated with or influence outcomes. This is often referred to as the theory of change [30]. In this systematic review, the research team developed a logic model to aid the process of understanding how and when the CAPE framework could be applied to interpret the role of different engagement variables in promoting outcomes in digital perinatal mental health and well-being programs. The project team collaboratively developed the logic model, drawing on themes in the literature and the team's collective knowledge and experience. To develop the logic model, we incorporated the types of engagement metrics found in the selected studies that could be used to assess engagement (Figure 1).

Figure 1. Proposed logic model. GP: general practitioner; DMHI: digital mental health intervention.



Quality Appraisal and Risk of Bias

The risk of bias for studies included in this review was based on the Cochrane Collaboration's tool for assessing the risk of bias for each category of study (ie, randomized controlled trials [RCTs] and non-RCTs), and the risk of bias was adapted for this review and classified as low, uncertain, or high based on the Cochrane risk of bias tool [31] and the primary aim of this systematic review (ie, engagement rather than efficacy). The assessment of study quality was undertaken by the first author (JAD) and reviewed by the project team. Multimedia Appendix 2 [17,32-46] provides the detailed risk of bias assessments of the included studies.

Synthesis of Results

As this systematic review synthesized the results from a diverse range of interventions, we used SWiM guidelines [28] to promote transparent reporting. The SWiM items enable studies to be grouped and provide guidance on the reporting of standardized metrics used for the synthesis of findings. Specifically, we undertook the following steps:

1. Summarized the characteristics of each study and reported intervention implementation, recruitment and engagement activities, study findings, reported attrition, and methodological quality
2. Determined which studies were similar enough to be grouped within each comparison by comparing across studies (eg, types of digital platform and postnatal vs antenatal)
3. Determined which data were available for synthesis
4. Synthesized the characteristics of the studies
5. Performed a statistical synthesis for appropriate quantitative data and comprehensive critical appraisal through a meta-synthesis approach for qualitative data
6. For each trial included in this systematic review, we recorded counts of trial participants who were assessed for eligibility, those who were recruited, and those who were allocated to the intervention and control arms; rates of

recruitment, trial completion, and loss to follow-up were synthesized by evaluating the proportion of recruitment, completeness, and loss to follow-up in base R (R Foundation for Statistical Computing) statistical package [47]; synthesized data were reported as forest plots [48].

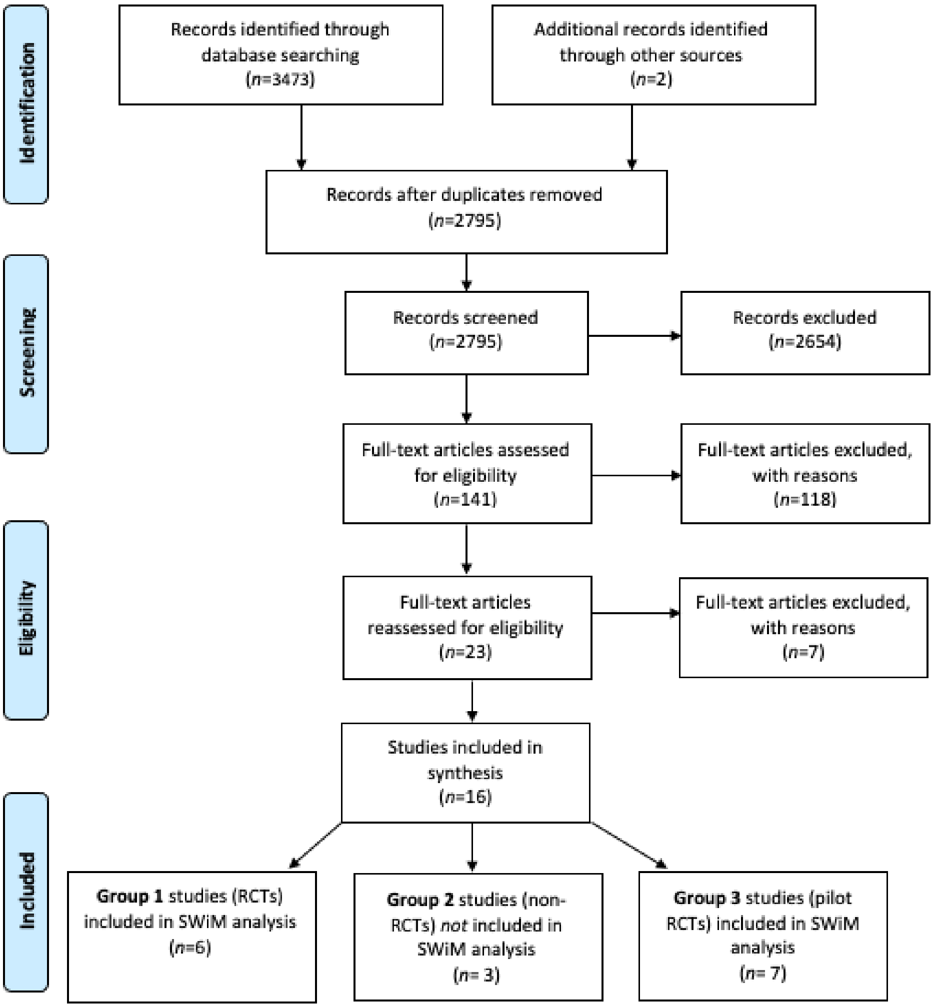
Results

Included Studies

The electronic searches generated a database of 3473 potentially eligible studies that were assessed using the review eligibility criteria. After duplicates were removed (680/3473, 19.58%), all titles and abstracts were screened for eligibility. In total, of the 3473 studies, 2795 (80.48%) records were screened, and 2654 (76.42%) were excluded based on the inclusion or exclusion criteria (Textbox 1). After the first screening, 5.31% (141/2654) of potential studies remained; the full-text articles were assessed for eligibility by the first and third authors. Of the remaining 141 studies, 125 (88.7%) were excluded on consensus by the project team; the first and third authors independently screened the papers that were verified by the team, resulting in a final selection of 16 (11.3%) studies to be included in the synthesis. The final studies were then grouped according to the study design.

The literature search and inclusion processes are detailed in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram (Figure 2). The search flow diagram indicates the papers that were selected for synthesis using the PRISMA guidelines [49]. A secondary rapid search conducted in 2022 did not yield any additional papers that met our specific inclusion criteria.

Figure 2. Search flow diagram (PRISMA [Preferred Reporting Items for Systematic Reviews and Meta-Analyses]). RCT: randomized controlled trial; SWiM: Synthesis Without Meta-analysis.



Synthesis of Results

Overview

The primary aim of this systematic review was to assess the engagement of women participating in digital mental health or well-being interventions; therefore, the standardized metric and transformation method [28] used across all studies were those used to evaluate engagement rather than well-being effect sizes. On analysis of study characteristics, we grouped the 16 interventions according to study design to provide a cohesive comparison in a broad range of study types. Group 1 was RCTs (6/16, 38%), with active and control arms. Generally, RCTs had a longer follow-up period (maximum of 12 months). Group 2 included non-RCTs (3/16, 19%), with no active comparators and brief or no follow-up period. Group 3 comprised pilot RCTs (7/16, 44%) with active and control arms and a follow-up period.

Study Characteristics

In all groups, there was a range of therapeutic approaches, including cognitive behavioral therapy, parenting education, positive psychology, mindfulness, and compassion-based training. Several studies used a psychoeducation approach to build parenting self-efficacy, such as Chan et al [50], Shorey et al [51], Corno et al [32], and Tsai et al [34]. In group 1, overall, 25% (4/16) were delivered as self-help internet interventions and 13% (2/16) as smartphone-based mobile apps; in group 2, all were delivered as self-help internet interventions; in group 3, all were delivered as internet interventions apart from the study by Barrera et al [37], which was delivered as an SMS text messaging program. In addition, 13% (2/16) of studies included the assessment of physiological biomarkers: Cornsweet [38] and Matvienko-Sikar and Dockray [41]. A summary of the study characteristics is reported in Tables 1-3 (a more detailed report is available in Multimedia Appendix 2, including intervention outcomes). For this review, we reported engagement measures collected for each study as CAPE metrics.

Table 1. Group 1: randomized controlled trials (N=6).

Intervention type, format, and duration	Study aims (sample size)	Engagement measures: connect	Engagement measures: attend	Engagement measures: participate	Engagement measures: enact
Self-guided; iWaWa[a]; 9 modules [13]	Assess the feasibility and acceptability of iWaWA among postpartum women with anxiety (89 participants)	• Assessed for eligibility (n=147): recruited via social media, posters, and flyers and numbers recruited • Reasons for exclusion • 89 enrolled and randomized to treatment and control	• Engagement with internet-based components • Attrition and attendance • Participant CONSORT[b] flow diagram (access, allocation, and follow-up)	• Module views, module completion, number and duration of support calls	• Treatment feasibility (engagement and usability) and acceptability (usefulness, satisfaction, and helpfulness) were assessed after treatment through semistructured interviews
Smartphone-based mobile app [50]	Assess the difference in the levels of antenatal and postnatal depression in participants (660 participants)	• Assessed for eligibility (n=803) • Reasons for exclusion • 660 enrolled and randomized (intervention or treatment as usual)	• Participant CONSORT flow diagram (eligibility, enrollment, randomization, follow-up, and analysis) • Retention rates	• The use of the app and other relevant services (eg, antenatal classes and other pregnancy resources: books and websites) documented by self-report	• Postintervention survey included • Use of the app
Web-based compassion-based intervention; *Kindness for Mums Online*; 5-6 weeks [52]	Assess the effect of the intervention on participants' well-being (206 participants)	• Assessed for eligibility (n=310) • Recruitment methods: social media and snowball sampling • Participant vouchers • Accessibility • Reasons for exclusion • 206 enrolled and randomized	• Participant CONSORT flow diagram (enrollment, allocation, follow-up, and analysis)	• Reporting of attrition and engagement (ie, completion of sessions and frequency or program use)	• Acceptability: participants were asked to rate the ease of use and satisfaction after the intervention
A Chinese version of the MBSP[c] program; 10 hours of training with 36 episodes; 6-week internet-based intervention [53]	Assess the effect of the mindful self-compassion intervention on preventing postpartum depression in a group of symptomatic pregnant women (314 participants)	• Assessed for eligibility (n=472) • Screening and baseline assessment (n=344) • Reasons for exclusion • Randomized (n=314)	• Participant CONSORT flow diagram (eligibility, allocation, follow-up, and analysis) • Attendance rates • Reporting of retention	• Reporting of attrition • Feasibility and acceptability • After completing each exercise, participants were instructed to exercise the steps during the day; participants provided a graphical overview and a web-based diary book where they registered their reflections	• Reporting of retention and attrition after the intervention
Condensed web-based version of an 8-week mindfulness course; "Be Mindful Online"; 4 weeks on the web [54]	Evaluate the potential of a web-based mindfulness course for expectant participant women (185 participants)	• Assessed for eligibility (n=237) • Recruitment methods (email lists, social media advertising, and posters in community settings) • Reasons for exclusion • Enrolled and randomization methods	• Participant CONSORT flow diagram (recruitment, allocation, follow-up, and analysis)	• Regular reminders to log on or contact the research team via email • Reporting of retention and attrition	• Postcourse evaluation 45 days after baseline

Intervention type, format, and duration	Study aims (sample size)	Engagement measures: connect	Engagement measures: attend	Engagement measures: participate	Engagement measures: enact
Mobile app for psychoeducation and postnatal depression; “Home-but not Alone” [51]	Examine the effectiveness of the program in improving participant parenting outcomes (250 participants [couples])	• Assessed for eligibility (n=360 couples) • Reasons for exclusion • Recruitment methods • Randomization methods to intervention or control	• Participant CONSORT flow diagram (eligibility, recruitment, allocation, follow-up, and analysis)	• The research team monitored the use of the app and parents received reminders each week	• Intervention posttest

[a] iWaWa: internet-based What Am I Worried About.

[b] CONSORT: Consolidated Standards of Reporting Trials.

[c] MBSP: Mindfulness-Based Strengths Practice.

Table 2. Group 2: non–randomized controlled trials—case series, open trial, and quasi-experimental (N=3).

Intervention type, format, and duration	Study aims (sample size)	Engagement measures: connect	Engagement measures: attend	Engagement measures: participate	Engagement measures: enact
Positive psychology web-based intervention; 5-week web-based self-applied positive psychology intervention specifically adapted for pregnant women; 4 modules [32]	Examine the effect of a positive psychology web-based intervention on indices of participants’ prenatal well-being (6 participants); case series design	• Eligibility and recruitment method • Preassessment on the web	• Weekly emails—reminders for assessments	• Compliance with the intervention measure was developed by the research team • No reported attrition	Exercise preferences were assessed at the posttest time point
Internet program plus weekly phone coaching sessions, individually or group-wise; MMB[a] program; 8 weeks [33]	Examine the feasibility, acceptability, and preliminary outcomes of MMB for use with pregnant women at risk for depressive relapse (37 participants); open trial—no control group	• Assessed for eligibility (n=48) • Reasons for exclusion • Recruitment methods—flyers and via service providers • Prescreening by phone • Intake interview in person or by phone • Participant enrollment and flow (eg, reasons for declining to participate)	• Participant CONSORT[b] flow diagram (eligibility, enrollment, follow-up, and analysis)	• Session completion and participation in phone coaching calls • Home practice completion • Participant engagement (eg, completion of sessions, practice per week, and time)	Self-reported satisfaction (perceived benefits and challenges) via questionnaire and engagement interview (qualitative) at session completion
Web-based modules: web-based maternity health records, antenatal health education, self-management journals, and infant birth records [34]	Investigate the effectiveness of a web-based antenatal care and education system on pregnancy-related stress, general self-efficacy, and satisfaction with antenatal care (135 participants) quasi-experimental design	• Eligibility—control (n=75) and experimental (n=80) group at pretest • Recruitment methods (convenience sampling) • Assignment methods to experimental or control groups	• Participant CONSORT flow diagram (enrollment, follow-up, and analysis) • Attrition	• Assistance was offered via telephone, email, web conferencing, or face-to-face guidance • Follow-up phone calls were made to the participants • Attrition	N/A[c]

Table 3. Group 3: pilot studies (N=7).

Intervention type, format, and duration	Study aims (sample size)	Engagement measures: connect	Engagement measures: attend	Engagement measures: participate	Engagement measures: enact
Brief web-based self-help intervention—5 components considered effective in challenging negative beliefs [35]	Assess positive mood in participating mothers of babies and toddlers (80 participants)	• Eligibility • Recruitment methods—internet, leaflets, and community postnatal groups • Randomization methods	• Only 1 session	• Compliance (missing data)	• Acceptability—an open-response question at the end of the intervention (qualitative) • Implications for policy and practice
Automated self-help internet intervention; 8 lessons—accessible anytime [36]	Assess the efficacy of the intervention to reduce the risk of postnatal depression in participating women (111 participants)	• Assessed for eligibility (n=5071) • Consented (n=2966) • Recruitment methods—web-based search engine directories, (eg, Google advertisements “sponsored links”) • Randomization methods • Initial log-ins to the website	• Participant CONSORT[a] flow diagram (eligibility, consent, allocation, follow-up, and analysis) • Adherence	• Automated email messages • Automated self-help via website • Log-ins, total time spent logged into the website, and the last lesson viewed recorded • Module feedback on the materials viewed (eg, usefulness and understandability) • Attrition	• Includes discussion on experience and engagement and feedback assessment
Minimal contact automated SMS text messaging; *Baby-Text* program [37]	Assess acceptability of an SMS text messaging program to prevent postpartum depression (10 participants [pregnant and postpartum women])	• Eligibility • Recruitment methods—flyers at general public bulletin boards and community agencies; websites and blogs	• Compliance	• Attrition	• Feedback assessment (qualitative) • Acceptability assessment
Intervention—self-guided; 15 steps, each of which takes 45 minutes [38]	Assess feasibility and acceptability; study 1 (n=6): effects of a single teaching and biofeedback session on maternal and fetal biofeedback; study 2 (n=9): effect of consumer satisfaction	• Study 1: eligibility and recruitment methods (flyers at antenatal classes) • Study 2: eligibility and recruitment methods (flyers at antenatal classes)	• Study 1: compliance with baseline and 2 conditions (teaching and practice) • Study 2: compliance to complete 15 steps	• Attrition • Feasibility and acceptability	• Study 1: no postintervention measures • Study 2: postintervention assessment and interview • Qualitative follow-up
8-week web-based prevention intervention; website plus initial phone call; 16 core didactic lessons plus 3 postpartum booster sessions and 5 associated tools [39]	Assess a CBT[b] peer support intervention to prevent postnatal depression in participants (24 participants)	• User-centered-design, recruited via flyers • Assessed for eligibility (n=216) • Completed baseline assessment (n=30) • Enrolled and randomization methods	• Participant CONSORT flow diagram (screened, completed the baseline assessment, and enrolled) • Adherence	• Email notifications • Total log-ins and completion of tools and lessons • Peer support features (likes, comments, nudges, and posts) • Reporting of attrition and site use (log-ins); usability and acceptability	• Usability and satisfaction (Usability, Satisfaction, and Ease of Use questionnaire)

Intervention type, format, and duration	Study aims (sample size)	Engagement measures: connect	Engagement measures: attend	Engagement measures: participate	Engagement measures: enact
Self-guided, web-based intervention to prevent postpartum depression symptoms; *Be a Mom*; 5 modules [40]	Explore the processes underlying therapeutic change for participants in the intervention (194 participants)	• Assessed for eligibility (n=643) • Email invitation to participate • Recruitment methods—in person and web-based • Reasons for exclusion • Baseline assessment (n=241) • Randomization methods (intervention or waitlist control)	• Participant CONSORT flow diagram (eligibility, enrolled, randomized, and follow-up) • Adherence	• Email reminders after 7 days without accessing intervention • Attrition	• Postintervention measures included emotion regulation, psychological flexibility, and self-compassion
Web-based mindfulness and gratitude intervention 4 times a week for 3 weeks [41]	Assess the effect of a novel gratitude and mindfulness-based intervention on prenatal stress, cortisol levels, and well-being in participating women (46 participants)	• Assessed for eligibility (n=362) • Recruitment methods—posters, leaflets, and pregnancy forums • Reasons for exclusion • Randomization methods • SMS text message reminders • No additional contact with the study team during the study period	• Participant CONSORT flow diagram (enrollment, allocation, follow-up, analysis)	• Participant adherence was evaluated as the total frequency of completion of the web-based diary entries • Proxy measure for full intervention use	• Limitations in fidelity evaluation

[a] CONSORT: Consolidated Standards of Reporting Trials.

[b] CBT: cognitive behavioral therapy.

Variables Assessed to Evaluate Engagement

Overview

Participant engagement was evaluated using the CAPE model of engagement [25], which is described in more detail in the following sections. Three-quarters of all the studies included a CONSORT (Consolidated Standards of Reporting Trials) participant flow diagram with similarities in reporting (ie, enrollment, allocation, follow-up, and analysis). In terms of strategies to prompt engagement and promote retention (attendance and participation), various methods were used and reported, including email and text reminders, peer support features, and phone calls to participants.

Connect: Exposure and Enrollment

Connect was operationally defined as the proportion of participants who entered the study and started the intervention relative to those who were aware of the study. Although many studies reported the *exposure* methods for the target audience, for example, advertising via Facebook, Twitter, web-based email lists, community sites (medical and retail), and third-party websites (Ashford et al [13], Krusche et al [54], and Felder et al [33]), there were rarely reporting of the total population size exposed to advertising and other recruitment means. Many studies reported eligible participants who made the initial contact. For example, Barrera et al [36] reported eligible participants (n=5071) as female, pregnant, aged ≥18 years, and interested in the study website for personal use. From this total group, 2966 participants went on to participate by signing an informed consent form. A further 2114 potential participants were excluded, and the reported reasons included website error, current or missing status of major depressive episodes, and incomplete baseline. The final number of randomized participants was 852. Given the substantial drop-off between exposure to recruitment methods and randomization, reporting metrics at each stage of this process can highlight where efforts must be targeted to increase engagement.

All studies in this review reported enrollment rates in the intervention, which we defined as those who commenced the intervention relative to those who expressed interest in the study. Conversion to commencement was based on multiple factors, not just the participants' decision to engage, both dependent and independent of the inclusion or exclusion criteria. Most studies in this review reported reasons for exclusion, ranging from lack of contact or completion of baseline surveys to elevated mental distress scores. Enrollment rates varied from a high rate of 82% (Chan et al [50]; group 1) commencing from the eligible study sample, with the lowest enrollment rate at 12% (Duffecy et al [39]; group 3). Generally, there were higher enrollment rates in the group 1 studies (clustering approximately

60%) than in group 3 (clustering approximately 25%). Only one of the studies reported strategies designed to increase enrollment. Duffecy et al [39] undertook a user-centered design process before the pilot trial to engage women from the target population in the intervention-building process. However, this study also reported the lowest enrollment rate.

Attend: Retention and Continuous Presence

In face-to-face interventions, *attendance* refers to the proportion of the sessions attended by each participant. Ideally, for digital interventions, attendance would be a measure of the amount of intervention completed (eg, the mean number of intervention modules relative to the total number of modules) or similar, such as the number of participants who completed all web-based interventions. This information was not stated in any of the studies included in this review. As a result, we calculated a proxy for intervention *attendance* as study attendance, operationally defined as intervention retention and continuous presence (continued interaction with the intervention), in both the intervention and control arms (where controls were used). All studies reported retention in terms of the rate of those who enrolled versus those who completed the study.

The highest reported study retention (groups 1 and 3) was reported by Ayers et al [35] at 90%. Barrera et al [36] had the lowest intervention retention at 13%. (Figure 3 [13,50-54] and Figure 4 [35,36,39-41]).

In the control arm, Guo et al [53] had the highest participant retention rate of 89%, whereas Barrera et al [36] had the lowest at 13%.

Figure 3. Participant retention in the intervention arm (group 1); 95% CIs determined by test of proportions [13,50-54].

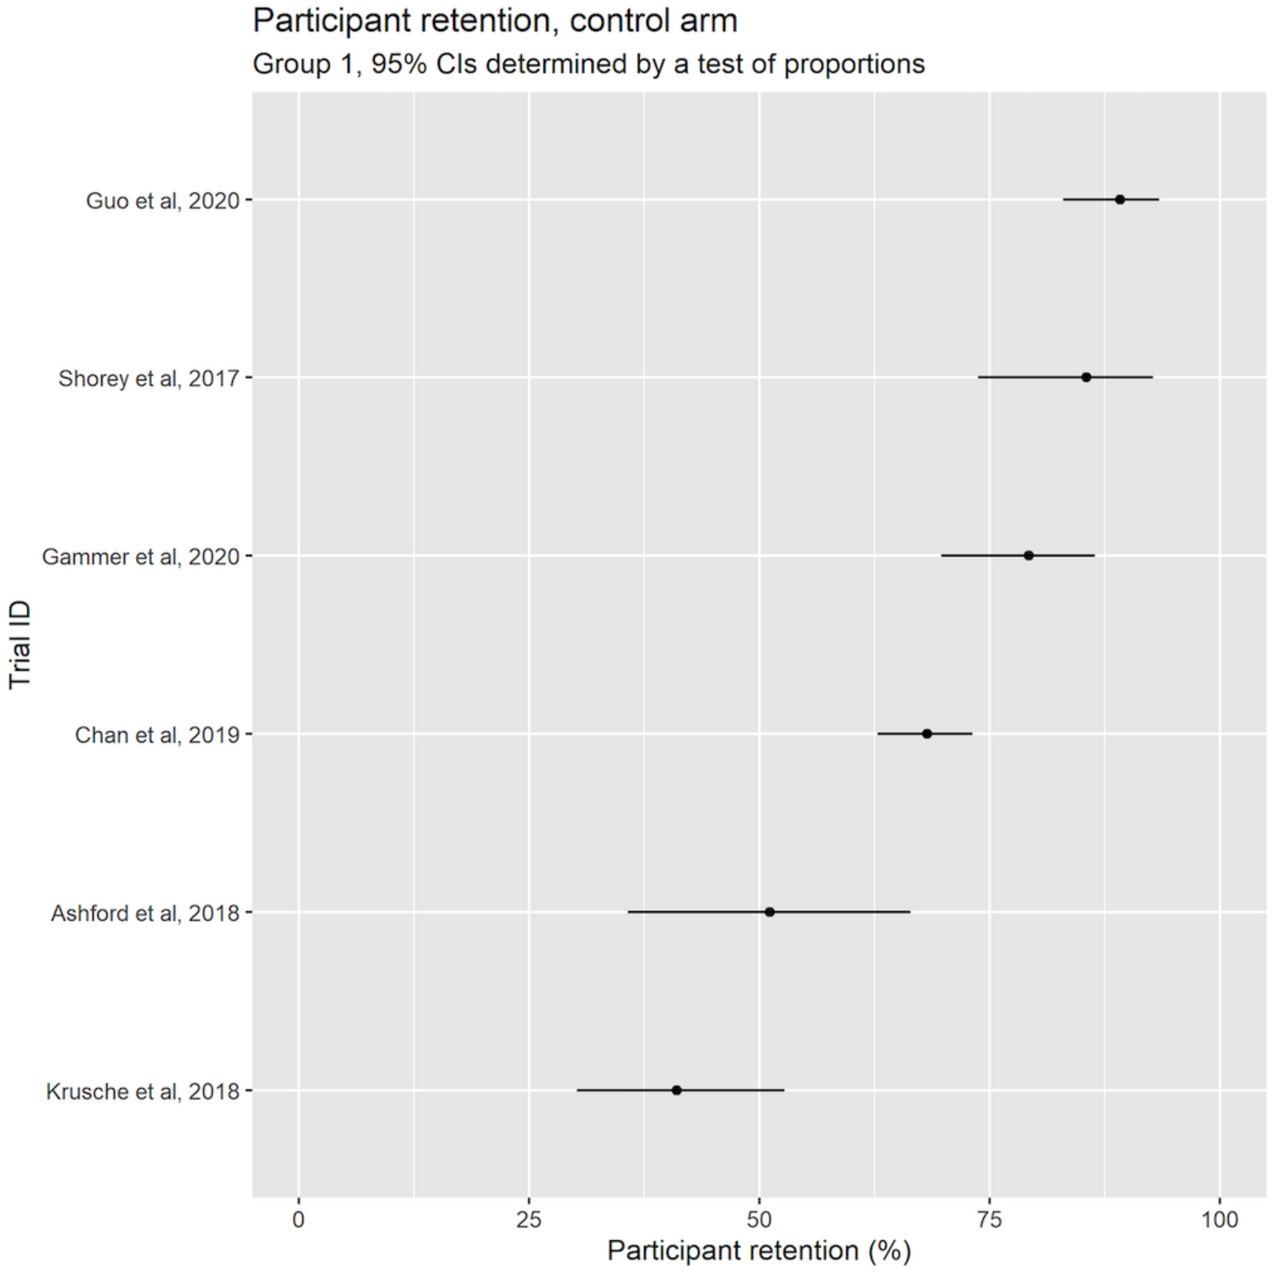

Figure 4. Participant retention in the intervention arm (group 3); 95% CIs determined by test of proportions [35,36,39-41].

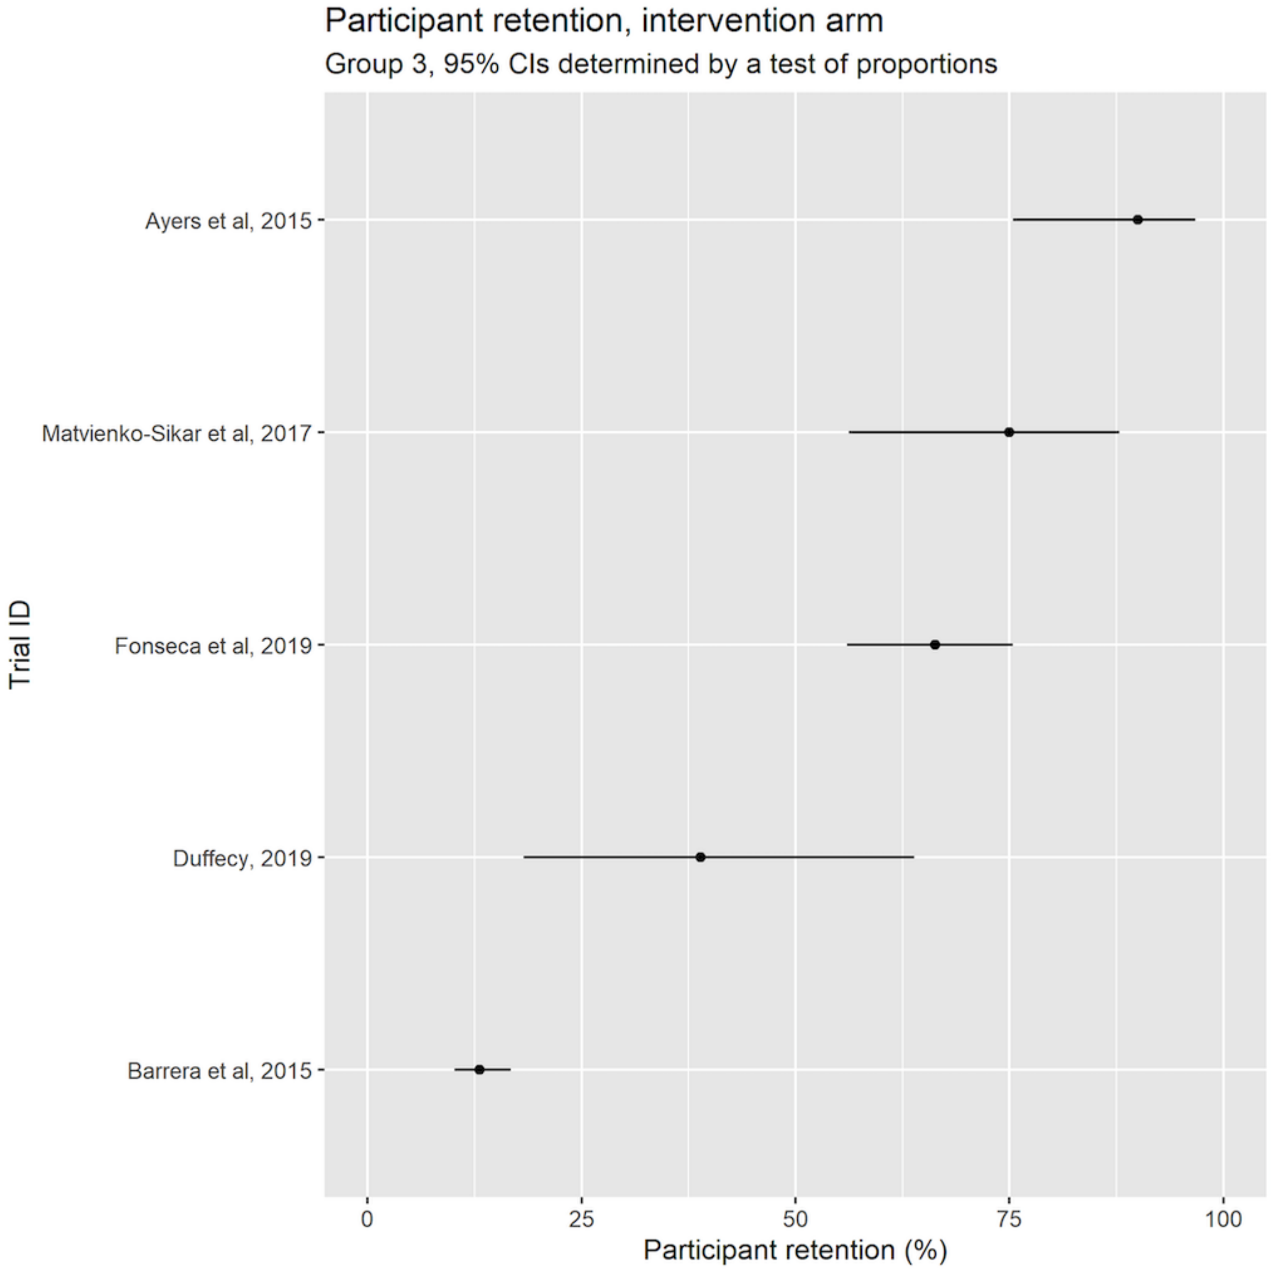

Participate: Active Engagement

Participation was operationally defined as the completion of intervention activities; that is, *active engagement* with the intervention material. Follow-up prompts to encourage participation varied across studies; however, there were mostly weekly reminders such as SMS text messages, emails, and phone calls. A broad spectrum of metrics was used to report ongoing participation in each study, including module views, module and home practice completions, engagement with web-based components, use of the app (frequency of log-ins) and other relevant services (eg, antenatal classes), number and duration of support calls, and web-based diary entries. The heterogeneous nature of recording these activities is appropriate for the types of intervention strategies but limits our ability to consistently report and compare across studies.

Enact: Sustained Practice (Leading to Long-term Well-being Effects)

The limited follow-up period restricted our ability to report against measures indicating that participants applied and practiced learning skills [24]. Immediate postintervention follow-up was reported by all studies through a combination of self-report assessments, interviews, program accessibility, acceptability, and satisfaction; however, this did not necessarily include commentary on putting skills into practice. Approximately 31% (5/16) of studies undertook postintervention interviews to unpack outcomes such as usefulness, satisfaction, experience, and engagement. These interviews contributed more robust information to the user experience and provided some insight into the reasons for participation or enactment (or lack thereof) but not necessarily on the enactment itself (ie, use of the intervention skills). For example, internet-based What Am I Worried About (Ashford, 2018) was experienced as not user-friendly enough, too long, and not smartphone-friendly. Parts of the content were experienced as not always relevant or appropriate. The participants felt that the program could be improved by having it in a smartphone app format and by making the content more concise and inclusive of different parenting styles. Guo et al [53] had the highest participation rate and longest follow-up period (12 months post partum), and participants rated the program as highly useful.

Logic Model Development

Through the analysis and reporting of each study, we recorded the types of quantitative and qualitative measures found in the selected studies that could be used to measure engagement. This enabled us to systematically construct a logic model based on our understanding of how interventions are expected to work. This was particularly pertinent for this systematic review as we did not perform a meta-analysis. As indicated, we grouped variables related to the CAPE framework; the logic model includes a range of metrics that could be systematically reported when synthesizing engagement data to visually interpret the underlying theory of change.

The logic model (Figure 1) contains 6 columns detailing the intended pathway from inputs (engagement strategies) to long-term outcomes or impacts. This approach takes a long-standing view of interventions to achieve their intended consequences. To build this model, we incorporated the types of measures undertaken in each study in this systematic review, as well as a broader range of CAPE measures found in the wider literature. The logic model indicates the point in the pathway at which the data should be collected. Mechanisms of action are factors that may facilitate engagement using a strength-based approach.

As part of this systematic review, we aimed to develop a guide for future data collection to enable consistent engagement reporting in web-based (and offline) interventions. Table 4 outlines a range of metrics that could be consistently applied in future data collection and reporting to enhance understanding of engagement and enable comparative intervention assessments.

Table 4. Proposed reportable metrics: engagement.

CAPE[a] model of engagement	Measures	Definitions
Connect	Exposure and enrollment (rates should be reported for each trial arm separately)	• Defined target population (ideally with population size if available) • Methods of recruitment and size or proportion of the population exposed to each recruitment method • Enrollment rate: proportion of participants who start the intervention relative to those who are exposed to the intervention and those who provide consent for the study • Connection rate: proportion of recruited participants electing to enroll relative to those who are eligible
Attend	Intervention retention	• Proportion of participants who complete the intervention relative to those who enroll in the intervention • Mean, SD, and range of the number of modules completed
Participate	Intervention activity	• Active engagement (depending on the nature of the intervention; this may be module completions, exercise completions, proportion of videos watched, and response to emails) • Log-ins (frequency and duration) • Time spent logged into the website or app • Use of recommended resources (eg, downloads of additional resources and clicks to suggested websites)
Enact	Sustained practice	• Follow-up reports (eg, questionnaires about the use and application of learned strategies or skills taught from the DMHI[b]) • Postintervention interviews about using skills in everyday life • Sustained behavior change

[a] CAPE: Connect, Attend, Participate, and Enact.

[b] DMHI: digital mental health intervention.

Discussion

Principal Findings

In this systematic review, we categorized the selected studies according to study type and assessed their individual and pooled characteristics. We applied the CAPE framework [25] to all studies so that we could collectively assess and compare *connection*, *attendance*, *participation*, and *enactment*. Reporting of connection and attendance measures was fairly standardized across studies and frequently reported using a CONSORT diagram; therefore, the number of people who were eligible and expressed interest in participating, proportion of participants recruited and entered in the study, and proportion of participants who were randomized and followed up, including *treatment not started* and attrition rates, was clear. Approximately 75% (12/16) of studies, provided a CONSORT participant flow diagram (indicating aspects of attendance); however, the reporting categories and terminology varied between diagrams. In general, the least frequently reported domain was enactment (ie, real-world use of intervention skills), with only 38% (6/16) of studies clearly recording and reporting results such as satisfaction, usefulness, helpfulness, and perceived benefits of the skills learned in the intervention.

Some studies reported strategies to increase *connection*. For example, Ashford et al [13] included specific details on recruitment methods, such as social media platforms, parenthood websites, and the use of posters and flyers in clinical settings. However, other studies reported minimal details of recruitment methods (eg, Guo et al [53]). No study reported information on the background target population size; that is, the total potential pool of eligible participants. This might be a useful future metric to determine and report as an indicator of the total target population reach and the effective strategies that engage them.

As previously defined, *attendance* is a measure of DMHI completion through modules or similar exercises. As this was not definitively reported, for *attendance*, we calculated a proxy for intervention *attendance* as study attendance, operationally defined as intervention retention and continuous presence, both in the intervention and control arms (RCTs). Guo et al [53] had the highest participant retention and the lowest lost to follow-up participant rate in both the intervention and control groups; the intervention group showed significant improvement in depressive and anxiety behaviors. The women in this study were at a higher risk of presenting with psychological distress at baseline; although they fit our inclusion criteria, they may have had increased motivation to attend. Duffecy et al [39] undertook a user-centered design process before the pilot trial to engage women from the target population in the intervention-building process and consult on aspects such as topics, sites, and usability of potential applications. In theory, this should support *attendance* by reducing attrition and improving retention; however, dropout from baseline assessments to 6 weeks post partum was high (63%) [39]. We recommend that future studies report both *intervention* attendance and *study* attendance as they are distinct metrics.

A key concern in web-based interventions is the lack of *participation* [18]. Logs of access and use of web-based interventions can give researchers insight into people's behavior. As Piotrowska et al [25] suggest, "The CAPE model proposes that despite the immense importance of connecting with parents and encouraging their attendance, it is active participation that has the greatest impact on parenting." Digital interventions provide tools for learning more about participant engagement and how this relates to retention and intervention outcomes, as well as how they might be improved through the use of different ongoing engagement strategies. Crouper et al [18] quantified participant engagement using data such as dosage, exposure, or adherence. In this systematic review, few studies reported clear metrics for participation, with the exceptions of Duffecy et al [39] and Barrera et al [36]. Other suggested metrics for future research include downloading suggested resources or websites, watching suggested videos, completing quizzes and homework, or other metrics that indicate that the participant is continuously engaging with the intervention. Additional features that have potential but continue to be underexplored and underused include chatbots, games, storytelling, rewards, avatars, and personalization [42]. These features could be developed to improve participation in interventions, general app use, and studies.

Enactment is difficult to define but should be represented by measures indicating that participants put what they learned from the program into practice [24]. The limited follow-up of these studies restricted our ability to report these criteria. Only one study, Guo et al [53], followed up for any length of time, and only 31% (5/16) of studies conducted exit or follow-up interviews [13,33,35-37]. These interviews contributed more robust information on the user experience. Studies assessing skill development and use underscore the potential pathways in self-guided internet therapy, such as cognitive behavioral therapy, as mechanisms of positive clinical change [43,44]. Although these studies target clinical groups, they contribute to reinforcing the need to capture behavioral skill adaptations beyond the duration of the intervention.

Understanding the barriers to and enablers of real-world utility and practice is crucial if app developers want pragmatic uptake and efficacy of interventions. Sufficient resourcing may be a factor in longitudinal follow-up; however, to leverage the impact and cost-effectiveness of interventions, studies should factor longer-term assessments in the design process from conceptualization. Nevertheless, easier and low-cost measures of enactment are possible and suggested for future research, including questionnaires on the frequency of using skills taught during the intervention.

Interpreting Results Using a Logic Model

As part of this review, we developed a logic model to facilitate the process of gathering and integrating studies of complex interventions to better inform our interpretations of cumulative results. The logic model included synthesized data capture and engagement methods used in each study. Theoretically, logic models need moderating or mediating factors to understand how the pathway develops. In these studies, there was a common strength-based approach, such as skill development, confidence, satisfaction, and self-efficacy. Overall, the heterogeneous nature of the data collection meant that we were unable to undertake a meta-analysis; however, the range of methods and types of data collection is useful in guiding future web-based interventions targeting this population group and helping decision-makers understand the rationale for how interventions are expected to work and what enablers keep participants engaged to ultimately achieve the intended outcomes.

There is a need for a greater understanding of the individual-level, real-world factors affecting engagement in home and minimal contact practice interventions to ascertain how participants experience interventions and how this relates to their outcomes [19]. Exit and follow-up interviews can provide a deeper understanding of participants' experiences to strengthen real-life sustained engagement in that modality. Experience of an intervention needs to be user-friendly, accessible, and positive, which should be considered in promoting material that is most effective and helpful for users to engage from the outset.

Limitations of This Systematic Review

As the studies in this review were diverse in terms of study design, therapeutic intervention approach and delivery, length of follow-up, and outcome measures, we summarized the engagement data using the CAPE framework but were unable to perform a meta-analysis of the data. Attrition rates were high in many studies, and the number of participants was small, particularly in some pilot studies. We were unable to report this in terms of increasing our understanding of sustained practice as there was limited follow-up in most studies. There are inconsistent reports and terminology regarding engagement behavior. Inconsistencies in language between studies and interchangeability of terms, for example, attrition, withdrawal, dropout, and loss to follow-up, make direct comparison and systematic analysis challenging. Another potential limitation of this review is the lack of inclusion of studies in languages other than English. In addition, the protracted nature of systematic reviews means that the original search was concluded in 2020 and was affected by delays because of the COVID-19 pandemic. Since then, additional studies may have been published and not included in this review but would not necessarily affect our general conclusions or implications for using the logic model or reporting matrix.

Strengths and Future Work

The ability to leverage several frameworks enhanced this systematic review. The SWiM guidelines, part of the Cochrane methods, directed our synthesis and reporting. In addition, the CAPE framework provided an evidence-based approach to reporting on intervention engagement; using this framework, we were able to propose clear metrics for future reporting. It is recommended that future research provide engagement analytics to more clearly delineate between study and intervention compliance, particularly longer-term enactment or sustained practice to reflect pragmatic efficacy. The research team has a strong focus on research translation; therefore, the incorporation of a logic model provides a clear pathway for decision-makers, such as policy makers and commissioners, to interpret and guide the key constructs and evaluation metrics in future digital interventions in this field of research.

There is substantial evidence that psychological programs delivered on the web can be effective in treating and preventing mental health problems; however, the uptake of these programs can be suboptimal, and there remains a lack of evidence on how to increase engagement with evidence-based programs [45]. Poor adherence is a common feature of web-based mental health programs, which affects intervention outcomes [45] and limits real-world efficacy. Eisenstadt et al [42] discussed in their recent systematic review that adherence and retention continue to be challenges to the quality of research, with little or no information about reasons for dropouts given across studies. Further research is needed to unpack the key constructs of experience, including microlevel reporting and qualitative, phenomenological investigation via one-to-one postprogram interviews. Future reporting of DMHI using the CAPE framework could be used to ascertain the cost-benefit of an intervention; that is, if the conversion, recruitment, retention, and participation rates are high, the intervention is likely to be more cost-effective. However, this must be considered alongside the efficacy of the intervention and real-world application. The motivation for engaging in research studies is very different from real-world engagement experiences.

Advances in technology, particularly the internet, have proven to be an effective tool for building individual skills as it is inexpensive and accessible, both geographically and temporally. Despite promising results, internet interventions are still not widely disseminated or well-integrated into health services; successfully doing so will, in part, depend on engagement. As mental health apps have proliferated, choosing among them has become increasingly challenging for not only patients but also clinicians [46]. To address this, we need to understand the barriers and enablers for the delivery and sustainability of internet interventions in practice [17], as well as how we can engage not only participants but also health practitioners to support and disseminate effective interventions. This increased understanding will enable appropriate investment, optimization, and uptake of targeted well-being programs, such as those developed for perinatal women, with the ultimate aim of preventing poor mental health among women and their children.

Conclusions

To invest in accessible, long-term, sustainable health solutions, researchers, policy makers, and clinicians must identify optimal interventions that can be targeted to help specific risk groups or in specific contexts. Advances in technology, particularly the internet, have proven to be an effective tool for building individual skills as it is inexpensive and widely accessible. Pregnancy and the postnatal period can be times of increased psychological distress; therefore, it is an optimal time to intervene with strength-based tools to build affirmative self-efficacy. Although several studies in this field demonstrate efficacy, few robustly explore the construct of engagement, and in particular, there is limited evidence of the long-term enactment of the strategies learned. Our results indicate a disparity in the reporting of short- and long-term participant engagement behaviors, and we recommend the adoption of standardized metrics for reporting DMHI engagement in both research and real-world settings. This systematic review provides a framework for understanding the pathways for enhancing the mental well-being of mothers and their infants. With the world experiencing an endemic escalation in poor mental health across the life course, both in low- and high-income countries [55], it is imperative that we create practical, evidence-based, cost-effective, and scalable solutions to protect current and future generations.

Abstract

Background: Cancer screening provision in resource-constrained settings tends to be opportunistic, and uptake tends to be low, leading to delayed presentation and treatment and poor survival.

Objective: The aim of this study was to identify, review, map, and summarize findings from different types of literature reviews on the use of mobile health (mHealth) technologies to improve the uptake of cancer screening.

Methods: The review methodology was guided by the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews). Ovid MEDLINE, PyscINFO, and Embase were searched from inception to May 2021. The eligible criteria included reviews that focused on studies of interventions that used mobile phone devices to promote and deliver cancer screening and described the effectiveness or implementation of mHealth intervention outcomes. Key data fields such as study aims, types of cancer, mHealth formats, and outcomes were extracted, and the data were analyzed to address the objective of the review.

Results: Our initial search identified 1981 titles, of which 12 (0.61%) reviews met the inclusion criteria (systematic reviews: n=6, 50%; scoping reviews: n=4, 33%; rapid reviews: n=1, 8%; narrative reviews: n=1, 8%). Most (57/67, 85%) of the interventions targeted breast and cervical cancer awareness and screening uptake. The most commonly used mHealth technologies for increasing cancer screening uptake were SMS text messages and telephone calls. Overall, mHealth interventions increased knowledge about screening and had high acceptance among participants. The likelihood of achieving improved uptake-related outcomes increased when interventions used >1 mode of communication (telephone reminders, physical invitation letters, and educational pamphlets) together with mHealth.

Conclusions: mHealth interventions increase cancer screening uptake, although multiple modes used in combination seem to be more effective.

Introduction

Background

Globally, cancer is the second leading cause of death; it accounted for approximately 9.6 million deaths in 2018 [1]. Cancer incidence and mortality are predicted to increase to 30.2 million cases and 16.3 million deaths by 2040, respectively, because of aging populations and the adoption of unhealthy lifestyles [2]. Delay between symptom onset and treatment leads to poorer cancer survival [3]. Screening increases the chance of early detection and treatment and, ultimately, survival. In many high-income countries, population-based cancer screening is available for four common cancers and has contributed to reduced breast cancer [4], cervical cancer [5], prostate cancer [6], and colorectal cancer [7] mortality. However, cancer screening in the majority of low- and middle-income countries (LMICs) is opportunistic, and uptake is low compared with cancer screening in high-income countries, leading to delayed presentation, treatment, and survival [8]; for example, the uptake of mammogram screening was 12% to 31% in Brazil [9] and 7% to 25% in Malaysia [10] compared with 66% in Germany [11] and 75% in Spain [12]. Low uptake of cancer screening might indicate poor awareness and knowledge of cancer and cancer screening among the public; for example, Asian Pacific populations with the lowest uptake of colorectal cancer screening, such as India, Malaysia, Indonesia, Pakistan, and Brunei, had correspondingly low levels of awareness and knowledge of colorectal cancer symptoms, risk factors, and screening tests [13]. Poor knowledge about, and negative perceptions toward, mammogram screening are major barriers to mammogram screening uptake in Malaysia [10].

Digital health care, that is, the use of digital technologies for health, is now commonly used in public health care as well as primary health care [14]. According to the World Health Organization Global Observatory for eHealth, *mobile health* (mHealth) is defined as “medical and public health practice supported by the use of mobile devices” such as mobile phones, smartphones, and tablet computers [15]. Worldwide, there are approximately 5.3 billion unique mobile phone users, representing 67.1% of the total population, and smartphones account for approximately 75% of the mobile phones in use [16]. The high penetration rate of mobile phones allows timely data collection as well as transmission and analysis of the data. Thus, mHealth holds great potential for improving health outcomes because of its mobility, instantaneous access, and ease of use. Some of the common mHealth apps offer patient education and behavior change communication, data collection and reporting, population health registries and vital event tracking, and electronic health records, as well as provider training and education [17]. mHealth interventions have a positive impact on clinical outcomes, adherence to treatment and care, health behavior changes, disease management, and primary care attendance rates with regard to various diseases [18]. mHealth has also been used in cancer self-care and self-management among cancer survivors to improve sleep and quality of life; reduce fatigue, stress, and pain; and promote health behaviors such as weight loss [19-22]. The role of mHealth in promoting cancer screening has been explored in different types of reviews. However, it is unknown whether similar findings are observed across the reviews.

Objectives

This scoping review aimed to map and summarize findings from systematic, scoping, narrative, and rapid reviews on the use of mHealth in cancer screening, as well as other screening-related outcomes such as attitudes toward screening and knowledge and awareness of screening. We also included implementation considerations for successful mHealth interventions in improving cancer screening uptake and screening-related outcomes.

Methods

Overview

This scoping review of reviews was conducted based on the framework of Arksey and O’Malley [23] and using the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [24]. The protocol of this review has not been preregistered. As the use of mHealth in relation to cancer screening is a relatively nascent field of study, a scoping review is useful in mapping the published literature comprehensively and systematically. The review was guided by the following 5-step framework: (1) identifying the research question; (2) identifying relevant studies; (3) study selection; (4) charting the data; and (5) collating, summarizing, and reporting the results.

Search Strategy

We first searched Ovid MEDLINE, PyscINFO, and Embase for relevant literature on February 1, 2021, using two categories of key terms: mHealth and early detection of cancer. We then refined the search on May 17, 2021. The key terms were based on Medical Subject Headings indexing as well as free-text terms. We combined key terms from the same category with OR and between categories with AND. The search strategy was developed in Ovid MEDLINE (Multimedia Appendix 1) and adapted for the other databases. We also hand searched the reference lists of selected reviews for relevant reviews. All searches were exported into EndNote (Clarivate), and duplicates were removed.

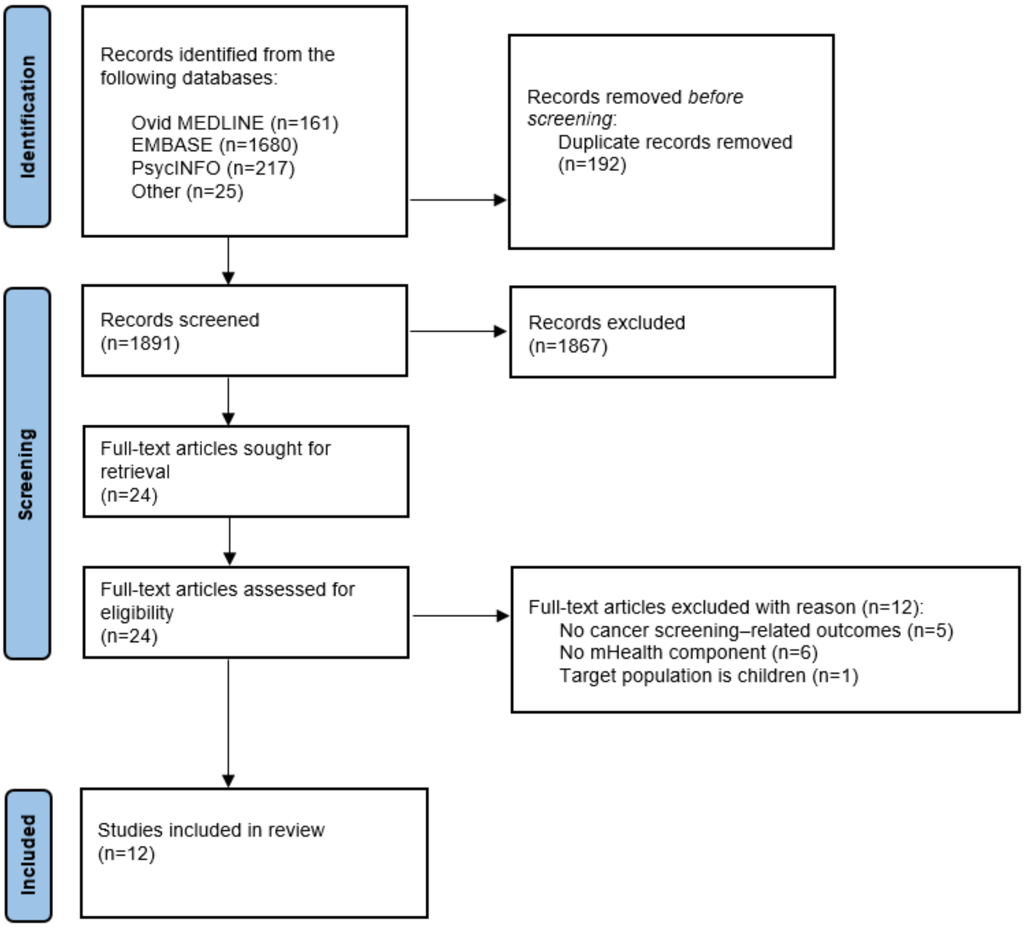
Inclusion Criteria

Papers were included if they satisfied all of the following criteria: (1) a review of any type, (2) the reviewed interventions related to cancer screening (for any cancer type) that were conducted on mobile devices such as mobile phones and tablet computers, (3) described the effectiveness and implementation of mHealth interventions on outcomes related to cancer screening, (4) included adults aged ≥18 years from the general population, and (5) published in English in peer-reviewed journals from inception up to May 2021. We excluded reviews that did not specify the use of mobile technologies but instead reported modes of delivery such as web-based and computer-delivered programs and videos.

Selection of Reviews

We selected the relevant reviews using a 3-stage process: (1) MMT and WMKH conducted the initial screening of titles and abstracts to determine eligibility for inclusion; (2) WMKH retrieved full texts, which were screened by DS, MMT, and WMKH independently for inclusion, with discrepancies resolved through discussion with DS, MMT, and WMKH; and (3) MMT and WMKH extracted relevant data. The screening process is provided in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.



Data Extraction and Charting

The following data were extracted by MMT and WMKH from each selected review into an Excel (Microsoft Corporation) spreadsheet:

- Review identifiers (author, year, country, type of review, number of studies, time range, intervention duration, and follow-up duration)
- Study aim
- Types of cancer mentioned in the relevant studies in the review
- Types of mHealth mentioned in the relevant studies in the review
- Details of intervention procedures
- Outcome measures (awareness, knowledge, or attitude; screening uptake; and implementation-related outcomes)
- Key stakeholders in delivering the mHealth intervention, if any

If the aforementioned data were not reported in the selected reviews, we referred to the individual studies included in the selected reviews. For reviews that included studies that focused on mHealth and studies that did not, we only extracted information specifically reported on the studies that included mHealth. Information related to the quality of the reviews was not assessed.

Results

Literature Search

Our initial search identified 2083 citations, resulting in 1981 (95.1%) unique citations after removal of duplicates (Figure 1). The titles and abstracts were assessed based on the inclusion criteria, and of the 1981 unique citations, 24 (1.21%) were included for full-text screening. Of these 24 reviews, 12 (50%) were excluded after the full-text screen: 5 (42%) did not include cancer screening-related outcomes, 6 (50%) did not include mHealth components, and 1 (8%) included children as their target population. Hence, of the 24 reviews included for full-text screening, 12 (50%) were included in this scoping review. Table 1 summarizes the characteristics of the included reviews.

Table 1. Characteristics of included reviews.

Study	Type of review	Aim	Time frame of search strategy	Total number of studies; number of relevant studies[a] by cancer type	Type of mHealth[b] in relevant studies[a]	Key stakeholders delivering mHealth interventions
Bhochhibhoya et al [25], 2020	Scoping review	To identify studies that examined mHealth programs that focused on increasing cervical cancer screening among women to determine if these interventions improved adherence to screening and what factors (barriers and facilitators) were most influential among participants	January 1, 2009, to September, 28, 2019	12; cervical cancer (n=12, 3 of which were qualitative studies)	• Telephone appointment (n=1) • Telephone reminder with tailored counseling versus telephone reminder with print materials (n=1) • SMS text message reminders (n=3) • 15 behavior change messages with transportation e-voucher versus SMS text messages of location and hours of the closest screening clinic (n=1) • Automated SMS text messages or telephone call reminders (n=1) • Automated SMS text messages versus telephone call reminders+manual telephone call+face-to-face interview (n=1) • 3 sequential SMS text message reminders, followed by 3 telephone call attempts (n=1)	• Telephone appointment by midwife (n=1) • Telephone counseling and reminders by research staff (n=1) • Invitation telephone call by clinical secretaries (n=1) • Telephone caller unspecified (n=1)
Uy et al [26], 2017	Systematic review	To assess the effect of SMS text messaging interventions on increasing patient adherence to screening for breast, cervical, colorectal, and lung cancers	January 2000 to January 2017	9; breast (n=5), cervical (n=1), and colorectal (n=3) cancers	• SMS text message reminder (n=5) • SMS text message reminder plus letter (n=4)	• None
Zhang et al [27], 2020	Systematic review	To qualitatively synthesize published articles reporting the impact of mHealth on cervical cancer screening–related health behaviors	Up to October 10, 2019	8 (1 cross-sectional study); cervical cancer (n=7)	• Invitation letter with pamphlet, followed by telephone reminder (n=1) • Educational SMS text messages (n=2) • Educational SMS text message versus SMS text message reminder (n=1) • Educational SMS text messages with transportation e-voucher versus SMS text messages of location and hours of the closest screening clinic (n=1) • Motivational interview over the telephone (n=1) • Training through SMS text message, electronic posters, infographics, podcasts, and video tutorial (n=1)	• Motivational interview through telephone call by nurses (n=1) • Telephone caller unspecified (n=1)

Study	Type of review	Aim	Time frame of search strategy	Total number of studies; number of relevant studies[a] by cancer type	Type of mHealth[b] in relevant studies[a]	Key stakeholders delivering mHealth interventions
Halake and Ogoncho [28], 2017	Scoping review	To establish the extent and nature of the published and gray literature on the use of mHealth-based technologies for cancer prevention, detection, and management in LMICs[c]	1990 to 2014	15; breast cancer (n=2)	• SMS text message invitation and cancer screening information (n=1) • Smartphone app to facilitate BSEd (n=1)	• Not described
Choi et al [29], 2018	Systematic review	To investigate recent research trends related to the use of mobile technology in the prevention and management of skin cancer, focusing on how such technology is evaluated and what impact it has in each phase across the cancer continuum	January 1, 2007, to December 31, 2017	18; skin cancer (n=1)	• Educational SMS text message about skin self-examination (n=1)	• Not described
Houghton et al [30], 2019	Systematic review	To determine how mobile apps are being used for breast cancer prevention among women across the cancer control continuum	Up to February 7, 2019	69; breast cancer (n=4)	• Mammopad, a decision aid mobile app on iPad Mini (n=1) • Mobile app to assist navigator (n=1) • mMammogram mobile app for SMS text message (n=1) • Mobile app for BSE (n=1)	• Mobile apps paired with community health navigators (n=2)
Plackett et al [31], 2020	Scoping review	To map the evidence for social media interventions to improve cancer screening and early diagnosis, including behavior change, and how the interventions facilitate behavior change	2004 to June 2019	23; breast (n=4) and cervical (n=1) cancers	• Facebook (n=3) • Snapchat (n=1)	• Not described
Musa et al [32], 2017	Systematic review and meta-analysis	To review the evidence of the effectiveness of provider recommendations for cervical cancer screening on screening rates in women at risk for cervical cancer	Up to August 2016	28; cervical cancer (n=5)	• Telephone counseling (n=1) • SMS text message or telephone reminder (n=1) • Email, telephone, or multimodal (letter+email+telephone) screening reminder and invitation and education flyer (n=1) • Telephone reminder (n=1) • Invitation letter and information pamphlet, followed by telephone reminder with counseling (n=1)	• Telephone caller unspecified (n=3) • Telephone counseling by health educator (n=1) • Telemarketing company (n=1)

Study	Type of review	Aim	Time frame of search strategy	Total number of studies; number of relevant studies[a] by cancer type	Type of mHealth[b] in relevant studies[a]	Key stakeholders delivering mHealth interventions

Peiris et al [36], 2014	Systematic review	To critically appraise the role of mHealth in improving health care quality for NCDs[f] in LMICs	Up to May 2014	48; breast cancer (n=1)	- SMS text message reminder	- Not described

[a] Relevant studies are studies that met the inclusion criteria for this review; for example, some reviews included diseases other than cancer. We only reported results from the studies evaluating cancer-related interventions.

[b] mHealth: mobile health.

[c] LMICs: low- and middle-income countries.

[d] BSE: breast self-examination.

[e] GP: general practitioner.

[f] NCD: noncommunicable disease.

Characteristics of Reviews

The included reviews (n=12) were published between 2012 and 2020 (Table 1). Of the 12 reviews, 6 (50%) were systematic reviews [26,27,29,30,32,36], of which 1 (17%) also included a meta-analysis [32]; 4 (33%) were scoping reviews [25,28,31,34]; 1 (8%) was a rapid review [33]; and 1 (8%) was a narrative review [35]. The 12 reviews reported different outcomes of the studies that were relevant to this review of reviews (Table 2): 5 (42%) reported solely the effectiveness of mHealth interventions on cancer screening [26,29,32-34]; 4 (33%) reported outcomes in relation to cancer screening, change in cancer knowledge, and attitudes to screening [25,27,30,31]; 2 (17%) reported outcomes in relation to breast self-examination (BSE) practice [35,36]; and 1 reported outcomes in relation to BSE and cancer screening [28]. Most (7/12, 58%) of the reviews included studies that were conducted mainly in high-income Western countries [25,26,29-33], whereas 42% (5/12) focused on LMICs [27,28,34-36], of which 20% (1/5) focused solely on sub-Saharan Africa [34]. In total, 33% (4/12) of the reviews focused on cervical cancer [25,27,32,34]; 8% (1/12) focused on skin cancer [29]; 8% (1/12) focused on breast cancer [30]; 8% (1/12) examined breast, cervical, lung, and colorectal cancers [26]; 25% (3/12) included any type of cancer [28,31,33]; and 2 reviews focused on disease prevention in general [35,36]. In terms of interventions, 42% (5/12) of the reviews included interventions of various types of mHealth technologies [25,27-29,36], 2 (33%) focused solely on SMS text messages [26,35], 1 (17%) focused on social media interventions [31], 1 (17%) was specifically about mobile apps [30], and 25% (3/12) included any type of communication (mHealth, face-to-face, and other media) [32-34].

Table 2. Summary of screening-related outcomes extracted from each review.

Study	Outcomes		
	Screening outcomes	Screening awareness-, knowledge-, and attitude-related outcomes	Implementation-related outcomes and measures
Bhochhibhoya et al [25], 2020	• Screening uptake: n=5/6[a] (9.1%-17.9% increase between intervention group versus control group; 9.3% increase after the intervention compared with before)[b] • Screening follow-up adherence: n=0/1 • Effective methods: stepwise approach (automated telephone calls and SMS text messages, followed by manual telephone call and face-to-face interview), SMS text messages only, telephone call only, telephone appointment by midwives, telephone reminders combined with other methods such as tailored counseling, and SMS text message with transportation e-voucher	• Knowledge improvement: n=2/2 • Attitude about screening: n=1/2 • Perceived behavior control: n=0/1 • Perceived barriers about screening: n=0/1 • Belief about screening: n=1/1 • Screening intention: n=0/2 • Effective methods: health-specific and spiritually based SMS text messages and personally tailored texts with statistical facts	• Advantages: convenient, time effective, ease of use, and able to receive notification • Concerns: confidentiality of SMS text messages, loss of the mobile phones, clarity of the language used, and receiving negative results through SMS text message • Barriers: inconvenient for older participants, lack of texting proficiency, difficulty in texting, and apprehension that SMS text messages might not be clearly understood • Enabling factors: contact preferences, cell phone ownership, and portability of same number • Enhancing factors: message content (reminder and informative) and short and simple messaging formats
Uy et al [26], 2017	• Screening uptake: n=5/9 (1.2%-9.9% absolute increase) • Effective methods: SMS text message reminder+letter and single SMS text message reminder	—[c]	—
Zhang et al [27], 2020	• Screening uptake: n=3/5 (12.9%-50.9% increase) • Screening follow-up: n=1/1 (91.8%-93.5%; OR[d] 1.37-1.40) • Effective methods: SMS text message with transportation e-voucher, invitation letter with telephone reminder, reminders sent through letter, registered letter, SMS text message or telephone call, and telephone reminders or educational telephone call	• Knowledge improvement: n=1/2 • Perceived benefits of Pap[e] test: n=1/1 • Reduced barriers to undergoing Pap smear: n=1/1 • Attitude about screening: n=0/1 • Effective methods: a combination of SMS text message, electronic posters, infographics, podcasts, and video tutorials	• Interest in receiving screening test results through SMS text message: n=0/1 • Interest in receiving screening test results using nonprivate telephone: n=1/1 (OR 0.31, 95% CI 0.18-0.51) • Interest in receiving appointment reminders through SMS text message: n=1/1 (OR 14.19, 95% CI 1.72-117.13) • Interest in receiving appointment reminders using nonprivate telephone: n=0/1
Halake and Ogoncho [28], 2017	• Screening uptake: n=1/1 (30.7% and 31.6% increase) • BSE[f] practice: n=1/1 • Effective method: BSE smartphone app	—	—
Choi et al [29], 2018	• Screening uptake: n=1/1 (27% absolute increase in skin self-examination) • Effective method: educational SMS text messages with reminders	—	—

Study	Outcomes		
	Screening outcomes	Screening awareness-, knowledge-, and attitude-related outcomes	Implementation-related outcomes and measures
Houghton et al [30], 2019	• Screening uptake: n=3/3 • Effective methods: community health workers (trained or untrained in patient navigation) equipped with smartphone app plus standard risk counselling and mMammogram (SMS text messages plus health navigator)	• Knowledge improvement: n=2/2 (33% increase) • Reduced decisional conflict: n=1/1 • Self-efficacy: n=1/1 • Screening intention: n=0/1 • Screening readiness: n=1/1 • Effective methods: smartphone app plus standard risk counseling, mMammogram (SMS text messages plus health navigator), and smartphone app decision aid (Mammopad)	• Intervention satisfaction (mMammogram): n=1/1 • Effectiveness satisfaction (mMammogram): n=1/1
Plackett et al [31], 2020	• Screening uptake: n=1/1 (12.9% increase) • Effective method: breast cancer screening service Facebook page	• Knowledge improvement: n=2/2 • Screening intention: n=1/1 (82% increase) • Effective methods: Facebook or face-to-face discussions for 2 weeks after 50-minute classroom cervical cancer prevention education lecture (female high school students), receiving breast cancer awareness information through Snapchat, and tailored SMS text message mammography campaign on Facebook during Breast Cancer Awareness Month	• Using Facebook is acceptable for delivering breast cancer screening information: n=1/1
Musa et al [32], 2017	• Screening uptake: n=5/6 (7.8%-31.1% absolute increase) • Reduced screening median time: n=1/1 • Effective methods: direct invitation mail+brochure+telephone counseling by health educators; telephone reminder with educational information and multimodal intervention; invitation letter and information pamphlet, followed by telephone reminder with counseling; telephone reminder with educational information; and multimodal intervention	—	—
Duffy et al [33], 2017	• Screening uptake: n=13/16 (5%-45% absolute increase) • n=3/3, SMS text reminder studies; n=11/13, telephone reminder studies	—	—
Lott et al [34], 2020	• Screening uptake: n=2/3 (8.6% difference in screening uptake between control and intervention groups; 51% increase after the intervention) • Effective methods: SMS text message about cervical cancer and context-specific barriers to screening (and SMS text message plus e-voucher for transportation) and enhanced patient-centered counseling with patient follow-up by telephone (with or without escort to cervical cancer screening)	—	—
Déglise et al [35], 2012	• BSE practice: n=1/1 • Effective method: SMS text message reminder to conduct BSE	—	—

Study	Outcomes		
	Screening outcomes	Screening awareness-, knowledge-, and attitude-related outcomes	Implementation-related outcomes and measures
Peiris et al [36], 2014	• BSE practice: n=1/1 • Effective method: SMS text message reminder to conduct BSE	—	—

[a] Number of studies that reported a positive outcome out of the total number of studies that included the particular outcome.

[b] Percentage of change or odds ratios are included if available.

[c] Not available (ie, not reported).

[d] OR: odds ratio.

[e] Pap: Papanicolaou.

[f] BSE: breast self-examination.

Types of mHealth Interventions

SMS text messages were the most commonly used mHealth technology and were used in 46% (31/67) of the interventions. They were mainly delivered as reminders of cancer screening appointments, alone or in combination with telephone reminders, physical invitation letters, and educational pamphlets. Educational SMS text messages, sent as a one-off or in a series over days or weeks, were also widely used. Their contents included information about cancer risk factors, benefits of screening, location and operating hours of screening clinics, spiritually based health messages, and facts about cancer (eg, incidence, mortality, and screening rates). Educational SMS text messages were used alone or in combination with an e-voucher (to subsidize the cost of transportation to and from the screening facility) [37].

Text messages were most commonly sent as SMS text messages. In later studies, they were also sent through IP-based messaging services such as Telegram and Snapchat and mobile apps specifically designed for the interventions. In almost all (10/12, 83%) reviews, the delivery of SMS text messages was one-way, 8% (1/12) of the reviews reported an intervention that included a specifically designed mobile app (mMammogram) that featured personally tailored messages [38], and 8% (1/12) used social media for communication [31].

Telephone calls were used in 40% (27/67) of the interventions mostly as cancer screening invitations and reminders and to arrange screening appointments. Telephone reminders, automated or live, were used alone or with SMS text message reminders, screening invitation letters, and pamphlets. Participants were contacted through telephone to confirm the receipt of a screening invitation letter. Motivational interviews were conducted over the telephone to increase participants' readiness to attend screening [27]. Knowledge about cancer was provided and barriers to screening addressed through telephone counseling [25,33,34].

A few breast cancer mobile apps were specifically designed for interventions. Mammopad, for example, is a decision aid, a tool that helps women to decide to participate in mammogram screening, that ran on the iPad Mini [30]. Another app was designed to assist community health workers (CHWs) in interviewing participants, reporting data, showing a motivational video, and offering a mammogram appointment for women with an abnormal clinical breast examination (CBE). A BSE-facilitating smartphone app included BSE date reminders and a reminder to encourage mother and daughter to practice BSE together [39].

Other mHealth platforms that were less frequently used were emails and social media. Emails were used to deliver screening invitations, reminders, web-based educational flyers, and cancer- and health-related information. Social media platforms such as Facebook and Snapchat were used as intervention modes to provide information about breast and cervical cancers and screening, promote mammogram screening, and schedule breast screening appointments, as well as a platform for discussions about cervical cancer after a lecture [31].

Almost all (11/12, 92%) reviews described mHealth interventions that included 1 or 2 mHealth technologies. There was only 1 intervention that used a combination of >2 types of mHealth technologies: a training in cervical cancer through SMS text message, electronic posters, infographics, podcasts, and video tutorials [40].

Key Stakeholders in mHealth Interventions

Of the 12 reviews, 5 (42%) included telephone call interventions that were delivered by a broad range of personnel [25,27,32-34]. Telephone reminders or telephone calls to make or confirm screening appointments were delivered by bilingual advocates from a community organization, local women recruited from a community charity, research assistants, general practitioner receptionist, volunteers, research nurses, midwives at antenatal health clinics, clinical secretaries, and telemarketers.

Among the important personnel in mHealth interventions were telephone counselors who called the participants to inquire about their screening intention and ascertain whether they had received the invitation letters, provided information about screening, addressed current or potential barriers to screening uptake through motivational interviews and applied a counseling approach to increase motivation for behavior change, or assisted with appointment scheduling. Telephone counseling was delivered by nurses or hospital-based health counselors.

Health navigator services were mentioned in 8% (1/12) of the reviews [30]. Health navigators used mobile apps to facilitate interviews, report data, show motivational videos, and offer screening appointments. Health navigators or CHWs guided participants in navigating cancer screening information, provided transportation and interpretation services, addressed technical problems related to mobile app use, and reminded participants to complete cancer screening.

Cancer Screening Uptake

All (12/12, 100%) reviews included in this review reported mainly improved cancer screening uptake or self-examination practice (for breast or skin cancer; Table 2). The increase in screening between the intervention and control groups (from relevant studies) ranged from 1.2% to 50.9%.

Overall, the reviews concluded that interventions that included >1 communication mode seemed more effective than those that included a single telephone call or SMS text message reminder. A 3-step sequential approach (an automated reminder telephone call and SMS text message, followed by manual telephone calls and face-to-face interviews) conducted at Portuguese primary health care units resulted in 51% of the women in the intervention group attending cervical cancer screening compared with 34% of the women in the control group who received only written invitation letters [25,41]. In another study, women in northern Tanzania who received transportation e-vouchers to cover return transportation to the nearest screening facility as well as a series of 15 behavior change messages delivered through SMS text message were more likely to attend cervical cancer screening (uptake: 18%; OR 4.7, 95% CI 2.9-7.4) compared with those who received only the same SMS text message (uptake: 12.9%; OR 3.0, 95% CI 1.5-6.2) and those who received 3 SMS text messages with the location and hours of the nearest screening clinic (uptake: 4.3%) [27,34,37]. Participants from Iran who received a Health Belief Model–based training in cervical cancer through SMS text messages, electronic posters, infographics, podcasts, and a video tutorial were more likely to complete a Papanicolaou (Pap) test (47.9%) than the participants in the control group (5.8%) [27,40].

A once-a-month SMS text message reminder over 6 months combined with a BSE training through a lecture, video, and demonstration of the technique on a breast model led to a 32% increase in BSE practice [35,36,42]. An Android operating system–based smartphone app that included a BSE date alarm, a reminder to encourage mother and daughter to practice BSE together, a *mother motivation function* that allows the user to call her mother using a notification function to practice BSE together, and educational videos increased the percentage of Korean women practicing BSE from 62.2% to 71.1% [39].

Of the 12 reviews, 1 (8%) included interventions that incorporated navigation to health services [30], which was found to be effective in increasing screening uptake. All (3/3, 100%) of the interventions that included health navigation services were effective in increasing screening uptake. Korean American immigrant women who received a series of 8 to 21 SMS text messages about breast cancer through a specially designed mobile app (mMammogram) and were provided with health navigation services had a significantly higher percentage of completed mammograms after 6 months than women who received printed brochures only (75% vs 30%; $P<.001$) [30,38]. CHWs in Bangladesh who used mobile apps to facilitate CBE, such as showing a motivational video and offering an appointment, detected 3 times more women with abnormal CBEs than CHWs without smartphone support (3.1% without navigation training and 3.2% with navigation training vs 1% without smartphone) [30,43]. CHWs who used mobile apps and were trained in navigation had the highest percentage of participants with an abnormal CBE who attended further clinical assessment compared with those who used mobile apps only or without smartphone support. In a study in the United States, participants who failed to complete a fecal occult blood test were much more likely to complete a second fecal occult blood test than those in usual care if they had been contacted through telephone call by colorectal screening navigators (82.2% vs 37.3% among those who received standard care; $P<.001$) [33,44].

There were a number (46/67, 69%) of studies that used only 1 mode of mHealth communication, and the findings related to screening uptake after the intervention compared with before the intervention were mixed; for example, in an email intervention study, whether an email message was loss-framed (focused on risk), gain-framed (focused on health and well-being improvement), or neutrally framed (provided only facts) had no effect on cervical cancer screening uptake [34,45]. An exception was a study conducted in western Sweden where there was telephone contact through midwives to offer an appointment for a Pap test, which increased the uptake of Pap tests compared with the usual annual invitations without telephone contact (uptake at 3-month follow-up: 13% vs 3.9%; risk ratio 3.37, 95% CI 2.83-4.01) [25,46]. Another exception was the use of Facebook to share breast cancer information and schedule breast screening appointments, which increased breast cancer screening attendance by an average of 12.9% [31,47].

A brief invitation SMS text message was as effective as a detailed informative SMS text message: there was no significant difference in screening uptake between Lebanese women who received an SMS text message mammogram invitation and those who received the same SMS text message and an additional informative SMS text message about the benefits of mammogram screening [28,48].

Screening Awareness, Knowledge, Intention, and Attitude

Of the 12 reviews, 4 (33%) [25,27,30,31] included studies specifically on knowledge, awareness, intention, or attitude in relation to cervical cancer screening (2/4, 50%), breast cancer screening (1/4, 25%), or both (1/4, 25%), and almost all of the individual interventions (7/8, 88%) reported improvements in knowledge, whereas few studies reported an improvement in screening intention (1/4, 25%; Table 2). Interventions that were successful in increasing screening uptake were also successful in increasing knowledge and awareness about screening for both cervical and breast cancer.

The CervixCheck intervention was designed for African American women and consisted of a series of 22 health-specific, spiritually based, cervical cancer–related SMS text messages (eg, on the importance of keeping the body healthy and attending screening) that were sent over 16 days. It resulted in a significant increase in knowledge about cervical cancer and the Pap test (mean difference=0.619; *P*=.001) [25,49]. A 1-week personally tailored SMS text message intervention significantly increased Korean American women's knowledge of cervical cancer screening guidelines (mean difference=0.31-0.71; *P*=.006) [25,50]. Participants who went through the Health Belief Model–based cervical cancer training scored significantly higher in perceived benefits of a Pap test and lower in barriers to obtaining a Pap test, in addition to a higher uptake of Pap tests [27,40]. Female high school students who participated in Facebook or face-to-face discussions for 2 weeks after a 50-minute classroom cervical cancer prevention education lecture that included knowledge about Pap testing increased their knowledge about cervical cancer compared with those in the control group (β=2.942; *P*<.001) [31,51]. Compared with a telephone reminder and invitation intervention, an educational telephone call that provided a brief explanation on cervical cancer, its risks, and colpocytological examination increased knowledge about colpocytological examination but not attitude toward it [27,52].

Korean women who used the mMammogram app and were provided with health navigation services had increased knowledge of breast cancer screening compared with the control group (group difference=mean 16.93, SD 4.77; *P*=.001) [30,38]. Users of Mammopad, a decision aid for mammogram screening, reduced decisional conflict and increased self-efficacy in relation to mammography, although there was no significant change in screening intention [30,53]. Saudi Arabian women who received breast cancer awareness information through Snapchat had better breast cancer awareness and knowledge, including knowledge about breast cancer screening (*P*=.01), than those in the control group who did not receive any awareness information [31,54]. Among women who were surveyed in the tailored SMS text message mammography campaign on Facebook during Breast Cancer Awareness Month, 82% intended to get a mammography in the next year [31,55].

Implementation Outcomes and Measures

Of the 12 reviews, 4 (33%) [25,27,30,31] included studies that examined outcomes related to the implementation of mHealth in cancer screening uptake interventions (Table 2). Of these 4 reviews, 3 (75%) reported a high acceptance of such interventions [25,30,31]. In a 1-week personally tailored SMS text message intervention, 83% of the participants expressed satisfaction with the intervention, and 97% reported that they would recommend the program to their friends [25,50]. In the CervixCheck intervention, 83% of the participants reported being either "satisfied" or "very satisfied," and 85% found the SMS text messages either "useful" or "very useful" [25,49]. The mMammogram intervention participants were satisfied with the intervention (*P*=.003) and agreed that it was effective (*P*<.001) [30,38]. In a tailored SMS text message mammography campaign on Facebook during Breast Cancer Awareness Month, 25% of the women surveyed agreed that they used Facebook to find breast cancer screening information, and 43% agreed with seeing more mammogram information on Facebook [31,55].

Some of the concerns of the participants regarding mHealth interventions included confidentiality of SMS text messages, loss of mobile phones, clarity of the language used, and receiving negative results through SMS text messages. Participants were interested in receiving SMS text message reminders for appointments; however, there was reluctance to receive screening results through SMS text messages in case someone else accessed their mobile phones and saw the results (OR 0.31, 95% CI 0.18-0.51), although they reported no issue with making an appointment.

The barriers to using mHealth in reaching out to people to encourage cancer screening included inconvenience for older participants, lack of texting proficiency, difficulty in texting, and apprehension that SMS text messages might not be clearly understood [56]. Including a reminder and keeping the SMS text messages informative, short, and simple was suggested to increase screening uptake [57].

Discussion

Principal Findings

This scoping review of reviews suggests that mHealth interventions can be effective in increasing cancer screening uptake and practice, as well as improving other screening-related outcomes such as knowledge and awareness about screening. The results are consistent across different types of reviews. The most commonly used mHealth technologies used were SMS text messages and telephone calls. Interventions that included >1 mode of communication, such as telephone calls and SMS text message reminders combined or together with invitation letters, health education, or navigation services, seemed to be more effective than interventions that included only 1 mode of communication. A few (4/12, 33.3%) of the reviews reported implementation measures, and 75% (3/4) suggested that mHealth interventions were well accepted by participants.

The effectiveness of interventions that used >1 mode of communication has been demonstrated in cancer screening uptake in LMICs [58]; for example, in Malaysia, mass media campaigns that used different channels of health promotion successfully increased symptom awareness of breast cancer [59] and colorectal cancer [60].

A very effective intervention was a combination of educational SMS text messages and e-vouchers to subsidize the transportation to attend screening [37], which is especially relevant in rural areas in LMICs. In many LMICs, public transport and e-hailing services are mainly available in cities, and the majority of health care facilities that offer cancer screening are located in town areas; for example, in Malaysia, travel distance to the nearest mammogram screening facility ranged between 2 km and 340 km with a median of 22 (IQR 12-42) km [61]. Longer travel distance to cancer services is associated with lower likelihood of cancer screening uptake [62] and presentation of more advanced stages of breast cancer [63] and colorectal cancer [64]. Interventions that increase knowledge might not translate into higher screening uptake if underlying structural barriers to screening, such as lack of transportation, are not addressed [25,27]. The use of e-vouchers has been described as a form of an "enablement" intervention that reduces “barriers to increase capability or opportunity” [65].

Approximately half (31/67, 46%) of the interventions included in the reviews included SMS text messaging, which uses a cellular network and is preinstalled on every mobile phone, unlike internet-based instant messaging apps. Almost 100% of SMS text messages are read, and 90% of them are read within 30 minutes of receipt compared with emails (approximately 18% are read) [66], which might explain the ineffectiveness of emails in improving cancer screening uptake and related outcomes. Worldwide, IP-based chat apps are gaining popularity: WhatsApp, Facebook Messenger, and WeChat have 2 billion users, 1.3 billion users, and 1.2 billion users, respectively [67]. Chat apps, especially those with high open rates, such as SMS text messaging [68], enable more efficient communication by allowing users to send longer messages; share pictures, videos, or audio messages; and chat in real time. However, because SMS text messaging is operator-based, it is more useful in rural areas where there is poor mobile internet coverage. In addition, SMS text messaging is simple to use and does not require additional apps, which might be more user friendly for those who are less tech savvy; for example, older adults.

In addition to SMS text messaging and chat apps, social networking sites, with their large numbers of users, hold great potential in mHealth interventions. As of July 2021, popular social networking sites such as Facebook and Instagram had 2.85 billion users and 1.39 billion users, respectively, and the numbers are increasing rapidly [67]. However, in the only review that examined social media solely [31], the studies included were mostly about low-level engagement (number of impressions, reach, likes, comments, and sharing of tweets and posts), and the review highlighted the lack of studies (1/4, 25%) that examined high-level engagement with social media interventions, such as uptake of screening [31]. This is likely because of the difficulty in linking screening uptake and social media data because social media posts are not designed for such analysis. The fast pace of social media means that social media contents could be outdated quickly or get inundated by other information, which reduces their reach to the target population and long-term sustainability. Running multiple campaigns on multiple social media platforms also means that it is difficult to pinpoint which campaign or platform has the greatest impact on behavior change. In addition, there are age differences in social media use; many individuals in the targeted age groups for cancer screening might not be reached through social media. In a survey of American adults, >80% of those aged 18 to 49 years and 73% of those aged 50 to 64 years used social media sites, whereas only 49% of those aged ≥65 years reported so [69].

mHealth interventions will only work if there is access to mobile phones and mobile internet. Globally, although the penetration of mobile phones and mobile internet is high, there is an unequal access to mobile technology and internet between urban and rural areas and between sexes. All urban areas are covered by a mobile broadband network; however, in some LMICs, 19% of the rural population are covered by only a second generation network, and 17% of the rural population have no mobile coverage at all [70]. The rural-urban gap is especially prominent in LMICs, where urban access to a mobile broadband network is 2.3 times as high as rural access [70]. In LMICs, women’s mobile phone ownership and internet use is significantly lower than that of men’s, and the gap ranges from 50% in South Asia and 20% in sub-Saharan Africa to 12% in the Middle East and North Africa [71].

The gap in mobile phone ownership and internet use has important public health implications. mHealth interventions to increase cancer screening uptake might be less effective in rural areas, where screening uptake is already low [72]. Many (57/67, 85%) of the mHealth interventions targeted cervical and breast cancers, the 2 most common cancers among women. Thus, the rural-urban gap in mobile access means that women from rural areas are at a greater risk of inequitable access to information and interventions on cancer screening.

Given the rapid development of mHealth technologies, there is a need for researchers to incorporate them effectively into interventions. However, the speed of research does not advance at the speed of mobile technology, and researchers have little control over app development [30]. Most smartphone apps address tertiary cancer prevention [30], such as support for patients with cancer in health information management [73], medication adherence [74], weight management [75], and mental health improvement among cancer survivors [76], and there is a lack of smartphone apps for secondary cancer prevention. Many of the apps developed for research are not available for download and have not been widely adopted after the studies were concluded.

mHealth holds great potential to reach out to many people in low-cost settings, and it is also safe in times of the COVID-19 pandemic where social contact has to be minimized. However, it might not be acceptable to pass on personal information through certain mHealth technology; for example, there were participants who mentioned that although it was acceptable to receive SMS text message reminders about their screening appointment, they would not want to be informed about their screening results through SMS text messages. The gap could be filled by CHWs, who could act as the link between mHealth technologies and participants by informing the latter personally through telephone calls of their screening results. A recent review found that CHWs play a critical role, particularly during pandemics, in community engagement [77]. CHWs are usually members from the same communities as the intervention participants and are knowledgeable about the resources available within the communities. They may be able to reach out to vulnerable populations and encourage uptake of cancer screening [78] and mobile technologies [79]. However, despite proven effectiveness of CHWs in cancer screening and early diagnosis interventions [80], there were very few (1/12, 8%) reviews that included interventions that combined mHealth and CHWs.

Limitations

Given the heterogeneity of reporting and differences in the details reported in each review, it was challenging to summarize the evidence from the reviews concisely. In addition, some reviews did not exclusively examine mHealth and cancer screening; they included other types of interventions and preventive measures. Furthermore, unlike in a systematic review, the quality of the selected articles was not assessed.

Future Research and Recommendations

Future interventions should consider combining at least two modes of mHealth communication, for example, SMS text messages and telephone calls, and screening interventions are likely to achieve better attendance when participants receive at least one reminder. In addition, future interventions should consider incorporating instant messaging apps such as WhatsApp, Facebook Messenger, and WeChat, in addition to SMS text messaging, because the number of users is increasing exponentially, and more educational information using videos, audio messages, or graphics could be shared. Social media platforms, especially Facebook, should be incorporated for health promotion, sharing of educational information, and appointment making. When social media platforms are used, there is a need to take into account their popularity and acceptability within the country where the interventions are conducted. In addition, engagement with different social media apps varies among age groups. Other incentives such as transport vouchers may be included when interventions are conducted among those with poor access to screening facilities. Facilitators to improving access to, and engagement with, mHealth among older adults have been described, including support from the government and family, addressing digital problems in deprived areas, and increasing accessibility to mobile phones or tablet computers [81]. CHWs and navigation services may be provided along with mobile technologies to support participants' needs, promote and facilitate the use of mHealth, and pass on information such as screening results.

Conclusions

mHealth interventions have the potential to increase cancer screening uptake and other cancer screening–related outcomes such as knowledge about screening and intention to screen. Combining >1 mode of communication may have a better impact on cancer screening uptake.

Acknowledgments

This work was supported by the UK Research and Innovation Medical Research Council (537084059) and the Newton Fund Impact Scheme 2020-2021 (MIGHT/CEO/NUOF/4-2020 (06) for the study "Improving early detection and diagnosis of breast cancer among multi-ethnic rural communities in Malaysia – the implementation of the community education and navigation programme (CENP)." MD and DS were also supported by the UK Research and Innovation Medical Research Council and Global Challenges Research Fund (MR/S014349/1) during the conduct and write-up of this study.

Authors' Contributions

DS and MMT developed the review protocol, MMT and WMKH conducted the screening independently, DS and MMT wrote the manuscript, and TTS and MD planned the study and led in revising the manuscript. DS, WMKH, DM, and NAT revised the manuscript. All authors provided feedback and helped shape the research, analysis, and manuscript. DS and MMT contributed to the study equally and are joint first authors of the manuscript. TTS and MD contributed equally to the study and are joint last authors of this manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Although most digital twin (DT) applications for health care have emerged in precision medicine, DTs can potentially support the overall health care process. DTs (twinned systems, processes, and products) can be used to optimize flows, improve performance, improve health outcomes, and improve the experiences of patients, doctors, and other stakeholders with minimal risk.

Objective: This paper aims to review applications of DT systems, products, and processes as well as analyze the potential of these applications for improving health care management and the challenges associated with this emerging technology.

Methods: We performed a rapid review of the literature and reported available studies on DTs and their applications in health care management. We searched 5 databases for studies published between January 2002 and January 2022 and included peer-reviewed studies written in English. We excluded studies reporting DT usage to support health care practice (organ transplant, precision medicine, etc). Studies were analyzed based on their contribution toward DT technology to improve user experience in health care from human factors and systems engineering perspectives, accounting for the type of impact (product, process, or performance/system level). Challenges related to the adoption of DTs were also summarized.

Results: The DT-related studies aimed at managing health care systems have been growing over time from 0 studies in 2002 to 17 in 2022, with 7 published in 2021 (N=17 studies). The findings reported on applications categorized by DT type (system: n=8; process: n=5; product: n=4) and their contributions or functions. We identified 4 main functions of DTs in health care management including safety management (n=3), information management (n=2), health management and well-being promotion (n=3), and operational control (n=9). DTs used in health care systems management have the potential to avoid unintended or unexpected harm to people during the provision of health care processes. They also can help identify crisis-related threats to a system and control the impacts. In addition, DTs ensure privacy, security, and real-time information access to all stakeholders. Furthermore, they are beneficial in empowering self-care abilities by enabling health management practices and providing high system efficiency levels by ensuring that health care facilities run smoothly and offer high-quality care to every patient.

Conclusions: The use of DTs for health care systems management is an emerging topic. This can be seen in the limited literature supporting this technology. However, DTs are increasingly being used to ensure patient safety and well-being in an organized system. Thus, further studies aiming to address the challenges of health care systems challenges and improve their performance should investigate the potential of DT technology. In addition, such technologies should embed human factors and ergonomics principles to ensure better design and more successful impact on patient and doctor experiences.

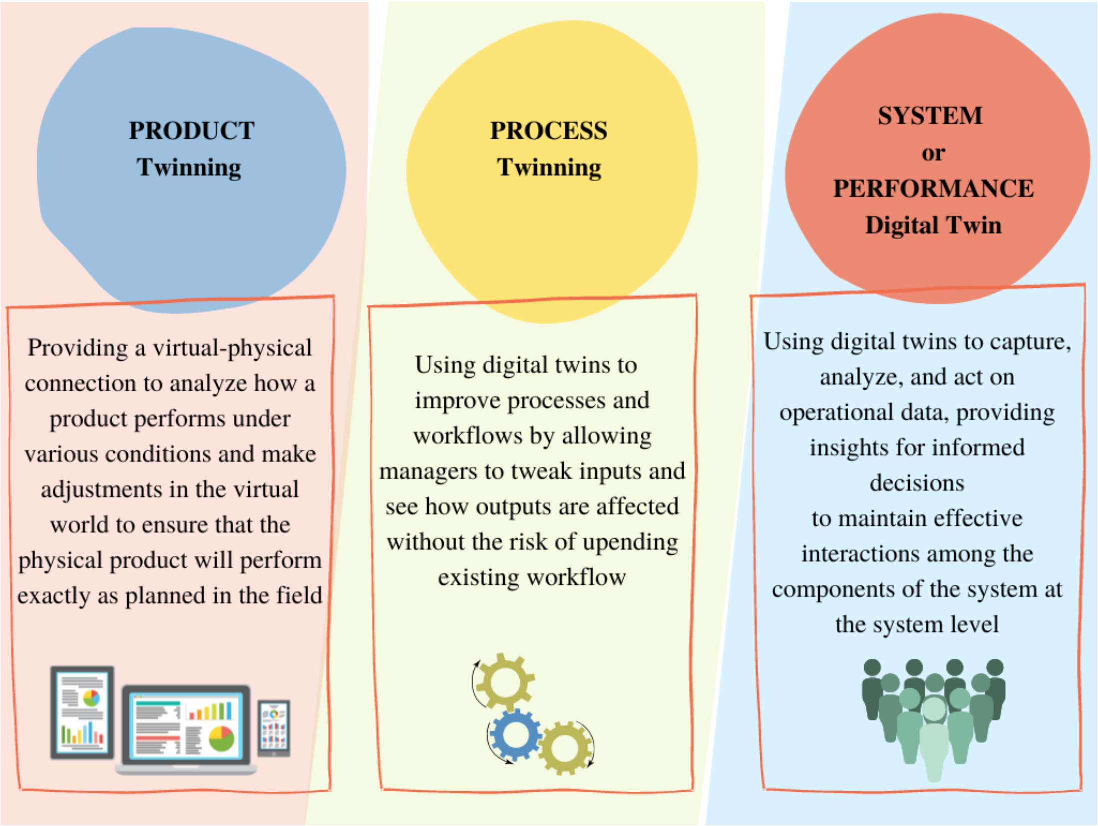
Introduction

One of the fastest growing sectors of the global economy is the health care industry [1,2]. For a complex system like a hospital, many problems and obstacles arise owing to the variability resulting from the incongruity between demand, and capacity and resource availability. In addition to the operational management of resources, having an almost instantaneous and reliable vision of the available resources would permit a more adaptive management of the resources as the demand varies. As the demand changes, managing staff schedules, patient flow, bed sizes, and room usage would be a challenge [1]. Technology-based strategies can be promising contributors to improving the efficiency of health care delivery. The increasing adoption of various health information technologies has created new channels for management [3] and communication [4] that revolutionize health care systems.

Meanwhile, a revolution toward an intelligent industry or "Industry 4.0" combining advanced technologies emerged in 2011 [5]. This revolution affected all sectors, including health care. One of the supporting concepts in implementing Industry 4.0 is the digital twin (DT) [6]. A DT is a virtual representation of a physical asset replicated virtually through data connection [7,8], making it possible to link the system with its virtual copies in a bidirectional way [9]. Digital technologies provide many opportunities to revolutionize health care. For example, real-time data can be provided by Internet of Things solutions, and large data flows are managed and secured by robust digital infrastructures. In addition, flows and decision-making support are improved by command centers, artificial intelligence, and machine learning [10-12]. However, it is through the creation of DTs that much of this can be brought together [8]. The medical DT concept is considered more beneficial for personalized medicine to help health care professionals realize more effective interventions by digitally replicating the human body, allowing prevention, early detection, and targeted treatments of many diseases [13,14]. This paradigm is not limited to medical practice improvement; it also offers a solution to the issues related to health care systems and supports their strategic management. A DT can help design, optimize, and test products; design and operate production systems; manage and control supply chains; diagnose problems; and provide after-market services [15]. There are 3 types of DTs, as illustrated in Figure 1.

In this context, this rapid review aims to highlight what DTs have accomplished in correlation with health care management support. We intend to cover the interventions that used DTs (products, processes, systems) to improve the management of medical services. We report the DT type and its role in the system (function). This classification of DTs is adopted from Siemens, classifying DTs into 3 types, with 1 related to processes (eg, production), 1 related to product design, and 1 related to system performance (eg, performance) [16]. The combination and integration of the 3 DTs as they evolve together is known as the digital thread [16].

Figure 1. Types of digital twins.



Methods

Study Design

We performed a rapid review of studies involving DT technology to improve health care services management. Rapid reviews are a form of evidence synthesis that can provide timelier decision-making information than standard systematic reviews. They are suitable for emerging research topics where systematic reviews are unpractical [17]. Rapid reviews typically do not include an exhaustive set of studies, do not involve formal analyses of the study quality, and report findings from prior studies via narrative synthesis by simplifying the evidence synthesis process [18].

Our protocol was registered on January 28, 2022, with the Open Science Framework [19]. The primary goal of this review was to identify the opportunities that DTs have offered to support the improvement of the health care system. We summarized the literature on existing applications of DTs and the challenges associated with their design, use, and implementation. Publications spanning the last 20 years were considered, from January 1, 2002, to January 25, 2022. We started in January 2002 because the concept of DTs was publicly first introduced in 2002 by Grieves [20]. Grieves proposed the DT as the conceptual model underlying product lifecycle management [20].

Search Strategy

We searched PubMed, Web of Science, IEEE Xplore, Scopus, and ScienceDirect using “digital twin” and “health” as the keywords. The studies included journal and conference articles that covered only the health care applications of DTs (no industrial, manufacturing, or energy-related initiatives). We excluded the following types of studies: studies published in a language other than English; reviews, short communications, and briefs not reporting the impact of DTs through empirical studies and approaches; papers that are not peer-reviewed; studies that present an initiative to support a medical practice (precision medicine, organ transplant, etc).

Studies are discussed based on the contribution of DTs to improving user experience in health care from human factors and systems engineering perspectives, accounting for the type of impact (product, process, or performance/system level).

Results

Of all the sources found, 72 papers were screened comprehensively, and 17 papers were included in this review. The screening process is summarized in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram shown in Figure 2.

Even though very few articles matched our scope, the research trend is evolving. The selected papers covered different application areas, including process development (n=5), a system improvement initiative (n=8), and developing/designing and testing a product (n=4). We adhered to conventions for narrative reviews by combining our results with interpretations and discussion in the Results and Discussion sections.

We identified 4 main functions that DTs perform in managing health care systems. We summarize the functions and their adopted definitions in Table 1.

Figure 2. PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) flow diagram of the article selection process.

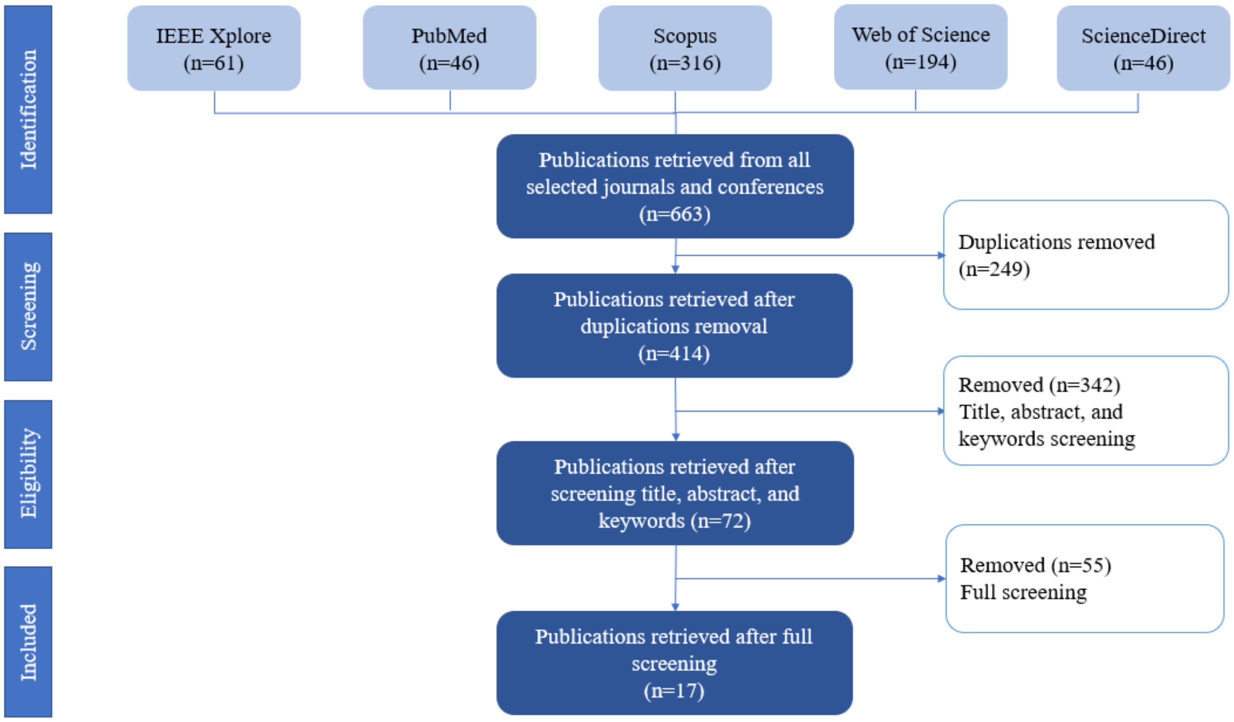


Table 1. Functions of digital twins identified in this study.

Function	Definition
Safety management	Avoiding unintended or unexpected harm to people during the provision of health care processes; identifying crisis-related threats to a system and helping control the impacts
Operational control	Ensuring high system efficiency levels by making sure that health care facilities run smoothly and offer high-quality care to every patient
Information management	Ensuring privacy, security, and real-time information access to stakeholders
Health management and well-being promotion	Empowering self-care abilities by enabling health management practices

These technologies have the potential to avoid unintended or unexpected harm to people during the provision of health care processes and identify crisis-related threats to a system and help control the impacts, which we define as safety management. They are also used to ensure privacy, security, and real-time information access to all stakeholders, which can be considered information management. Another function identified is well-being promotion and health management, where DTs empower the self-care abilities of patients by enabling health management practices. The last function is operational control and management. This technology has the potential to ensure a high system efficiency level by ensuring that health care facilities run smoothly and offer high-quality care to every patient.

Table 2 summarizes the functions of DTs, along with the key findings of the studies considered in this review.

Our findings are presented per the function of DTs (safety management, information management, health management and well-being promotion, and operational control). The operational control findings are presented in 5 subparts (process control of anomalies, scheduling of interventions, resource allocation, operation optimization, and strategy optimization). After presenting the state of the art of DT use, we present the challenges associated with the use and implementation of DTs, followed by the limitations of our study.

Table 2. Functions and key findings.

Function and type of DT[a]	Key findings
Safety management	
System (Jovanović et al, 2021) [21]	The DT used allows management of the infection peak and development of precisely targeted vaccination strategies that allow targeting based on individuals' number of social contacts.
System (Talukder, 2021) [22]	A DT architecture is proposed to ensure safety within an ecosystem disrupted by COVID-19. It mitigates the system challenges and increases patient safety in post–COVID-19 health care delivery.
System (Alrashed et al, 2022) [23]	A DT was used to simulate the different possible strategies and scenarios to predict the spread of the COVID-19 virus and minimize the impacts while ensuring continuity in providing services to citizens.
Information management	
Product (Lutze, 2019) [24]	DTs embedded in wearable devices were used to gather personal information to make group or system decisions.
System (Pang et al, 2021) [25]	A city DT was developed based on federated learning principles to serve as a local central server of information. It allows centralizing information, sharing knowledge, sharing local strategies, and sharing responses to adopted plans in real time among multiple cities.
Health management and well-being promotion	
Product (Díaz et al, 2021) [26]	The DT developed (DTCoach) serves as not only an accompanying educator but also as a mentor that can be used on portable devices like smartphones. It enables web-based pose estimation and performance measurement by providing a person-centered digital coaching experience with a platform that serves as a coach, an accompanying educator, and a mentor who can help make the necessary adjustments based on the individuals' capabilities.
Product (Liu et al, 2019) [27]	The suggested cloud-based system, ClouDTH, uses personal data from digitally twinned wearable medical devices to achieve interaction and convergence between physical and virtual medical spaces to facilitate personal health management for elderly patients.
Product (Tröbinger et al, 2021) [28]	The DT product developed serves as an alternative to telemedicine solutions. It presents a new approach to the remote doctor visit. The dual doctor-patient twin paradigm involves 2 robotic systems (patient GARMI, doctor MUCKI). Control, interaction, and knowledge transfer are enhanced by artificial intelligence, visual motion, and facial expression analysis in the DT. Thus, it enables a transparent remote doctor visit and better-informed and robot-assisted telerehabilitation with bidirectional telepresence control.
Operational control	
Process (Nonnemann et al, 2019) [29]	DTs of the processes in an ICU[b] station are integrated into a system (Health@Hand) to allow remote monitoring; it detects faults and anomalies immediately and will enable interventions at an early stage.
Process (Chase et al, 2021) [30]	DTs of the processes are used to optimize the interventions in a medical ICU. They aim to optimize patient care by clinical staff at the enterprise level for more productivity and quality improvement.
System **(**Karakra et al, 2018) [31]	The hospital's DT proposed developing a predictive decision support model that employs real-time services data drawn from these systems and devices. This model enables assessing the efficiency of existing health care delivery systems and evaluating the impact of changes in services without disrupting the daily activities of the hospital. It allows foreseeing the effectiveness of changes in the models before they are applied in reality.
System (Augusto et al, 2018) [32]	The DT of an emergency unit is developed to optimize the pathway of patient care in the unit. The system accounts for various arrival processes to account for massive arrivals in case of a crisis and determine the best available leverages to optimize the operations of the system.
Process (Mylrea et al, 2021) [33]	BioSecure DT monitors every step in the supply chain process to ensure good productivity and cybersecurity by applying Cyber-Informed Engineering.
Process (Karakra et al, 2019) [34]	It predicts the near future and monitors the processes in real time through the HospiT'Win (DT) system. It allows detection of unexpected situations before problems occur in real life (delay, change in schedule, etc). It will enable the tracking of data flow from the real world to the virtual world.

Function and type of DT[a]	Key findings
System (Karakra et al, 2020) [35]	Using discrete event simulation and DTs through a system called HospiT'Win allows tracking the pathways of patients inside the health care organization to manage growing demand and decrease waiting times and delays. The solution enhances resilience to sustain critical operations under expected and unexpected conditions. It conveys key information to decision-makers in real time.
System (Rodríguez-Aguilar et al, 2020) [36]	The DT of the health care system is developed to better respond to contingencies and ensure optimal allocation of available resources in a DHPES[c].
Process (Croatti et al, 2020) [37]	A trauma DT is used to digitalize and support the process of severe trauma management, considering it as a physical asset that is mirrored by 2 DTs.

[a] DT: digital twin.

[b] ICU: intensive care unit.

[c] DHPES: Digital Health Public Emergency System.

Discussion

State of the Art of DT Usage

Health care has evolved away from focusing solely on illness toward primary health care and health promotion, considering health care as a complex ecosystem [38]. The most significant contributions of digital twinning in health care have been precision medicine efforts that provide patients with targeted treatment and diagnosis [39]. However, its use to develop novel customized health care management approaches started in 2018 and is still an evolving concept [40].

Safety Management

The goal of the patient safety movement is to reduce adverse outcomes or injuries resulting from health care processes. It is imperative that these adverse outcomes are avoided, prevented, or minimized [41]. With the improvements in safety standards and policies, more attention is accorded to analyzing safety issues and the sources of these issues [42]. Errors and inefficiencies in inpatient care are frequently the results of conflicting, incomplete, or suboptimal systems in which patients participate and interfere [43]. The report published by the Institute of Medicine at the beginning of the 21st century resulted in the increased and rapid adoption of health information technology in health care settings, especially for patient safety purposes [44]. For example, the wrong site, wrong side, wrong procedure, and wrong individual (WSWP) errors have been mitigated to some degree by electronic health records. However, these errors continue to be quite significant [45]. DT-assisted safety management systems can be implemented within the Safety 4.0 framework to manage complex safety procedures with minimum human error [46]. In addition to providing operators with contextual information about the surroundings, DTs can guide them through safety tasks [47].

Our study found different DT applications (n=3) that contribute to patient and system safety management through system twinning and product twinning. For instance, an opportunity that DT developers seized was the COVID-19 safety crisis within the health care ecosystem [21]. In 2020, COVID-19 disrupted the health care system and caused an ecosystem crisis that harmed public safety, including resource shortages, misinformation, and medical errors. Virtual interventions and technology initiatives became the preferred mode of service. For example, DTs could accurately contribute to vaccination strategy development. Vaccinations can be targeted based on the number of social contacts of each individual, and infections can be restricted to isolated hotspots and delayed by precisely targeted vaccination, inherent immunity, and public health measures that reduce the infection peak. Thus, DT technology supports decision-making to control the spread of the virus [21]. Apart from this, twinning systems contributed toward predicting the COVID-19 spread. Alrashed et al [23] used a DT system to simulate different strategies and scenarios to minimize the impacts of the virus spread and prevent it while continuing to provide necessary services to citizens with no interruptions to ensure their safety with minimal risk. Safety risk for patients was not only caused by the virus itself but also by the inability of the systems to respond to the new challenges. These challenges will continue to impact the system even after the COVID-19 crisis. Talukder [22] suggested a system architecture that ensures safety within an ecosystem disrupted by COVID-19. It mitigates system-related challenges and increases patient safety in post–COVID-19 health care delivery [22]. In conclusion, DTs (systems and products) can ensure safety management in health care systems by identifying potential threats, redesigning the systems to mitigate hazards, and improving the safety strategies implemented. This leads to the right care at the right price and time for everyone and everywhere at any point of care in a safe manner.

Although the applications of DT technology in patient safety were inspired by COVID-19, it is essential to investigate its potential in other settings and crisis situations. In addition, this technology helps address safety issues in health care without interrupting day-to-day work; it can also be used to address other medical safety issues, such as surgical errors, workplace safety issues, and medical bias in diagnosis.

Information Management

The American Health Information Management Association describes health information management as the process of collecting, analyzing, and securing digital and traditional medical records that are vital to providing quality patient care [48]. Health care organizations seek to analyze patients' information efficiently and quickly, both internally and externally [49]. However, they face many challenges such as privacy, exchange restrictions, and extensive data. Increasing amounts of patient data are forcing health care institutions to replace traditional approaches that cannot cope with increases in data. The United States is taking steps to boost health care information and communication access by leveraging advances in information and communication technologies [50]. Health information management systems have grown rapidly in recent years and are being used to derive important health trends and provide timely preventive care [51]. DT technology can revolutionize clinical research with the changes that it can bring to the basis of health care systems and medical practices. By leveraging this technology, users can better ask questions, get better answers, and gain data-driven actionable insights without compromising the health of real-life subjects. In fact, using a DT, people can gather, aggregate, and represent individual information about their health and well-being [52]. As more data are collected, more DTs will be enabled, leading to more discoveries and better treatment, thus allowing the assembly of more data with less cost, and especially eliminating the risks and consent issues associated with actual human subjects [53]. In our review, we found applications related to information management DTs (n=2).

According to Lutze [24], eHealth systems can manage knowledge by implementing DTs that are based on artificial intelligence. He proposed a DT that collects daily activity data from smart assistance systems linked to wearable sensors for elderly people and extracts behavioral knowledge for information management. The technology suggested accounts for systems, processes, and group changes to provide unbiased conclusions based on learned, trained data. It has a human-centered design, as it allows the self-determination and autonomy of patients to share or refuse the usage of their data with providers and clinical staff. It also establishes solid robustness by automatically tracing the use of all knowledge sources and verifying conclusions drawn about patients after system changes [24]. Auditability is established by tracing the use of all knowledge sources and recording and verifying conclusions drawn about patients and users after system changes. Robustness is supported by automatically checking the containment of a patient within the designated user group of the system and verifying the continued validity of the assessed acceptance conditions after system changes. Moreover, human oversight is facilitated in all critical situations [24].

Another example of an information management DT was suggested by Pang et al [25]. During pandemics, sharing information among different cities and countries in real time through a shared learning model (federated learning) remains critical while ensuring enhanced privacy protection. Pang et al used DT technology in a novel collaborative paradigm that allows DTs in multiple cities to share the local strategy and status quickly without violating any privacy rules to help manage the COVID-19 pandemic [25]. These 2 examples show that DTs allow information management and knowledge extraction by encoding, storing, retrieving, and sharing data in a secure, smart, and real-time environment.

Health Management and Well-being Promotion

Health and well-being goals are challenging to achieve for many individuals. In response to this challenge, a growing number of technologies are being developed to improve people's diet, physical activity, sleep, and mental health. By promoting behavior change and controlling health care costs through modern digital health interventions, people can maintain better health and a healthier lifestyle. Today, a variety of sensors are miniaturized and widely used to track basic physiological indicators on the move to help with better health and well-being management. Moreover, because smartphones are extremely easy to access, mobile health apps are currently considered the most beneficial platform for promoting healthy lifestyles and changing behavior [54]. In modern medicine, personal health management services are viewed as electronic, remote, and digitally enabled care that helps individuals manage their own care and reduce the need for in-clinic visits that are typically expensive and time-consuming [55].

In our review, we found that DTs were used for health management and well-being promotion (n=3). One such DT was introduced by Díaz et al [26] in 2021. Their DT application was called DTCoach. It is a user-centered smart coach that serves as a mentor and an accompanying educator to the users. It helps the users make the necessary adjustments in their posture and performance based on measurements taken that characterize their individual capabilities [26].

Another example was ClouDTH, suggested by Liu et al [27]. This cloud-based health care system uses personal data from digitally twinned wearable medical devices to achieve a convergent interaction between the medical and physical spaces, and their virtual twins. Then, it facilitates self-management of health for elderly patients [27]. Patients' needs depend on many factors, and age is one of them. Elderly patients have higher demands for many medical services. Therefore, DTs are used extensively in geriatric care to support health management promotion of elderly patients. Furthermore, another example that we cover in our review was introduced by Tröbinger [28], which is a new DT approach serving as an alternative to telemedicine. It consists of a transparent remote doctor visit and a better-informed and robot-assisted telerehabilitation initiative that allows bidirectional telepresence control [28]. In summary, DTs are used to accompany patients and give them control over their health by promoting well-being and lifestyle activities and supervising them to maximize their performance in a safe environment.

Operational Control

Operating a health care facility on a day-to-day basis impacts patient experiences and organizational goals [56]. Thus, operations management helps in understanding and optimizing the business processes inside medical departments to reduce and alleviate the effects of overcrowding, waiting times, delays, and other problems that facilities are facing [57]. DTs have the potential to contribute to the effective operation of health care units. Our review found that most DT initiatives to improve health services have health care operations management focusing on revolutionizing clinical processes and enhancing medical care. They replicate hospitals or treatment facilities and help improve their performance in a safe manner with less risk. Applications are numerous and range from predicting resource shortage to managing patient flow. Using DT technology, an institution can execute a digital stress test to observe how the technology would fare under extreme conditions like crises. By creating a virtual twin of a hospital, stakeholders can review the operational strategy, capacity, staffing, and care model on the DT to determine what actions to take and mitigate future challenges. Our review identified extensive efforts (9 out of 17studies) to support operational control and account for health care system challenges. The efforts consisted of digitally twinned systems and processes for performance control.

Detecting anomalies in processes is essential to prevent hazards and predict the corrective actions that need to be implemented. With some interventions, such as the solution suggested by Croatti et al [37], DTs can be used to support physical processes through their digital representations and monitor their changes. In this study, by mirroring the real system by building an agent-based smart DT, they aimed to digitalize and support the process of severe trauma management [37]. This DT represents the operative phase of trauma management and starts when the trauma is marked as severe in the previous phase. The fact that this DT starts before the patient's arrival to the unit is very important for this case study [37]. In this way, the trauma team is prealerted about the incoming patient and starts collecting and receiving information directly from the accident site. Its internal state changes when the patient is delivered to the emergency department, where the trauma team starts taking care of the patient. A very preliminary version of a system prototype has been developed according to the designed conceptual model [37].

Another example is Health@Hand, suggested by Nonnemann et al [29]. They twinned the processes of an intensive care unit (ICU) station and integrated them into a digital system (Health@Hand) to allow remote monitoring of the processes. With this intervention, hospital managers can detect anomalies and faults immediately and intervene in an early stage. Moreover, while improving the productivity and efficiency of processes, some digital interventions forget to address the problem of cybersecurity, which may harm the systems. As a solution to this problem, Mylrea et al [33] propose BioSecure. It is a process twinning that allows managers to monitor every step in the supply chain process to ensure good productivity and cybersecurity to secure the system and data by applying Cyber-Informed Engineering.

One of the challenges in health care is providing an optimized scheduling strategy that can effectively use the hospital's resources and prevent delays, errors, and long lengths of stay. An application in the same settings (ICU and process twins) was developed by Chase et al [30] that aimed to optimize patient care by clinician staff at the enterprise level to improve the productivity of the staff and the quality of care delivered to patients. In addition, using resources effectively has always been a challenging decision for managers in all industries. In health care, resource allocation needs to be regulated by providing efficient services on time. Rodríguez-Aguilar et al [36] suggested a DT for a hospital that supports resource allocation (financial and human) called the Digital Health Public Emergency System (DHPES). DHPES provides efficient health services [36]. The DT design seeks to generate virtual instances that emulate the real operation of the provision of highly specialized public services, including the supply of medications, supplies, devices, and equipment as well as the management of human resources and financial resources in the event of a contingency [36].

Another DT initiative called HospiT'Win was developed to manage the patients' pathways inside the hospitals [34,35]. This DT can help hospitals equilibrate demand and supply and control the growing workload while reducing waiting times, lengths of stay, and delays. It also provides key information to decision-makers in real time, controlling the real-time flow of data. As high demand can disturb health care systems, such DT systems might be useful in times of crisis. Hospit'Win performed well during the COVID-19 pandemic by managing the demand [34,35].

Some operational strategies need to be implemented first to evaluate their efficiency. In hospitals, evaluating interventions would disrupt the daily services and activities of the units. This is where DTs could be most useful. Karakra et al [31] proposed a decision support system that employs real-time services data drawn from real systems and devices to enable evaluation of the impact of changes in services without disrupting the daily activities of the hospital. This idea allows foreseeing the effectiveness of changes in the models before they are applied in reality [31].

Providing patients safe and high-quality care is a demanding process. A DT framework for a system is proposed by Augusto et al [32] to optimize a patient’s care pathway in health care units. The system accounts for various arrival processes and simulates different scenarios to determine the best available leverages to optimize the operations of the system even under high demand and variability to account for uncertainties [32]. The framework has been conceived and tested in close collaboration with health care professionals to be as close to the real system as possible. Furthermore, the framework is intended to be used regularly by the head of the emergency unit [32]. Data collection was performed using the hospital information system for the following parameters: patient arrivals, the total length of stay; type of patient including less critical (fast and normal track), moderately critical, and life-threatening emergencies; and number of requested paraclinical examinations per patient. On the other hand, processing times were recorded by interviewing doctors, nurses, caregivers, and interns because the related data in the hospital information system were not reliable enough [32]. The model was validated and shown to reduce the waiting time and length of stay in different scenarios.

Future of DTs: Challenges Associated With Use and Implementation

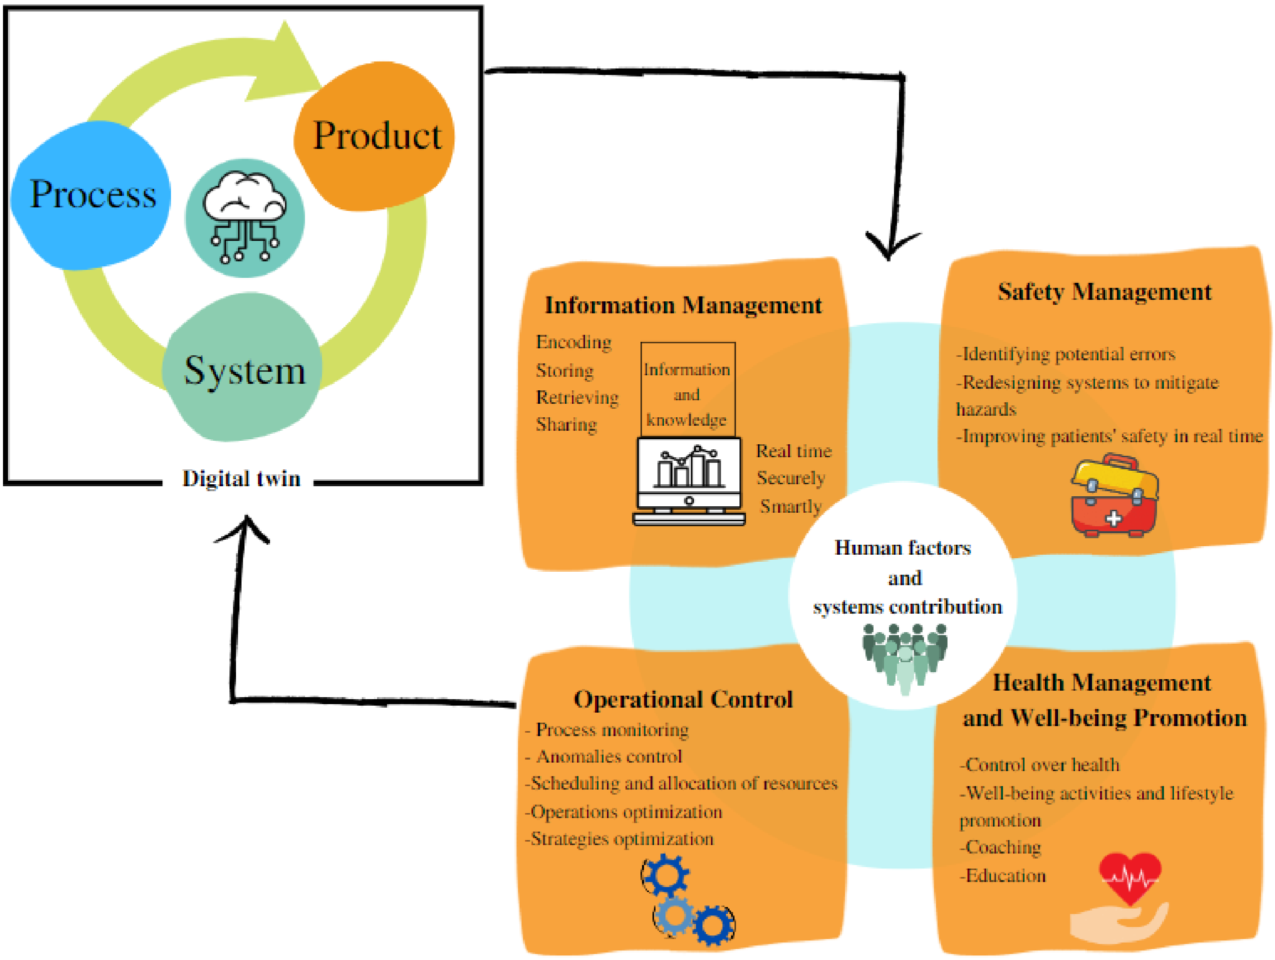
A DT system would provide patients with a safe and secure monitoring option; medical staff would have safe and secure monitoring methods, and authorities would be able to track extreme crisis scenarios in real time accurately. However, digital twinning is facing many challenges that are hindering its growth. The first obstacle is the infrastructure of data flow. For example, to prevent false positives in the digitally twinned sensors, we need a good understanding of the variability in the personal parameters and characteristics of the users [58]. Another concern to be addressed before DTs can go mainstream is data security and privacy. The data used by DTs are confidential and sensitive, and interconnected devices are an easy target for cyberattacks that can harm health care systems. Therefore, governments and policy makers need to consolidate the law regulation factor to have more protected data-sharing procedures. Moreover, as data form the core of DTs, quality control protocols need to be embedded in the real physical systems to merge the data with the simulated systems (twins) and ensure good performance of the DT models. Additionally, ethical concerns like ownership of the data extracted with DTs are still not addressed. Finally, it is essential to explore factors that affect DT implementation and adoption.

DTs also have the potential to offer new important pathways for various care processes in health care. For instance, strategies to improve communication and patient-centered care can be implemented digitally to evaluate their effectiveness before adopting them in real life to avoid repetitive trials that may disturb patients' pathways. In addition, some patients are hard to deal with because of their critical medical situations. Digital twinning of the care processes for these patients can give more visibility to health care professionals to understand the best possible care strategy for these patients. Furthermore, usability studies are sometimes costly in terms of facilities, equipment, and time. DTs can facilitate remote usability testing across diverse populations, accounting for their lower literacy or health literacy and individuals with cognitive or physical disabilities. They can also help testers gain time, reduce effort, and earn money while providing real-time decision support by solving recruitment problems for surveys, interviews, and clinical trials.

As illustrated in Figure 3, we suggest a framework that highlights the possible contributions of DTs from human factors and systems perspectives. Irrespective of whether the technology designed is by twinning a system, process, or tool, a good DT design can potentially improve safety management, improve operational control of the health care system, allow better information management, and promote the health and well-being of patients.

Finally, this study also has several limitations. The included studies largely reported postintervention data, so we could not determine the preintervention-to-postintervention change or ascertain whether the intervention groups were matched at baseline for key characteristics and outcome measure scores. In addition, we may have missed some articles in our screening because the research was limited to the following databases: PubMed, Web of Science, IEEE Xplore, Scopus, and ScienceDirect.

Figure 3. Framework of the impact classification of digital twins from human factors and systems perspectives.



Conclusions

DTs are replications of systems, products, or processes that bridge reality using data and expand the same to virtual models. In medical services, DTs are primarily used in personalized medicine; however, they also have the potential to be used at the system level. These applications vary from safety to information management, health and well-being promotion, and operations control. This rapid review shows that digital twinning for health care system management is still an emerging field with considerable potential that was also used during the COVID-19 pandemic. Therefore, interdisciplinary teams from various disciplines, including human factors and ergonomics, human-computer interaction, data science, and digital health, should further investigate the potential of this technology and address the challenges that may influence the design and adoption of this technology in the health care system.

Authors' Contributions

Both SE and OA conceptualized the study and participated in the literature review, finding interpretation, and manuscript writing. Both the authors have approved the final version of the manuscript.

Abstract

Background: Patients undergoing heart surgery may experience a range of physiological changes, and the postoperative recovery time is long. Patients and their families often have concerns about quality of life (QoL) after discharge. eHealth interventions may improve patient participation, ensure positive and effective health management, improve the quality of at-home care and the patient's quality of life, and reduce rates of depression.

Objective: The purpose of this study was to evaluate the effects of eHealth interventions on the physiology, psychology, and compliance of adult patients after cardiac surgery to provide a theoretical basis for clinical practice.

Methods: We conducted systematic searches of the following 4 electronic databases: PubMed, Embase, CINAHL, and the Cochrane Central Register of Controlled Trials. Mean (SD) values were used to calculate the pooled effect sizes for all consecutive data, including QoL, anxiety, and depression. Where the same results were obtained using different instruments, we chose the standardized mean difference with a 95% CI to represent the combined effect size; otherwise, the mean difference (MD) with a 95% CI was used. Odds ratios were used to calculate the combined effect size for all dichotomous data. The Cohen Q test for chi-square distribution and an inconsistency index (I^2) were used to test for heterogeneity among the studies. We chose a fixed-effects model to estimate the effect size if there was no significant heterogeneity in the data ($I^2 \leq 50\%$); otherwise, a random-effects model was used. The quality of the included studies was assessed using the Cochrane risk-of-bias tool for randomized trials (RoB 2).

Results: The search identified 3632 papers, of which 19 met the inclusion criteria. In terms of physical outcomes, the score of the control group was lower than that of the intervention group (MD 0.15, 95% CI 0.03-0.27, I^2=0%, P=.02). There was no significant difference in the mental outcomes between the intervention and control groups (MD 0.10, 95% CI –0.03 to 0.24, I^2=46.4%, P=.14). The control group's score was lower than that of the intervention group for the depression outcomes (MD –0.53, 95% CI –0.89 to –0.17, I^2=57.1%, P=.004). Compliance outcomes improved in most intervention groups. The results of the sensitivity analysis were robust. Nearly half of the included studies (9/19, 47%) had a moderate to high risk of bias. The quality of the evidence was medium to low.

Conclusions: eHealth improved the physical component of quality of life and depression after cardiac surgery; however, there was no statistical difference in the mental component of quality of life. The effectiveness of eHealth on patient compliance has been debated. Further high-quality studies on digital health are required.

Introduction

Quality of Life and Cardiac Surgery

More than 1.5 million patients worldwide undergo heart surgery annually, and this number continues to grow [1]. Patients experience a series of psychophysiological changes before and after surgery. Preoperative anxiety and depression trigger the psychological response system, which in turn activates the endocrine and autonomic nervous systems, affecting postoperative outcomes, length of hospital stay, and quality of life [2,3]. Moreover, psychological changes related to chronic stress, such as anxiety and depression, can affect not only quality of life but also physiological parameters such as respiratory rate, heart rate, blood pressure, inflammatory markers, and brain activity, which may be detrimental to postoperative recovery [4-6]. The recovery period after cardiac surgery is relatively long, and most of the recovery processes, such as the healing of surgical wounds and the recovery of cardiac function, take place at home or in other facilities outside the hospital [7]. After cardiac surgery, patients and their families often have concerns regarding quality of life after discharge [8,9], since they will be solely responsible for at-home care [10,11]. Many problems can arise due to a lack of self-care knowledge and skills, and these problems increase with inadequate follow-up for patient education, counseling, and postoperative care [12].

eHealth Interventions

In recent years, both health professionals and patients have been increasingly involved in eHealth [13], which includes mobile health, mobile and wireless technologies, health information technology, telemedicine, and personalized medicine, to improve clinical care, such as public health, health administration, and health-related education [14]. eHealth is often designed to support the achievement of health goals. With the increasing social demand for electronic technology, the use of mobile devices has the great potential to transform conventional health care and implement patient-centered initiatives [15-17]. Increased patient engagement is a key factor in eHealth and has the potential to motivate users and enable them to become more proactive and effective in managing their own health, ultimately improving quality of care [18]. The quality of health care has improved significantly with the use of telemedicine [19]. In addition, electronic medical interventions are already widely used in perioperative nursing [20].

Approximately 70% of patients consult the internet for information soon after learning about their upcoming surgery [21,22]. Studies [23,24] have reported that eHealth interventions for cardiac rehabilitation can also improve patients' quality of life. These interventions provide continuous education regarding patient care and treatment, and offer counseling and support to at-home care providers while allowing access to vital information for patients, their families, and health care providers [25].

Many studies have evaluated the potential benefits of eHealth interventions in patients who have undergone cardiac surgery. However, to date, there has been no systematic evaluation of the effectiveness of these eHealth interventions compared to conventional care in terms of physiology, psychology, and compliance of adult patients after cardiac surgery. Therefore, we conducted this systematic review to assess the impact of eHealth interventions after cardiac surgery on quality of life, psychology, and compliance.

Methods

Design

This study was conducted and reported in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement (Multimedia Appendix 1) [26]. The systematic review protocol was registered in PROSPERO (International Prospective Register of Systematic Reviews; CRD42022327305).

Search Strategy and Data Sources

The PubMed, Embase, CINAHL, and the Cochrane Central Register of Controlled Trials databases were searched from inception to April 2022. The search strategy consisted of 2 components: clinical situation (adult, cardiac surgery) and intervention type (health management using mobile phones, wearables, personal digital assistants, and other wireless devices). Relevant search items and combinations of Medical Subject Headings were used to identify trials related to eHealth and cardiac surgery. Searches were not limited to a specific geographic region, language, or period, but any literature without its full text was excluded. We exclusively included randomized controlled trials. The exact search terms used in each of the databases and the corresponding number of results are provided (Multimedia Appendix 2). EndNote 20 (Clarivate) was used for database management.

Inclusion and Exclusion Criteria

The inclusion criteria were as follows: (1) patients aged 18 years or older at the time of heart surgery and studies that did not specify the type of heart surgery, (2) studies that evaluated any type of eHealth intervention, and (3) randomized controlled clinical studies.

Exclusion criteria were as follows: (1) studies where the full text could not be obtained, (2) insufficient clinical data that were reported in the form of meeting abstracts and did not provide detailed treatment methods or report the relevant results, and (3) duplicate studies.

Document Screening and Data Extraction

Two researchers (RN and ML) independently performed the literature screening and data extraction according to the literature inclusion and exclusion criteria. Decisions on inclusion or exclusion were made by the researchers after a joint discussion of the results. Disagreements were resolved by a third party.

One researcher extracted the data using a literature data extraction table, and a second researcher confirmed the accuracy and authenticity of the data. The extracted content included study information (research topic, author, publication date, and region), baseline characteristics of the study participants (sample size and age), specific details of the intervention, follow-up time, and other outcome indicators (quality of life, anxiety and depression, cardiovascular events, treatment, and medication compliance).

Data Analyses

Mean (SD) values were used to calculate the pooled effect sizes for all consecutive data, including quality of life and depression. When measuring the same outcome using different instruments, we chose the standardized mean difference with a 95% CI to represent the combined effect size; otherwise, we used the mean difference (MD) with a 95% CI to represent the combined effect size. Odds ratios were used to calculate the combined effect size for all dichotomous data. The Cohen Q test for chi-square distribution and an inconsistency index (I^2) were used to test for heterogeneity among the studies. We selected a fixed-effects model to estimate the effect size if there was no significant heterogeneity in the data ($I^2 \leq 50\%$). Otherwise, a random effects model was used. A sensitivity analysis was performed using the leave-one-out method. All meta-analyses were performed using the Stata software (version 15.1; StataCorp).

Quality Assessment

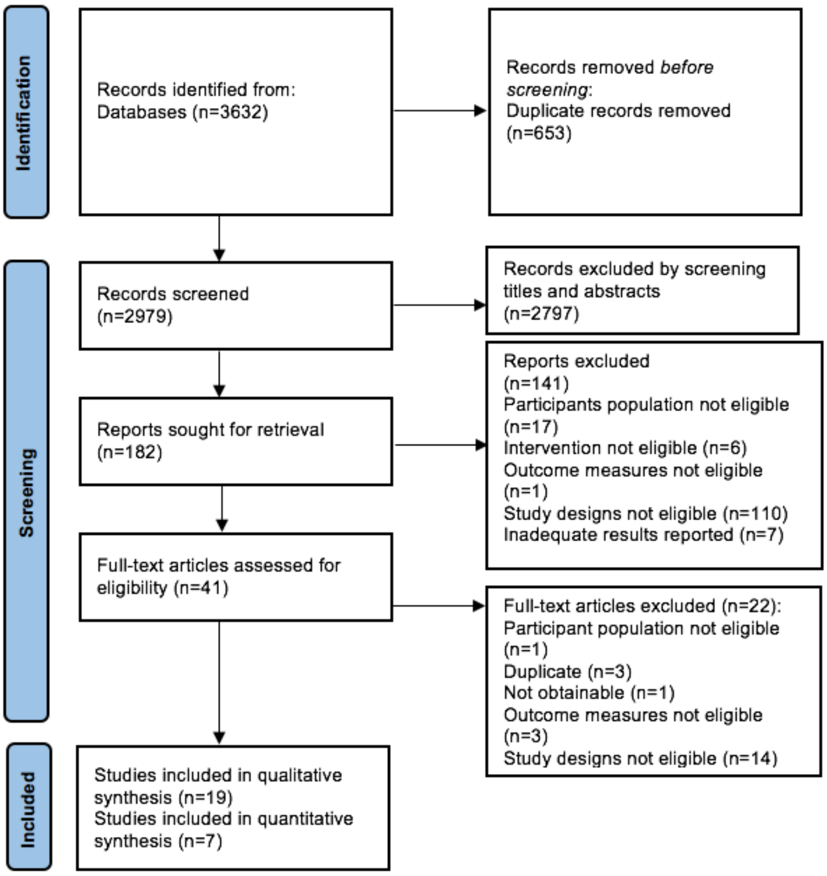
Before analyzing the extracted data, 2 researchers independently assessed the quality of the included studies. A discussion with a third reviewer was conducted until a consensus was reached and disagreements were resolved. The quality of each study was assessed according to the guidelines provided by the Cochrane risk-of-bias tool for randomized trials, version 2.0 (RoB 2) [27]. The overall quality of evidence for each outcome was assessed using the GRADE (Grading of Recommendations, Assessment, Development and Evaluations) approach [28].

Results

Identification of Studies

The PRISMA flowchart in Figure 1 summarizes the search results and selection process for all studies included in our synthesis. A total of 3632 articles were retrieved through a systematic literature search. After removing duplicate studies, the remaining 2979 records were screened. After reading 41 eligible full-text articles, 22 were excluded, and 19 were selected [29-47]. A summary of the study characteristics and participant demographics are presented in Multimedia Appendix 3 [29-47].

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.



Meta-analysis

Primary Outcome

Quality of Life

The fixed-effects analysis model was used to analyze the physical and mental outcomes of quality of life. In terms of physical outcomes, the scores of the control group were lower than those of the intervention group (MD 0.15, 95% CI 0.03-0.27, I^2=0%, P=.02) (Figure 2). However, there was no significant difference in the mental outcomes between the intervention and control groups (MD 0.10, 95% CI –0.03 to 0.24, I^2=46.4%, P=.14) (Figure 3).

Figure 2. Forest plot of the effect of physical outcomes of quality of life after cardiac surgery. SMD: standardized mean difference.

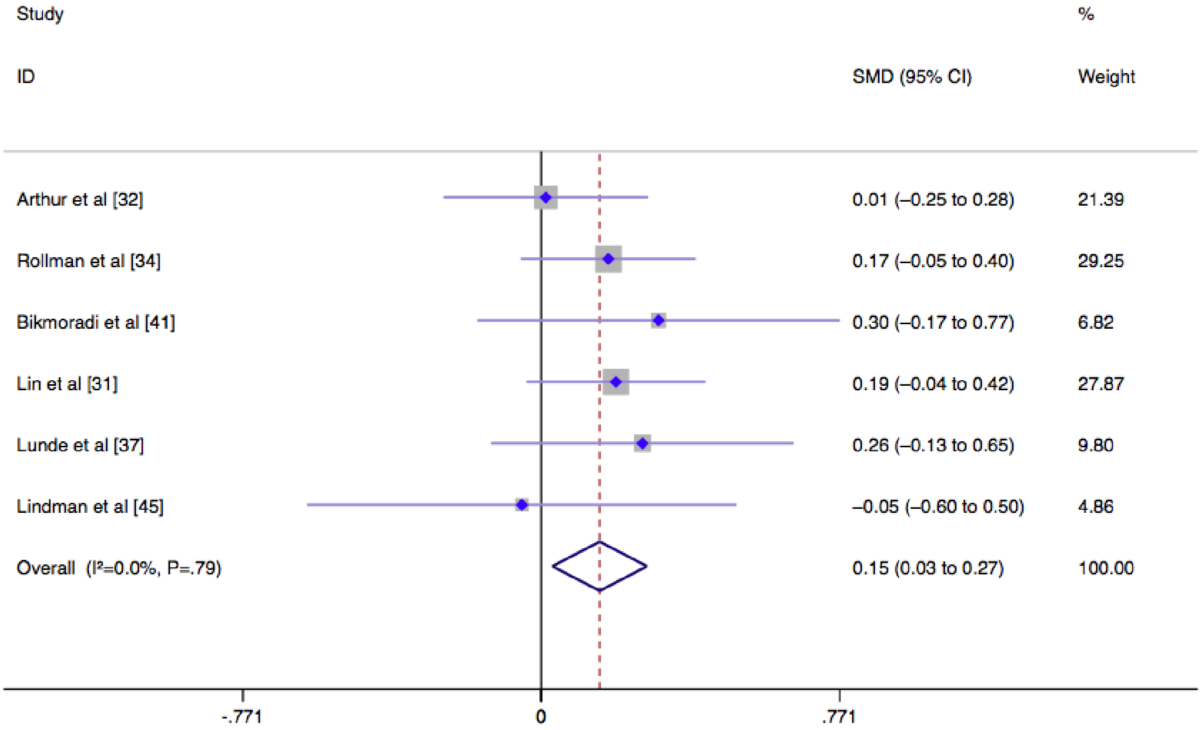


Figure 3. Forest plot of the effect of mental outcomes of quality of life after cardiac surgery. SMD: standardized mean difference.

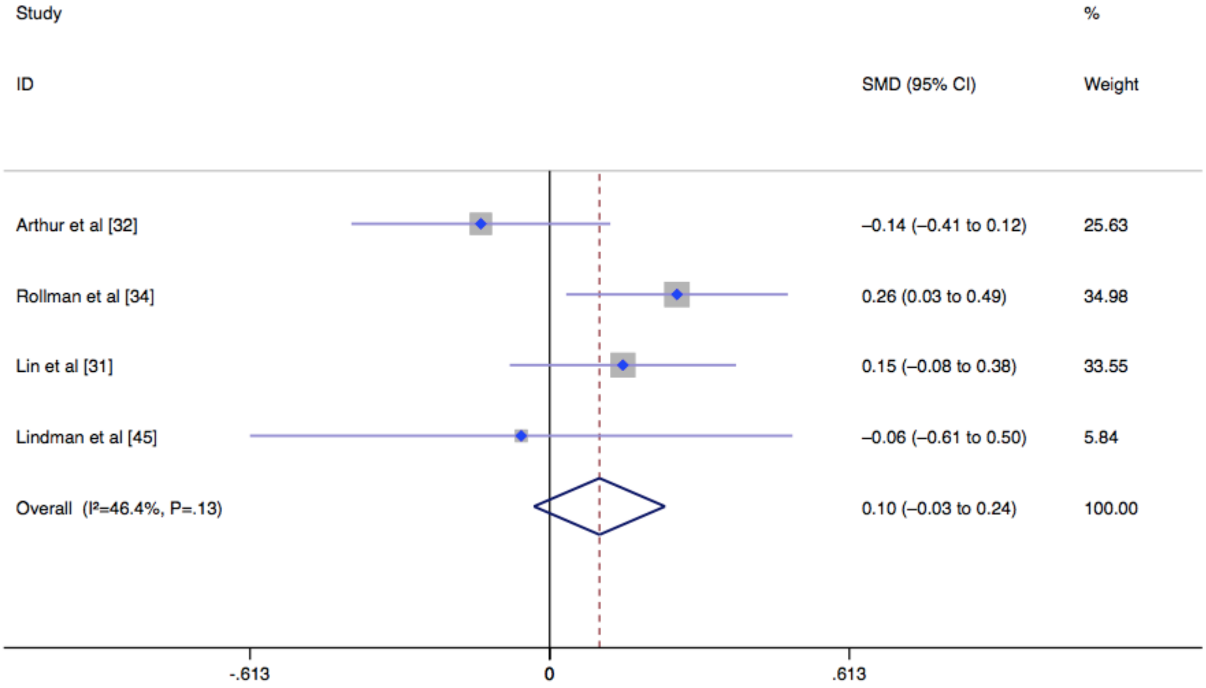
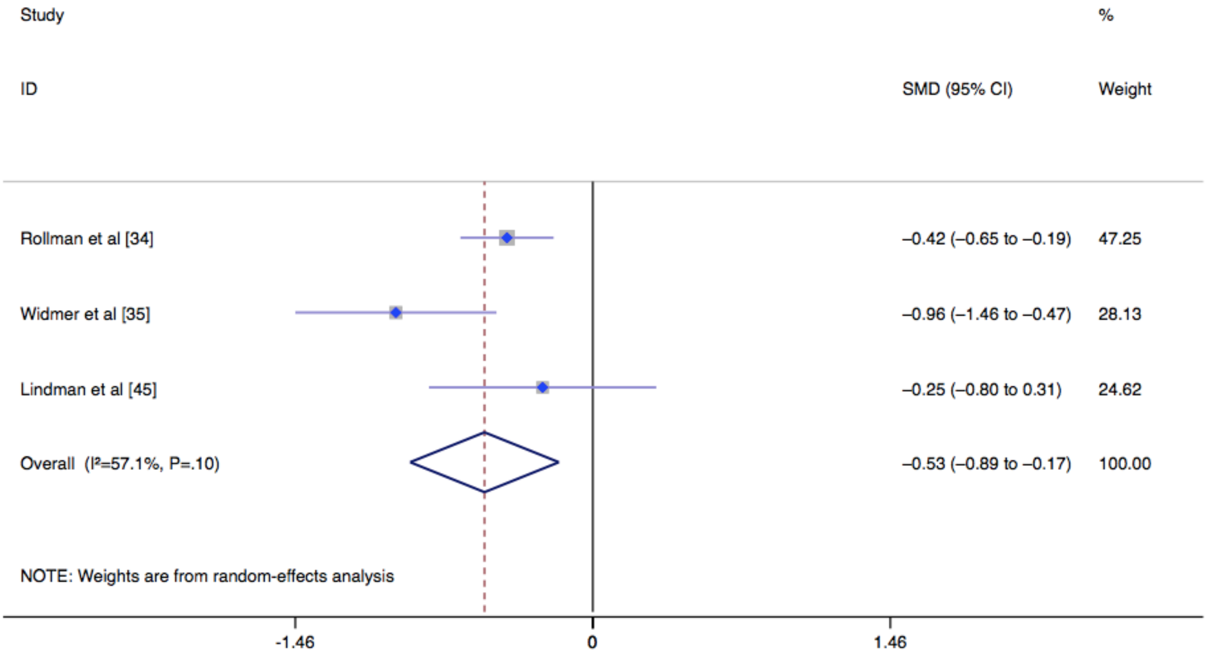


Depression

To evaluate depression outcomes, we used a random-effects analysis model. The score of the control group was lower than that of the intervention group (MD –0.53, 95% CI –0.89 to –0.17, I^2=57.1%, *P*=.004) (Figure 4). Owing to sparse data, there was no subgroup analysis of the main outcome indicators based on a follow-up period of 3 months.

Figure 4. Forest plot of the effect of depression after cardiac surgery. SMD: standardized mean difference.



Other Outcomes

Three studies [29,30,42] reported no significant difference in the improvement of anxiety between the intervention and control groups. The occurrence of mortality was reported in 4 studies [31,32,36,39], of which 1 study [31] showed a statistically significant reduction in mortality in the intervention group, while the other 3 studies reported different conclusions. A total of 4 studies [30,35,39,42] reported no statistical significance for readmission between the intervention and control groups. Among the 3 studies [31,39,43] that reported on compliance, 2 studies [31,43] showed better compliance in the experimental group compared to the control group. However, 1 study [39] showed no statistical difference in compliance between the two groups. Two studies [35,37] indicated that none of the 4 lipid indexes had statistical significance. We generated 2 forest plots to show the effects of eHealth on other outcomes (Multimedia Appendices 4 and 5). Most of the studies had no significant differences in their results, apart from those for compliance, bleeding events, secondary prophylactic medication, patient satisfaction, and time in the therapeutic range (Multimedia Appendices 4 and 5).

Sensitivity Analysis

A sensitivity analysis of quality of life and depressive outcomes was performed using the leave-one-out method, as shown in Multimedia Appendix 6 [31,32,34,35,37,41,45], and the results were consistent.

Quality Assessment

RoB 2 [27] was used for quality evaluation. Overall, the included studies had a low to moderate risk of bias, as shown in Figure 5. Most articles did not clearly report the randomization process. The overall quality of evidence for each outcome was assessed using the GRADE approach [28]. The quality rates of each outcome are shown in Multimedia Appendix 7. In summary, although the quality of some outcomes was moderate, the overall quality was low.

Discussion

Principal Findings

In this systematic review, we assessed the impact of eHealth interventions on cardiac surgery recovery based on the results of 19 studies. These studies reported at least an equal (n=6) [29,30,33,38,39,42] or positive effect (n=13) [31,32,34-37,40,41,43-47] of the eHealth intervention compared to conventional care. According to the results of the meta-analysis, when compared with the control group, the eHealth intervention group showed an improvement in both the physical component of quality of life and the depressive status of patients after cardiac surgery. The mental component of quality of life was not significantly different in the two groups. This may be related to the shorter follow-up period of the included studies. Lin et al [31] showed that an effect on quality of life was not observed until the follow-up after 18 months, which was not long enough for most of the studies we included. van der Meij et al [48] showed that eHealth interventions have similar effects on different types of postoperative outcome measurements. The results for physical and psychological indicators were comparable. Therefore, we only conducted a meta-analysis on quality of life and depression. Study results on patients with different types of heart surgery, eHealth interventions, and measured outcomes varied widely. Due to the lack of reported data and heterogeneity, analysis of the other results using statistical methods was not performed. The economics of eHealth interventions have also not been studied yet. In terms of medication adherence, 2 of the 3 studies reported improved medication adherence after eHealth intervention [31,43]. Fewer than 10 studies were included in the quantitative analysis for each outcome; therefore, publication bias analysis was not performed. However, the findings should be interpreted with caution, as the overall quality of the body of evidence was low to moderate because of the risk of bias in the included studies.

Patients undergoing different cardiac surgeries have different postoperative needs. The studies in this review included eHealth interventions for medication education, consultation, follow-up, postoperative exercise, and rehabilitation. eHealth interventions were also used specifically for postoperative pain [38], anticoagulant management [44,47], and secondary drug prevention [33,35,39]. Martorella et al [38] revealed that patients in the experimental group did not experience less intense pain but reported significantly less pain interference when breathing or coughing (*P*=.04). However, the experimental group consumed more opioid medication (mean 31.2, SD 23.2 mg) than the control group (mean 18.8, SD 15.3 mg; *P*=.001). Two studies [44,47] showed that the use of eHealth improved efficacy in maintaining the therapeutic range of prothrombin time. Another study [44] showed improvement in self-management knowledge, self-efficacy, and improved behavior of patients undergoing cardiac valve replacement, as well as reduced adverse events for bleeding thrombosis [47] through eHealth intervention. Qu et al [33] showed that eHealth interventions have limited ability to increase prescription rates for statins or other drugs. Widmer et al [35] showed that eHealth interventions can improve the secondary prevention of cardiovascular diseases. Yu et al [39] showed that the intervention group had no significant impact on mortality, major adverse cerebrovascular events, and cardiovascular rehospitalization, which may be related to low patient participation.

Limitations

First, due to sparse data, there was no subgroup analysis of the main outcomes according to follow-up time, nor was there a comparative analysis of the pros and cons of different types of electronic interventions and different types of cardiac surgery on postoperative effects. Moreover, due to the limited number of included studies and the lack of publication bias analysis, the number of measured depression outcomes was small, and there was a possibility of deviation. Finally, allocation hiding was not explicitly reported in most of the included studies. The quality of the study outcomes was relatively low, and more high-quality randomized controlled trials should be included in the future.

Comparison With Prior Work

According to our literature review, there have been many studies on the clinical application of eHealth interventions. However, to our knowledge, there is no systematic study on the impact of electronic interventions on patients after cardiac surgery. This is the first published systematic evaluation of the effects of using eHealth on patients who have undergone cardiac surgery. We ensured the use of robust methodology to conduct this review by following the PRISMA guidelines [26].

Among the published systematic evaluations, studies on the application of electronic interventions included patients with cancer, respiratory diseases, and arthritis. In terms of quality of life, 3 studies [49-51] reported that electronic interventions were ineffective, but 7 [52-58] reported improvement in quality of life. Two articles [51,57] reported that electronic intervention was ineffective in relieving anxiety, and another [59] showed mixed views. Electronic intervention was reported to be ineffective for depression in 2 studies [51,60], whereas 3 articles [54,55,59] provided mixed conclusions. There were mixed results regarding the effect of pain relief, with some studies [50,51] indicating no effect on pain relief, and others [55,61] reporting the opposite. Seven studies reported on patient compliance: 2 studies [51,62] showed no statistical significance in improving patient compliance, 3 studies [63-65] showed a positive impact, and according to the remaining 2 studies [66,67], the impact was uncertain. Another study [68] indicated that electronic intervention could effectively improve maximum aerobic capacity and alter cardiovascular risk factors. In addition, we found that the effectiveness of electronic interventions may be related to the disease type. eHealth interventions showed positive effects on the outcome of some patients [52-55], but studies reporting on patients with cancer [49] and patients with arthritis [50,51] reported negative results.

There are many different types of cardiac surgery, such as valve replacement, bypass, and heart transplantation. The various results relating to different disease types might indicate that the effect of eHealth intervention may vary according to patient type. More high-quality studies are needed to verify these findings.

Conclusions

Based on this systematic review, the eHealth intervention group showed improvement in both the physical component of quality of life and depressive status after cardiac surgery, but the positive effects of the intervention were small. Moreover, the mental component of quality of life was not significantly different between the two groups. The overall quality of the evidence was low to medium. The compliance outcomes improved in most intervention groups. In the future, higher-quality randomized controlled studies of eHealth interventions are needed to provide more evidence for clinical practice.

Abstract

Background: Digitalization is not fully implemented in clinical practice, and several factors have been identified as possible barriers, including the competencies of health care professionals. However, no summary of the available evidence has been provided to date to depict digital health competencies that have been investigated among health care professionals, the tools used in assessing such competencies, and the effective interventions to improve them.

Objective: This review aims to summarize digital health competencies investigated to date and the tools used to assess them among health care professionals.

Methods: A systematic review based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist was performed. The MEDLINE, Cumulative Index to Nursing and Allied Health Literature, PsycINFO, and Scopus databases were accessed up to September 4, 2021. Studies assessing digital health competencies with quantitative designs, targeting health care professionals, and written in English were included. The methodological quality of included studies was evaluated using the Joanna Briggs Institute tools.

Results: A total of 26 studies, published from 1999 to 2021, met the inclusion criteria, and the majority were cross sectional in design, while only 2 were experimental study designs. Most studies were assessed with moderate to low methodological quality; 4 categories and 9 subcategories of investigated digital health competencies have been identified. The most investigated category was “Self-rated competencies,” followed by “Psychological and emotional aspects toward digital technologies,” “Use of digital technologies,” and “Knowledge about digital technologies.” In 35% (9/26) of the studies, a previously validated tool was used to measure the competencies assessed, while others developed ad hoc questionnaires.

Conclusions: Mainly descriptive studies with issues regarding methodology quality have been produced to date investigating 4 main categories of digital health competencies mostly with nonvalidated tools. Competencies investigated might be considered while designing curricula for undergraduate, postgraduate, and continuing education processes, whereas the methodological lacks detected might be addressed with future research. There is a need to expand research on psychological and emotional elements and the ability to use digital technology to self-learn and teach others.

Introduction

Background

Over the last few decades, the increasing technology development has led to a wide digitalization of several work processes in health care settings. The World Health Organization (WHO) has recently defined and categorized digital health interventions in the health care context as "a discrete function of the digital technology to achieve health care sector objectives" [1]. The framework developed by the WHO includes a wide range of digital tools and interventions, such as telemonitoring, the use of artificial intelligence, decision-making algorithms, and health data collection [1]. According to the evidence available, digitalization has improved the quality of care, affecting several outcomes at the system level (eg, safety in medication administration and length of in-hospital stay) and at the individual level (eg, increasing functional/cognitive abilities and patients' satisfaction) [2].

Despite its potential effectiveness, digitalization is not fully implemented in clinical practice. Several factors have been identified as possible barriers, including the availability of technology, financial resources, and health care professionals' skills in using digital technology [3]. To improve health care digitalization, health professionals have been recognized as a key factor in the digital transformation of the health care sector. Therefore, they should be equipped with digital health competencies, from basic (eg, computers, tablets) to more complex skills, such as teaching patients about the safe and appropriate use of digital data sources and technology [3].

Digital Health Competencies

Different terms have been established to date by the literature to refer to digital health competencies. The most common term is eHealth literacy, which has been defined as the ability to use information retrieved from an electronic source to solve a health problem [4]. Conceptual frameworks describing the concept and components of eHealth literacy have been developed to date for citizens and patients [5]. For example, Norman and Skinner's Lily framework [4] includes 6 literacy competencies, namely, health, traditional, information, scientific, computer, and media literacy. These competencies have been further expanded, with updated frameworks such as the "Patient Readiness to Engage in Health Internet Technology" (PRE-HIT) and the "eHealth Literacy Framework" (eHLF). These include different elements promoting or hindering eHealth literacy such as motivation, engagement, willingness, anxiety, expectations, and beliefs [6,7]. However, the concepts and components considered in these frameworks should be conceived differently when referring to health care professionals, given that they are expected to have the competencies required to solve patients' problems rather than a personal health problem [8]. As a result of this gap, and in light of the required competencies to overcome barriers in health care digitalization processes [3], an emergent area of investigation has been set around the digital health competencies of health care professionals.

Different frameworks have been developed also in this context, mostly targeting a specific profession, mainly nurses, and using the methodology of expert consultation, surveys, and consensus (eg, the Delphi study) [5]. Among the most recent frameworks, the Health Information Technology Competencies (HITCOMP) [9] framework and the Technology Informatics Guiding Education Reform (TIGER) version 2.0 framework [10] have both identified 33 areas of competence articulated in domains. Specifically, the HITCOMP framework [9] has provided 5 domains, namely, (1) administration, (2) research/biomedicine, (3) direct patient care, (4) informatics, and (5) engineering/information systems/information and communications technology (ICT).

The TIGER framework has described relevant competencies [10] for those who provide direct patient care, including communication, documentation, quality and safety management, teaching, training/education, and ethics in health information technology [10].

In this context, a recent review dared to summarize the digital health competencies expected by health care professionals by synthetizing 30 available frameworks [5]. According to the findings, discrepancies and overlapping are still present across available frameworks regarding the different categorization of the competencies, the methods used to conceptualize such frameworks, and the competencies included [5]. These inconsistencies rely on the different health care professions targeted, including health professionals not involved in direct care, such as engineers [10]. Moreover, half of the 30 frameworks [5] emerged from gray literature and 30% were developed with the involvement of students, thus with different expected responsibilities and competencies [5].

Furthermore, the development of the digital health competencies according to the emergence of new technologies requires a continuous updating of both competencies to consider relevant and methods to assess appropriately these competencies [5]. However, to the best of our knowledge, no recent systematic reviews have been performed on digital health competencies among health care professionals. Providing a systematic summary of literature might inform policymakers, managers, and educators about how to appropriately measure the level of competencies in health care sector and how to develop adequate training programs to fill the gap in the digital health competencies. Moreover, a summary of the available evidence may inform researchers about the gaps in this field of investigation. Therefore, this systematic review aims to summarize which digital health competencies have been studied in literature and with what tools they have been measured to date among health care professionals.

Methods

Research Questions

Two main research questions have been addressed: (1) Which digital health competencies have been investigated to date among health care professionals? (2) How have these competencies been assessed?

Study Design

We conducted a systematic review by adopting the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; Multimedia Appendix 1) checklist [11] both in protocol development and in method and finding reporting. The protocol has been submitted for evaluation to the International Prospective Register of Systematic Reviews (PROSPERO; registration number CRD42021282775).

Eligibility Criteria

Studies satisfying the following criteria were included: (1) assessing digital health competencies as an umbrella term (thus including terms related and similar to, eg, digital literacy [12], health informatics competencies [10], or eHealth competencies [13,14]); (2) targeting health care professionals; (3) adopting a quantitative design (eg, randomized control trial, quasi-experimental trial, longitudinal, cross-sectional studies); and (4) written in English. Therefore, qualitative studies, commentaries, editorials, letters, PhD dissertations, conference abstracts, and all studies that investigated technology accessibility were excluded.

Data Searching

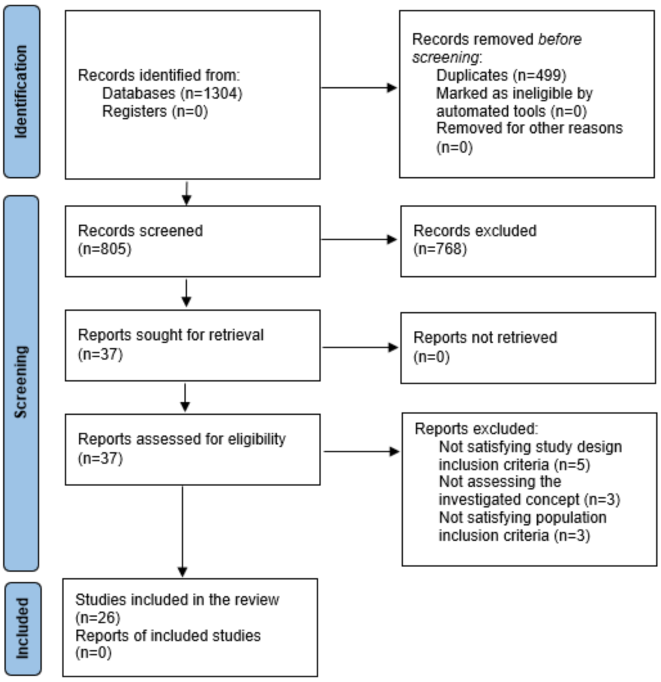
The search string was designed and developed with the support of an expert research librarian and then preliminarily piloted in a database to ensure its accuracy according to the review aims. The final string search included the following keywords: (1) “digital competencies” and “eHealth literacy” in their similar and affiliated terms (eg, digital Health Literacy,” “digital literac*,” “digital competenc*,” “digital skill*”; and (2) “health professionals” in its affiliated and similar term (“health care practice*,” “nurs*”) as fully reported in Multimedia Appendix 2. The search string was applied in the following databases: MEDLINE, Cumulative Index to Nursing and Allied Health Literature, PsycINFO, and Scopus up to September 4, 2021, with an English language restriction filter. In addition, the “TITLE-ABS-KEY” filter was adopted for the SCOPUS database to detect relevant studies. The reference lists of the included studies, the available trial registries, and the references of systematic reviews were screened by hand-searching to retrieve all relevant studies. Moreover, Mendeley Reference Manager was used to manage all references and delete duplicates.

Study Selection

The title, the abstract, and the full-text screening of eligible studies were performed by 2 researchers (JL and GR) independently, and disagreements were resolved by a third researcher (AP). Interrater reliability was assessed using Cohen κ statistics, and it resulted in a value of 0.83 (95% CI 0.73-0.93), meaning an almost perfect level of agreement [15].

The study selection process is summarized in Figure 1 according to the PRISMA flow diagram [11].

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for new systematic reviews that included searches of databases and registers only (Page et al [11]).



Methodological Quality Assessment

Studies were assessed for their methodological quality by 2 researchers (JL and GR) independently, and a third researcher (AP) was consulted to resolve disagreements.

Joanna Briggs Institute tools for analytical cross-sectional [16], prevalence [17], and randomized control trial studies [18] were adopted according to the design used in the included studies. Specifically, regarding observational studies, we considered analytical cross-sectional studies when the statistical analysis was performed to identify associations between variables; otherwise they were considered prevalence studies [17].

For all quality assessment tools adopted, the scores applied were “Y” (yes) when the item was satisfied, “N” (no) when the item was not satisfied, and “U” (unclear) when the information contained in the study was not sufficient. Cut-off criteria were established through an agreement process among researchers based on previous evidence [19,20]. A moderate methodological quality level was identified when positive answers (= yes) were scored from 5 to 6 in analytical cross-sectional studies, from 6 to 7 in prevalence studies, and 10 or 11 in randomized control trials. Positive answers below and above these values were considered low and high methodological quality, respectively.

However, to comprehend all studies, their methodological quality was not considered an exclusion criterion.

Data Extraction, Analysis, and Synthesis

The following data were extracted from each included study: author(s); year of publication; country; study design; population characteristics (eg, age, work profile) and number of participants; investigated digital health competencies; definition(s) provided of the assessed competencies (as reported in the “Study Background” or in the “Methods” sections); tools; and data collection methods used to assess the competencies investigated.

Two Excel grids were developed to extract data from the included studies according to the study aims. The grids were piloted among 3 studies to ensure their feasibility, and consistency was also assessed among the researchers (JL and GR) who performed the data extraction.

After having extracted the data, first, the study characteristics were summarized according to the study design (analytical cross-sectional, prevalence, and randomized control trial studies), reporting their main features and methodological quality. Second, following the aims of this systematic review, digital health competencies were summarized by extracting and analyzing items as open- or closed-ended questions included in the tools used to assess such competencies in each study, irrespective of their formats [21]. The items that emerged were grouped into categories and, when needed, into subcategories through a content analysis [22]. In the content analysis, the researchers adopted a systematic coding and categorizing approach to textual information extracted from the studies to merge patterns, and structure them into main categories and subcategories, by also reporting the frequency [23]. Two researchers (JL and GR) independently performed the entire process, and disagreements were resolved by a third researcher (AP). From the analysis of 362 extracted items used to assess digital health competencies in the included studies, 4 main categories emerged, namely, “Self-rated competencies,” “Psychological and emotional aspects toward the use of digital technologies,” “Use of digital technologies,” and “Knowledge about digital technologies.” Then, the number of items used across studies and the number of studies that assessed each specific category of competence were counted. Furthermore, tools used to assess the competencies in included studies were summarized into their main features.

Results

Main Characteristics of Studies Identified

A total of 1304 studies were identified from literature searches, of which 26 met the inclusion criteria (Figure 1). The majority were cross-sectional studies, of which 11 [24-34] were considered prevalence data studies, and 13 [35-47] as analytical cross-sectional studies (Table 1). Among the remaining ones, 2 were experimental studies [48,49]. The studies included were conducted over a wide range of years, from 1999 [25] to 2021 [27], and more than 65% (17/26) of them [26-28,32,33,35,37,39,40,42,44] have been published in the last 5 years.

In total, 5 studies were conducted in the United States of America [25,30,38,40,41], while the others were performed in different European countries (eg, Germany [34,35] and Finland [25,26]), and in low-income countries (eg, Malawi [48] and Uganda [43]). In terms of the setting, 9 studies [32,33,36,37,43-46,49] were conducted in hospitals. By contrast, the others were performed in mixed settings (eg, acute care [26], local health departments [25], and community [48]).

A total of 8 studies [26,32,36,38,41,42,47,49] involved nurses and 7 [25,27,28,33,39,44,45] covered health care professionals, while the others involved specific roles (eg, psychiatrists [40], pharmacists [31], maternal and child professionals [30]; Tables 1 and 2). The sample size was variable across the studies, ranging from 36 [30] to 5209 participants [39] with a variable age mostly comprised between 30 [46] and 50 years [27].

Table 1. Characteristics of included analytical cross-sectional and prevalence studies.

Study type and reference	Country	Study design	Setting(s)	Sample and profession; age	Competencies assessed	Definition provided of the competencies assessed	Tools/data collection method(s) and items
Analytical cross-sectional studies							
Campbell and McDowell [38]	United States	Descriptive	Community hospital (100 beds)	112 registered nurses; 35 (31.2%) born in the 1960s	Self-perceived computer literacy	Computer literacy: "the skills necessary for accessing and using information, managing files, navigating an operating system, and using common applications, such as word processing" (source: "Background" section)	Gassert/McDowell Computer Literacy Survey (15 items)
Do et al [39]	Vietnam	Cross sectional	12 hospitals and 3 health centers	5209 HCPs[a], 905 (17.4%) aged between 41 and 60 years	eHealth literacy	N/A[b]	eHEALS[c] questionnaire [15] (8 items to measure consumers' combined knowledge, comfort, and perceived skills at finding, evaluating, and applying eHealth information to health problems)
Duffy et al [40]	United States	Cross sectional	Mixed settings	152 psychiatrists; 67 (44 %) aged between 50 and 64 (mean 56.9) years	• Comfort in using computers and other electronic devices for professional, personal, and clinical aims • Computer use for specific clinical tasks	N/A	Web-and-paper-based survey (open- and closed-ended questions)
Elhadi et al [37]	Libya	Cross sectional	Hospitals	673 specialists/senior physicians, physician trainees; 442 (65.7%) aged between 30 and 40 years	• Using computer ability • Awareness, knowledge, attitude, and computer skills about telemedicine	• Awareness: N/A • Knowledge: N/A • Attitude: N/A • Computer skills: level of "information technology and computer skills" (source: "Methods" section)	AKAS[d] questionnaire [27] (Awareness, 12 items; Knowledge, 11 items; Attitude, 11 items; information technology/computer skills, 13 items)
Gaumer et al [41]	United States	Cross sectional	Mixed settings	241 nurse practitioners; N/A	• Use of information technology (general and for specific function) • Benefits perceived from using technology (caregiving, time saving, patient safety) • Self-perceptions about information technology competence	N/A	• Questionnaire: Use of information technology (general: 1 item, specific functions: N/A) • Perceived benefit, 3 items • Self-perceptions about information technology competence, 1 item

Study type and reference	Country	Study design	Setting(s)	Sample and profession; age	Competencies assessed	Definition provided of the competencies assessed	Tools/data collection method(s) and items
Gürdaş Topkaya and Kaya [36]	Turkey	Cross sectional	Hospitals	688 nurses; 293 (42.6%) aged between 20 and 29 years	Computer literacy and attitudes toward computers in health care	Computer literacy: "briefly defined as the ability to use a computer" as well as "the ability to control [a] computer in achieving certain goals," "to use different computer applications," "to comprehend [the] economic, psychological and social effects of computer[s] on [the] individual and society," and "to use [a] computer [for] access to information, [for] communication and [in the] problem solution process" (source: "Background" section)	• Multicomponent Assessment of Computer Literacy, 24 items • Pre-test for Attitudes Towards Computers in Healthcare Assessment Scale version 2, 40 items
Hennemann et al [35]	Germany	Cross sectional	Rehabilitation facilities	149 participants (nurses, psychologists, physical therapists, physicians, patient administration, social workers, art/body/occupational therapists, nutritionists, medical technical assistants); mean 44.35 (SD 11.27) years	• Acceptance of eHealth intervention and of online aftercare • Information technology literacy • eHealth literacy • Performance expectancy • Effort expectancy • Internet anxiety • Knowledge of eHealth interventions	• Acceptance (operationalized according to the UTAUT[e]) "the intention to use eHealth interventions for patients' health promotion in work context, and adoption of online aftercare" • eHealth literacy: the ability to find, evaluate, and utilize internet-based health information to health problems" (source for both: "Methods" section) • N/A for others	• Self-administered web-based questionnaire (acceptance, 4 items; information technology literacy, 1 item; performance expectancy, 2 items; effort expectancy, 2 items; internet anxiety, 2 items; knowledge of eHealth interventions, 2 items) • eHEALS questionnaire [15] (8 items)
Kritsotakis et al [42]	Greece	Cross sectional	Secondary and primary general-care hospitals	200 nurses and nursing assistants; 70 (35%) aged 45-54 years	eHealth literacy	"The ability to find and assess health-related information online at the individual level" (source: "Methods" section)	eHEALS questionnaire [15] (8 items)

Study type and reference	Country	Study design	Setting(s)	Sample and profession; age	Competencies assessed	Definition provided of the competencies assessed	Tools/data collection method(s) and items
Olok et al [43]	Uganda	Cross sectional	Hospitals	68 doctors; 33 (48.5%) aged 31-40 years	• Attitudes toward eHealth • Level of ICT[f] use and skills	N/A	Questionnaire: internal consistence evaluated (level of ICT use and skills on the same 18 items—list of facilities and tools; attitudes, 25 items divided into relative advantages, compatibility, complexity, trialability—not considered, observability)
Shiferaw and Mehari [44]	Ethiopia	Cross sectional	Hospital	287 HCPs; mean 30.09 (SD 5.025) years	• Internet use (types and frequency) • eHealth literacy	• Internet use: “Health professionals’ practice of using the Internet for browsing health-related information to make sound decisions” • eHealth literacy: “participants’ ability to locate and use credible information from the Internet” (source: “Methods” section)	• Internet use, 15 items • eHEALS questionnaire [15] (8 items)
Tesfa et al [45]	Ethiopia	Cross sectional	Teaching hospitals	383 HCPs (nurses, doctors, midwives, pharmacists, laboratory technicians); mean 28.3 (SD 3.37) years	• Electronic health information resource utilization (information searching, technical skills) and purpose of use • Computer literacy • eHealth literacy • Awareness • Attitude • Motivational factors (perceived usefulness and use)	N/A	• Questionnaire (purpose of use, 5 items; N/A for others) • eHEALS questionnaire [15] (8 items)
Thapa et al [46]	Saudi Arabia	Cross sectional	Hospitals	218 physicians and nurses; 61 (28%) aged between 31 and 35 years	• Willingness to use digital health tools in patient care • Attitudes and self-efficacy toward using digital health tools • Digital health tools use perceived benefits and costs	• Willingness: N/A • Self-efficacy: “The belief in one’s own ability to successfully perform various specific actions related to the use of digital tools in patient care” • Attitude: “The perceived relevance/value of different functions of digital tools for active engagement of patients in their own treatment/care” • Perceived benefits: “Positive consequences of using digital tools” • Perceived costs: “Potential psychological, financial, technological and administrative burden” (source: “Methods” section)	Questionnaire (willingness, 1 item; self-efficacy, 12 items; attitude, 10 items; perceived benefit and costs, 20 items)

Study type and reference	Country	Study design	Setting(s)	Sample and profession; age	Competencies assessed	Definition provided of the competencies assessed	Tools/data collection method(s) and items
Vehko et al [47]	Finland	Cross sectional	Hospitals, primary care, private practice, social care, and others	3407 registered nurses; mean age 46.2 (SD 10.99) years	Nurses' informatics competence: classification competence; e-care competence; e-documentation competence; ethics competence	• Classification competence: "Planning, implementation and evaluation of care needs, and the use of the care process according to Finnish Care Classification" • E-care competence: "Use of eHealth tools in tailoring patient care" • E-documentation competence: "Electronic recording of patient data" • E-ethics competence: "Competence in the ethical and safe way to use patient information systems" (source: "Methods" section)	Questionnaire (16 items)
Prevalence studies							
Brady and Knox [24]	Northern Ireland	Cross sectional	N/A	98 psychiatric trainees/consultants (specialist registered, senior house officers, staff grades, consultants); age N/A	Self-rated computing skill levels	N/A	Questionnaire (6 items)
Hollander and Martin [25]	United States	Cross sectional	344 local health departments	Some of or all public health professional staff working in the local health departments; age N/A	Staff internet use and resources used	N/A	Questionnaire (N/A)
Kirchberg et al [34]	Germany	Cross sectional	N/A	93 physicians; 37 (40%) aged between 30 and 45 years	Level of knowledge of eHealth apps and data safety; mobile phone use; attitude toward (evaluation) medical apps for physician and patient use; evaluation of importance of medical app characteristics	N/A	Questionnaire (mobile phone use, 4 items; purpose of mobile phone use, 9 items, level of knowledge of eHealth apps and data safety, 9 items; evaluation of medical apps for physician use, list of 6 apps for patients and 5 apps for physicians; evaluation of importance of medical app characteristics, 7 items; evaluation of importance of privately used app characteristics, 7 items)

Study type and reference	Country	Study design	Setting(s)	Sample and profession; age	Competencies assessed	Definition provided of the competencies assessed	Tools/data collection method(s) and items
Kleib and Nagle [26]	Canada	Cross sectional	Acute care, community, other settings	2844 nurses (generalist registered nurses and registered psychiatric nurses); 1257 (44%) aged ≥50 years	Use of patient care technology; self-perceived informatics competencies (foundational ICT skills, information and knowledge management, professional and regulatory accountability, and use of ICT in delivery of patient care)	Developed framework	• Use of patient care technology (1 item) • Self-perceived informatics competencies: Canadian Nurse Informatics Competence Assessment Scale (21 items)
Kocher et al [27]	Switzerland	Explanatory sequential mixed method	University hospital, regional hospital, rheumatology outpatient clinics	47 professionals (registered nurses, physiotherapists, rheumatologists, occupational therapists, advanced practice nurses, general practitioners, psychologists, social workers, health policy); median age 41 (IQR 31-51) years	eHealth literacy (access, understand, appraise, apply)	• eHealth literacy: “people’s knowledge, motivation and competence to ‘access’, ‘understand’, ‘appraise’ and ‘apply’ health information from electronic sources to address or solve a health problem” • Access: “the ability to seek, find and obtain health information” • Understand: “the ability to comprehend information” • Appraise: “interpret and evaluate information” • Apply: “the ability to use health information to make informed decisions” (source: “Background” section)	Questionnaire based on previously validated instruments (access, 6 items; understand and appraise, 5 items; apply, 9 items)
Kujala et al [28]	Finland	Cross sectional	Public health organization	701 HCPs (nurses, social workers, physicians, dentists, ward secretaries, physiotherapists and other therapists, instrument or facility care personnel, health administration workers, psychologists); mean 44.1 (SD 11.9) years	Self-perceived eHealth competencies; actual patient guidance behaviors	eHealth competence: “A broad set of skills employing ICT and eHealth services, information management, multi-channel health coaching, patient communication, development and implementation” (source: “Background” section)	Questionnaire (self-perceived eHealth competencies, 9 items; actual patient guidance behaviors, 4 items)

Study type and reference	Country	Study design	Setting(s)	Sample and profession; age	Competencies assessed	Definition provided of the competencies assessed	Tools/data collection method(s) and items
MacLure and Stewart [29]	Scotland	Cross sectional	Community and hospital pharmacies	94 participants (pharmacists, reregistration pharmacy graduates, pharmacy technicians, dispensing assistants, medicine counter assistants); 34 (36.2%) aged ≤29 years	Self-reported digital literacy	The British Computer Society defines digital literacy as “Being able to make use of technologies to participate in and contribute to modern social, cultural, political and economic life”. A similar definition of digital literacy is adopted in the United States: “the ability to use information and communication technologies to find, evaluate, create, and communicate information; it requires both technical and cognitive skills” (source: “Background” section)	Self-reported digital literacy (1 item)
Polhamus et al [30]	United States	Cross sectional	N/A	36 maternal and child health professionals; 82% aged ≥40 years	Beliefs in the value of and confidence in using technology	Beliefs in the value of technology: “the extent to which they agreed with a set of questions about the value of a specific technology skill” (source: “Methods” section)	Questionnaire (beliefs, 3 items; confidence, 3 items)
Thomas and Rutter [31]	England	Cross sectional	Mixed settings	386 pharmacists, 83 (21.5%) aged between 50 and 59 years	Confidence in basic computer skills and use of key software applications	N/A	Questionnaire (16 items)
van Houwelingen et al [32]	The Netherlands	Cross sectional	Hospitals	1017 registered nurses; median age 41 (IQR 30-53) years	Confidence in their telehealth knowledge, skills, and attitudes	N/A	Questionnaire (31 items)
Zayapragassarazan and Kumar [33]	India	Cross sectional	Teaching hospitals	120 Health professional faculty working; 57 (40%) aged between 30 and 40 years	Using computer ability; awareness, knowledge, attitude, and computer skills about telemedicine	N/A	AKAS questionnaire [27] (awareness, 12 items; knowledge, 11 items; attitude, 11 items; information technology and computer skills, 13 items)

[a] HCP: health care professional.

[b] N/A: not available.

[c] eHEALS: eHealth Literacy Scale.

[e] UTAUT: Unified Theory of Acceptance and Use of Technology.

[f] ICT: information and communications technology.

Table 2. Characteristics of included randomized controlled trial studies.

Reference	Country	Study design	Setting	Sample and profession; age	Competence(s) assessed and definitions	Intervention	Tools/data collection method(s)
Jouparinejad et al [49]	Iran	Interventional study	Hospitals	60 nurses; 26 (43.3%) aged between 30 and 40 years	• Nursing informatics competencies: Computer literacy: "The psychomotor skills to use computer tools, and knowledge of basic hardware and software functionality" • Informatics literacy: "Nurses' abilities to recognize, retrieve, evaluate and use information for patient care appropriately" • Information management skills: "apply the data to support clinical decisions, documentation, data integrity, confidentiality and security" (source: "Methods" section)	Three-day workshop with theory and practice to develop nursing informatics competencies	Questionnaires: Adapted Nursing Informatics Competence Assessment Tool (30 items): computer literacy (10 items), informatics literacy (13 items), information management skills (7 items)
Mastellos et al [48]	Malawi	Randomized controlled trial	Community	40 community health professionals; 23/39 (49%) aged ≥40 years	• Self-rated ICT[a] knowledge; attitudes toward using computers, tablets, and smartphones	3-week blended learning "Introduction to ICT and eHealth" course (intervention) versus traditional course (control) on same contents	Questionnaire including 10 items to assess self-rated ICT knowledge, and 10 items to assess attitudes

[a] ICT: information and communications technology.

Quality Assessment

The methodological quality was high in 5 analytical cross-sectional studies [35,39,42,46,47] (out of 12; Multimedia Appendix 3), in 1 prevalence study [26] (out of 11; Multimedia Appendix 4), and in 1 randomized control trial study [48] (out of 2; Multimedia Appendix 5). A total of 3 cross-sectional [38,41,43] and 7 prevalence studies [24,25,28-30,33,34] reported a low methodological quality. Among the former, no confounding factors were identified. By contrast, for all studies, the "Not applicable" option was assigned to the item regarding the use of "objective, standard criteria used for measurement of the condition." Among the prevalence data studies, the most unclear item (10/11 studies) was regarding the adequacy of the sample size. By contrast, the item most often scored as "No" (5/11 studies) was the sample description.

Digital Health Competencies Investigated

As many as 13/26 studies [27-30,35-38,42,44,46,47,49] reported the definitions of the concept assessed, which were retrieved from the "Methods" section in 8 studies [30,35,37,42,44,46,47,49].

As summarized in Table 3, "Self-rated competencies" were assessed with 140 items grouped into 4 subcategories. "Digital literacy" emerged as the first subcategory in terms of frequency (59 items, 14 studies) and included items used to assess the self-perceived level of competence in using technology without a specific health goal (eg, in using tablets and mobile phones [43], apps [24], the internet [48], digital cameras [43], and computer literacy [45]). The second was the "eHealth literacy" subcategory, which included the 40 items provided by the 8-item eHealth Literacy Scale (eHEALS) [15] adopted by 5 studies [35,39,42,44,45]. Then, "Patient-oriented competencies" (21 items, 4 studies) included items aimed at assessing the ability, for example, to train and advise patients about technology [32], suitable websites [44], and apps [27], to create confidentiality, to maintain an ethical attitude and convey empathy through videoconferencing [28,32], and to assess the needs of patients regarding telehealth [32]. Lastly, the "Process of care-oriented competencies" subcategory (20 items, 11 studies) included those items assessing the level of competence in retrieving, evaluating, and applying online information, as well as in using eHealth tools to inform the decision-making process in patient care [26,47,49].

The second category, "Psychological and emotional aspects toward digital technologies," was assessed with 110 items by 18 studies. The first subcategory, "Attitudes and beliefs" (82 items, 14 studies), included items assessing attitudes regarding the perceived benefits of the care delivered to and for patients (eg, quality of care and opportunity for self-care [46]); the work benefits perceived (eg, saving [41] and easy access to data [28]); the complexity [43]; the importance, value [28,30], and the feasibility in work [43] of using digital technologies and telemedicine [33,37]. Then, in the second subcategory, "Confidence" (21 items, 6 studies), most items were aimed at assessing the confidence in performing specific activities such as “searching the internet” [31] or “monitoring the patients’ health data using mobile apps” [46]. Finally, in the “Awareness” subcategory (7 studies, 4 items), items assessing the general level of awareness of telemedicine or health information resources and awareness meant as observability were included (eg, to observe the high use of information and communication technology in the workplace [43]).

The third category, “Use of digital technologies” (98 items, 13 studies), included the subcategory “General use of digital technologies” (51 items, 9 studies), which was adopted to investigate the extent to which health care professionals applied the digital technologies in general, for example, the use of computers, printers, the internet, email, and the “Use of digital technologies for specific functions” (47 items, 7 studies) for investigating specific functions as, for example, in documenting care [41], communicating with patients [40], or for research purposes [45].

Lastly, the fourth category, “Knowledge about digital technologies” (14 items, 5 studies), included items aimed at assessing knowledge regarding, for example, telemedicine [37], technical aspects [34], data protection and privacy requirements [32], security, and appropriateness of communication application (eg, WhatsApp, medCrowd) [34].

Table 3. Investigated areas of digital health competencies.

Category and subcategories	Item examples and references	Items, n (n=362)	Studies, n
Self-rated competencies		140	19
Digital literacy	• Self-rated level of computer skill on the application PowerPoint [43] • Level of skills in using body scanner [43]	59	14
eHealth literacy	• 8-item eHEALS[a] tool [15]	40	5
Patient-oriented competencies	• “Can put patients at ease when they feel insecure about using technology?” [32] • “Do you recommend apps to your patients that support them in a healthy lifestyle?” [28]	21	4
Process of care-oriented competencies	• “Can combine my nursing knowledge and experience effectively when using telehealth technology and decision-making” [32] • “I am able to recognize (at a distance) the needs of the patient and determine the care situation” [32]	20	11
Psychological and emotional aspects toward the use of digital technologies		110	18
Attitudes and Beliefs	• “I believe that using ICT[b] is cumbersome” [43] • “Using ICT is compatible with all aspects of my work” [43] • “Be a better caregiver by using information technology” [41]	82	14
Confidence	• “I believe I would be able to use a computer or mobile app to provide patient care” [48] • “Confidence using the Internet logging on” [31]	21	6
Awareness	• “Awareness of telemedicine” [37] • “ICT is very visible in the hospital where I work” [43]	7	4
Use of digital technologies		98	13
General use of digital technologies	• “Do you use and own a mobile phone?” [34] • “If you use the internet, how frequently do you use it?” [44]	51	9
Use of digital technologies for specific functions	• “Do you use the Internet regularly for medical/professional updates?” [44] • Using a computer for a specific clinical task: “Access online patient educational materials” [40]	47	7
Knowledge about digital technologies	• “Is it appropriate to use common email for professional communication in health systems?” [34] • “Do you think a legal obligation for external certification of medical apps is required?” [34]	14	5

[a] eHEALS: eHealth Literacy Scale.

[b] ICT: information and communications technology.

Tools Used to Assess Digital Health Competencies

In 9/26 studies [26,35-39,42,44,45], previously developed and validated tools were adopted to self-assess the competencies, with 5 studies [35,39,42,44,45] reporting the use of the e-HEALS tool [15], while the remaining used the Gassert/McDowell Computer Literacy Survey [38], the Canadian Nurse Informatics Competency Assessment Scale [26], the Awareness, Knowledge, Attitude, Skills tool [37], the Multicomponent Assessment of Computer Literacy, and the Pre-test for Attitudes Towards Computers in Healthcare Assessment tools [36]. The authors of the other studies developed ad hoc questionnaires, using 1 (eg, [32]) or multiple (eg, [49]) questionnaires with the number of items ranging from 1 [29] to 47 [33], mainly including several general dimensions (eg, Awareness, Self-efficacy, Attitudes) [32,33]. In most studies, tools were described in detail by reporting the dimensions of competencies under evaluation and the number of items; only in a few studies was the description poor (eg, [25]; Tables 1 and 2).

Discussion

The discussion has been developed under 2 main lines: around the principal findings emerged and the comparison of evidence emerged with available studies, by including in each the future directions recommended for both practice and research in this field.

Principal Findings

Despite the increased relevance of digital health competencies among health care professionals [50], in the last 20 years, only a few studies have been published, slightly more than 1 per year, with an increase in the last 5 years. Moreover, although there is an urgent need to equip health care professionals with appropriate competencies given the progressive digitalization [1], most studies available to date are cross sectional or prevalence in design and only 2 are experimental studies. In addition, a few studies have been conducted with high methodological quality, suggesting improvements in this research field.

Studies available have been conducted in developed (eg, United States, Europe) and developing (eg, Uganda) countries where different health digital transformations are in place. Therefore, our findings may help policymakers and educators to set competencies according to the stage of digitalization experienced regarding the infrastructures available. However, roughly half of the studies have been focused on hospitals, whereas the community settings and districts have been involved to a lesser extent despite their increased need to implement digitalization with competent health care professionals to address emerging inequalities and issues in terms of health care accessibility [51]. Moreover, studies have more often involved nurses, doctors, or mixed samples of health care professionals, suggesting that all health care profiles have been involved to date, albeit to a limited extend for some (eg, physiotherapists [8]). Given the progressive and expansive permeation of digitalization in the health care sector, all health care professionals should be involved in the assessment of digital health competencies aimed at tailoring educational strategies. Meriting attention is the variable age of participants involved in the studies, from new graduates to mature health care professionals close to retirement. The new generations, also called the “digital native generation” [52], have more attitudes toward digitalization [53], and this suggests the need to deepen this area of study by investigating in future studies specific digital health competencies, despite including other elements such as attitudes (eg, using a computer) that might be relevant only among mature health care professionals.

At the overall level, only half of the studies [27-30,35-38,42,44,46,47,49] reported the definitions of the competencies assessed, and these have been reported mainly in the “Methods” and “Background” sections.

This finding suggests that future studies should be strengthened in their conceptualization and grounded in their development on clear conceptual frameworks and definitions.

Four main categories of investigated areas regarding digital health competencies have emerged, along with 9 subcategories. The area most investigated to date is self-rated competencies, in line with available literature [4,9,10]. In particular, this area includes, among the others, competencies aimed at solving patients’ health or care plan issues. This point suggests an interest among the scientific community in investigating these competencies from innovative perspectives. Training, advising, and supporting patients in the appropriate and confident use of technologies and information retrieved from different ICTs, social media, and internet sources are crucial [54], as also underlined by the framework recently developed by a consortium of multiple European countries [14]. The interest in investigating psychological and emotional aspects of the use of digital technologies has grown increasingly over the years, being assessed in 18 studies. The perceived usefulness for smoothing the care processes, improving its quality and patient satisfaction, and understanding health conditions and the adherence to treatments are crucial elements. Attitudes, acceptance, and confidence [8,12] in using digital technologies, such as electronic prescriptions, remote monitoring, and electronic databases, have demonstrated a positive effect on care processes and patients’ outcomes [2].

A limited number of studies have investigated the use of and the knowledge regarding digital technologies. However, a review of frameworks on digital health competence identified these topics in almost 60% of them [5], suggesting an evident need to promote the awareness of these issues in future research, given the increasing threats to data safety from illegal hacking [55].

A lack of validated tools to measure digital health competencies has emerged. One-third of studies have used a validated tool, the eHEALS of Norman and Skinner [15], although it was developed for patients, thus requiring a specific validation process and adaptation in the field of health care professionals. Moreover, a propensity to develop ad hoc instruments rather than using those already validated has emerged. The reasons for this may rely on the limitations perceived by those available, as well as the rapid evolution of digital technologies and instruments that may require a continuous updating of the competencies to assess. Moreover, in all studies, the tools were intended to assess the perceptions of health care professions rather than measuring their digital health competencies objectively. Self-rated competencies might be useful while educational needs are investigated; however, the actual performance requires objective measurement systems that should be developed in this field.

Comparison With Prior Work

Comparing the categories of competencies emerged in available studies with frameworks established in this field might inform the future directions in both educational practice and research. At the overall level, similarities and divergences emerged. The most common competence between previous frameworks [5,7] and that emerged in our study included the technical skills and the ability to manage and understand information retrieved from technology, including the internet. Psychological and emotional aspects were also highly investigated [4,10,12,14] among the studies included in this review in line with Norgaard and colleagues' [7] eHLF for eHealth users. The engagement, the ability to take responsibility, the perception of feeling safe, and motivation were part of the framework as elements expressing the interaction between the person and the system [7]. Therefore, a debate on how these aspects may influence the digital health competence among health care professionals as well as how to transform them into professional competencies to evaluate merits further consideration.

A recent review indicated that most interventions that aimed to improve the digital health competencies of health care professionals focused on the capability rather than motivation in using eHealth [56]. Interventions promoting digital health competencies should also consider social and environmental factors, foreseeing participatory approaches, to bolster also the emotional and psychological factors toward the use of technology [56]. On the other side, discrepancies emerged regarding teaching, self-development, and learning abilities [12]. The National Health Service (NHS) framework on digital capability [12] embeds domains regarding the abilities, for example, to use digital technologies for personal learning and teaching others [12]. No similar elements emerged in our review. Therefore, future research should focus on the measurement of competencies regarding those aspects, while also considering increased use of blended learning and massive online open courses in continuing education [57].

As highlighted by a previous review [56], we also found that the competencies investigated are still mainly focused on health care professionals' perspectives. However, increased attention is required when considering the competencies to assess patients' needs, attitudes, barriers, facilitators, and potential benefits of being trained by health care professionals in the safe and appropriate use of technology and electronic information for health issues [47]. Therefore, from a self-perceived competence assessment mainly concerning general issues, efforts should now be addressed at developing patient-centered digital health care assessment tools capable of detecting all specific competencies involved in the entire process.

Strengths and Limitations

This systematic review has several limitations. First, despite the accuracy of the process preventing the risk of publication bias by screening 4 databases and the reference lists of the included studies, as well as the trial registries [58], some studies may have been missed given that we adopted the English language filter and gray literature has not been searched.

Second, we adopted "digital health competencies" as an umbrella term to refer to all concepts that emerged from the literature. Although the use of all possible terms (eg, "digital health literacy") in the search string and the inclusion process might have ensured inclusiveness, the summary provided under the same umbrella term might have introduced some limitations. Different aspects of digital health competencies, such as confidence, self-efficacy, attitude, and beliefs regarding digital technologies, have been considered relevant as affecting their use and appropriate adoption in the health care sector. Therefore, we included these elements as part of the umbrella term "digital health competencies," relying on the previous frameworks including them [6,7]. This process has been considered a strength of this review because of the consideration of the full range of competencies as assessed in available studies. Third, previous frameworks [5] mainly focused on the categorization according to technical skills or functions (eg, safety management or care coordination); the content analysis [22,23] performed allowed to include all competencies as documented in retrieved studies, not limiting them to just skills and behaviors. Therefore, we valued also self-concepts, values, personal traits, and motivation (eg, [43]) to map all factors involved. However, the content analysis conducted to categorize the competencies that emerged from included studies was performed by researchers with different backgrounds (eg, nursing, physiotherapy). Although carefully conducted and its reliability assessed with the interreliability rate, their interpretations might have influenced the final categorizations. Lastly, we have synthesized studies originating from different countries, thus differences in health care digitalization might affect the generalizability of the conclusion drawn on future directions for research and training of health care professionals. These should be targeted and adapted according to the characteristic of the countries by training health care professionals based on the technologies available at a local level.

Conclusion

Digital health competence among health care professionals is a new field of research that exploded in the last 5 years. However, studies conducted to date are mainly descriptive and have some methodological quality issues, suggesting lines of improvement. Moreover, with the increased decentralization of the health care sector, more studies are required in community settings, involving a wide range of health care professionals to assess the differences and commonalities in the competencies possessed and tailor specific educational strategies. Furthermore, with the increased size of the digital native generation among health care workers, specific digital health competencies instead of general ones should be investigated.

The different areas of competencies investigated to date might be considered while designing curricula for undergraduate, postgraduate, and continuing education processes. From the perspective of researchers, these competencies may drive the development of competence assessment tools, given the lack of validated instruments in this field, identifying more objective measures in addition to those based on self-perception. Furthermore, researchers should consider moving attention from the self-rated technical competencies to those embodying a patient-centered digital health care approach and related aspects that might affect the use of digital technologies.

In future frameworks and measurement tools, digital health competencies should be considered as a multicomponent competence, not limited to the technical skill, but rather expanded toward elements that might affect them. As our review showed, confidence, attitudes, beliefs, and awareness have been studied with increasing interest, suggesting the need to explore the relationships between different elements and understand how to train health care professionals properly. Curricula embedding the development of technical skills, knowledge, and psychological and emotional aspects of digital technology are recommended.

Abstract

Background: Promoting health behaviors and preventing chronic diseases through a healthy lifestyle among those with a low socioeconomic status (SES) remain major challenges. eHealth interventions are a promising approach to change unhealthy behaviors in this target group.

Objective: This review aims to identify key components, barriers, and facilitators in the development, reach, use, evaluation, and implementation of eHealth lifestyle interventions for people with a low SES. This review provides an overview for researchers and eHealth developers, and can assist in the development of eHealth interventions for people with a low SES.

Methods: We performed a scoping review based on Arksey and O'Malley's framework. A systematic search was conducted on PubMed, MEDLINE (Ovid), Embase, Web of Science, and the Cochrane Library, using terms related to a combination of the following key constructs: eHealth, lifestyle, low SES, development, reach, use, evaluation, and implementation. There were no restrictions on the date of publication for articles retrieved upon searching the databases.

Results: The search identified 1323 studies, of which 42 met our inclusion criteria. An update of the search led to the inclusion of 17 additional studies. eHealth lifestyle interventions for people with a low SES were often delivered via internet-based methods (eg, websites, email, Facebook, and smartphone apps) and offline methods, such as texting. A minority of the interventions combined eHealth lifestyle interventions with face-to-face or telephone coaching, or wearables (blended care). We identified the use of different behavioral components (eg, social support) and technological components (eg, multimedia) in eHealth lifestyle interventions. Facilitators in the development included iterative design, working with different disciplines, and resonating intervention content with users. Facilitators for intervention reach were use of a personal approach and social network, reminders, and self-monitoring. Nevertheless, barriers, such as technological challenges for developers and limited financial resources, may hinder intervention development. Furthermore, passive recruitment was a barrier to intervention reach. Technical difficulties and the use of self-monitoring devices were common barriers for users of eHealth interventions. Only limited data on barriers and facilitators for intervention implementation and evaluation were available.

Conclusions: While we found large variations among studies regarding key intervention components, and barriers and facilitators, certain factors may be beneficial in building and using eHealth interventions and reaching people with a low SES. Barriers and facilitators offer promising elements that eHealth developers can use as a toolbox to connect eHealth with low SES individuals. Our findings suggest that one-size-fits-all eHealth interventions may be less suitable for people with a low SES. Future research should investigate how to customize eHealth lifestyle interventions to meet the needs of different low SES groups, and should identify the components that enhance their reach, use, and effectiveness.

KEYWORDS

eHealth; lifestyle interventions; health behaviors; low socioeconomic status; intervention development; barriers; facilitators; prevention; intervention evaluation

Introduction

Chronic diseases, such as cardiovascular disease and type 2 diabetes, accounted for 74% of deaths globally in 2019 [1]. These diseases are often preventable and treatable. Adopting a healthy lifestyle, such as smoking cessation, increased physical activity, a balanced diet, and decreased alcohol consumption, can reduce the risk of developing a chronic disease [2]. Traditional lifestyle interventions have been shown to be effective in helping people adopt a healthy lifestyle [3,4]. However, these interventions mostly focus on the general population and often disregard vulnerable groups, such as those with a low socioeconomic status (SES; people with a low income or low education, or who are from deprived neighborhoods). There is firm evidence that people with a low SES often engage in more risky lifestyle behaviors and have an increased risk for various chronic diseases and premature death than those with a high SES [2,5-7]. Health inequalities for low SES are associated with a reduced life expectancy of 5 to 10 years and a reduced disability-free life expectancy of 10 to 20 years [8]. Furthermore, it seems that low income and poverty are more often associated with poorer mental health [9,10]. A systematic review by Bull et al [11] found that when lifestyle interventions focus on people with a low SES, most result in small and variable effects [11]. These findings may be due to designers not tailoring lifestyle interventions specifically to people with a low SES or not taking into account their specific characteristics and needs [12,13]. For instance, compared to the general population, individuals with a low SES living in poverty may focus more on coping with their current stressful everyday life (ie, money-related stress and unfavorable work environment). These stressors can lead to choosing unhealthy coping strategies, such as tobacco smoking [14], which could be detrimental to long-term health [14]. These challenges call for a different approach to help this priority group adopt and maintain a healthy lifestyle.

eHealth interventions could proactively support people with a low SES to adopt lifestyle changes [15]. The use of the latest information and communication technologies, such as websites, smartphones, email, text messaging, tablets, and smartwatches [16], offers health professionals and researchers more options to tailor intervention content to the specific needs and characteristics of the user [17]. Furthermore, eHealth interventions can provide users with the information, skills, and resources needed for a positive lifestyle change efficiently and interactively [18]. Health practitioners can reach diverse populations more easily with these interventions than with traditional interventions [18]. eHealth interventions can be supported by video or audio and delivered in an accessible manner to patients for use in their own time and home environment [19]. However, current eHealth interventions require users to have good digital skills and a high literacy level, which are often lacking in low SES groups. Moreover, such interventions must consider their different life situations, health care needs, and eHealth expectations [20]. When eHealth interventions do not consider the needs of this target group, intervention uptake can hinder and reinforce the inequitable use of eHealth, exacerbating health inequalities [21,22].

Studies have shown promising results for eHealth among people with a low SES [23]. For instance, Brown et al [23] showed that their eHealth lifestyle intervention for low SES individuals yielded small but significant changes in behavior. Hayba et al [24] suggested that even modestly effective interventions, sustainably deployed to target vulnerable groups (eg, low SES groups), would add value to the field of public health. Even though there is a growing body of research on eHealth lifestyle interventions for this vulnerable group, there is a lack of insight into how eHealth interventions are currently developed, used, and implemented for people with a low SES. Recently, there has been an increased focus on the specific needs and characteristics of low SES groups to bridge this digital divide. For example, the World Health Organization’s digital intervention guidelines for eHealth usage to improve patient care devoted special attention to the needs, preferences, and circumstances of vulnerable groups, such as people with low (digital) literacy skills [25]. However, current guidelines fall short for researchers and developers who want to develop eHealth lifestyle interventions tailored to people with a low SES. Therefore, this scoping review aims to identify intervention components, barriers, and facilitators in the development, reach, use, evaluation, and implementation of existing eHealth lifestyle interventions for low SES populations.

Methods

Scoping Review Methodology

We conducted a systematic scoping review from June to September 2019. In July 2021, we updated the search following the same procedures. There were no restrictions on the date of publication for articles retrieved upon searching the databases. Since the research area of eHealth lifestyle interventions for low SES groups is still in its infancy, a scoping review method was chosen because it is an appropriate methodology to map key concepts and identify knowledge gaps. A scoping review also offers the opportunity to review published literature with different methodological designs. It further examines the existing literature concerning the volume, nature, and characteristics of the primary research [26]. We used Arksey and O'Malley's methodological framework as a guide for the review [26].

Search Strategy and Eligibility Criteria

We defined the following 5 categories based on 2 frameworks used for the development process of eHealth interventions: development, reach, use, evaluation, and implementation [27,28]. The first framework is the Center for eHealth Research (CeHRes) roadmap, a framework for eHealth development, implementation, and evaluation that combines and uses aspects from approaches like human-centered design, persuasive technology, and business modeling [27]. The second framework is RE-AIM (reach, effectiveness, adoption, implementation, and maintenance), which describes the stages in intervention development and implementation [28]. The categories *development*, *use*, and *evaluation* were derived from the CeHRes roadmap, and the categories *reach* and *implementation* were derived from the RE-AIM framework.

After we defined the scope of the review, we developed a search strategy together with an experienced librarian and domain experts (Multimedia Appendix 1). We searched PubMed, MEDLINE (Ovid), Embase, Web of Science, and the Cochrane Library, using a combination of the following key constructs: eHealth, lifestyle (physical activity, nutrition, alcohol, smoking, and sleep), low SES, and development, reach, use, evaluation, and implementation. The definitions of these key constructs are provided in Multimedia Appendix 2. These databases were chosen because they cover a wide range of scientific articles on eHealth. For each construct, several keywords (spelling variations and synonyms) were used. Exclusion and inclusion criteria were defined based on relevant literature and in consultation with domain experts, after which relevant studies were selected (Textbox 1).

Textbox 1. Inclusion and exclusion criteria for selecting the studies.

Inclusion criteria

- Description of an eHealth/web-based intervention or mHealth/telemedicine intervention
- Definition of socioeconomic status (SES) as the position of an individual on a socioeconomic scale that measures factors by a single variable, such as education, income, or neighborhood status, or multiple variables
- Focus on at least one lifestyle component (physical activity, diet, alcohol, smoking, sleep, or overweight)
- Targeting of a low SES population (>18 years of age)
- Presentation of information on development, use, reach, evaluation, or implementation
- Publication of full text in English
- Any study type (included study protocols)

Exclusion criteria

- Measurement of SES using other variables (eg, race and ethnicity)
- Conference abstracts and reviews presenting filtered information, such as systematic reviews, scoping reviews, and narrative reviews

Data Extraction and Analysis

The eligibility criteria were used to review the articles. Initially, IA screened the titles and abstracts for the first selection of articles. Then, IA checked the bibliographic reference lists of publications that remained after full-text selection to identify any additional eligible publications. Any doubt about the included studies was discussed with the other authors. We extracted general study characteristics (eg, the year of publication and country), and details on SES, effectiveness, development, reach, use, evaluation, and implementation. Data were extracted as barriers or facilitators if they were related to the development, reach, use, evaluation, or implementation phases of the intervention and they were identified or mentioned as facilitators or barriers by the included studies. Even if the barriers and facilitators were mentioned in one of the included studies, they were eligible for inclusion. If there were uncertainties concerning under which phase the barriers and facilitators fell, they were discussed with the other authors.

Furthermore, we selected additional categories based on the CONSORT-EHEALTH checklist (V1.6), which provides helpful guidance on what eHealth studies should report [29]. These added categories were the (behavioral) theories or models used to develop and evaluate an eHealth intervention. The categories also included the level of human involvement in the intervention (eg, automated or human guidance) during the development, evaluation, and implementation (eg, health professionals and researchers).

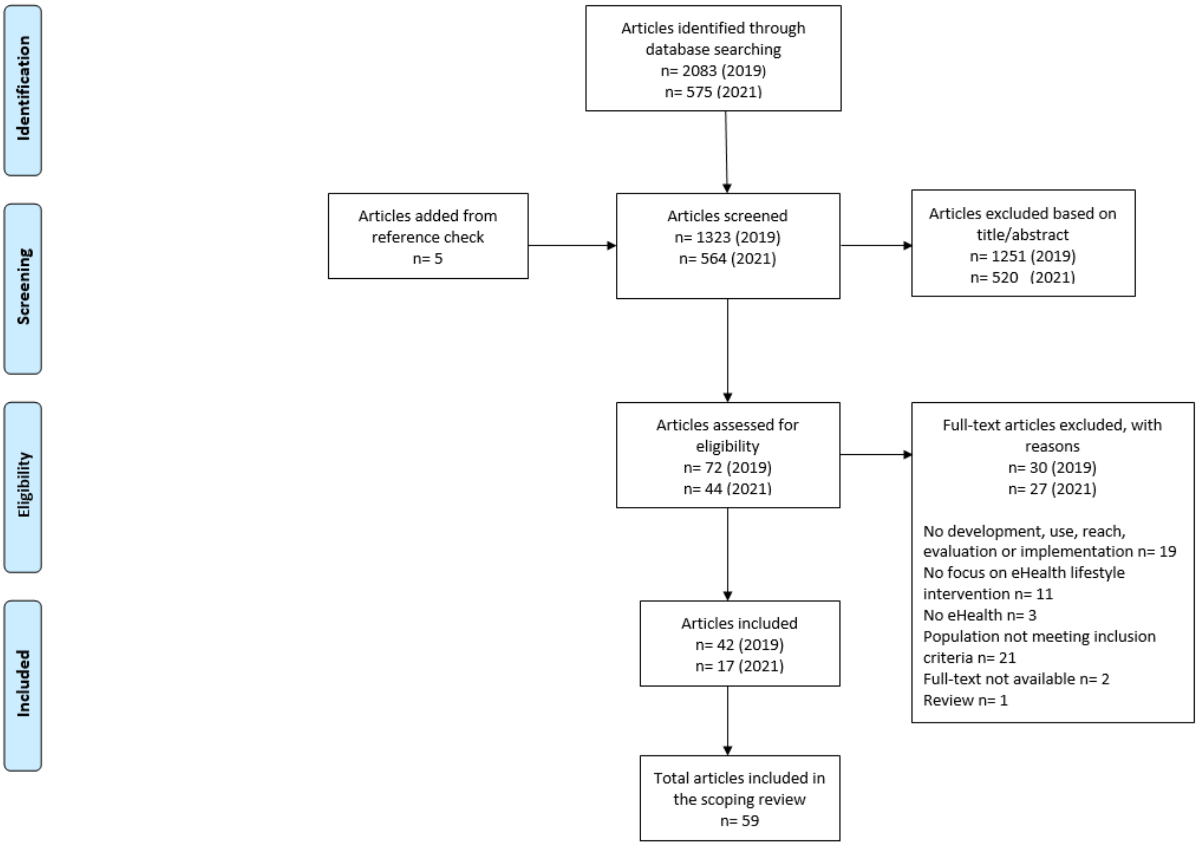
The selected articles were mapped, and data were recorded in Microsoft Excel (Multimedia Appendix 3). Data were synthesized narratively, and the findings were then summarized and grouped into themes as defined by the authors.

Results

Study Selection

The systematic search across the databases revealed 2083 potentially relevant citations. After removing duplicates (n=765) and screening 1323 titles and abstracts, 72 full-text articles were screened for eligibility. Of these, 42 articles met the eligibility criteria and were included in this review (Figure 1). The updated search led to 17 articles that were included in this review.

Figure 1. Flow diagram of the article selection process.



Description of the Included Studies

The studies included were randomized controlled trials (RCTs) [23,30-40], observational studies [41-56], and design studies [57-77]. Several RCTs and observational studies evaluated eHealth interventions on health outcomes (eg, BMI, blood pressure, and hemoglobin A_{1c}) [30, 34, 35-37, 40, 43, 45, 47, 48, 53, 78], nutrition-related behavior outcomes [32, 38, 39, 79, 80], physical activity–related outcomes, smoking-related outcomes [23,31,46,51,81,82], usage outcomes [33,49,54], and reach [44], as well as feasibility and acceptability outcomes [47,80] (Multimedia Appendix 3). Design studies examined recruitment [57], usability, feasibility [57-65], development, or acceptability of eHealth interventions [58-60,64,65,67,68,70].

The interventions were aimed at weight loss (n=9), physical activity (n=9), healthy eating (n=11), smoking (n=13), and alcohol use (n=2), and 17 interventions focused on multiple behaviors. The target audience of these interventions was mainly low SES participants; several studies also targeted a highly educated population [31-33,36,44,53,82].

The different studies assessed the education level [23,30-33,36,40,44,46,53-55,78,82], occupation [23,67], or income level of the participants [43,45,48,51,73,74]. In addition, the participants were recruited from a low SES neighborhood (residents who were unemployed, had a low education, or had a financial disadvantage) [60,64]. A summary of the study characteristics is presented in Table 1.

Table 1. Summary of the study characteristics (N=59).

First author, year	Study design	Target population	Type of eHealth technology
Aguilera [83], 2020	Protocol	Low income[a]	App (and SMS text messaging)

Wayne [78], 2014	Single arm	Low SES	App
Whittemore [70], 2020	Design	Low income	SMS text and MMS messaging
Yee [69], 2020	Design	Low income[a]	SMS text messaging

[a] Socioeconomic status was not specified in the study.

[b] RCT: randomized controlled trial.

[c] SES: socioeconomic status.

[d] Low education, unemployment, or living in poverty.

[e] Socioeconomic status was determined by the occupation and employment status of the household's primary income earner.

Intervention Development and Evaluation

In the various stages of the development and evaluation of the intervention (ie, problem definition, development, and implementation for the study) [48,50,59,60,64,66,69,70,84], several studies involved stakeholders, which included family members, experts, key informants [50,61,69,75,84,86], health professionals, and end users [48,54,64-66,68-70,73,75,83]. However, some studies provided little information on the identification of stakeholders and did not clarify the level of involvement of stakeholders and end users [37,44,50,56,66,70,78,79,81,83,87]. The studies used multiple methods, such as interviews, focus groups, and user testing [50,54,57,64-70,73,75,83], to gain insights from end users and stakeholders. Researchers used focus groups to map the needs and problems of the (potential) users [58,59,61,62,66,68,70,73] and to gain input from stakeholders to adapt existing interventions [61,70,77,86]. These methods also helped the researchers to gain insight into the challenges that participants experienced while using the intervention [65,73,86] and their thoughts on the requirements of successful participation [65,66,68,77,86]. Furthermore, other methods used the Community Engagement Studio [74], a consumer panel [32], and a collective discussion group [60]. The researchers used these methods to improve the accessibility of the interventions for the end users [60,74]. For the development phase, facilitators and barriers were related to technology and content factors. However, regarding the evaluation of the interventions, limited facilitators and barriers were mentioned. Several studies adapted existing interventions, which were developed and tested in different SES groups with various health concerns, such as diabetes, hypertension, mental disorders, and pregnancy [38,45,47,49,56,57,61,70,72,77,79,81,85-87].

Studies adapted these interventions and the delivery modality for use in different low SES groups. Nevertheless, many studies retained most of the content and components of the existing interventions [45,56,57,61,70,72,77,79,81,87]. Many studies chose to adapt the content of the intervention and apply linguistic and content simplification, such as using plain language and low content load through the use of images and videos [57,61,70,81,86,87]. Some studies also made cultural adaptations by using updated cultural components [61,86], translating the content into a second language (eg, Spanish), and employing bilingual coaches [61,86]. Although intervention adaptation was common, documentation of the adjustment process was scarce. Only 3 studies [70,77,85] described in detail the adaptation process and what changes they performed. Furthermore, 2 studies used frameworks (Stirman and the intervention mapping protocol) [77,85], and 1 study [87] used a model (Stage Model) to adapt the intervention.

Tailoring

The majority of the studies tailored the eHealth interventions in various ways to the characteristics and skills of people with a low SES [23, 31-37, 40, 45, 46, 50, 58, 61, 62, 64, 66, 69-72, 74-77, 81-86, 88]. One method of customizing the eHealth intervention matched the content delivery (eg, visual or text information) to the user's language and digital literacy skills [34,50,54,61,64,66,69,70,75,80,84,86]. Another method tailored feedback, advice, and information to the characteristics (eg, cultural adaptations and practical advice relevant to their situation) of individuals with a low SES [23,31,33,35-37,39,40,45-47,58,64,66,74,75,77,81-83,85] or the timing and type of text messages (eg, feedback) [83]. However, it is unknown how tailoring was applied (technology or human tailoring, or a combination of both methods). A few studies based tailoring on theoretical models of behavioral change [31-33,46,70] and gathered information through questionnaires [31-33,36,40,47,55,58,62,66,85], self-monitoring data [23,37,46,55,77,83], or intervention goals [32,74]. However, tailoring the intervention system to deliver feedback or advice proved challenging as it required technological expertise and financial recourses [33,40]. It is unclear whether tailoring led to better results. Because of tailoring the feedback, 1 study showed that lower-educated smokers were more likely to revisit the intervention website [82].

Reach

The included studies applied multiple strategies to recruit low SES participants. However, some studies (n=5; 8%) provided limited details on the strategies they used to reach their participants [35,38,39,62,79]. The recruitment strategies and places are summarized in Table 2.

Different methods were found to be helpful to reach low SES participants. Lohse et al [52] found that Facebook is an effective tool to reach low-income women. Furthermore, the studies that used a personal approach to recruit participants reported a higher enrollment rate [61,82,86,87]. For example, Patten et al [87] found that reaching the targeted population with a face-to-face outreach method was more successful compared to recruitment through flyers. Kim et al [86] found that personal or telephone approaches to recruiting participants were responsible for most of the enrollments in their study. Moreover, participants indicated that they were more receptive to participating in a study when their doctor had previously discussed it with them [86]. Another study found that smokers recruited through general practitioners were more likely to be lower educated and already living with smoking-related illnesses than participants recruited through the internet [82].

Some studies experienced challenges in reaching low SES groups. These studies reached mainly medium or highly educated [33,44] participants with stable incomes and relatively healthy lifestyles [33]. van Dongen et al [44] indicated that people with a low SES may be reached with the right strategies, such as integrating an eHealth intervention into standard midwifery care, increasing awareness about the intervention's existence by expanding mass media use, and involving key community representatives of the target group. Additionally, some studies recommended increasing the reach of lifestyle interventions by collaborating with other experts, such as designers and health professionals [44,61,62]. Tables 3 and 4 show the barriers and facilitators for reach found in the studies.

Table 2. Participant recruitment, places, and strategies.

Recruitment characteristic	Number of studies
Individuals involved in recruitment	
Health professionals [30,34,42,44,74,78,81-85].	11
Researchers [37,40,58,61,81] and research assistants [38,40,80]	8
Study coordinators [86], managers [40,41], organization staff [68], and agent assistance [48]	5
Paraprofessionals [63,79] and volunteers [60,66]	4
Snowballing (*participants recruited other participants*) [58,65,67,82]	4
Recruitment places	
Health care setting [30,35,44,45,53,54,59,61,64,65,68,75,78,80,81,83-86]	19
Federal Benefit and Assistance Program for low-income women [38,42,49,50,56,72,73] and families [43,47,48,57,79]	12
Workplaces [40,77] and care services [34,60]	4
Local communities [59,66,68,71,87]	5
Food bank distributors [39,43,62]	3
Public health insurance [70]	1
Local nongovernmental organizations [51,60]	2
Public places [47,67]	2
Research agencies [31,71]	2
Recruitment strategies	
Online [23,30,32,37,40,43,44,46,47,51,52,55,58,59,61,65,68,73,74,76-78,82,84-87]	27
Newspaper advertisements [33,85], banners [44], flyers, and posters [45,47,50,57,59,61,66,68,77,78,83,85,87]	16
Personal contact (face-to-face) [33,40,45,58,65,67,68,74,80,83] or via phone [51,66]	12
Postal invitation letters [32,37,57]	3
Local television campaigns [32,82]	2
Regional health authority [33]	1

Table 3. Overview of facilitators identified in the eHealth interventions.

Facilitators per phase	Studies
Development	
Iterative design of the intervention (user-centered approach)	[40,46,58,59,61,62,65,66,68,69,74-77,85]
Study staff collaborating with other experts or a digital health company	[53,54,61,62,65,69,88]
Broad number of data sources to inform development	[65,75]
Participants’ knowledge of technology	[60,65]
Providing devices	[39,51]
Concise and clear content	[54,56-59,61,63,64,66,69,70,75]
Use of visual and multimedia elements	[23,30,40,47,56,59,60,63-66,69,70,73]
Resonating content of the intervention with participants	[53,60,61,66,85]
Evaluation	
Conducting formative evaluation in the early stage of the intervention	[40,41,46,55,58,61,62,65,66,68,70,74-76,85]
Reach	
Recruitment through Facebook, and active recruitment through health care professionals and tailored recruitment strategies	[44,47,52,65,82,87]
Collaborating with other experts, such as designers and health professionals, and local community services	[44,61,62,66,75,76]
Use	
Social support (friends, family, and peers)	[34,39,45,50,56,59,60,62,63,69,74]
Self-monitoring	[34,45,48,49,58,61,66,67]
Human coach can be helpful for participants	[30,47,49,50,56,57,87]
Practical advice to incorporate a healthy lifestyle in daily life	[54,56,58,60,63,64,66,73]
Reminders	[33,45,53,59,67,69]
Trust (eg, have a familiar face posting on a social media page) and credible information	[54,60,63,66,69]
Recipes and meal ideas may be useful	[47,54,66,69,73]
Helping participants with technology use	[57,61,66,86]
User friendliness and simplicity	[64,66,70,73]
Interactive features	[64-66,68,69]
Providing incentives and rewards (eg, virtual or financial rewards)	[35,48,53,58]
Links to more information	[64,66,69]
Combining social media with face-to-face group sessions	[47,56]
Networking with others encourages participants’ use of social media interventions	[56,63]
Activities must focus on pleasure and not obligation	[61,66]
Incorporating affordable options	[61]
Implementation	
Supplying the intervention through different platforms	[36]
Increasing direct communication with the health coach	[61]
Training health care professionals	[70]
Collaborating with health insurance	[70]
Server support staff and marketing team continually monitoring the intervention for technical issues	[76]

Table 4. Overview of barriers identified in the eHealth interventions.

Barriers per phase	Studies
Development	
Technical challenges with the intervention software or prototype	[53,58,60,62,70,71,78,86]
Amount of information or visuals	[40,56,59,63,66,68,85]
Limited financial resources for the intervention	[39,53,58,72]
Optimal frequency for reminders or messages	[33,59,68]
Evaluation	
Evaluation is time-consuming	[62]
Slow iterations of the intervention in the academic field	[65]
Reach	
Introductory study presentations and sending reminders to clinicians had a limited effect on increasing referrals	[86]
Passive recruitment (flyers)	[87]
Use	
Technical difficulties using a self-monitoring device or eHealth intervention (eg, lack of internet access, problems with telephones, and poor signal)	[34,40,45,49-51,56,58,60,61,65,66,68,70,71,73,85]
Limited digital skills of users and lack of knowledge of innovative technologies	[34,60,61,65,66,86]
Not wanting extra push notifications and lost notifications among all the notifications from other apps	[40,58,68]
Not allowed to carry a smartphone during work or does not carry a phone	[58,75]
Literacy and not mastering the language	[32,34,60,66,70]
Lack of time in a low SES[a] group	[34,45,49,54,56,60,61,68,69,73,78]
Financial problems (eg, paying bills)	[60,68,69]
Lack of familiarity with other participants before using social media and trust in social media or the internet	[45,60]
Waning participant interest toward the end of the intervention period and low motivation	[40,49,61]
Implementation	
Limited time of staff or coaches	[39,53,74]
Limited financial resources	[39,72]
Difficulties getting medical data of participants from participating health care facilities	[86]
Limited ability of peer coaches	[72]

[a] SES: socioeconomic status.

Use of eHealth Interventions

Most studies did not mention how the participants used the eHealth lifestyle interventions. However, many studies gained insight into the intervention usage by evaluating the concepts of adherence, user engagement, and acceptance [23,40,46,47,49,53,54,56,58,59,61,71,72,74,80,81]. Most of the studies showed that participants with a low SES accepted the eHealth interventions [40,46,47,53,54,56,58,71,74,80]. When there was high adherence, usage, and user engagement, interventions seemed effective [23,81].

Several studies mentioned explicitly measuring intervention usage with Google Analytics (eg, user interactions with content) [40], log data [23,47,54,61], registration data [44], emails sent, quiz questions accessed [44], questionnaires [39,40,44,64], or self-monitoring questionnaires [39]. The data analysis demonstrated that interventions were used as intended [23,61,81]. However, Régnier et al [60] found that the intervention was used to a less extent due to different barriers, such as technical issues, lack of language skills, and searching for real contact. In addition, Simons et al [40] reported decreased use during the intervention because of lesser engagement with the intervention. It also emerged that there was a difference between users within the interventions [33,40,81]. For example, in a study, it was found that the users who received notifications with tips, facts, and feedback mostly used the intervention [40]. Using periodic email prompts significantly increased the reuse of the intervention [33]. Schneider et al [33] concluded that it is crucial to develop strategies that encourage engagement from people with a low SES. Furthermore, hedonic elements (eg, visual elements) in the intervention were significantly associated with increased use [54]. In another study, personal and nuisance factors were associated with lower intervention use, including lower educational achievement and perceived barriers (eg, no time or interest and technical problems) [49]. Barriers and facilitators for using the interventions were diverse and varied in terms of individual and technological factors (Tables 3 and 4).

Other studies have analyzed adherence to interventions [31,35,49,87] by measuring the numbers of messages sent by participants, completion of coach calls [35,87], or intention to visit or revisit the intervention, or using specific features of the intervention, self-monitoring data, and days that participants used the intervention [31,49]. Adherence to the intervention decreased gradually in certain studies [35,49]. Griffin et al [48] showed that noncompleters of the intervention had certain characteristics (were younger, were African American, had a high BMI, had a lower education [high school or lower], and had a low income) when compared with participants who completed the intervention. Engagement with interventions was measured through the self-management behavior of participants [86], the tracking of their behavior via self-monitoring devices [86], self-reporting [56,64], and the presence of several likes, comments, and posts or messages assessed throughout the intervention delivery [47,56,59,72,86], as well as by capturing the frequency of user logins [86]. At the time when intervention engagement was high in several studies [59,61,72], in other studies, engagement decreased during the use of the intervention [45,47,51,71]. In 1 study, participants were more engaged with text messages than voice messages [34]. Another study showed that participant contributions appeared to vary across time of the day and day of the week (more active in the beginning part of the week and during the middle of the day) [47].

Delivery Mode of the Intervention

There was a wide variation in the delivery mode of the intervention. Table 1 provides an overview of the modes used to deliver the intervention. The studies cited several reasons for using a certain delivery mode. Using the internet [23,31,33,42,44,45,55,56,61,63,66,79,81,86], smartphone apps [58,60,73,75,78], or text messages [34,35,50,70,71,75] offers many benefits. Internet-based [36,42,44,45,52,56,64,86] and text-based [34,43,71,77,87] interventions are good channels for reaching hard-to-reach groups and might be effective in changing healthy behavior [32,34,44,47,48,50,54,59,66,70]. They also help to investigate new channels or to deliver interventions to low SES individuals [33,45,47,53,56,57,74,79]. Finally, low SES individuals use the internet, which provides the interventions an opportunity to reach this target group [39,42,45,52,56-58,62,73,86].

Studies reporting on the effectiveness of the delivery mode demonstrated no unequivocal results. Three studies showed that a web-based intervention was more effective for low SES participants [35,41,79] than non-eHealth interventions, such as in-person counselling for low SES participants [79] and game-based versions [41], and website users had deeper knowledge and a higher intention to use the website henceforth [41]. Another study [53] demonstrated that a gamified intervention significantly improved heart failure self-management knowledge in low SES and high SES participants. Participants with lower education levels and older adults preferred a digital game to any other medium for receiving information on self-management of heart failure. One RCT reported no interaction effects between delivery strategy (video versus text advice) and education level in terms of message processing mechanisms and future use of a smoking cessation intervention [82].

Implementation

Most studies did not adequately describe how their respective eHealth lifestyle interventions were implemented, perhaps because almost all the interventions were pilot projects and were not implemented in practice after the study was completed. The few barriers and facilitators that were identified are listed in Tables 3 and 4.

Several studies reported that they collaborated with different disciplines for implementation [55,61,70,72,77,85]. Golsteijn et al [85] created a network of hospitals and radiotherapy institutes to implement the intervention. However, their results on implementation are unknown. Furthermore, it appears that health professionals play an important role in the implementation of interventions [70].

Very few studies discussed the cost of their eHealth interventions. Limited finances and staff time presented several challenges in implementing these interventions [39,72]. Tabak et al [77] considered practicality and sustainability of the intervention by choosing interventions that prevented higher cost, for example, providing automatic feedback instead of individualized feedback. Other examples include finding enough coaches with the expertise to guide participants [72] and working with their time constraints [74]. Studies that reported on how they evaluated the implementation of their interventions were scarce. However, 1 study [85] used intervention mapping to develop an implementation plan. Two studies plan to evaluate implementation in the future. Whittemore et al [70] aimed to document an implementation analysis, and Foley et al [37] aimed to evaluate implementation through the RE-AIM framework.

Effectiveness

A number of studies (n=19) [23, 30, 32, 33, 34, 35, 36, 38, 39, 41, 43, 45, 46, 48, 50, 79-82] investigated the effectiveness of interventions for smoking cessation [23,46,51,81], healthy eating behaviors [32,39,79], alcohol [38,80], weight loss [35,37,45,47], physical activity [34,36,40], and multiple lifestyle changes [30,33,43,48,78]. Three studies [23,46,81] were effective in achieving smoking cessation in the low SES group. Furthermore, some studies reported significant improvements in eating behaviors [32,39,43,79], reduction in weight [35,43,48], and increase in physical activity [34,36,48]. Two RCTs showed that interventions were more effective in high SES participants than in low SES participants [32,36]. One study [32] found educational differences in high-energy snack intake. In this previous study, the plus group (environmental-level factors) received information on the availability and location of healthy food in the home environment and the prices of healthy food products in the supermarkets that the participants usually shop at. The plus approach targeted higher-educated participants more effectively than the basic approach, which was more effective for lower-educated participants. The authors argued that higher-educated participants understood and applied the environmental-level information easier than the lower-educated participants. The intervention as described by Golsteijn et al [36] resulted in a significant improvement in self-reported physical activity. However, the highly educated group initially participated more on the web than their lower-educated peers. In contrast to a study, they found minor effects in low SES participants, but no effect in participants with a higher SES [23]. The authors stated that this is likely because the user testing of the intervention was conducted exclusively with smokers with a low SES, which contributed to its effectiveness in the low SES group.

Two studies [33,45] reported minor significant improvements and modest effects on reuse of a healthy lifestyle program [33]. Other studies reported an insignificant effect [40] due to lower user engagement and dropouts.

Intervention Components

Studies applied diverse components within the interventions. For example, they employed visual and multimedia elements, such as images, infographics, videos, and social support. To a lesser extent, there was human or virtual coaching, and incentives were used. Table 5 presents an overview of the components in eHealth lifestyle interventions.

Table 5. Overview of the eHealth lifestyle intervention components (N=59).

Components	Studies, n (%)
Multimedia (images, infographs, and videos) [23,30,31,35-38,41,46,47,49,55-57,59-66,68,70,76,78,79,84-86]	30 (51)
Self-monitoring [23,30,34-37,40,43,45-49,51,56,58,60,61,65,67,70,76-78,83,84,85,86]	28 (47)
Tips [23,38-40,43-45,48,49,53,54,58,60-62,64,66,68,71,75-77,79,84-88]	28 (47)
Social support [33,34,36,37,40,43,45,47,49,53,55,58,61,62,67,69,71-74,77,84-87]	25 (42)
Reminders [23,30,32,33,36,37,40,45,46,48,49,51,53,55,58,59,65,67,69,78,84-86]	23 (39)
Rewards/incentives [32,34,35,38,41,45-48,50,51,53,56,64,68,73,74,76,79,80,83,87]	22 (37)
Coach [30,35,37,47,51,56,61,66,70,72,74,75,77,78,84-87]	18 (31)
Theoretical frameworks [23,31-34,37,43,46,48-50,55,64,69,70,73-76,80,81,83,85]	23 (39)

Theoretical Frameworks

Several studies (n=23, 39%) stated that they used one or more theoretical frameworks in their interventions [23,31-34,37,43,46,48-50,55,64,69,70,73-76,80,81,83,85]. The frameworks most commonly used were the social cognitive theory [34,37,43,48,64,70,73,85], I-Change Model [31,33,85], and theory of planned behavior [32,81,85], followed by the Health Belief Model [69,76,85], theories of self-regulation [32,85], and Precaution Adoption Process Model [32,85]. However, several studies mentioned using the Techniques of Behavior Change [23,45,46,67,77]; the theories for the rest of the studies can be found in Multimedia Appendix 3. Few studies used the frameworks to develop, adapt, evaluate, or implement the eHealth interventions [37,56,76,79]. It is unclear whether these theories were associated with desirable effects. Although not all studies have reported why they chose the theories [33,53,82], a few mentioned using the constructs or determinants of the theories [32,37,43,81,85], due to their suitability and available evidence [23,34,40,46,55,58,85]. Furthermore, it appeared that some interventions included components, such as self-monitoring, reminders, and social support based on behavioral strategies or theoretical frameworks, to promote lifestyle change or maintain healthy behaviors.

Multimedia and Visual Elements

Many studies included multimedia in their interventions, such as videos [35, 36, 37, 61, 79, 85, 86] or images [23, 38, 40, 46, 53, 55, 59, 62, 63, 89]. Although it was unclear why studies included these materials; some used videos [35-37,61,79,85,86] to introduce the intervention components [37,61], provide skills training [37,79], give home exercise instructions [36,85], or introduce the participants to their coach [86]. Other studies used visual materials, such as images and videos, to increase engagement [56,76]. Interventions applied images because of their visual appeal and ease to recall [55], or to enhance learning and motivate users to continue using the program [76]. There was almost no mention of using graphic artists [62,76] or photographers [76] to create illustrations for the interventions. However, Evans et al [62] stated that selecting illustrations for the app was challenging because matching the main text with illustrations was not always easy and required more iterations to meet the criteria. It was also challenging to find the right graphic artist to design proper images based on the given assignment. In 1 study [56], long videos resulted in lower engagement with Facebook participants. Another qualitative study [60] found that participants who experience language barriers rely more on visual materials (ie, videos) than written materials. However, a study reported that illustrations crowded with visual details confused participants [62]. Another study [63] highlighted that participants emphasized the importance of photos and visual appeal. In the study by Silfee et al [56], participants were more likely to read and comment on Facebook posts containing messages with images. One study [40] made it possible for the participants to see their daily steps via graphs. Although participants appreciated graphs, they used them significantly less at the end of the intervention due to decreased interest and outdated graph data. Only 1 study chose audio to increase the media on the website and facilitate relapse prevention and coping [55].

Social Support

Participants' peers [35,45,47,56,61,63,86] or significant others [34,72,74,87] provided social support, online or offline [35,45,56,61,63,71,86]. Other studies only gave advice on how people can get social support to help each other to adopt new behaviors [40,59,70,85,88]. Three studies mentioned that participants had positive experiences with the social support provided by their significant others [34] or peers [47,56,71] (they perceived a sense of community and social [71], emotional, and instrumental support [34]) and that peers motivated them [56]. For others, the ability to network and interact with peers was an important reason to visit the social media of the intervention [63]. However, it is difficult to determine whether social support contributed to the increased effectiveness of some interventions.

Several studies provided support through social media [35,45,56,61,63,86]. Participants were part of an online social network where they could, for example, discuss their goals [61,86] and challenges [86], and offer each other social support [35,47,61]. However, the studies identified different challenges in supporting active participation in the social support component, such as lack of a connection with other participants before accessing the eHealth intervention, limited engagement with other participants on social media [45,61], and not receiving timely responses from other participants [63]. Furthermore, in a qualitative study [61], participants experienced their level of literacy as an obstacle to taking part in online discussions, while in another study, posting about themselves made some participants with low SES uncomfortable [56], and others did not want to share their unsuccessful weight loss [56]. Involving support persons in the intervention appears to be complicated; some participants with low SES had no support person or did not want to involve one [34,74]. Furthermore, Pathak et al [75] showed that participants who had no family disliked messages that alluded to family support, and the term was replaced by loved ones (similar to familial relations). The interventions [45,56,63] offered many solutions to encourage the use of social support on social media, such as team-building exercises and enlisting friends [45]. The majority of participants of a smoking intervention relapsed, nonrelapsers reported significantly less temptation to smoke, and the qualitative data showed that nonrelapsers were able to manage temptation and reported greater support [50].

Self-monitoring

Several studies used few self-monitoring devices, based on emerging evidence or previous studies [37,85], such as pedometers [34,43,45,56,61,85,86] and weight scales [37,43,45,56,61,86]. Participants with a low SES monitored their diets digitally [30,60], with a calorie-counting book [45], or kept paper records [34,56]. Physical activity was also tracked through Fitbit devices [40,58,77] and MyFitnessPal [56]. Participants entered self-monitoring data [30,43], or this was done automatically [30,37,40,56,77,86]. Simons et al [40] found that continuous engagement with a self-monitoring device was challenging, due to participants not wearing the tracker or forgetting to charge it. Few studies provided information about the participants' experiences, or why the studies chose self-monitoring devices. However, some studies mentioned that participants found self-monitoring devices easy [40,61] and comfortable to use [40,58]. In 2 studies, participants struggled to use tracking devices [34,56], while in another study, participants desired digital apps for calorie counting [45]. It is difficult to determine whether self-monitoring led to increased effectiveness of the intervention. However, 1 study found that food photo journaling improved dietary choices more than having a health coach only [30].

Reminders

Sending reminders to participants was used by many studies; however, it is unclear in some studies how they applied the reminders in their interventions [32,45,53,71]. Two studies applied reminders to improve the adoption of and adherence to healthy behaviors [30,78] and to improve heart failure self-management skills [53]. Other studies applied reminders to encourage participants with low and high SES to visit or revisit the intervention [32,33,86], to remind users about their goals [58,85], and to remind users to submit their self-monitoring information [37]. Reminders were often used in the form of automatic emails [33,46,86,89], push messages via smartphones [40,58,78,86], text messages via mobile phones [37,59], and news updates [85]. The majority of studies did not report on how the participants evaluated the reminders. However, 2 studies showed that participants with a low SES found reminders helpful [53,58]. Furthermore, 2 studies indicated that participants had a greater need for reminders [45,59]. Some interventions that employed reminders appeared to be effective [32,33]. For example, in an RCT, reminders increased revisits to the intervention [33].

Coaches

Several studies included a coaching component in the intervention [30,35,37,47,51,56,61,66,70,72,74,75,77,78,84-87]. The coaches provided guidance mainly by telephone [30,35,37,61,72,74,75,77,78,84,87], followed by face-to-face counselling [30,37,61,74,78,87], text messages, email [30,61,66,78], online counselling [36,49,56,85,86], or combinations of these methods [30,37,61,78]. This was done through health professionals [30,36,37,72,85], researchers [51,56,74,75,77,87], parahealth professionals [49,72], and automatic phone [37,72]. The roles of the coaches varied and included guiding participants in setting goals [35,37], helping to solve problems [85], and providing behavioral skills training [37,56], and they also stimulated discussions on the online platforms of the interventions [56,86]. Interactions with the coaches varied from single, daily, or regular monthly contact [30,35,37,56,72,77,87] to ad hoc, based on needs [85].

Some coaches were experienced in behavioral change methods [30,35,37,56,76,78,87], and 3 coaches applied motivational interviewing [37,72,87]. It is difficult to determine whether coaching led to increased effectiveness of the intervention. However in 3 studies, the coaching component seemed promising [47,49,56]. The coaching component was positively associated with intervention usage [49] or higher engagement [47]. Furthermore, several studies reported that participants with a low SES appreciated the coaches [56,61,74,87]. Moreover, in 1 study, after the coach stopped engaging on social media (eg, posting and commenting), intervention engagement considerably decreased and passive engagement increased [56].

Incentives

Many studies [23, 32, 34, 35, 38, 41, 45, 52, 53, 56, 71, 76, 79, 87] offered participants incentives (eg, gift cards) [23, 32, 34, 35, 38, 41, 45, 52, 53, 56, 71, 76, 79, 87] for completing the assessments [32,34,38,41,45,52,56,71,79,87] to improve response rates [23,52], when submitting their saliva [35,87] or sending their self-monitoring data [35]. Nonetheless, it is unclear whether incentives delivered positive results. In fact, Radhakrishnan et al [53] found that the rewards and incentives offered in a game intervention did not match the real-time behavior, while in another study, participants suggested a greater frequency of incentives [45].

Tips

Providing practical information as tips was mentioned in several studies [23, 38-40, 43-45, 48, 49, 53, 54, 58, 60-62, 64, 66, 68, 71, 75-77, 79, 84-88]. Various studies chose this practical component based on theories [55,68,69,75]. Participants appreciated tips or found it useful to receive practical solutions as tips [54,56,58,66,68]. However, tips have to fit into the socioeconomic and sociocultural realities of people with a low SES [60,61,68]. It is unclear whether tips led to increased effectiveness of the intervention. However, Greene et al [54] found that intervention use was significantly higher among those who found the “Tip of the Day” motivating.

Discussion

Principal Findings

This scoping review provides an overview of the most commonly applied components in eHealth lifestyle interventions (development, reach, use, evaluation, and implementation) for people with a low SES. It also investigates the most common barriers and facilitators for current eHealth lifestyle interventions. The components that emerged can be classified into behavioral components (such as basic theoretical foundation, coaching, social support, reminders, self-monitoring, and incentives) and technological components (such as visual multimedia, reminders, and self-monitoring). Nevertheless, we found considerable heterogeneity in components, barriers, and facilitators, showing significant variation between studies. Moreover, we believe that the majority of barriers and facilitators for development and use are related to technology (eg, technical difficulties) and environmental factors (eg, financial resources of the intervention developers or target group). However, there was limited reporting about the barriers or facilitators within specific interventions, partly because many authors did not always share the lessons learned within their interventions. We should note that the barriers and facilitators may not be generalizable across different lifestyle behaviors, and few may apply to all SES groups and not only to eHealth interventions for low SES groups.

The studies examined the effectiveness of eHealth lifestyle interventions and showed promising but inconsistent results. They showed small effects of smoking cessation, nutrition, increased physical activity, and weight loss. These studies provided limited information about which components contributed to the effectiveness of the intervention, making it difficult to conclude why these interventions worked when compared to those that were unsuccessful. This is in line with the results of the systematic review by Kohl et al [90], which found that effect sizes were small, variable, and unsustainable in eHealth lifestyle interventions for different SES populations and concluded that the efficacy of intervention elements were unclear.

Different Delivery Methods

The results of this review suggest that eHealth lifestyle interventions delivered via different delivery modes (ie, websites, SMS text messages, or apps) or combined with professional personal support seem to be accepted by people with a low SES. However, it is still unclear which delivery method is the most effective for this target group because each delivery mode has its advantages. Danaher et al [91] and Iribarren et al [92] suggested that interventions delivered via text messages may be an attractive option as they are inexpensive, suitable for most mobile phones, and require little user effort. Conversely, interventions delivered via websites or apps provide a visually pleasing option (ie, videos) for communicating the information and make the intervention interactive. However, it is crucial to consider the digital literacy levels of people with a low SES when choosing the delivery method of an intervention. Blended care (combination of face-to-face services with eHealth) offers people with a low SES timely guidance, which can promote engagement and adherence to the intervention. Therefore, we suggest that combinations of varied eHealth delivery modes and face-to-face elements (ie, human coaching) could engage people with a low SES successfully.

Reaching the Low SES Group

Overall, it was clear from the studies that it was difficult to reach low SES individuals for participation in eHealth interventions, which is typical for this group. Thus, a different approach to reach this group is crucial. For example, studies have been successful in reaching participants with active recruiting strategies, such as face-to-face or personal contact [31]. The personal approach may reduce the distance between intervention staff and potential users, create a sense of security, and increase engagement [93]. Long-term relationships build trust between health professionals and patients, and such an approach is needed to reach people with a low SES [93,94]. Moreover, with this rapport, individuals may perceive health professionals as more credible, especially within ethnic minorities [94]. Another promising strategy is collaboration with the social network of people with a low SES (eg, caregivers, relatives, and experts) [44]. Recent studies identified the importance of using a personal approach and connecting via existing networks (ie, community centers or ambassadors) to successfully recruit low SES populations for lifestyle interventions [20,93]. Furthermore, we found that social media may achieve this goal since it has a broad reach, but the lack of robust evidence makes it difficult to draw firm conclusions. Social media may be particularly effective to reach young people. However, reaching people with a low SES remains challenging as there is no clear reach strategy. A similar pattern of results was obtained in the systematic review by Bonevski et al [95], which found that proven strategies to reach socially disadvantaged groups were rare. This highlights the importance of tailoring reach strategies, both online and offline, to target different types of groups (eg, young populations and ethnic minorities) within the low SES population. Lessons can also be drawn from traditional lifestyle interventions that provide insight into reaching low SES groups [96].

First Phase of Intervention Design and Co-creation

We noted that few studies based their interventions on behavioral theories. When behavioral theories were reported, authors rarely elaborated on how they applied these theories. These results seem to be consistent with other research that found that behavioral theories were seldom applied in interventions [88,97,98]. One possible explanation for this might be that intervention components are developed with a practical viewpoint in mind or a pre-existing belief in the benefit of these components, since they have been used previously in effective interventions [98] Alternatively, it may be that certain behavioral theories were not found to be useful for the development of the intervention at hand and were therefore not applied [99]. However, using theories in interventions has been indicated to increase their effectiveness.

There are several issues to consider in the co-creation of eHealth interventions, such as how and when stakeholders and users get involved. In recent years, more attention has been paid to the role of stakeholders (including users) in public interventions; however, involving stakeholders (eg, people with a low SES and health professionals) from the beginning is time-consuming and expensive [32]. Follow-up research needs to explore the best way to actively involve low SES individuals in developing and evaluating interventions, as co-creating with end users seems promising.

Implementation

The results of this review show that the development, evaluation, and implementation of eHealth are difficult to distinguish from each other and that the implementation of the intervention takes place during its development. As advocated by Pieterse et al [100], eHealth development and implementation should be intertwined. Implementation should be accounted for from the start of the development process; this is especially true for people with a low SES, since their characteristics, such as low digital skills, may hinder the interventions' implementation [61].

A shortage of resources is also known to impact implementation. These findings are directly in line with previous findings. For example, Lau et al [101] and Ross et al [102] found in their reviews that available resources, including time, funding, and staff, can be both barriers and facilitators in the implementation of interventions.

Recommendation for Design and Research, and Limitations

There are still unanswered questions in the development, reach, use, evaluation, and implementation of eHealth interventions for a low SES population, as the research is in its infancy. Using existing guidelines (eg, the CONSORT checklist) or other frameworks could guide in reporting information comprehensively and clearly [29]. For instance, use of the behavior change technique taxonomy by Michie et al [89] can help researchers to report on the behavioral theories and techniques applied in the intervention. Furthermore, it is vital to report more detailed information on how participants use the components of eHealth interventions, which may help identify elements that contribute to the effectiveness of eHealth interventions. This information could be beneficial for future studies and interventions as it can guide developers in the design and implementation of effective eHealth interventions. Another recommendation is to collaborate with researchers, developers, and stakeholders (including users) in the development, evaluation, and implementation of eHealth lifestyle interventions, to fine-tune these to the target group's needs and requirements. Involving the social networks (eg, relatives and peers) of low SES participants in eHealth lifestyle interventions also seems promising. Research shows that engaging social networks can support low SES participants who experience problems with their digital skills [60]. It is therefore important to investigate what role social networks should play within eHealth lifestyle interventions. Finally, although many studies advised making the content of eHealth interventions accessible to people with low skills, clear recommendations for developers and researchers on how eHealth interventions for low SES populations can be developed, implemented, and evaluated were lacking. Future research should focus on how we can devise holistic eHealth guidelines that can assist developers and researchers with the creation of eHealth interventions that take the capabilities and requirements of this target group into account.

This review is the first to focus on state-of-the-art available knowledge about developing and evaluating eHealth lifestyle interventions, and reaching people with a low SES to realize behavioral change and improve health in these people. The barriers and facilitators that we found offer promising elements that eHealth developers can use as a toolbox to connect eHealth with low SES target groups. Further research on the method of using these tools is still needed. However, this review has some limitations. First, we only included studies on eHealth interventions that focused on lifestyle behaviors and excluded studies on interventions aimed at other relevant areas for low SES individuals (mental health, and medical, legal, and financial issues). These interventions may provide additional insights. Second, as the primary focus was to gain insight into how eHealth lifestyle interventions are developed and evaluated for low SES individuals, we did not assess the quality of the studies and their results (ie, systematic review). Finally, we focused on the low SES group in general and did not distinguish between subgroups. Although ethnicity is not an indicator of SES, ethnic minorities (eg, non-Western immigrants and African American individuals) were often mentioned as prominent groups in the studies. It is therefore important to consider the differences within the low SES population, with the aim of not further increasing health disparities.

Conclusions

This scoping review provides an overview of the available scientific knowledge on the behavioral and technological components, barriers, and facilitators in the development, evaluation, and implementation of eHealth lifestyle interventions. Although eHealth intervention development is diverse, contributing to the varying results in this review, certain factors may be beneficial for building and using eHealth interventions and reaching people with a low SES. Iterative design of interventions, use of visual and multimedia elements, and social support seem to be important facilitators for eHealth interventions. Technical challenges using eHealth interventions, lack of time in low SES groups, and limited resources appear to be key barriers for eHealth interventions. Understanding these barriers and facilitators may generate insights into how to optimize eHealth interventions for people with a low SES. Developing eHealth interventions for people with a low SES requires consideration of their specific needs and characteristics, and the involvement of users. This may contribute to the use of interventions and may facilitate their implementation.

Guidelines should be developed to aid stakeholders in developing and evaluating eHealth interventions. Moreover, high-quality studies are needed to investigate how eHealth lifestyle interventions can be customized to meet the needs of participants with a low SES. Future studies could benefit significantly from detailed reporting on eHealth interventions for this target group.

Acknowledgments

Abstract

Background: The number of artificial intelligence (AI) studies in medicine has exponentially increased recently. However, there is no clear quantification of the clinical benefits of implementing AI-assisted tools in patient care.

Objective: This study aims to systematically review all published randomized controlled trials (RCTs) of AI-assisted tools to characterize their performance in clinical practice.

Methods: CINAHL, Cochrane Central, Embase, MEDLINE, and PubMed were searched to identify relevant RCTs published up to July 2021 and comparing the performance of AI-assisted tools with conventional clinical management without AI assistance. We evaluated the primary end points of each study to determine their clinical relevance. This systematic review was conducted following the updated PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines.

Results: Among the 11,839 articles retrieved, only 39 (0.33%) RCTs were included. These RCTs were conducted in an approximately equal distribution from North America, Europe, and Asia. AI-assisted tools were implemented in 13 different clinical specialties. Most RCTs were published in the field of gastroenterology, with 15 studies on AI-assisted endoscopy. Most RCTs studied biosignal-based AI-assisted tools, and a minority of RCTs studied AI-assisted tools drawn from clinical data. In 77% (30/39) of the RCTs, AI-assisted interventions outperformed usual clinical care, and clinically relevant outcomes improved with AI-assisted intervention in 70% (21/30) of the studies. Small sample size and single-center design limited the generalizability of these studies.

Conclusions: There is growing evidence supporting the implementation of AI-assisted tools in daily clinical practice; however, the number of available RCTs is limited and heterogeneous. More RCTs of AI-assisted tools integrated into clinical practice are needed to advance the role of AI in medicine.

Introduction

Background

Artificial intelligence (AI) was first described in the 1950s as a theory of human intelligence being exhibited by machines, including but not limited to learning, reasoning, and problem-solving [1]. With an exponential increase of computational power, reduced cost of data storage, improved algorithmic sophistication, and increased availability of health data from electronic health records, the era of AI has arrived in different specialties of medicine [2-4]. AI-assisted tools have been successfully applied in various clinical settings to assist diagnosis [5], improve therapy [6], and predict risk of mortality [7]. To date, 64 AI-powered medical devices and algorithms have been approved by the Food and Drug Administration in the United States [8].

The number of AI-related articles (using the Medical Subject Headings term, "artificial intelligence" as the search keyword) in the health care literature has increased dramatically from 6802 articles in 2016 to 21,160 in 2020. However, only a minority of these are prospective clinical studies, and there are few randomized controlled trials (RCTs). Several systematic reviews have been conducted to summarize the performance of recent AI-assisted tools in specific clinical settings, such as AI-assisted adenoma detection during colonoscopy [9], AI-assisted mammography in detecting breast cancer [10], AI-assisted intracranial hemorrhage recognition on computed tomography head imaging [11], AI-assisted glycemic control for patients with diabetes, and AI-assisted diagnosis of diabetes and its related complications [12]. A recent systematic review examined all studies of AI application in clinical practice, but was limited by restriction to English language and only searching full manuscripts published between January 2010 and May 2020 [13].

Objectives

To date, no systematic review has been restricted to RCTs regarding the clinical performance of AI-assisted tools in real-life practice. As RCTs represent the best clinical evidence to examine the effects of an intervention while controlling for unmeasured confounding factors, a comprehensive search of all RCTs studying AI-assisted tools in clinical practice would provide information regarding areas of opportunity for AI to affect real-world patient care [14]. We conducted a systematic review of all RCTs studying AI-assisted tools in clinical care.

Methods

Search Strategy

The systematic review was conducted following the updated PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines [15]. We comprehensively searched CINAHL, Cochrane Central, Embase, MEDLINE, and PubMed from inception to July 14, 2021, to identify RCTs of AI-based tools across all medical specialties. Details of the full search strategy are provided in Multimedia Appendix 1. The search strategy included a combination of keywords and standardized Medical Subject Headings terms: "Artificial Intelligence," "Deep Learning," "Computer-Assisted Diagnosis," "Computer Assisted Diagnosis," "Computational Intelligence," "Computer Reasoning," "Computer Vision System," "Knowledge Acquisition," "Knowledge Representation," "Machine Intelligence" or "Machine Learning" or "Transfer Learning" or "Hierarchical Learning." The search was limited to RCTs. We also hand searched the references of the included studies to identify additional studies of interest. To include as many previous endeavors in this research area as possible, our search was not limited to peer-reviewed information. Conference abstracts and preprints were also included. The authors had no funding source for this study. This study was registered on PROSPERO (CRD42021286539).

Study Selection

After removing duplicates, two study authors (TYTL and MFKC) independently screened the title, abstract, and full text (if available) of each article to determine their eligibility. Unresolved disagreements were resolved by consulting the senior author (JJYS). Discrepancies were resolved by consensus. The complete manuscript was downloaded if the study met the inclusion criteria. We included studies that met the following inclusion criteria: (1) application of AI-assisted tools in clinical practice, which is defined as diagnosis, treatment, and prognostication on medical conditions that are seen and managed in daily clinical practice in hospitals or clinics. This does not include cellular or tissue cultures, animal studies, or experimental conditions such as induced cardiac arrhythmia and metabolic abnormalities. We classified the tool as AI-powered if the expressions, "artificial intelligence," "AI," "machine learning," "deep learning," "deep neural network," and "neural network" were used to describe the tool within the articles or other publicly available information resources; (2) patients or health care providers must be involved; (3) study design must be an RCT; and (4) control group must be without AI assistance. The exclusion criteria were as follows: (1) studies without implementation of clinical AI-assisted tools for patient management; (2) studies that were not conducted as original RCTs, for example, secondary analysis of a published RCT; and (3) clinical outcome not clearly defined. Reasons for exclusion were also recorded.

Data Extraction

After identifying relevant studies, the same two authors (TYTL and MFKC) independently extracted the data from each included study. Study design (racial information, sample size, RCT setting and design, and AI intervention and control) and AI-assisted tool characteristics (AI-assisted tool name, AI subtype, data type, and training and validation data) were documented. If AI development–related data were not available in the included articles, previously published articles of the same AI-assisted tool were reviewed to obtain the relevant information. Study end points (performance metrics used in primary and secondary end points) were listed. Clinically relevant end points were defined as whether the AI-assisted tools led to subsequent clinical interventions focusing on specific end points: (1) further diagnostic workup and investigation of the medical conditions, (2) changes in treatment strategy, (3) requirement of hospitalization, (4) escalation of care to the intensive care unit, and (5) influence on survival and mortality. Two independent researchers (TYTL and MFKC) resolved disagreements through discussion. If there were unresolved disagreements, consultation from senior author (JJYS) was sought.

Assessment of Risk of Bias

Risk of bias was assessed using the Cochrane risk-of-bias tool for randomized trials [16]. We specifically assessed the risk of bias of randomization process, deviations from intended interventions, missing outcome data, measurement of the outcome, and selection of the reported results. The overall risk of bias was classified as low, some concerns, or high.

Results

Overview

The search performed on July 14, 2021, yielded 11,839 articles (n=2232, 18.85% from MEDLINE; n=1406, 11.88% from Embase; n=2264, 19.12% from PubMed; n=5229, 44.17% from Cochrane Central; and n=708, 5.98% from CINAHL); of these, 6823 (57.63%) were screened after removal of duplicates (n=5016, 42.37%). After screening the titles and abstracts, 6676 articles were excluded, because they did not fulfill the inclusion criteria. A total of 147 full manuscripts were individually assessed, of which 34 (23.1%) met the inclusion criteria. In addition, 4 more articles were identified by examining the references of the listed articles and manual searches (Figure 1). A total of 39 articles were included in this systematic review [6,17-54] as listed in Table 1.

Wu et al [52], 2021	Evaluating the effects of an artificial intelligence system on endoscopy quality and preliminarily testing its performance on detecting early gastric cancer: a randomized controlled trial	China	Original article	Gastroenterology and hepatology
Yao et al [53], 2021	Artificial intelligence-enabled electrocardiograms for identification of patients with low ejection fraction: a pragmatic, randomized clinical trial	The United States	Original article	Cardiology
Brown et al [54], 2021	Deep learning computer-aided polyp detection reduces adenoma miss rate: a US multi-center randomized tandem colonoscopy study (CADeT-CS trial)	The United States	Original article	Gastroenterology and hepatology

Study Characteristics

There were very few RCTs on AI-assisted medicine published until 2017. There was 1 RCT published in 2009, and the remaining 38 were published in the past 5 years (2 in 2017, 3 in 2018, 7 in 2019, 14 in 2020, and 12 in the first half of 2021; Figure 2).

These RCTs were conducted across 16 countries in North America, Europe, and Asia, with most of them conducted in the United States (13/39, 33%) and China (12/39, 31%). Furthermore, 18% (7/39) of the RCTs were published as conference abstracts only. Of these 39 publications, 16 (41%) were related to gastroenterology, whereas other specialties included anesthesiology (n=3, 7.7%), cardiology (n=3, 7.7%), endocrinology (n=3, 7.7%), psychiatry (n=2, 5%), neurology (n=3, 7.7%), orthopedics (n=2, 5%), oncology (n=2, 5%), surgery (n=1, 2.6%), ophthalmology (n=1, 2.6%), respiratory medicine (n=1, 2.6%), family medicine (n=1, 2.6%), and emergency medicine (n=1, 2.6%; Figure 3).

Figure 2. Number of randomized controlled trials of artificial intelligence–assisted medicine per year.

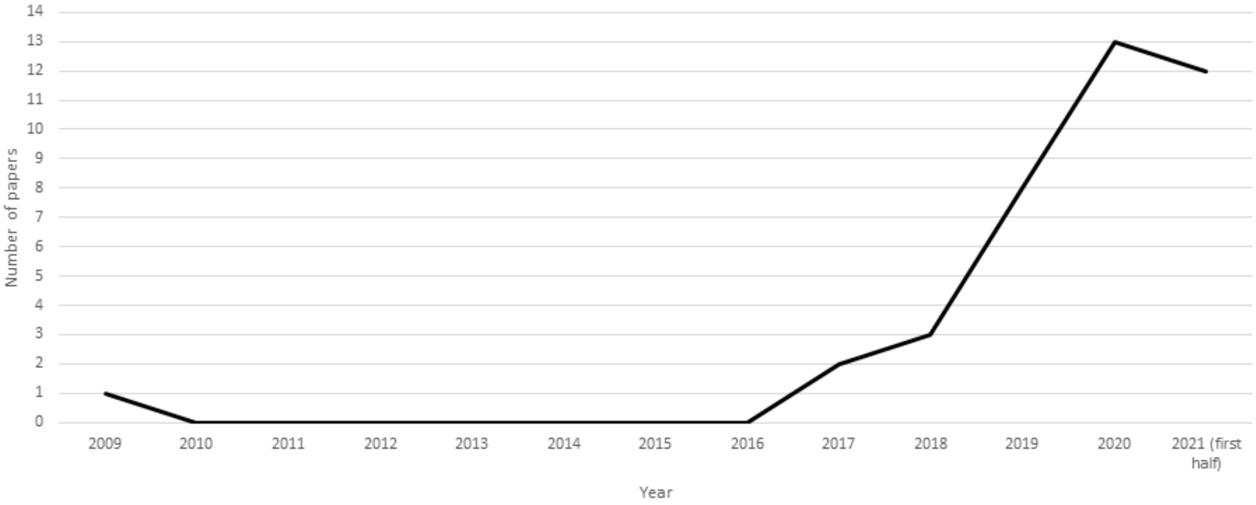

Figure 3. Distribution of original of publications and specialty.

Study Design

Multimedia Appendix 2 shows the study design and AI-assisted tool characteristics of each selected RCT. Most studies were single centered with a limited number of patients. Of these 39 studies, 35 (90%) had a sample size <1000 participants, 11 (28%) studies recruited fewer than 100 participants, 2 (5%) studies had a sample size of >1000 participants, and only 2 (5%) studies recruited >10,000 participants. More than half of the included RCTs (23/39, 59%) were conducted in a single center, 36% (14/39) of the studies were conducted across multiple centers, and 5% (2/39) of the studies did not mention how many centers were involved. A total of 16 open-label studies were conducted. Only 7 studies mentioned the racial information of the participants. A total of 13 blinded randomized trials were identified, of which 4 (31%) were double blinded and 9 (69%) were single blinded. The remaining 10 studies did not mention the level of blinding. Furthermore, 8 studies had a crossover study design. Most RCTs (36/39, 92%) compared the AI-assisted tools to control arms using the standard of care. Furthermore, 5% (2/39) of the studies used a sham treatment without AI assistance as the control group. A study used a mobile app without AI assistance as the control arm.

AI-Assisted Tool Characteristics

Biosignal-based AI tools are more common than clinical data–based tools. A total of 26 AI-assisted tools were biosignal based. Endoscopic images were the most commonly used biosignal (15/26, 58%). Furthermore, 50% (13/26) of the AI-assisted tools used clinical or biochemical data for analysis (patients' demography, self-administered questionnaire, and other relevant clinical data such as blood test results, blood pressure, and continuous positive airway pressure). No AI-assisted tool used both biosignal and clinical data combined as source data in the algorithm.

Most AI-assisted tools relied on static data (34/39, 87%) input to build the algorithm instead of dynamic data input (5/39, 13%). Static data refer to a snapshot of image or data of patients at a specific time point, whereas dynamic data are those captured continuously over a certain period during the study. For example, still images of the intestinal lumen captured during colonoscopy for AI-assisted adenoma detection are static data, whereas hourly captured vital signs and selected available laboratory tests for AI-assisted prediction of severe sepsis are dynamic data [18].

Approximately half of the studies (19/39, 49%) reported the AI-assisted tools development process. Of these, three AI-assisted tools in 8 studies, namely, GI-Genius, EndoScreener, and CC-Cruiser, were developed using data from multiple centers, whereas others were developed using data from a single center. A total of 35 studies reported the AI developer. Of these, 18 (51%) AI-assisted tools were developed by industry and 17 (49%) were developed by academic institutions.

Study End Points

Table 2 presents the study objectives and end points. Approximately half of the studies (18/39, 46%) used diagnostic accuracy as primary end point. The most common diagnostic end point is adenoma or polyp detection rate during colonoscopy. A total of 13 studies measured treatment response after AI-assisted intervention. Quality assurance of interventions was examined in 7 studies. End point measures of 27 studies were considered clinically relevant: 19 (70%) led to further investigation, 6 (22%) indicated the need for change in treatment, 1 (4%) reported in-hospital mortality and length of hospitalization, and 1 (4%) reported hospital admission.

Table 2. Study objectives and end points (primary and secondary).

Author (publication year)	Study objective	Primary end point	Secondary end point	Clinical relevance
El Solh et al [17], 2009	To test the effectiveness of an ANN[a] application for CPAP[b] titration on the time required to achieve an optimal CPAP pressure and CPAP titration failure	Time to optimal CPAP pressure	Titration failure rate	Change of treatment
Shimabukuro et al [18], 2017	To test the use of a machine learning–based severe sepsis prediction system for reductions in average length of stay and in-hospital mortality rate	Average hospital length of stay	In-hospital mortality rate; ICU[c] length of stay	Mortality and hospital and ICU length of stay
Labovitz et al [6], 2017	To evaluate the use of an artificial intelligence platform on mobile devices in measuring and increasing medication adherence in patients with stroke on anticoagulation therapy	Medication adherence	Nil	Nil
Gracey et al [19], 2018	To evaluate the effectiveness of using artificial intelligence to target which patients should receive interventions compared with traditional targeting approaches to improve medication adherence	Medication adherence	Nil	Nil
Liu et al [20], 2018	To assess the effects of clinical decision support system of graph-based machine learning algorithms on blood pressure management and economic burden of disease	Blood pressure reduction in patients with hypertension	Economic burden	Change of treatment
Vennalaganti et al [21], 2018	To evaluate the use of WATS[d] as an adjunct to biopsy sampling for the detection of HGD[e] or EAC[f] in a referral population with BE[g]	Rate of detection of HGD or EAC	Neoplasia detection rates based on the procedure order (WATS vs biopsy sampling first) of each procedure separately and the additional time required for WATS	Further investigation
Biester et al [22], 2019	To evaluate the safety and efficacy of 60-hour glucose control using the MD-Logic system in individuals with type 1 diabetes at home for day and night use, particularly without remote monitoring	Percentage of glucose sensor readings within 70 to 180 mg/dL (3.9-10 mmol/L)	Percentage of glucose sensor readings <60 to 70 mg/dL (3.3-3.9 mmol/L), percentage of glucose sensor readings >180 to 240 mg/dL (10-13.3 mmol/L), average and SD of glucose sensor readings, and overnight percentage of readings (“overnight” defined as 11:00 PM-7:00 AM) <70 mg/dL (3.9 mmol/L)	Further investigation
Pouska et al [23], 2019	To assess the use of HPI[h] to avoid hypotension in major intracranial surgery	Number of hypotension events; duration of hypotension events	Number of hypotension events in maintenance phase of anesthesia	Further investigation
Lin et al [24], 2019	To compare the diagnostic efficacy and treatment decision-making capacity between CC-Cruiser and ophthalmologists in real-world clinical settings	Accuracy of the diagnosis normal lens versus cataract	Evaluation of the disease severity; time required for making the diagnosis; patient satisfaction	Further investigation
Kamdar et al [25], 2019	To examine the impact of ePAL on cancer pain severity, attitudes toward cancer pain, and health care use	Pain severity	Attitudes toward cancer treatment (Barriers Questionnaire II); anxiety (General anxiety Disorder-7); pain-related hospital admissions	Hospitalization
Persell et al [26], 2020	To evaluate the effectiveness of an artificial intelligence smartphone coaching app to promote hypertension self-management	SBP[i] measured at 6 months	Self-reported medication adherence; home monitoring and self-management practices; self-efficacy related to BP[j] and BMI; self-reported health behaviors	Change of treatment

Author (publication year)	Study objective	Primary end point	Secondary end point	Clinical relevance
Voss et al [27], 2019	To test the efficacy of a wearable machine learning tool for intervention on a core ASD[k] deficit in the natural home environment	SRS-II[l] total score; Vineland Adaptive Behavioural Scales, Second edition; Developmental Neuropsychological Assessment, Second edition; Emotion Guessing Game	Moderator analysis; child behavior checklist; and the Vineland Adaptive Behavioural Scales, Second edition adaptive composite score	Nil
Wang et al [28], 2019	To investigate whether a high-performance real-time automatic polyp detection system can increase polyp and ADRs[m] in the real clinical setting	ADR	PDR[n]; mean number of polyps detected per colonoscopy; mean number of adenomas detected per colonoscopy; rate of false positives and false negatives	Further investigation
Wu et al [29], 2019	To evaluate the effectiveness of WISENSE to monitor blind spots, time the procedure, and automatically generate photo documentation during EGD[o] and thus raise the quality of everyday endoscopy	Blind spot rate	Inspection time; completeness of photo documentation generated by endoscopists; completeness of photo documentation generated by WISENSE in WISENSE group; completeness of photo documentation generated by WISENSE and endoscopists in WISENSE group; the percentage of patients being ignored in each site	Further investigation
Pavel et al [30], 2020	To evaluate the performance of the ANSeR[p] algorithm in real time by assessing the diagnostic accuracy for the detection of neonatal electrographic seizures with and without the use of ANSeR as a support tool for clinicians at the cot side	Diagnostic accuracy (sensitivity, specificity, and false detection rate) of health care professionals to identify neonates with electrographic seizures and seizure hours with and without the support of the ANSeR algorithm	Summary measures of seizure burden (total seizure burden, maximum hourly seizure burden, and median seizure duration); number of inappropriate antiseizure medications given	Change of treatment
Alfonsi et al [31], 2020	To test the app's usability and potential impact on carbohydrate counting accuracy	Carbohydrate counting accuracy	Quality of life for youth; self-care; patient or parent responsibility	Nil
Auloge et al [32], 2020	To evaluate technical feasibility, accuracy, safety, and patient radiation exposure granted by a novel navigational tool integrating augmented reality and artificial intelligence during percutaneous vertebroplasty of patients with vertebral compression fractures	Technical feasibility of trocar placement using augmented reality or artificial intelligence guidance	Comparison between groups A and B in terms of accuracy, procedural safety, time for trocar placement, and patient radiation exposure (dose area product and fluoroscopy time)	Nil
Avari et al [33], 2020	To evaluate the safety and efficacy of the PEPPER system compared with a standard bolus calculator	Difference in change in percentage time in range (3.9-10.0 mmol/L; 70-180 mg/dL) between the intervention arm that receives the PEPPER safety system with adaptive bolus advice and the control arm	Percentage time spent in euglycemia, hypoglycemia, and hyperglycemia; number of episodes of serious hypoglycemia; episodes of hypoglycemia within 5 hours postprandially; severe hypoglycemia (defined as a hypoglycemia event requiring third party assistance); postprandial mean area under the curve at 5 hours (expressed as mmol/L min); glycemia risk and variability measures	Change of treatment
Chen et al [34], 2020	To compare blind spots of sedated C-EGD[q], unsedated U-TOE[r], and unsedated C-EGD with and without the assistance of ENDOANG	The blind spot of 3 types of EGD with the assistance of ENDOANGEL	Blind spot rate of unsedated U-TOE and unsedated and sedated C-EGD with or without the assistance of ENDOANGEL; consistency between ENDOANGEL and endoscopists' review	Further investigation

Author (publication year)	Study objective	Primary end point	Secondary end point	Clinical relevance
Gong et al [35], 2020	To evaluate whether the ENDOANGEL system could improve polyp yield during colonoscopy	ADR	The ADR for adenomas of different sizes (diminutive [≤5 mm], small [>5 to<10 mm], and large [≥10 mm]); locations (cecum, ascending colon, transverse colon, descending colon, sigmoid colon, and rectum); PDR; PDR for polyps of different sizes; locations; mean number of adenomas per patient; mean number of polyps per patient; withdrawal time (time spent viewing as the endoscope is withdrawn during a colonoscopy, excluding biopsy or treatment time); adverse events and serious adverse events	Further investigation
Liu et al [36], 2020	To investigate whether the integration of a CADe[s] system into the primary monitor used during colonoscopy may increase polyp and adenoma detection without increasing physician fatigue	ADR	PDR; polyps per colonoscopy and adenomas per colonoscopy	Further investigation
Nicolae et al [37], 2020	To evaluate the noninferiority of day 30 dosimetry between a machine learning–based treatment planning system for prostate low-dose-rate brachytherapy and the conventional manual planning technique	The 1-month postoperative follow-up results between expert-planned low-dose-rate treatments (conventional) and the PIPA[t] machine learning approach	The efficiency of the PIPA approach in a standardized preoperatively planned workflow; total treatment planning time; need and extent of modifications	Nil
Repici et al [38], 2020	To assess the safety and efficacy of a CADe system in detection of colorectal neoplasias during real-time colonoscopy	ADR	Proximal ADR; total number of polyps detected; sessile serrated lesion detection rate; mean number of adenomas per colonoscopy; cecal intubation rate; withdrawal time	Further investigation
Su et al [39], 2020	To develop an automatic quality control system and assess whether it could improve polyp and adenoma detection in clinical practice	ADR	PDR; mean number of adenomas detected per colonoscopy; mean number of polyps detected per colonoscopy; withdrawal time (biopsy time was excluded by stopping the clock); adequate bowel preparation rate, defined as the percentage of colonoscopies with each segmental BBPS[u] score 2	Further investigation
Wang et al [40], 2020	To compare adenoma miss rates of CADe colonoscopy vs routine white-light colonoscopy.	Adenoma miss rate	Polyp miss rate; miss rate of advanced adenomas; sessile serrated adenoma or polyps; patient miss rate; ADR for the first pass; adenoma per colonoscopy; polyp per colonoscopy	Further investigation
Wang et al [41], 2020	To perform a double-blinded study using a sham control to more rigorously assess the effectiveness of a CADe system for improving detection of colon adenomas and polyps. We also aimed to analyze the characteristics of polyps missed by endoscopists	ADR	PDR; number of polyps per colonoscopy; number of adenomas per colonoscopy; sensitivity; specificity of the 3 skilled endoscopists	Further investigation
Wijnberge et al [42], 2020	To test whether the clinical application of the early warning system in combination with a hemodynamic diagnostic guidance and treatment protocol reduces intraoperative hypotension	Time-weighted average of hypotension during surgery	Incidence of hypotension (the number of hypotensive events per patient): total time with hypotension and percentage of time spent with hypotension during surgery; incidence of hypertension (the number of hypotensive events per patient): total time with hypertension and percentage of time spent with hypertension during surgery	Further investigation
Weisinger et al [43], 2021	To explore the benefit of BrainQ's novel and noninvasive, artificial intelligence–powered, frequency-tuned ELF-EMF[v] treatment (BQ) in improving upper extremity motor function in a population with subacute ischemic stroke	Fugl-Meyer Assessment-Upper Extremity score	Modified Rankin Scale; Action Research Arm Test; Box and Block Test; NIHSS[w]	Nil

Author (publication year)	Study objective	Primary end point	Secondary end point	Clinical relevance
Blomberg et al [44], 2021	To examine how a machine learning model trained to identify OHCA[x] and alert dispatchers during emergency calls affected OHCA recognition and response	Rate of dispatchers' recognition of subsequently confirmed OHCA	Dispatchers' time to recognition of OHCA; rate of DA-CPR[y]	Change of treatment
Browning et al [45], 2021	To assess the clinical effectiveness of using a predictive algorithm based on behavioral tests of affective cognition and subjective symptoms and to guide antidepressant treatment	Treatment response of depression symptoms	Change in anxiety scores at week 8 (measured using the Generalized Anxiety Disorder Assessment, 7 item version [30]); remission of depression at week 8 (defined as QIDS-SR-16[z] score of ≤5); change in the individual item scores from the QIDS-SR-16 measuring restlessness and sadness at week 8; change in symptoms of depression (treated as a continuous variable) across 12 months (measured using QIDS-SR-16); change in observer-reported symptoms of depression (treated as dichotomous response and as a continuous variable and measured using the MADRS[aa] at week 8); change in functional outcome across 12 months (measured using the SAS[ab] screener); patients also completed detailed health economic, acceptability, and cognitive functioning measures that will be reported separately	Nil
Jayakumar et al [46], 2021	To assess the effect of an artificial intelligence–enabled patient decision aid that includes education, preference assessment, and personalized outcome estimations (using patient-reported outcome measurements) on decision quality, patient experience, functional outcomes, and process-level outcomes among individuals with advanced knee osteoarthritis considering total knee replacement in comparison with education only	Decision process score of the knee decision quality instrument questions 3.1 to 3.5	Level of shared decision-making (assessed using the CollaboRATE survey); patient satisfaction with the consultation (numerical rating scale); condition-specific symptoms and functional limitations (Knee Injury and Osteoarthritis Outcome Score, Joint Replacement); duration of consultation in minutes; total knee replacement rates (proportion of patients undergoing surgery); treatment concordance (knee decision quality instrument question 1.6)	Nil
Kamba et al [47], 2021	To clarify whether adenoma miss rate could be reduced with the CADe assistance during screening and surveillance colonoscopy	Adenoma miss rate	Polyp miss rate; sessile serrated lesion miss rate; ADR	Further investigation
Luo et al [48], 2021	To explore whether artificial intelligence–assisted colonoscopy could improve the PDR in the actual clinical environment	PDR	Number of polyps detected; the number of diminutive polyps (diameter <6 mm); the number of polyps of each Paris type detected; the number of false positive results	Further investigation
Rafferty et al [49], 2021	To determine whether Heali, a novel artificial intelligence dietary mobile app can improve adherence to the LFD[ac], IBS[ad] symptom severity and quality of life outcomes in adults with IBS or IBS-like symptoms over a 4-week period	Adherence to the LFD	IBS symptom severity; quality of life outcomes	Nil
Repici et al [50], 2021	To assess the efficacy of a CADe system in detection of colorectal neoplasias in a nonexpert setting to challenge the CADe impact in a real-life scenario	ADR	Proximal ADR; total number of polyps detected; sessile serrated lesion detection rate; mean number of adenomas per colonoscopy; cecal intubation rate; withdrawal time	Further investigation
Strömblad et al [51], 2021	To assess accuracy and real-world outcome from implementation of a machine learning model that predicts surgical case duration	Accurate prediction of the duration of each scheduled surgery	Effects on patients and systems were measured by start time delay of following cases; time between cases; the time patients spent in presurgical area	Nil
Wu et al [52], 2021	To verify the effectiveness of ENDOANGEL in improving endoscopy quality and pretest its performance in detecting EGC[ae] in a multicenter randomized controlled trial	Number of blind spots	Performance of ENDOANGEL in predicting early gastric cancer in a clinical setting	Further investigation

Author (publication year)	Study objective	Primary end point	Secondary end point	Clinical relevance
Yao et al [53], 2021	To assess whether an ECG-based, artificial intelligence–powered clinical decision support tool enables early diagnosis of low EF[af], a condition that is underdiagnosed but treatable	Rate of newly diagnosed low EF, defined as EF≤50% within 90 days	Completion of an ECG within 90 days; other findings (eg, valvular heart disease), except low EF present on ECGs	Further investigation
Brown et al [54], 2021	To assess the comparative adenoma miss rate for CADe-assisted colonoscopy when compared with high-definition white light colonoscopy alone	Adenoma miss rate	Polyp miss rate; hyperplastic polyp miss rate; sessile serrated lesion miss rate; ADR; PDR; adenoma per colonoscopy; polyp per colonoscopy; sessile serrated lesion per colonoscopy	Further investigation

[a] ANN: artificial neural network.

[b] CPAP: continuous positive airway pressure.

[c] ICU: intensive care unit.

[d] WATS: wide-area transepithelial sampling.

[e] HGD: high-grade dysplasia.

[f] EAC: esophageal adenocarcinoma.

[g] BE: Barrett’s esophagus.

[h] HPI: hypotension probability indicator.

[i] SBP: systolic blood pressure.

[j] BP: blood pressure.

[k] ASD: autism spectrum disorder.

[l] SRS-II: Social Responsiveness Scale II.

[m] ADR: adenoma detection rate.

[n] PDR: polyp detection rate.

[o] EGD: esophagogastroduodenoscopy

[p] ANSeR: Algorithm for Neonatal Seizure Recognition.

[q] C-EGD: conventional esophagogastroduodenoscopy.

[r] U-TOE: ultrathin transoral endoscopy.

[s] CADe: computer-assisted detection.

[t] PIPA: prostate implant planning algorithm.

[u] BBPS: Boston Bowel Preparation Scale.

[v] ELF-EMF: extremely low frequency and low intensity electromagnetic fields.

[w] NIHSS: National Institutes of Health Stroke Scale.

[x] OHCA: out-of-hospital cardiac arrest.

[y] DA-CPR: dispatcher-assisted cardiopulmonary resuscitation.

[z] QIDS-SR-16: Quick Inventory of Depressive Symptomatology (16-Item) (Self-Report).

[aa] MADRS: Montgomery-Åsberg Depression Rating Scale.

[ab] SAS: Social Adjustment Scale.

[ac] LFD: low fermentable oligo-, di-, mono-saccharides and polyols diet.

[ad] IBS: irritable bowel syndrome.

[ae] ECG: electrocardiogram.

[af] EF: ejection fraction.

Study Outcomes

Table 3 shows the study results and limitations of each RCT. Of the 39 RCTs, 30 (77%) reported a positive study outcome where AI-assisted interventions outperformed the control arms. Of these 30 studies with positive outcomes, 22 (73%) AI-assisted interventions were biosignal based, and 8 (27%) studies used clinical data–based AI-assisted intervention for clinical outcome improvement. In addition, 21 of these 30 (70%) studies reported positive results of clinically relevant end points. Of these, 18 (86%) led to further investigations, 1 (5%) led to change in treatment, and 2 (9%) reduced the length of hospitalization.

Table 3. Study results and limitations.

Author (publication year)	Primary end point result	Secondary end point result	Study outcome	Underpowered	Study conclusion	Limitations
El Solh et al [17], 2019	Time to optimal CPAP[a] pressure: AI[b] mean 198.7 (SD 143.8) minutes versus control mean 284.0 (SD 126.5) minutes	Titration failure: AI 16% versus control 36%; drop of residual obstructive apnea–hypopnea events and oxygen desaturations	Positive	No	Maximizing the time to achieve optimal CPAP and in reducing CPAP titration failure	Single center only; possible analysis bias as technologists were not blinded
Shimabukuro et al [18], 2017	AI 10.3 days versus control 13 days	In-hospital mortality: AI 8.96% versus control 21.3%; ICU[c] length of stay: AI 6.31 days versus control 8.40 days	Positive	No	Significant decrease in the hospital LOS[d] and in-hospital mortality	Small sample size; heterogenous population; trial was conducted in the 2 ICUs only; metrics were not monitored prospectively during the study because of the likely misrepresentation of such results; false positive rate, sensitivity, and prediction rate may be affected as clinicians may have initiated treatment before severe sepsis onset owing to advanced notice from the predictive algorithm; the use of overall metrics, LOS, and in-hospital mortality for all comers may underestimate the impact of the intervention on outcomes for patients with sepsis; potential for competing risks in the selected end points, mortality may shorten a patient's LOS; this study was patient-outcome oriented
Labovitz et al [6], 2017	Mean (SD) cumulative adherence based on pill count was 97.2 (4.4%) for the AI platform group and 90.6% (5.8%) for the control group. Plasma drug concentration levels indicated that adherence was 100% (15/15) and 50% (6/12) in the intervention and control groups, respectively	Nil	Positive	Unknown	Real-time monitoring has the potential to increase adherence and change behavior, particularly in patients on direct oral anticoagulant therapy	Not mentioned
Gracey et al [19], 2018	Likelihood of being adherent: AI>control, 6.11%; likelihood of being adherent: AI>traditional, 7.8%; no significant difference in likelihood of being adherent	Nil	Positive	Unknown	Using AI to target interventions can increase the effectiveness of medication adherence intervention programs	Not mentioned

Author (publication year)	Primary end point result	Secondary end point result	Study outcome	Underpowered	Study conclusion	Limitations
Liu et al [20], 2018	AI versus control: no significant difference	Economic burden of disease—AI versus control (all): no significant difference; economic burden of disease—AI: 46,006 (SD 40,831) yuan (US $6901 [SD 6125]) versus control (in surgical dept): 64,192 (SD 67,968) yuan (US $9629 [SD 10195])); benefit-cost ratio of AI: 1.15; net present value of benefit-cost of AI: 5792 yuan; direct medical costs—AI: 43,467 (SD 39.716) versus control: 61,205 (SD 66,576) yuan	Negative	Unknown	A clinical decision support system based on the graph-based machine learning algorithms changed the antihypertensive prescriptions and reduced the medical expense among patients with hypertension	Not mentioned
Vennalaganti et al [21], 2018	HGD[e] or EAC[f] detection—WATS[g] alone: 29 versus control alone: 7; AI (alone)>control (alone) 4.2 times	Neoplasia detection rates: not mentioned; average time required for WATS; additional time required for WATS: 11 minutes 26 seconds versus control: 6 minutes 55 seconds	Positive	Unknown	WATS increases the detection of HGD and EAC in a high-risk BE[h] surveillance population when used as an adjunct to biopsy sampling compared with biopsy sampling alone	Single center research only; potential of population bias as study population (20%) was enriched with patients with BE with a known history of dysplasia or referred for endoscopic therapy; no long-term follow-up
Biester et al [22], 2019	AI: 66.6% versus control: 59.9%	Percentage <60 mg/dL—AI: 0.64% versus control: 0.38%; percentage <70 mg/dL—AI: 2.31% versus control: 1.45%; percentage >180 mg/dL—AI: 28.32% versus control: 36.43%; percentage >240 mg/dL—AI: 8.53% versus control: 8.71%; Mean —AI: median (IQR) 153.11 (142.33-174.81) versus control: 163.84 (150.17-186.54); SD—AI: median (IQR) 52.71 (44.75-66.39) versus control: 54.95 (46.19-69.19)	Positive	No	The MD-Logic system was safe and associated with better glycemic control than SAP[i] therapy for day and night use. The absence of remote monitoring did not lead to safety signals in adapting basal rates nor in administration of automated bolus corrections	High rate of communication errors between the tablet computer running the algorithm and the insulin pump
Pouska et al [23], 2019	No significant difference in number of hypotension events between 2 groups (4/20 vs 2/20)	AI: 10 versus control: 4	Negative	Unknown	On the basis of our data, it seems that the inclusion of HPI[j] into a goal-directed treatment strategy could lower the incidence of hypotension within maintenance phase of anesthesia	Not mentioned

Author (publication year)	Primary end point result	Secondary end point result	Study outcome	Underpowered	Study conclusion	Limitations
Lin et al [24], 2019	Accuracy—AI: 87.4% versus control: 99.1%	No significant difference in evaluation of the disease severity between AI and control; AI: 2.79 minutes versus control: 8.53 minutes; rating of overall satisfaction—AI: mean 3.47 (SD 0.501) versus control: mean 3.38 (0.554)	Negative	No	CC-Cruiser exhibited less accuracy compared with senior human consultants in diagnosing childhood cataracts and making treatment decisions, but it has the capacity to assist human physicians in clinical practice in its current state	Patients without symptoms were less willing to participate in; patients with slightly opaque lens may have missed; CC-Cruiser provided treatment suggestions without considering the patients' general conditions; lack of internet accessibility limited the implementation of CC-Cruiser in low-income areas; possibly sufficient statistic power because cluster RCT[k] was adopted in trial, whereas RCT was used in sample size calculation
Kamdar et al [25], 2019	Difference of BPI[l] between AI and control: ß=−.09	Difference of BQ-II[m] between AI and control: ß=−.037; difference of General Anxiety Disorder-7 between AI and control: ß=.21; AI: 4 versus control: 20	Positive	Unknown	AI significantly decreases pain scores and pain-related hospitalizations in patients with cancer-related pain	Not mentioned
Persell et al [26], 2020	AI: mean systolic blood pressure (SD) 132.3 (15.0) mm Hg versus control: 135 (13.9) mm Hg	Significant improvement in self-reported medication adherence in AI group than control; no significant difference between home monitoring and self-management practices; AI group has 26.7 minutes per week (−5.4 to 58.8) more than control group in self-reported physical activity	Negative	Unknown	Adults with hypertension randomized to a coaching app plus home monitor had similar SBP[n] compared with controls receiving a tracking app and home monitor	Blinding to participants and research staff is impossible; some outcomes were self-reported; not specifically select participants who were likely to use a health-coaching app; small sample size; the app used in the study was a beta version; the AI and machine learning technology used here in this app gains information with larger numbers of users contributing data; cannot exclude the possibility that some patients may have well-controlled hypertension; limited generalizability because only iOS device users were recruited
Voss et al [27], 2019	SRS-II[o] showed large, not significant, positive mean changes in treatment participants; the VABS-II[p] socialization subscale score significantly increased between the start and end of the intervention in treatment-to-control comparisons	Moderator analyses showed a moderation effect for girls showing greater improvement; no significant changes from intake to posttest 1 were observed on Child Behaviour Checklist; the VABS-II adaptive composite score showed slightly greater improvement in younger participants	Positive	Yes	This study underscores the potential of digital home therapy to augment the standard of care	According to the poststudy empirical variance, this study may be underpowered by a factor of 2; low treatment adherence; bias in recruitment of participants; bias owing to the inherent demographic and behavioral heterogeneity of patients; second posttest appointments were not available for control participants before crossing over into treatment

Author (publication year)	Primary end point result	Secondary end point result	Study outcome	Underpowered	Study conclusion	Limitations
Wang et al [28], 2019	AI: 29.1% versus control: 20.3%	AI: 0.45 versus control: 0.29 (OR[q] 1.995, 95% CI 1.532-2.544); AI: 0.97 versus control: 0.51; AI: 0.53 versus control: 0.31; false positive rate of AI: 0.075 per colonoscopy; false negative rate of AI: not mentioned	Positive	No	In a low prevalent ADR[r] population, an automatic polyp detection system during colonoscopy resulted in a significant increase in the number of diminutive adenomas detected as well as an increase in the rate of hyperplastic polyps	Endoscopists were not blinded; lack of external validity; despite low false positive rates, potential distraction during the procedure could also be caused; fatigue level of participating endoscopists were not controlled; inadequate sample size of colonoscopies performed by junior endoscopists; only Olympus colonoscopy equipment was used
Wu et al [29], 2019	AI: 5.86% versus control: 22.46%	AI: 5.03 minutes versus control: 4.24 minutes; AI: 71.87% versus control: 79.14%; AI: 90.64% versus control: 79.14%; AI: 92.91% versus control: 79.14%; percentage of patients being ignored in majority gastric sites were significantly lower than control	Positive	No	WISENSE greatly reduced blind spot rate, increased inspection time, and improved the completeness of photo documentation	Only Olympus and Fujifilm endoscopes were used in this trial; the withdrawal time in this trial was generally less than recommended 7 minutes of EGD[s] in the guideline
Pavel et al [30], 2020	Diagnostic accuracy (sensitivity, specificity, and false detection rate) for recognition of a neonate with seizures were not significantly different between the 2 groups; sensitivity of seizure hours—AI: 66% versus control: 45.3%; false detection rate of seizure hours was not mentioned	No significant differences found in seizure characteristics; AI: 37.5% versus control: 31.6%; difference 5.9%	Negative	No	In conclusion, this clinical investigation was the first to assess the performance of a machine learning algorithm for neonatal seizure detection in real time and in the real-world setting of busy neonatal ICUs throughout Europe	Excluded seizures with a duration of <30 seconds from both groups; analysis was done using seizure hour instead of looking at each individual seizure
Alfonsi et al [31], 2020	Absolute error at 3-month follow-up—AI: 27.45% (10.90%) versus control: 38.00% (14.74%); error>10 g at 3-month follow-up—AI: 21.43% (16.82%) versus control: 32.27% (16.31%)	No significant difference between groups A and B in terms of accuracy, procedural safety, time for trocar placement, and patient radiation exposure (dose area product and fluoroscopy time)	Positive	No	The data suggest that use of iSpy is associated with improved carbohydrate counting and that usability and acceptability of the app is quite positive	Single tertiary pediatric center only; the number of foods recognized by iSpy is not all encompassing; detailed information about other factors that can influence care such as education level, socioeconomic status data, family dynamics, or details of treatment regimen were not acquired; text reminders to the control participants was not provided

Author (publication year)	Primary end point result	Secondary end point result	Study outcome	Underpowered	Study conclusion	Limitations
Auloge et al [32], 2020	Group A technical feasibility was 100% with successful segmentation and generation of safe or accurate trajectory in all cases	No significant difference in accuracy; no complications or unintended effects were observed in either group—AI: mean 642 (SD 210) seconds, range 300-963 versus control: mean 336 (SD 60) seconds, range 240-438; DAP[t]—AI: mean 182.6 (SD 106.7) mGy cm^2, range 27-355 versus control: mean 367.8 (SD 184.7) mGy cm^2, range 115-644; fluoroscopy time—AI: 5.2 (SD 2.6) seconds, range 1.6-8.7 versus control: mean 10.4 (SD 4.1) seconds, range 4.2-17.9	Positive	Yes	Augmented reality or AI–guided percutaneous vertebroplasty appears feasible, accurate and safe and facilitates lower patient radiation exposure compared with standard fluoroscopic guidance	Small sample size; surgeon bias due to inherent nonblinding; lack of power to assess differences in vertebroplasty complication rates; accuracy of final trocar position was estimated on augmented fluoroscopic images rather than CBCT[u]; no clinical follow-up is presented
Avari et al [33], 2020	AI: 62.5% (52.1%-67.8%) versus control: 58.4% (49.6%-64.3%)	No significant difference for percentage of time in euglycemia, hypoglycemia, and hyperglycemia; no episode of serious hypoglycemia; no episodes of hypoglycemia within 5 hours postprandially; case of severe hypoglycemia; AI: 0 versus control: 1; no significant difference in glycemic risk	Negative	Yes	The PEPPER system was safe but did not change glycemic outcomes compared with control	The potential need for additional time required for the adaptive insulin recommender system to be effective; the algorithm is likely to be most beneficial to individuals maintaining regular work patterns rather than shift workers; the algorithm only adapts for bolus insulin and assumes that the basal insulin has been optimized; the system is dependent on meal scenarios where the user has not ingested a significant snack or taken an insulin bolus correction within 5 hours of a meal for revision
Chen et al [34], 2020	Sedated C-EGD versus unsedated U-TOE[v] versus unsedated C-EGD: 3.42% (0.89/26) versus 21.77% (5.66/26) versus 31.23% (8.12/26), respectively	Blind spot rate of Sedated C-EGD—AI: 3.42 versus control: 22.46; blind spot rate of unsedated U-TOE—AI: 21.77 versus control: 29.92; blind spot rate of unsedated C-EGD—AI: 31.23 versus control: 42.46; the average accuracy, sensitivity, and specificity of EN-DOANGEL in sedated C-EGD were 88.3%, 92.6%, and 90.2%, respectively; in unsedated U-TOE, were 91.3%, 84.5%, and 90.1%, respectively; and in unsedated C-EGD, were 87.8%,8 2.8%, and 87.8%, respectively	Positive	No	In summary, our study showed that the number of blind spots in conventional sedated EGD was the lowest compared with unseated U-TOE and unsedated EGD, and the addition of ENDOANGEL had a maximal effect on unsedated C-EGD	Single-center study; endoscopist were not blinded

Author (publication year)	Primary end point result	Secondary end point result	Study outcome	Underpowered	Study conclusion	Limitations
Gong et al [35], 2020	ITT[w]—AI: 16% (58/355) versus control: 8% (27/349); PP[x]—AI: 17% (54/224) versus control: 8% (26/318)	ITT diminutive—AI: 46 (13%) versus control: 25 (7%); ITT small—AI: 4 (1%) versus control: 1 (<1%); ITT large—AI: 10 (3%) versus control: 1 (<1%); no significant differences were found comparing adenoma locations: ITT—AI: 47% (166/355) versus control: 34% (118/349); ITT diminutive—AI: 158 (45%) versus control: 114 (33%); ITT small—AI: 9 (3%) versus control: 7 (2%); ITT large—AI: 11 (3%) versus control: 3 (1%); significant different was only found in sigmoid colon—AI: 79 (22%) versus control: 48 (14%); AI: 0.18 versus control: 0.08; AI: 1.17 versus control: 0.68; AI: 6.38 minutes versus control: 4.76 minutes; no adverse and serious adverse events	Positive	No	In conclusion, the ENDOANGEL system is a quality improving system for colonoscopy that uses computer vision, real-time monitoring of withdrawal speed, and timing of colonoscopy intubation and withdrawal and provides reminders to endoscopists of blind spots, in addition to live tracking previously seen frames during colonoscopy	AI was validated at 1 center only; the withdrawal speed was artificially divided into safe, alarm, and dangerous by assessing videos from Renmin Hospital of Wuhan University; the difference between assisted and unassisted colonoscopy for adenomas of 6-9 mm was not significant, which could be attributable to small numbers
Liu et al [36], 2020	AI: 29.01% versus control: 20.91%	AI: 47.07% versus control: 33.25%; AI: 1.07 versus control: 0.51; AI: 0.48 versus control: 0.29	Positive	No	In conclusion, real-time visual alarms provided by a high-performance CADe[y] system embedded into the primary colonoscopy monitor, with nearly unnoticeable latency, have been shown to cause a significant improvement in ADR because of an increased detection of diminutive adenomas without increasing physician fatigue level during colonoscopy	Open-labeled study; the fatigue score was subjective and susceptible to factors other than the visual alarms; whether a polyp was first detected by CADe before the endoscopist was based on the operating endoscopist's own judgment; the fact that the CADe system detected a polyp before the endoscopists does not necessarily mean that the endoscopists would have missed that lesion
Nicolae et al [37], 2020	No significant difference in CTV[z] V_{100}, CTV D_{90}, and Rectum V_{100} at 1-month postoperative follow-up	AI: mean 2.38 (SD 0.96) minutes versus control: mean 43.13 (SD 58.70) minutes; no significant difference in need and extent of modifications	Positive	Yes	A machine learning–based planning workflow for prostate LDR[aa] brachytherapy has the potential to offer significant time savings and operational efficiencies, while producing noninferior postoperative dosimetry to that of expert, conventional treatment planners	Single-center study; examining only preoperatively planned cases

Author (publication year)	Primary end point result	Secondary end point result	Study outcome	Underpowered	Study conclusion	Limitations
Repici et al [38], 2020	AI: 54.8% versus control: 40.4%	AI: 123 versus control: 97; AI: 353 out of 262 patients versus control: 243 out of 198 patients; AI: 7% versus control: 5.2%; AI: 1.07 versus control: 0.71; AI: 95.6% versus control: 98.5%; withdrawal time: not mentioned	Positive	No	In a multicenter, randomized trial, we found that including CADe in real-time colonoscopy significantly increases ADR and adenomas detected per colonoscopy without increasing withdrawal time	Psychological bias could not be excluded; the equivalence in withdrawal time excludes a somewhat reduced degree of mucosal exposure in the control arm; low detectors and inexperienced or nongastroenterologist endoscopists were not involved in this study
Su et al [39], 2020	AI: 28.90% versus control: 16.51% (OR 2.055, 95% CI 1.397-3.024; *P*<.001)	AI: 38.31% versus control: 25.40%; AI: 0.367 versus control: 0.178; AI: 0.575 versus control: 0.305; AI: mean 7.03 (SD 1.01) minutes versus control: mean 5.68 (SD 1.26) minutes; AI: 87.34% versus control: 80.63%	Positive	No	In summary, AQCS[ab], an automatic quality control system, could be used in real time for timing, supervising withdrawal stability, evaluating BBPS[ac], and detecting polyp	Single endoscopic center; some false prompts occurred with the AQCS; fatigue level of participating physicians was not controlled; used 4 intraprocedural quality metrics to form the AQCS, without performing preliminary testing to evaluate whether just 2 or 3 or 4 of these metrics had the same quality improvement; did not test the sole effect of colonoscopy stability; the DCNNs[ad] were trained only on images obtained from a Pentax imaging system
Wang et al [40], 2020	AI: 13.89% versus control: 40%	AI: 12.98% versus control: 45.90%; no statistical differences in the miss rate of advanced adenomas and sessile serrated adenoma or polyps; no significant difference in patient miss rate; no significant difference in ADR for the first pass; no significant difference in adenoma per colonoscopy; no significant difference in polyp per colonoscopy	Positive	No	The results from this study suggest a significantly lower AMR[ae] when a CADe technology is used compared with routine white light colonoscopy. The detection of diminutive and small adenomas with nonadvanced histology and nonpedunculated shape could be effectively improved by CADe colonoscopy	AMR obtained in the tandem study cannot reflect the absolute miss rate; subjective bias in open-labeled trial; tandem colonoscopy in each patient was performed by the same endoscopist; study population was not restricted to screening-only participants according to guidelines; only skilled endoscopists were allowed to participate in this study; subjected bias may be introduced as the judgments made by the panel of 3 experts who reviewed the video record were not a gold standard as pathology
Wang et al [41], 2020	AI: 165 (34%) versus sham control: 132 (28%)	AI: 252 (52%) versus sham control: 176 (37%); AI: 1.04 versus sham control: 0.64; AI: 0.58 versus sham control: 0.38	Positive	No	The CADe system is a safe and effective method to increase ADR during colonoscopy	Potential bias in the presence of a second senior endoscopist; bias in patient recruitment; the actual alert numbers of the sham system should have been measured in the trial to show equivalence

Author (publication year)	Primary end point result	Secondary end point result	Study outcome	Underpowered	Study conclusion	Limitations
Wijnberge et al [42], 2020	AI: median 0.10, IQR 0.01-0.43 mm Hg versus control: median 0.44, IQR 0.23-0.72 mm Hg	AI: 3.00, IQR 1.00-8.00 versus control: 8.00, IQR 3.50-12.00; AI: 8.00, IQR 1.33-26.00 minutes versus control: 32.67, IQR 11.50-59.67 minutes; AI: 2.8%, IQR 0.8%-6.6% versus control: 5.6%, IQR 3%-9.4%; AI: 2.0 (0.0 to 3.0) versus control: 0.0 (−1.0 to 0.0); AI: 4.0 (0.0 to 10.7) minutes versus control: −0.7 (−4.3 to 0.7) minutes; AI: 1.5% (0.0 to 3.3) versus control: −0.2% (−1.4 to 0.3)	Positive	No	In this single-center preliminary study of patients undergoing elective noncardiac surgery, the use of a machine learning–derived early warning system compared with standard care resulted in less intraoperative hypotension. Further research with larger study populations in diverse settings is needed to understand the effect on additional patient outcomes and to fully assess safety and generalizability	Single center only; small sample size; patient may have their own personal minimal MAP to be maintained during surgery; depth of anesthesia was not measured; the early warning system is validated only for invasive continuous blood pressure monitoring; an observer being present in the operating room may have influenced protocol adherence
Weisinger et al [43], 2021	Fugl-Meyer Assessment-Upper Extremity: week 4—AI: mean 23.2 (SD 3.91) versus control: mean 9.9 (SD 3.2); week 8—AI: mean 31.5 (SD 2.97) versus control: mean 23.1 (SD 4.99)	AI: 2.5 (0.18) points versus control: 1.3 (0.16) points; significance improved: Action Research Arm Test-Pinch subscale; significance improved: Box and Block Test; significance improved: NIHSS[ae]	Positive	Unknown	BQ treatment significantly improves upper extremity motor function in a population with subacute ischemic stroke across multiple clinical metrics. Further studies are planned and ongoing with larger study populations and in related indications	Nil
Blomberg et al [44], 2021	AI: 93.1% (296/318) versus control: 90.5% (304/336)	AI: 1.72 (1.52) minutes versus control: 1.70 (1.63) minutes; AI: 64.8% versus control: 61.9%	Negative	Yes	This randomized clinical trial did not find any significant improvement in dispatchers' ability to recognize cardiac arrest when supported by machine learning even though AI did surpass human recognition	Not 100% compliance with the machine learning model; the servers analyzing the phone calls had downtime, because the server was underdimensioned
Browning et al [45], 2021	QIDS-SR-16[af] at week 8—AI: 55.9% versus control: 51.8	Generalized Anxiety Disorder Assessment, 7 item version (week 8)—AI: −5.44 versus control: −6.12	Negative	Yes	Use of a predictive algorithm to guide antidepressant treatment improves symptoms of anxiety and functional outcomes provides initial support for the use of personalized medicine approaches in the treatment of depression	The accuracy of the predictive algorithm was modest at 57.5%; effectiveness was focused rather than efficacy, requesting but not requiring clinicians to alter treatment in response to a prediction of nonresponse; randomization occurred at the level of the patient rather than the site, and thus, the treatment as usual arm may have been influenced by behavior learned in the active arm

Author (publication year)	Primary end point result	Secondary end point result	Study outcome	Underpowered	Study conclusion	Limitations
Jayakumar et al [46], 2021	AI: mean 68.9 (SD 19.8) versus control: mean 48.8 (SD 14.5)	CollaboRATE median—AI: 8 of 69 versus control: 28 of 60; number of patient-rated satisfaction scores lower than the median value of 10—AI: 9 of 69 versus control: 19 of 60; no significant difference in duration of consultation in minutes; no significant difference in TKR[ag] rates and treatment concordance	Positive	No	In this randomized clinical trial, an AI-enabled decision aid significantly improved decision quality, level of shared decision-making, satisfaction, and physical limitations without significantly impacting consultation times, TKR rates, or treatment concordance in patients with knee osteoarthritis considering TKR. Decision aids using a personalized, data-driven approach can enhance shared decision-making in the management of knee osteoarthritis	Single-center study; surgeons were not masked; we did not assess the effect of the decision aid on patient knowledge; the typical course of a formal osteoarthritis in-clinic diagnosis possesses a general limitation in limiting the time frame over which the tool may be applied
Kamba et al [47], 2021	AI first: 13.8% versus control first: 35.7%	AI first: 14.2% versus control first: 40.6%; AI first: 13% versus control first: 38.5%; AI first: 64.5% versus control first: 53.6%	Positive	No	The reduction of AMR by assisting with CADe based on deep learning in a multicenter randomized controlled trial	Nil
Luo et al [48], 2021	AI: 38.7% versus control: 34%	The number of polyps detected in the control group and the research group was 80 and 105, respectively; AI: 91 versus control: 69; polyp type 0-IIa—AI: 87 versus control: 61; polyp type 0-Is—AI: 5 versus control: 8; polyp type 0-Ip—AI: 13 versus control: 11; 52 false positive result in AI group; in average, 0.35 false positive per colonoscopy	Positive	No	This study shows that an AI system based on deep learning and its real-time performance led to significant increases in colorectal PDR[ah]	Single center study; small sample size; AI has different effects on improving the PDR among different physicians; ADR was not compared between 2 groups in this trial
Rafferty et al [49], 2021	IBS[ai] symptom score—AI: −170 versus control: −138; quality of life score—AI: 31.1 versus control: 11.8	No significant difference; AI: 8.3 (4.4-13.1) versus control: 10.4 (7.4-14.0)	Negative	Yes	Results showed that the Heali app was able to significantly increase quality of life outcomes in IBS participants over a 30-day intervention period	Small sample size; self-reporting bias in survey may resulted owing to lack of blinding; stratification was not done; participants were not randomized to groups until study day 10, which was after the collection of baseline data; although anthropometric measures (bodyweight and height) were collected at baseline, they were not collected at the end of the trial, and it is possible that changes in body weight influenced the outcome variables; adherence may be affected by social impacts of the COVID-19 pandemic

Author (publication year)	Primary end point result	Secondary end point result	Study outcome	Underpowered	Study conclusion	Limitations
Repici et al [50], 2021	AI: 176/330, 53.3% versus control: 146/330, 44.2%	AI: 41.5% versus control: 36.1%; AI: 1.98 (range 0-15) versus control: 1.61 (range: 0-17); AI: 3.3% versus control: 5.2%; AI: 1.26 (SD 1.82) versus control: 1.04 (SD 1.75); 100% in both groups after excluding patients with inadequate bowel preparation; AI: mean 815 (SD 1.6) versus control: mean 7.98 (SD 1.5)	Positive	No	CADe in real-time colonoscopy significantly increases ADR and adenomas detected per colonoscopy in a nonexpert setting	No comparison of AI assistance with alternative educational interventions among inexpert endoscopists; this study design was not fit to assess the sensitivity or specificity of the device; no power calculations were done for any of our secondary outcomes
Strömblad et al [51], 2021	Mean absolute error—AI: 49.5 minutes {66} versus control: 59.3 minutes {72}	Mean patient wait time: overall—AI: 16.3 minutes versus control: 49.4 minutes (67.1% improvement); turnover time: overall—AI: 69.1 minutes versus control: 70.6 minutes (2% improvement); patient time in facility—AI: 148.1 versus control: 173.3 (14.5% improvement)	Positive	No	Implementing machine learning–generated predictions for surgical case durations may improve case duration accuracy, presurgical resource use, and patient wait time, without increasing surgeon wait time between cases	Small sample size; prediction accuracy may be affected if the submitted procedure codes deviate significantly from the procedures that are performed; a less common occurrence were multipanel cases in which multiple surgeons from different services operated on the same patient during the same case; there was no stratification by days
Wu et al [52], 2021	AI: 5.38 (SD 4.32) versus control: 9.82	AI: 5.40 (SD 3.82) minutes versus control: 4.38 (SD 3.91) minutes; the median percentage of patients with blind spots at each site—AI: 21% versus control: 38.9%; per-lesion accuracy: 84.7%; sensitivity: 100%; specificity: 84.3%	Positive	No	ENDOANGEL was an effective and robust system to improve the quality of EGD and has the potential to detect electrocardiogram in real time	We only conducted a feasibility analysis on real-time detection of gastric cancer based on deep learning in a clinical setting; the enrolled patients were not followed up for a long time; statisticians were not blinded
Yao et al [53], 2021	In overall cohort—AI: 2.1% versus control 1.6%; among 1356 patients who had a positive result—AI: 19.5% versus control: 14.5%	No significant between AI and control on disease discovery	Positive	No	An AI algorithm run on existing electrocardiograms enabled the early diagnosis of low ejection fraction in a large cohort of patients managed in routine primary care practices. Because electrocardiography is a low-cost test that is frequently performed for a variety of purposes, the algorithm could potentially improve early diagnosis and treatment of a condition that is often asymptomatic but has effective treatments and thus reduce the disease burden in broad populations	Echocardiogram may not be ordered by clinician as nearly all the patients had insurance coverage; study was not designed to determine the long-term clinical impact; for example, heart failure hospitalizations and mortality

Brown et al [54], 2021	AMR—CADe first: 20.12% versus HDWL[aj] first: 31.25%	PDR—CADe first: 20.7% versus HDWL first: 33.71%; HPMR[ak]—no significant difference in the hyperplastic polyp miss rate; SSLMR[al]—CADe first: 7.140% versus HDWL first: 42.11%; no statistically significant difference in ADR during first pass, second pass, and whole process; no statistically significant difference in PDR during first pass, second pass, and whole process; adenoma per colonoscopy during first pass—CADe first: 1.19 versus HDWL first: 0.90; no statistically significant difference during second pass and whole process; polyp per colonoscopy during first pass—CADe first: 2.0 versus HDWL first: 1.59; polyp per colonoscopy during second pass—CADe first: 0.52 versus HDWL first: 0.81; no statistically significant difference during whole process; SSLPC[am] during second pass—CADe first: 0.01 versus HDWL first: 0.07; no statistically significant difference during first pass whole process	Positive	No	This study showed a decrease in AMR with the use of a deep learning CADe system when compared with HDWL colonoscopy alone and a decrease in polyp and sessile serrated lesion miss rates and an increase in first-pass adenomas per colonoscopy	Not powered to detect a difference in ADR; the tandem colonoscopy design limited in terms of generalizability to the real-world clinical setting; only included experienced endoscopists with a high baseline ADR at US academic medical centers; used a second monitor adjacent to the primary endoscopy monitor

[a] CPAP: continuous positive airway pressure.

[b] AI: artificial intelligence.

[c] ICU: intensive care unit.

[d] LOS: length of stay.

[e] HGD: high-grade dysplasia.

[f] EAC: esophageal adenocarcinoma.

[g] WATS: wide-area transepithelial sampling.

[h] BE: Barrett's esophagus.

[i] SAP: sensor-augmented pump.

[j] HPI: hypotension probability indicator.

[k] RCT: randomized controlled trial.

[l] BPI: Brief Pain Inventory.

[m] BQ-II: Barriers Questionnaire II.

[n] SBP: systolic blood pressure.

[o] SRS-II: Social Responsiveness Scale II.

[p] VABS-II: Vineland Adaptive Behavioural Scales, Second edition.

[q] OR: odds ratio.

[r] ADR: adenoma detection rate.

[s] EGD: esophagogastroduodenoscopy.

[t] DAP: dose–area product.

[u] CBCT: cone-beam computed tomography.

[v] U-TOE: ultrathin transoral endoscopy.

[w] ITT: intention to treat.

[x] PP: per protocol.

[y] CADe: computer-assisted detection.

[z] CTV: clinical target volume.

[aa] LDR: low-dose rate.

[ab] AQCS: automatic quality control system.

[ac] BBPS: Boston bowel preparation scale.

[ad] DCNN: deep convolutional neural networks.

[ae] AMR: adenoma miss rate.

[af] QIDS-SR-16: Quick Inventory of Depressive Symptomatology (16-Item) (Self-Report).

[ag] TKR: total knee replacement.

[ah] PDR: polyp detection rate.

[ai] IBS: irritable bowel syndrome.

[aj] HDWL: high-definition white light.

[ak] HPMR: Hyperplastic polyp miss rate.

[al] SSLMR: sessile serrated lesion miss rate.

[am] SSLPC: sessile serrated lesion per colonoscopy.

Study Limitations

The most common limitations listed by the authors among these studies were single-center study design (22/39, 56%) and small sample size (n<1000; 33/39, 85%). This limits the generalizability and statistical power of the AI-assisted tools in different studies. There were 7 studies which were underpowered because of small sample size. Of these, 5 (71%) studies included <100 participants. Another common limitation is the open-label design (15/39, 38%).

Assessment of Risk of Bias

Detailed assessment results of the risk of bias using the second version of the Cochrane risk-of-bias tool for randomized trials are reported in Table 4. On the basis of the overall risk-of-bias assessment, 20% (8/39) of the trials had a low risk of bias, 31% (12/39) trials had some concerns, and 49% (19/39) had a high risk of bias. Missing outcome data and outcome measurements were the most common risk factors.

Table 4. Quality assessment outcome based on the second version of the Cochrane risk-of-bias tool for randomized trials.

Discussion

Principal Findings

Despite the plethora of claims for the benefits of AI in enhancing clinical outcomes, there is a paucity of robust evidence. In this systematic review, we identified only a handful of RCTs comparing AI-assisted tools with standard-of-care management in various medical conditions. Among these RCTs, two-thirds demonstrated improved primary or secondary end points compared with the standard-of-care management. However, not all of these end points are clinically relevant, that is, leading to a change in the management plan, improving the treatment results, shortening or avoiding hospital admissions, or reducing mortality. Although we acknowledge that our definition of a *clinically relevant end point* may be relatively narrow, we believe that the absence of such end points in the RCTs shows a clear deficit in the available evidence.

As expected, most of these studies came from economically advanced, industrialized countries, which constituted two-thirds of the RCTs included in this systematic review. China, as a single nation, accounted for one-third of the RCTs. China's research in this area is empowered by immense amount of resources invested in AI or machine learning (ML), internet, its vast patient population, and the availability of a nationwide electronic health record for hospitalized patients [55]. The geographical distribution of these studies is important as AI or ML relies on data fed to the system. Differences in genomic, metagenomic, and even environmental factors may influence disease patterns and the presentation of diseases. Therefore, it is desirable to develop an AI or ML tool based on data collected from different ethnic groups and tested in individual regions to prove its efficacy. There is only one AI-assisted tool, EndoScreener, which uses different ethnic groups in its development and validation. It was originally developed and trained using a different data set of endoscopic images including an open-source database of endoscopic images from Spain. Subsequently, the tool was validated in 4 prospective RCTs in China and had been recently validated in a multicenter RCT in the United States, proving its effectiveness. Future studies should focus on validation of AI-assisted tools across different ethnic groups and patient populations to ensure generalizability.

More biosignal-based AI-assisted tools have been studied than clinical data–based tools in RCTs. The most widely used were endoscopic images detecting adenoma during colonoscopy. The adenoma detection algorithm appears to be easier for cross-compatibility because of the distinct difference in appearance between adenoma (or polyp) and normal mucosa [56]. There were a total of 5 different AI-assisted adenoma or polyp detection systems tested in 9 separate RCTs, all of which successfully assisted endoscopists to detect more adenomas or polyps during colonoscopy. However, only one study successfully showed that the AI-assisted adenoma detection system could improve adenoma detection of all sizes. Other studies could only show improvement in diminutive adenoma (<5 mm) or small adenoma (<10 mm) detection [39]. Advanced adenoma or colorectal cancer detection was not improved by the AI-assisted adenoma detection system used in these studies. The US Multi-Society Task Force on Colorectal Cancer [57] suggested that patients with 1 to 2 nonadvanced adenoma sized <10 mm are at low risk and could have their surveillance colonoscopy in 7 to 10 years. The value of improvement in diminutive or small adenoma detection is uncertain. Among all studies, there was only one reported long-term outcome, that is, in-hospital mortality. Future studies should emphasize on the impact of AI-assisted tools on the long-term clinical end points.

Classical prediction models are typically clinical risk scores derived from regression-based statistical models, which could be considered an ML model that has been modified for clinical use. Ideally, RCTs should be designed with a control arm (usual clinical care), a "standard-of-care" clinical risk score arm, and a novel AI-assisted tool arm. However, given the expense and effort of a clinical trial, the SPIRIT-AI (Standard Protocol Items: Recommendations for Interventional Trials-Artificial Intelligence) extension guidelines clearly state the importance of pre-existing evidence for AI intervention, with evidence that the AI-assisted tool produces better performance compared with the standard of care [58]. Although none of the RCTs found in this systematic review used a multi-arm design, there have been well-designed studies where more "complex" ML approaches have outperformed regression-derived clinical risk scores on external validation [7,59,60].

Conclusions and Recommendations

The findings of this systematic review are by no means to discourage the use of AI in medicine. AI or ML can detect signals in an immense data pool to develop algorithms for clinical decision. Unlike humans, AI or ML can process enormous quantities of data, perform consistently, and constantly improve its performance by learning from new data. However, for AI or ML to be implemented in daily clinical practice, assisting clinicians in making important decisions, proof-of-concept evidence is not sufficient. AI-assisted tools must demonstrate unequivocal improvement in clinically relevant outcomes in properly designed randomized controlled clinical trials in which AI-assisted management is compared with standard-of-care practice. Researchers should not only focus on demonstrating the robustness of the AI algorithm in concept studies but also on translating from code to bedside by conducting RCTs in real-life clinical settings. From our systematic review, automated polyp detection is the most widely implemented AI technology in clinical practice, which sets a good example of the pathway from algorithm development to the implementation of AI technology in real-life clinical practice. Another obstacle to the implementation of AI or ML in daily clinical practice is the regulation of these technologies [8]. To grant approval from regulatory bodies, scientific evidence is required to support the safety and effectiveness of an AI-assisted tool in clinical practice. The framework for AI health care product development highlighted that RCTs are often recommended to provide strong evidence to validate the clinical efficacy and safety of an AI-assisted tool in real-world settings [61]. More RCTs of AI-assisted tools integrated into clinical practice are required to advance the role of AI or ML in medicine. We should also test how machine intelligence and human intelligence can work together on personalized management of patients.

Acknowledgments

Author DS is the co-corresponding author of this manuscript and can be reached by email at dennis.shung@yale.edu.

Data Availability

The full search strategy is provided in Multimedia Appendix 1. Additional data are available on request.

Authors' Contributions

JJYS developed the concept of the systematic review. TYTL, MFKC, YLM, KML, and JJYS contributed to the development of the study protocol. YLM and KML refined the search strategy and searched for articles. TYTL and MFKC performed study selection, data extraction, data verification, and critical appraisal. JJYS gave an independent view in case of any discrepancies. TYTL drafted the manuscript. DS and JJYS critically revised the manuscript for intellectually important content. All authors had full access to all the data presented in this manuscript and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Artificial intelligence (AI) is rapidly expanding in medicine despite a lack of consensus on its application and evaluation.

Objective: We sought to identify current frameworks guiding the application and evaluation of AI for predictive analytics in medicine and to describe the content of these frameworks. We also assessed what stages along the AI translational spectrum (ie, AI development, reporting, evaluation, implementation, and surveillance) the content of each framework has been discussed.

Methods: We performed a literature review of frameworks regarding the oversight of AI in medicine. The search included key topics such as “artificial intelligence,” “machine learning,” “guidance as topic,” and “translational science,” and spanned the time period 2014-2022. Documents were included if they provided generalizable guidance regarding the use or evaluation of AI in medicine. Included frameworks are summarized descriptively and were subjected to content analysis. A novel evaluation matrix was developed and applied to appraise the frameworks’ coverage of content areas across translational stages.

Results: Fourteen frameworks are featured in the review, including six frameworks that provide descriptive guidance and eight that provide reporting checklists for medical applications of AI. Content analysis revealed five considerations related to the oversight of AI in medicine across frameworks: transparency, reproducibility, ethics, effectiveness, and engagement. All frameworks include discussions regarding transparency, reproducibility, ethics, and effectiveness, while only half of the frameworks discuss engagement. The evaluation matrix revealed that frameworks were most likely to report AI considerations for the translational stage of development and were least likely to report considerations for the translational stage of surveillance.

Conclusions: Existing frameworks for the application and evaluation of AI in medicine notably offer less input on the role of engagement in oversight and regarding the translational stage of surveillance. Identifying and optimizing strategies for engagement are essential to ensure that AI can meaningfully benefit patients and other end users.

KEYWORDS

artificial intelligence; translational science; translational research; ethics; engagement; reproducibility; transparency; effectiveness; medicine; health care; AI

Introduction

Artificial intelligence (AI) allows computers to accomplish tasks that normally require the use of human intelligence. Creating AI, or an AI computer system, begins when developers feed the system existing data and allow it to “learn.” This learning experience enables AI to understand, infer, communicate, and make decisions similar to, or better than, humans [1,2]. The use of AI in medicine is an area of rapid growth, with worldwide spending on health care AI technologies estimated to reach US $45 billion by 2026 [3]. AI is used across numerous medical specialties, and can be applied to inform medical decision-making in numerous ways, such as through expediting and reducing the costs of drug discovery [4]; offering insight that aids clinicians in diagnosing, prognosing, or optimizing treatment plans at the point of care; and automating medical administration activities such as appointment reminders [5].

Numerous concerns have been raised regarding a lack of oversight for the rapid development and expansion of AI in medicine. Commentators have drawn attention to the potential weaknesses and limitations of AI in medicine, including challenges spanning ethical, legal, regulatory, methodological, and technical domains [6]. These perspectives have highlighted pitfalls such as implicit bias, reproducibility, and clinical validity [7-9]. There is further concern that the methods for development and approaches for evaluation of AI are not as robust and rigorous as those of other medical interventions [10]. Although several best practices for the design, implementation, and evaluation of AI can be informed by the biostatistical and data science literature, such guidelines are not sufficient to address all concerns related to AI in medicine [11].

Translational science is the study of how to turn concepts, observations, or theories into actions and interventions by following defined stages of research and development. This is done to improve the health of individuals and society [12]. The stages of the translation for typical diagnostics and therapeutics often follow a traditional pathway from ideation to community implementation and social benefit [13]. Very clear, albeit complex, translation pathways exist for diagnostics and therapeutics, and are enforced by regulatory, funding, and ethical review. For AI, the translational pathway is less well-defined and overseen, but generally includes stages such as development, design, validation, reporting, implementation, and scaling [14]. Nevertheless, questions remain regarding how to adapt translational oversight mechanisms for AI in medicine [15].

Developing robust guidance for the oversight of AI along its translational pathway is essential to facilitating its clinical impact [16]. Several professional organizations have developed frameworks to address concepts specific to the development, reporting, and validation of AI in medicine [2,16-20]. These frameworks are focused primarily on informing the technological developers of AI (such as by offering guidance on how to promote transparency in the design and reporting of AI algorithms), rather than informing the clinical application of AI [2,20]. Regulatory oversight of AI is also in nascent stages. Guidance on how to critically evaluate actual applications of AI in medicine are currently in development by the US Food and Drug Administration (FDA) [21]. The European Commission has led a multidisciplinary initiative to increase the trustworthiness of AI [22,23], and the European Medicines Agency has identified the regulation of AI as a strategic priority [24].

Identifying considerations for the oversight of AI across the translational spectrum is essential to increasing the utility of AI in medicine. In this study, we explored and characterized existing frameworks regarding the oversight of AI in medicine. We then identified specific considerations raised in these frameworks and mapped them to different stages of the translational process for AI.

Methods

Identification of Frameworks

We performed a literature review to identify guidance on the use of predictive analytic AI in medicine. The search spanned the PubMed, Web of Science, and Embase databases, and also included a grey literature search of Google. Key terms for searching included "artificial intelligence," "machine learning," "guidance as topic," and "translational science." Documents were included if they provided generalized guidance (ie, were a framework) on applying or evaluating AI in medicine. Documents that described specific AI applications without offering overarching guidance on the use of AI were excluded. The reference lists of included frameworks were screened for additional relevant sources. Frameworks were not restricted to the use of AI in any specific condition or medical setting. The time period of the review was January 2014 to May 2022; 2014 was selected as the cut-off point, as this was the year when regulatory agencies in the United States and Europe began using the authorization designation of "software as a medical device," which includes regulation over AI.

Data Abstraction, Coding, and Analysis

A structured abstraction process was used to collect general information about each framework, including title, author/affiliation, year, summary, and intended audience. Frameworks were analyzed using content analysis, which is an approach for exploring themes or patterns from textual documents [25]. Content analysis of text-based sources can be either qualitative, where theory or themes are identified, or quantitative, wherein numeric information is derived [26]. We employed both approaches in this study. We first used qualitative content analysis to identify the different topics ("domains") discussed by frameworks. Codes for these domains were not developed a priori but were rather identified inductively through a reading of the frameworks. Frameworks were evaluated to assess whether they discussed each domain in relation to each of the translational stages [27]. Stages of AI translation were predefined to reflect the full AI product lifecycle, including development, validation, reporting, implementation, and surveillance. We used evaluation matrix methodologies [28-30] to depict how many frameworks described the domains identified through content analysis.

Data were visualized using several approaches. First, we used spider plots to visualize, for each individual framework, how many stages of translation were discussed in relation to each of the five domains. Second, we applied a heatmap to depict the number of frameworks discussing a given domain across each translational stage. The heatmap cross-walked the domains across the five stages of translation.

Results

Overview of the Frameworks

A total of 14 documents were included in the review, which are summarized in Table 1. One framework was published in 2016 (*Guidelines for Developing and Reporting* [31]) and all others were published from 2019 to 2020. Several of the frameworks were developed through pathways with professional organizations (*AI in Health Care* [32], *CONSORT-AI* [20], *SPIRIT-AI* [2], *DECIDE-AI* [33]). All frameworks were published as journal articles, and *AI in Healthcare* was published as both a journal article [7] and a White Paper [32]; since the journal article was a synopsis of the White Paper, the latter was used as the primary document of reference for this review. The frameworks explored in this review were generally consensus- rather than evidence-based. All but three frameworks [19,34,35] identified greater than one intended audience, and typical audiences included AI developers, investigators, clinicians, patients, and policymakers. Frameworks provided either general guidance on the use of AI in medicine, typically in narrative prose (herein referred to as "descriptive frameworks") [19,32,34-37] or guidance specifically on the reporting of AI studies in medicine, typically in checklist style (herein referred to as "reporting frameworks") [2,17,20,31,33,38-40].

Table 1. Summary of frameworks for the use of artificial intelligence (AI) in medicine.

Frameworks	Summary	Audience
Descriptive frameworks		
AI in Healthcare, Matheny et al [32][a]	Describes general challenges and opportunities associated with the use of AI in medicine	AI developers, clinicians, patients, policymakers
Clinician Checklist, Scott et al [34]	Describes recommendations on evaluating the suitability of AI applications for clinical settings	Clinicians
Ethical Considerations, Char et al [36]	Describes a roadmap for considering ethical aspects of AI with health care applications	AI developers, investigators, clinicians, policymakers
Evaluating AI, Park et al [37]	Describes an evaluation framework for the application of AI in medicine	Investigators, health care organizations
Users' Guide, Liu et al [19]	Describes an approach for assessing published literature using AI for medical diagnoses	Clinicians
Reporting and Implementing Interventions, Bates et al [35]	Describes barriers to the implementation of AI in medicine and provides solutions to address them	Health care organizations
Reporting frameworks		
20 Critical Questions, Vollmer et al [17]	Proposes 20 questions for evaluating the development and use of AI in research (20 reporting items)	Investigators, clinicians, patients, policymakers
Comprehensive Checklist, Cabitza and Campagner [38]	Proposes a comprehensive checklist for the self-assessment and evaluation of medical papers (30 reporting items)	Investigators, editors and peer reviewers
CONSORT[b]*-AI*, Liu et al [20][a]	Provides reporting guidelines for clinical trials evaluating interventions with an AI component (25 core and 15 AI-specific reporting items)	AI developers, investigators
CAIR[c]*Checklist*, Olczak et al [39]	Provides guidelines and an associated checklist for the reporting of AI research to clinicians (15 reporting items)	Investigators, developers, clinicians
DECIDE-AI, Vasey et al [33][a]	Provides reporting guidelines for evaluations of early-stage clinical decision support systems developed using AI (10 generic and 17 AI-specific reporting items)	Investigators, clinicians, patients, policymakers
Guidelines for Developing and Reporting, Luo et al [31]	Provides guidelines for applying and reporting AI model specifications/results in biomedical research (12 reporting items)	AI developers, investigators
MINIMAR[d], Hernandez-Boussard et al [40]	Provides minimum reporting standards for AI in health care (16 reporting items)	AI developers, investigators
SPIRIT[e]*-AI*, Rivera et al [2][a]	Provides guidelines for clinical trials protocols evaluating interventions with an AI component (25 core and 15 AI-specific reporting items)	AI developers, investigators

[a] Publication associated with a professional organization; AI in Healthcare=National Academy of Medicine; CONSORT-AI=CONSORT Group; DECIDE-AI=DECIDE-AI Expert Group; SPIRIT-AI=SPIRIT Group.

[b] CONSORT: Consolidated Standards of Reporting Trials.

[c] CAIR: Clinical AI Research.

[d] MINIMAR: Minimum Information for Medical AI Reporting.

[e] SPIRIT: Standard Protocol Items: Recommendations for Interventional Trials.

Descriptive Frameworks

AI in Health Care

Matheny and colleagues [32] synthesized current knowledge related to the accountable development, application, and maintenance of AI in health care. This narrative describes existing and upcoming Al solutions, and underscores current challenges, limitations, and best practices for AI development, implementation, and maintenance.

Clinician Checklist

Scott and colleagues [34] proposed a checklist to evaluate the potential impact on clinical decision-making and patient outcomes of emerging machine-learning algorithms. Targeted toward clinicians, the checklist has been tailored for nonexperts, and provides a brief background of relevant machine-learning concepts and examples. The checklist addresses issues such as validity, utility, feasibility, safety, and ethical use.

Ethical Considerations

Char and colleagues [36] outlined a systematic approach for addressing ethical concerns surrounding machine-learning health care applications, and highlighted the need for interdisciplinary collaboration of diverse stakeholders. Evaluation and oversight tasks are described at each stage of the machine-learning pipeline from conception to implementation. Key questions and ethical considerations address common concerns found through a literature search as well as considerations that have received less attention.

Evaluating AI

Park and colleagues [37] highlighted the need for real-word evaluations of AI applications in health care. They present the phases of clinical trials for drugs and medical devices along with how AI applications could be evaluated in a similar manner. For each phase (including discovery and invention, technical performance and safety, efficacy and side effects, therapeutic efficacy, and safety and effectiveness), they propose appropriate study designs and methods for AI evaluation.

Users' Guide

Liu and colleagues [19] presented a users' guide to inform primarily clinicians about the major principles of machine learning. They describe the need for effective machine-learning model validation, review basic machine learning concepts, and provide recommendations on effective ways to implement machine-learning models in clinical medicine.

Reporting and Implementing Interventions

After presenting clinical examples of beneficial AI use, Bates and colleagues [35] discuss three major bottlenecks slowing the adoption of AI and machine-learning technologies in health care: methodological issues in evaluating AI-based interventions, the need for standards in reporting, and institution hurdles. They also highlight the role of FDA regulation and consider the need for rapid innovation in AI development.

Reporting Frameworks

20 Critical Questions

Vollmer and colleagues [17] provided a set of 20 questions focused on improving the transparency, replicability, ethics, and effectiveness of AI methods in health care. Statutory regulators and members of national advisory bodies and academic organizations, mostly from the United Kingdom and United States, collaboratively developed the questions.

Comprehensive Checklist

Cabitza and Campagner [38] proposed an extensive 30-item checklist to assess the quality of medical machine-learning studies. The checklist has been formatted both for authors to evaluate their own contributions and for reviewers to indicate where revisions may be necessary, and is organized in six phases: problem understanding, data understanding, data preparation, modeling, validation, and deployment.

CONSORT-AI

Liu and colleagues [20] extended the CONSORT (Consolidated Standards for Reporting Trials) framework to include additional considerations for the reporting of AI trials. The primary purpose of the extension is to facilitate the transparent reporting of interventional trials using AI, and the reporting checklist also provides some guidance for the development and critical appraisal of AI intervention studies.

CAIR Checklist

Olczak and colleagues [39] proposed a checklist for reporting medical AI research to clinicians and other stakeholders. They describe common performance and outcome measures that clinicians should be familiar with, and incorporate guidance about which metrics should be presented at each stage of a manuscript into the checklist. They also address ethical considerations that arise from AI use in health care.

DECIDE-AI

Vasey and colleagues [33] presented reporting guidelines for early-stage clinical trials of AI decision-support systems. The checklist focuses on four key aspects: proof of clinical utility, safety, the evaluation of human factors, and preparation for larger trials. This checklist was developed through a consensus process involving 151 experts and 20 stakeholder groups.

Guidelines for Developing and Reporting

Luo and colleagues [31] generated a set of guidelines on reporting machine-learning predictive models in biomedical research. The objective of these guidelines is to provide best practices for AI in biomedical research. This framework includes a list of minimum reporting items to be included in research manuscripts and a set of recommendations for optimal use of predictive models.

MINIMAR

Hernandez-Boussard and colleagues [40] proposed a list of minimum information that should be reported for all medical AI technologies. This list is intended to promote broader discussion and help inform extensions to other checklists. The four essential components in their guidelines include study population and setting, patient demographic characteristics, model architecture, and model evaluation.

SPIRIT-AI

Rivera and colleagues [2] presented reporting guidelines to evaluate clinical trial protocols involving interventions with an AI component. The purpose of the guidelines is to promote transparency and comprehensiveness for clinical trials with AI interventions. The guidelines were developed as AI extensions to the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) and CONSORT guidelines.

Content Domains

Overview of Domains

We identified five domains through the content analysis, including transparency, reproducibility, ethics, effectiveness, and engagement. These domains are described in turn below. Table 2 depicts each framework's coverage of content domains across translational stages. Figure 1 depicts the coverage of each individual framework and Figure 2 presents the aggregate coverage of frameworks as a heatmap.

Table 2. Coverage of frameworks across content domains and translational stages.

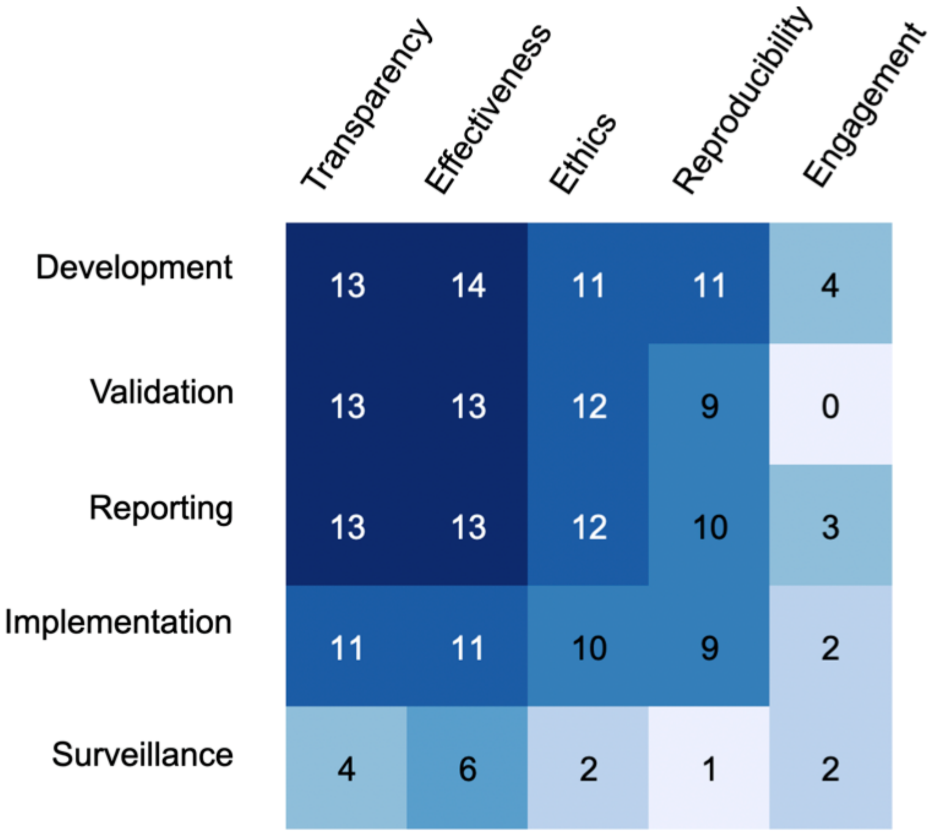

Figure 2. Heatmap of the frameworks' coverage across the five stages of translation. Darker boxes indicate areas where more frameworks offered guidance, whereas lighter boxes indicate areas where fewer frameworks offered guidance.

	Transparency	Effectiveness	Ethics	Reproducibility	Engagement
Development	13	14	11	11	4
Validation	13	13	12	9	0
Reporting	13	13	12	10	3
Implementation	11	11	10	9	2
Surveillance	4	6	2	1	2

Transparency

Transparency describes how openly and thoroughly information is disclosed to the public and the scientific community [41]. Transparency allows for independent evaluation of an AI algorithm's predictive power [42]. Involving stakeholders to help identify errors and bias in development or implementation also requires transparency [43]. Health care providers need transparency to interpret and justify medical decisions that result from AI use.

All but one framework (*Evaluating AI)* provided input on transparency with regard to the development and reporting of AI. Only four frameworks (*AI in Health Care*, *Comprehensive Checklist*, *Evaluating AI*, *20 Critical Questions)* commented on transparency with regard to surveillance. Two frameworks (*20 Critical Questions*, *Comprehensive Checklist*) commented on transparency in regard to all five stages of translation. The number of translational stages considered for transparency ranged from 3 to 5, with an average score of 3.9 across all frameworks. On average, descriptive frameworks discussed transparency in regard to fewer stages of translation than reporting frameworks (3.5 vs 4.1).

Reproducibility

Reproducibility describes how likely it is that others could develop or apply an AI tool with similar results. Reproducibility is a basic tenet of good scientific practice [44]. The ability to reproduce AI models is key to external validation [45]. Reproducibility accounts for burdens such as costs and high computational needs. Reproducibility in implementation and surveillance is necessary to improve the widespread, equitable use of AI.

All frameworks commented on reproducibility. Only one (*20 Critical Questions)* commented on reproducibility in regard to all five stages of translation, and this was also the only framework to comment on reproducibility in regard to the surveillance of AI. Most frameworks described reproducibility in relation to the validation, reporting, and implementation of AI. Scores for reproducibility ranged from 1 to 5 with a mean score of 2.9 across all frameworks. On average, descriptive frameworks discussed reproducibility in regard to fewer stages of translation than reporting frameworks (2.3 vs 3.3).

Ethics

Ethics considers values such as benevolence, fairness, respect for autonomy, and privacy. Such values are essential to avoiding harm and ensuring societal benefit in AI use [46]. Ethical practice for the use of AI in medicine relies on collaboration with ethicists, social scientists, and regulators. Racial, gender, and insurance provider biases are the largest ethical concerns with AI use [47].

Only one framework commented on ethical considerations across all stages of translation (*Ethical Considerations)*. Four frameworks (*AI in Health Care*, *20 Critical Questions*,*CAIR Checklist*, and *SPIRIT-AI)* addressed ethical considerations for development, validation, reporting, and implementation, and one tool addressed ethical considerations for development, validation, implementation, and surveillance (*Evaluating AI*). Scores for ethics ranged from 2 to 5 with a mean score of 3.4. On average, descriptive frameworks discussed ethics in regard to more stages of translation than reporting frameworks (3.7 vs 3.2).

Effectiveness

Effectiveness describes the success and efficiency of models and methods when they are applied in a given context. Effectiveness is concerned with matters such as data quality and model fit during the development of AI models [48]. External validation helps ensure effective discrimination and calibration to prevent overfitting [49]. Measures of effectiveness should be clearly and consistently reported [20,48]. There is a lack of appropriate benchmarks and standards of care to accurately measure the clinical benefit of many AI models [50]. Strategies are needed to continually measure effectiveness after implementation [17].

Four frameworks (*Ethical Considerations, Users' Guide, 20 Critical Questions, Comprehensive Checklist*) commented on effectiveness across all translational stages. All frameworks reported on effectiveness as a consideration for the development of medical AI. All but one framework (*AI in Healthcare*) reported on effectiveness during validation. Six frameworks commented on effectiveness as a consideration for surveillance (*AI in Health Care, Ethical Considerations, Evaluating AI, Users' Guide, 20 Critical Questions, Comprehensive Checklist*). Scores for effectiveness ranged from 3 to 5 with a mean score of 4.1. On average, descriptive frameworks discussed ethics in regard to more stages of translation than reporting frameworks (4.3 vs 3.9).

Engagement

Engagement explores to what extent the opinions and values of patients and other end users or stakeholders are collected and accounted for in decision-making. The degree of engagement can range from consultation (lowest level) to partnership and shared leadership [17]. In health research, using engagement approaches has been demonstrated to increase study enrollment, improve data quality, and improve the relevance of research design and conduct [51]. Patient engagement can also improve the quality and efficiency of health care, and reduce costs [52].

No frameworks considered engagement across all five stages. Engagement was discussed in relation to development by four frameworks (*AI in Health Care, Ethical Considerations, 20 Critical Questions, DECIDE-AI*) and in relation to reporting by three frameworks (*Ethical Considerations, DECIDE-AI, SPIRIT-AI*). No frameworks explored engagement in the validation stage of translation. Scores for engagement ranged from 0 to 3 with a mean of 0.8, which did not differ across descriptive and reporting frameworks.

Discussion

Principal Findings

Frameworks for applying and evaluating AI in medicine are rapidly emerging and address important considerations for the oversight of AI, such as those regarding transparency, reproducibility, ethics, and effectiveness. Providing guidance on integrating stakeholder engagement to inform AI is not a current strength of frameworks. Frameworks included in this review were the least likely to provide guidance on using engagement to inform the translation of AI in comparison to other considerations. The relative paucity of guidance on engagement reflects the larger AI landscape, which does not actively engage diverse end users in the translation of AI. For many stakeholders, AI remains a black box [53,54].

More than half of the frameworks provided reporting guidance on the use of AI in medicine. Additionally, nearly all frameworks in this review were published in 2019 or later. Given the rapid expansion of the field, it is essential to assess the consistency of recommendations across reporting frameworks to build shared understanding.

A near-miss in this review was the Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis (TRIPOD) Statement [55], which provides reporting guidelines for studies using prediction models for diagnosis or prognosis. As this framework is often used to evaluate AI models, we did evaluate its content and found that it offered comments on transparency, reproducibility, and effectiveness in the translational stages of development, validation, and reporting. It also provided considerations for ethics in the validation of models, but not in other translational stages. It did not pose any guidance on the use of engagement. A TRIPOD-AI [18] extension is forthcoming, which is engaging diverse stakeholders in its development. We hope that the guidelines themselves will recommend the use of end-user engagement.

The content domains and stages of translation that we have considered are far from exhaustive, and there are many other features and specific stages of AI development, application, and evaluation that are worthy of discussion. For instance, as the scope of AI in medicine expands, it will require broadened evaluation. For instance, there have been few economic evaluations of AI tools in medicine, which may be a barrier to their implementation [56]. Another form of evaluation might include the use of randomized controlled trials to assess the efficacy of tools in clinical contexts. Another consideration is regarding conflicts of interest, and it will be important to establish approaches to evaluate and mitigate potential conflicts of interest.

None of the frameworks included in this review used an explicit translational science lens to provide explicit guidance across the AI life cycle. Having resources that detail considerations for AI application and evaluation at each stage of the translational process would be helpful for those seeking to develop AI with meaningful medical applications. Resources that could be helpful would include patient/community-centered educational resources about the value of AI, a framework to optimize the patient-centered translation of AI predictive analytics into clinical decision-making, and critical appraisal tools for use in comparing different applications of AI to inform medical decision-making.

There was a paucity of guidance regarding the surveillance of AI in medicine. Although some research has described the use of AI to inform primarily public health surveillance [57,58], little work—even outside of the frameworks included in this review—has provided specific guidance on how to surveil the use of AI with medical applications. Existing recommendations for the surveillance of pharmaceutical and other medical interventions might be applicable to AI, but tailored recommendations will also be needed. It is likely that surveillance will need to be an ongoing process to provide up-to-date information on how AI tools perform in light of new clinical information and research, and to recalibrate AI tools to incorporate this knowledge into clinical predictions [59].

The goal of the framework evaluations was not intended to reflect the *quality* of the frameworks but rather to indicate the *coverage* of AI guidance either at the individual framework level (Figure 1) or across the literature (Figure 2). These evaluations could be used as a quick reference for clinicians, developers, patients, and others to identify which framework(s) may provide the most relevant recommendations to their specific AI application. For instance, *CONSORT-AI* was specifically developed as a checklist to inform the reporting of AI research. Although it had the lowest overall score, it provided recommendations for reporting relevant to four out of the five considerations raised in this review.

The field of AI in medicine could stand to learn from the clearer methodological standards and best practices currently existent in established fields such as patient-centered outcomes research (PCOR) [51,60]. PCOR works to advance the quality and relevance of evidence about how to prevent, diagnose, treat, monitor, and manage health care; this evidence helps patients, caregivers, clinicians, policymakers, and other health care stakeholders make better decisions. The translation of AI in medicine lacks the user-centeredness that is central to PCOR [61]. At a minimum, AI for use in medicine should be developed by multidisciplinary teams, where stakeholders from relevant fields (eg, bioinformatics, specific medical specialties, patient experience) offer their expertise to inform the development of a given AI application. Ideally, more integrated transdisciplinary approaches, wherein stakeholders from relevant fields collectively create shared knowledge that transcends their individual disciplines, would be used to develop AI. Using a transdisciplinary approach has the potential to create AI that is technically robust, provides clinically relevant information, and can be easily integrated into the clinical workflow to inform patient and clinician decision-making.

Conclusion

There is a growing literature offering input on the oversight of AI in medicine, with more guidance from regulatory bodies such as the US FDA forthcoming. Although existing frameworks provide general coverage of considerations for the oversight of AI in medicine, they fall short in their ability to offer input on the use of engagement in the development of AI, as well as in providing recommendations for the specific translational stage of surveilling AI. Frameworks should emphasize engaging patients, clinicians, and other end users in the development, use, and evaluation of AI in medicine.

Abstract

Background: There is little consensus regarding effective digital health interventions for diverse populations, which is due in part to the difficulty of quantifying the impact of various media and content and the lack of consensus on evaluating dosage and outcomes. In particular, digital smoking behavior change intervention is an area where consistency of measurement has been a challenge because of emerging products and rapid policy changes. This study reviewed the contents and outcomes of digital smoking interventions and the consistency of reporting to inform future research.

Objective: This study aims to systematically review digital smoking behavior change interventions and evaluate the consistency in measuring and reporting intervention contents, channels, and dose and response outcomes.

Methods: PubMed, Embase, Scopus, PsycINFO, and PAIS databases were used to search the literature between January and May 2021. General and journal-based searches were combined. All records were imported into Covidence systematic review software (Veritas Health Innovation) and duplicates were removed. Titles and abstracts were screened by 4 trained reviewers to identify eligible full-text literature. The data synthesis scheme was designed based on the concept that exposure to digital interventions can be divided into intended doses that were planned by the intervention and enacted doses that were completed by participants. The intended dose comprised the frequency and length of the interventions, and the enacted dose was assessed as the engagement. Response measures were assessed for behaviors, intentions, and psychosocial outcomes. Measurements of the dose-response relationship were reviewed for all studies.

Results: A total of 2916 articles were identified through a database search. Of these 2916 articles, the title and abstract review yielded 324 (11.11%) articles for possible eligibility, and 19 (0.65%) articles on digital smoking behavior change interventions were ultimately included for data extraction and synthesis. The analysis revealed a lack of prevention studies (0/19, 0%) and dose-response studies (3/19, 16%). Of the 19 studies, 6 (32%) reported multiple behavioral measures, and 5 (23%) reported multiple psychosocial measures as outcomes. For dosage measures, 37% (7/19) of studies used frequency of exposure, and 21% (4/19) of studies mentioned the length of exposure. The assessment of clarity of reporting revealed that the duration of intervention and data collection tended to be reported vaguely in the literature.

Conclusions: This review revealed a lack of studies assessing the effects of digital media interventions on smoking outcomes. Data synthesis showed that measurement and reporting were inconsistent across studies, illustrating current challenges in this field. Although most studies focused on reporting outcomes, the measurement of exposure, including intended and enacted doses, was unclear in a large proportion of studies. Clear and consistent reporting of both outcomes and exposures is needed to develop further evidence in intervention research on digital smoking behavior change.

Introduction

Background

There are few published data on exposure to and evaluations of digital behavior change interventions, and to date, there is little consensus regarding effective interventions for diverse populations. This is because of the difficulty of quantifying digital health interventions that use various media and content and the lack of consensus on how to evaluate and report dose and outcomes. However, digital health is developing rapidly, and understanding the latest evidence is critical for research in this field.

Digital media is central to and an integral part of modern life; however, the study of its effects on health behavior is just beginning [1]. As reported by the World Bank, 45% of the world's population or 3.5 billion people use social media. Worldwide, the average user spends approximately 3 hours of their day on social media [2]. Given the widespread exposure to digital technologies such as social media, it is increasingly important to understand how digital media affects individual health decision-making and behavior, as well as social networks and communities. These facts make it critically important to understand how digital media influences behavior. Social and behavioral scientists who study digital media must learn how to design and evaluate effective behavior change interventions, the evidence-based approaches that are effective, and how digital media affects targeted outcomes.

Efforts to understand the practice of digital media interventions have historically been made by public health scientists. Hu [3] reviewed 348 journal articles and structured the subject, health topics, technologies, and methods used for digital interventions between 2008 and 2012. Abad et al [4] conducted a scoping review on digital public health surveillance and revealed that only 0.8% of the related studies between 2005 and 2020 deployed a digital health surveillance system that can be used for monitoring and targeted interventions, despite its impact on the study methodology and public health actions. A recent systematic review by Seiler et al [1] found relatively few rigorous studies on the effectiveness of digital media–related behavior change campaigns and interventions. This review also found that the reporting of design, measures, data collection, and other methods needs to be improved and systematized. Recommendations for improvements included clarification of what is meant by *dose* and *dose-response*; how and with what intensity interventions are delivered; and measurement of outcomes, including attitudes, beliefs, social norms, and health behavior. This review also reiterated a previous finding that evidence for behavior change using digital interventions stems primarily from studies conducted in high-income countries [5-9].

Although digital media has been used for a variety of public health programs, one of the most rapidly changing areas is digital smoking behavior change interventions. Owing to the emerging products, devices, and policy changes, it has been more difficult to systematically quantify and evaluate the effectiveness of interventions in this area. Despite the importance of using consistent measures and evaluation methods to understand the impacts of interventions, little effort has been made to understand the common measures and methods used to evaluate the effectiveness of these interventions. There is a need for an assessment of the measures used in this area to inform future research to accurately evaluate the outcomes across a variety of products and devices, as well as rapid policy and market change. To the authors' knowledge, no previous systematic review has focused on the detailed measurements used in digital smoking interventions.

Although tobacco use has declined overall [10], it remains at unacceptable levels, exacting personal and social costs, particularly among young adults [11,12]. Tobacco is the leading preventable cause of death in the United States [13]. In the United States, 18.2% of young adults aged 18 to 24 years reported current use of tobacco products, and 10.4% reported being current cigarette smokers [14]. Although the age at which smokers initiate cigarette use has been increasing over time, almost all cigarette use initiation occurs before the age of 26 years [12], making young adults a critical target for prevention efforts. Given the widespread use of digital media among the young adult population [15], digital interventions may be promising.

Objective

To address these gaps in digital smoking behavior change interventions, this review aimed to (1) systematically review and codify the measures used for digital health interventions in tobacco and nicotine use research, (2) evaluate the quality of reporting of dose and response, and (3) identify areas for improvement in the field.

Methods

This review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The protocol was registered in PROSPERO (International Prospective Register of Systematic Reviews; ID CRD42021285655).

Study Search

The PubMed, Embase, Scopus, PsycINFO, and PAIS databases were used to search the literature. The search terms included "digital intervention," "health promotion," "health education," "health communication," "digital technology," "social media," "social marketing," "health," "measures," "methods," "frequency," "impression," and "reach." General and journal-based searches were combined to find literature that was directly related to the scope of the study. Specific journals that were searched included *The Lancet Digital Health*, *Journal of Medical Internet Research*, *Digital Health*, *Social Networks*, *npj Digital Medicine*, *Digital Medicine*, *Digital Biomarkers*, *Frontiers in Digital Health*, *Communication Methods and Measures*, *Health Technology Assessment*, *BMC Medical Research Methodology*, *Computers in Human Behavior*, *Computers in Biology and Medicine*, *Journal of Health Communication*, *Journal of Communication in Healthcare*, *Health Communication*, *Health Communication Science Digest*, *Health Education and Behavior*, *Digital Medicine*, *International Journal of Digital Healthcare*, *Journal of Health and Social Behavior*, *American Journal of Health Behavior*, *Journal of Behavioral Health*, *The Journal of Behavioral Health Services and Research*, *Health Behavior Research*, *American Journal of Health Promotion*, *Health Promotion Practice*, *Journal of Prevention and Health Promotion*, *Health Promotion International*, *International Journal of Health Promotion and Education*, and *Journal of Health Promotion and Behavior*. The literature was searched between January and May 2021, followed by a series of monthly searches to identify additional studies. Search strategies and terms were developed in collaboration with librarians at George Washington University.

All records searched through the database were imported into Covidence systematic review software (Veritas Health Innovation) and duplicates were removed.

Screening

Titles and abstracts were screened by 4 trained reviewers to identify eligible full-text literature. Each study was screened by 2 reviewers, and disagreements were resolved through discussion between the reviewers. The inclusion criteria were (1) publication after 2000, (2) full text available in English, (3) peer-reviewed original journal articles, (4) health-related topics, (5) at least one behavior change intervention defined, (6) use of the internet or mobile-based platform for mass or targeted communication, (7) use of digital devices, and (8) measurement of original data related to behavior or psychosocial measures.

Behavior change interventions were defined as planned programs that had stated objectives related to behavior change, target populations, and targeted messages in text, audio, video, graphics, or other distributed forms in a one-to-many format. Studies that assessed at least one behavioral or psychosocial measure defined in the social behavioral theories were included. Studies that only measured engagement were excluded. Digital media is defined as an internet-based platform for mass and targeted communications, including social media, apps, websites, software, blogging, and one-to-one chat platforms used for mass and targeted communications (eg, WhatsApp). Video games, emails, radio, and television were excluded from digital media. Studies that used digital media as a channel for one-to-one communication such as conversations between health care providers and patients were also excluded.

After literature was screened using the abovementioned criteria, articles related to smoking were extracted for this review. The terms used for this process included “tobacco,” “smoking,” “cigarette,” “vaping,” “vape,” “e-cig,” “ENDS,” “nicotine,” “hookah,” “JUUL,” “cigar,” “e-liquid,” “flavor,” “smokeless,” “smoker,” and “vaper.” The literature search was repeated replacing the term “health” with “smoking” and “vaping” on the database, and we checked for the coverage of the articles on the abovementioned topics.

Data Extraction and Synthesis

The data extraction and synthesis scheme was designed to identify the format of the digital media intervention, the measurement of each component that assessed dose and response in the intervention, and the study design used in the research. Dose measurement items were developed based on the concept that exposure to digital health interventions can be divided into 2 parts [16]. The first part is the intended dose, which refers to planned exposure by the intervention side. The other part is an enacted dose that corresponds to a portion of the intended dose that is actually completed by the participant. The dose measurement items were designed so that doses can be expressed as the frequency of the intervention multiplied by the length of intervention component and amount of engagement, which offers supplemental information about active involvement by participants. In this review, the intended dose comprises the frequency and length of the intervention, and the enacted dose comprises engagement. Engagement was defined as the interaction between the intervention content and the participants, such as views, clicks, likes, comments, and shares. Response equals the outcomes of the intervention, including behavior, intention, and other psychosocial factors that were previously confirmed to be connected in social behavioral change theories. A dose-response relationship was defined as the association between different levels of doses (exposure) and responses (outcomes), and its application was assessed in this review.

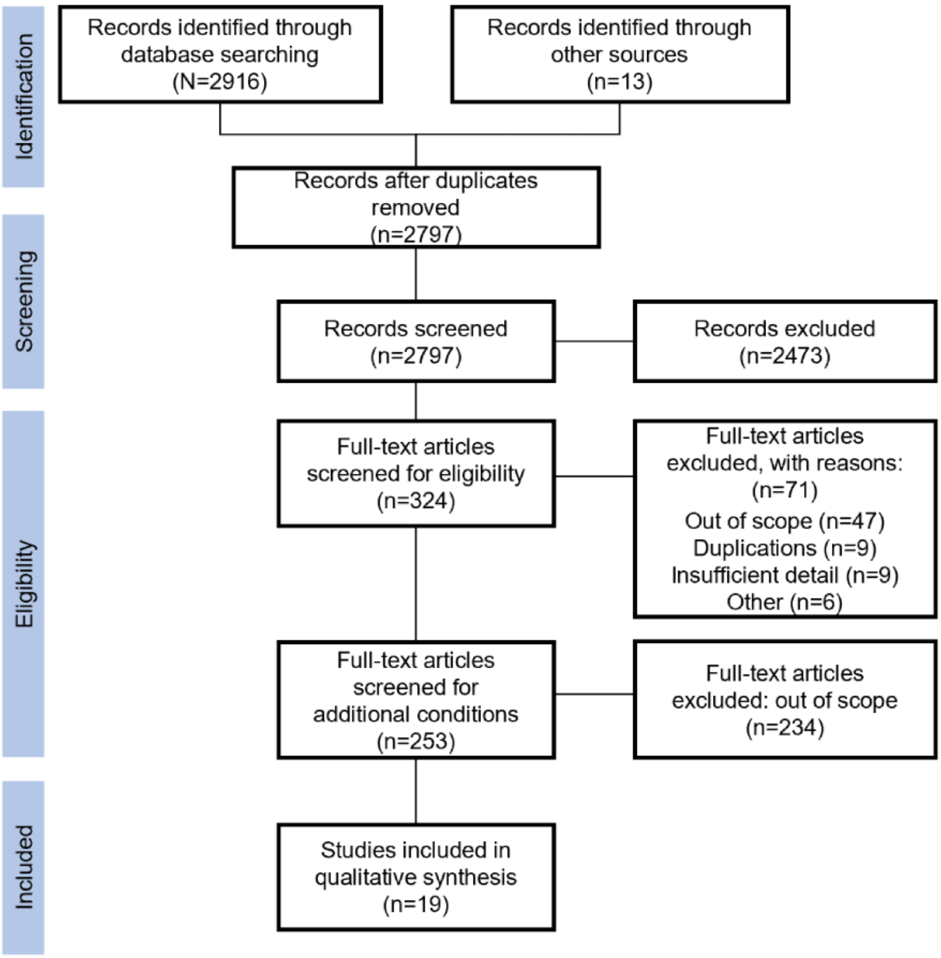
The codebook for data extraction and synthesis was developed in a Microsoft Excel format and piloted using 20 randomly selected articles on digital health behavior change interventions. The extracted data included basic information about the study, types of digital media and devices used, modes of intervention, measures used for intervention exposure, outcomes, engagement, study designs, model applications, cost and funding information, and source of bias. Data were converted into standardized forms where necessary and checked for clarity of reporting. The codebook had 3 types of input formats, including categorical options with data validation; hence, coders could only type prespecified responses, dichotomous options with data validation that indicated yes or no, and free answers where coders could leave notes. Coders were the same as the reviewers in the screening phase, who had 4 weeks of training using this codebook. The coding for this review started after the interrater reliability met 80% agreement in the training. Disagreements were resolved by discussion. The specific items extracted and synthesized are summarized in the *Results* section.

Results

Overview

A total of 2916 articles were identified through a database search, of which 2797 (95.92%) records were screened for titles and abstracts after duplicates were removed. Title and abstract review of the 2797 articles yielded 324 (11.58%) articles for possible eligibility, and 253 (9.05%) articles were screened for the subject matter. Ultimately, of the 253 articles, 19 (7.5%) articles on digital smoking behavior change interventions were included for data extraction and synthesis. The flow of literature screening is presented in Figure 1.

Figure 1. Flowchart of literature screening.



Digital Interventions

A summary of digital smoking behavior change interventions is presented in Table 1. Of the 19 studies included, 13 (68%) focused on smoking cessation and some also included smoking reduction as a secondary outcome that led to smoking cessation. Several articles focused on promoting a social movement for rejecting tobacco and reducing the influence of peer smoking, and others had more general topics such as promoting healthy lifestyles, tobacco-free lifestyles, and antitobacco norms.

Of the 19 studies, 10 (53%) studies used multiple digital media platforms. Websites, apps, and social media were the most frequently used channels. Among the studies that used single digital media, Facebook (3/19, 16%), apps (3/19, 16%), websites (1/19, 5%), YouTube (1/19, 5%), and software (1/19, 5%) were used. Multiple devices, including laptops, tablets, and smartphones, were used in 53% (10/19) of the studies. Of the 19 studies, 2 (11%) used smartphones, and 1 (5%) study each used tablets, cell phones, and a special device developed for the intervention, respectively. Approximately 21% (4/19) of studies did not explicitly report the devices used.

Of the 19 studies, 9 (53%) combined multiple modes of communication for the intervention. SMS text messages, images, and videos were typically used. Studies focusing on a single mode used text messages (3/19, 16%), videos (1/19, 5%), or images (1/19, 5%). Approximately 16% (3/19) of the studies were unclear about the modes of communication.

Table 1. Format of digital smoking interventions.

Source	Topic	Digital media	Device	Mode	Theoretical model	Conceptual model
Baskerville et al [17], Canada	Smoking cessation	Website, app, Facebook, and YouTube	Laptop and smartphone	Video, image, and articles	No	No
Davis et al [18], United States	Smoking cessation	YouTube and television	Desktop or laptop, mobile device, and television	Digital video advertisements and television advertisements	No	No
Goldenhersch et al [19], Argentina	Smoking cessation	App and cardboard headset device	Smartphone	Video, audio, and group chat	No	No
Guillory et al [20], United States	Tobacco-free lifestyle	Digital and social media (not reported specifically), radio, print, out of home, and local events	Laptop and smartphone	Unclear	Yes	No
Hair et al [21], United States	Antitobacco social movement	Social media, website, YouTube, and television	Laptop, tablet, and smartphone	Unclear	No	No
Kenfield et al [22], United States	Smoking as part of multiple themes	Website, Fitbit One, and SMS text messaging	Laptop, smartphone, and FitBit	SMS text message	No	No
Kim et al [23], United States	Smoking cessation	Website (video, mobile, and search advertisements that direct the campaign website) and display	Laptop, tablet, and smartphone	Video and image	No	No
Kim et al [24], United States	Smoking cessation and reduction	Facebook	Laptop and smartphone	Video-, text- and, image-based materials	No	No
An et al [25], United States	Smoking as part of multiple themes	Websites	Laptop and phone	SMS text message, image, video, and phone call	Yes	No
Marler et al [26], United States	Smoking cessation and reduction	Apps	Other (The Pivot Breath Sensor, a mobile Pivot app)	SMS text message	Yes	No
Masaki et al [27], Japan	Smoking cessation	App, a connected cloud system, a paired mobile exhaled carbon monoxide checker device, and a web-based PC software	Smartphone and laptop	Digital diary, videos, chatbot, and biomedical recording	No	No
Namkoong et al [28], United States	Antitobacco social movement	Facebook	Not reported	Videos, text, and pictures	Yes	Yes
Onezi et al [29], Saudi Arabia	Smoking cessation (smoking relapse prevention)	Twitter and WhatsApp	Not reported	Other (social media–based support groups)	No	No
Romer et al [30], United States	Reduction of influence of peer smoking	YouTube	Not reported	Video	No	No
Thrul and Ramo [31], United States	Smoking cessation	Facebook	Laptop, tablet, and smartphone	Unclear	Yes	No
Tsoh et al [32], United States	Smoking cessation	Facebook	Tablet	Assessment, video messages, 1-page summary printout, or email	No	No
Webb et al [33], United Kingdom	Smoking cessation	App	Smartphone	Video, audio, quizzes, and quit coach through digital chat	No	No
Bary-Weisberg et al [34], Israel	Smoking cessation	Website and SMS text messaging	Cell phone (for SMS text messaging)	SMS text message	No	No

Source	Topic	Digital media	Device	Mode	Theoretical model	Conceptual model
Burford et al [35], Australia	Smoking cessation	Other (The APRIL Face Aging software)	Not reported	Image	Yes	No

Approximately 68% (13/19) of the articles stated that specific theoretical models applied to interventions, whereas 32% (6/19) did not report any models. These models were defined as previously published theoretical models related to social, cognitive, and behavioral factors. Specific models mentioned in the literature include the social cognitive theory [36], transtheoretical models [37], theory of reasoned action, d theory of planned behavior, self-determination theory [38,39], and social branding framework. This study also reviewed the application of conceptual models defined as frameworks designed for specific interventions in the literature. Approximately 95% (18/19) of the studies did not mention any conceptual model specific to the interventions.

Measures of Dose and Response

The measures used to assess the dose (exposures), response (outcomes), and form of measurement are summarized in Table 2. For response measures, 32% (6/19) of studies reported multiple behavioral outcomes. Measures included smoking status, smoking reduction, abstinence, quit attempts, successful quitting, information search related to smoking cessation, campaign-related topics, and the use of cessation aids. Of the 19 studies, 5 (23%) used multiple psychosocial measures, and 4 (21%) reported a single psychosocial measure. Approximately 37% (7/19) of studies did not report any psychosocial measures. Intention (4/19, 21%), self-efficacy (4/19, 21%), awareness (3/19, 16%), norms (2/19, 11%), and stage of change (2/19, 11%) were mainly used.

For dose measurements, the frequency of exposure, length of exposure, and engagement were assessed. This was designed under the assumption that the amount of dose can be expressed as the sum of the intended dose and the enacted dose; the intended dose equals the frequency of exposure multiplied by the length of exposure planned by the intervention side, and the enacted dose equals the amount of engagement that was actively received by the targeted. Approximately 37% (7/19) of studies explicitly reported the frequency of exposure, whereas 63% (12/19) of studies were unclear on that point. Of the 19 studies, 3 (16%) studies reported the frequency per week, 3 (16%) other studies reported the frequency per day, and 2 (11%) studies reported that the frequency varied for each week. The length of exposure was explicitly reported in 21% (4/19) of studies, whereas 79% (15/19) of studies were unclear about this. All 4 studies that mentioned the length of exposure used videos for the intervention. Engagement was measured in 58% (11/19) of studies. Of the 19 studies, 8 (42%) reported multiple measures, and 3 (16%) reported a single measure. Visits, clicks, log-ins, and views were measured most frequently across different modes of the intervention. Social media interventions reported subscriptions, likes, comments, and postings of content. Finally, 42% (8/19) of studies did not report on engagement.

The dose-response relationship was assessed in 16% (3/19) of studies using different levels of exposure. One of the studies compared the effects of intervention between a standard-dose group and a higher-dose group. Another study examined the interaction between the time of exposure and the treatment arm. One of the studies examined the relationship between participants' levels of active engagement and the targeted behavior. Outcome assessment was self-reported in 68% (13/19) of studies and a combination of self-report and objective measurements in 21% (4/19) of studies. One of the studies applied only objective measurements using tracking software, and another study used an aggregated self-report measure that assessed population-level awareness.

Table 2. Measures used to assess dose and response.

Source	Response (outcome)		Dose (exposure)			Dose-response	Outcome report
	Behavioral	Psychosocial	Frequency of exposure	Length of exposure	Engagement		
Baskerville et al [17], Canada	Smoking cessation and use of cessation aid	Intention to quit	No	No	Visit, installation of the app, and posting content	No	Self-reported
Davis et al [18], United States	Not measured	Advertisement awareness	No (gross rating points used); depends on the size of the market	Yes (30-second advertisements)	Not measured	Yes	Self-reported
Goldenhersch et al [19], Argentina	Abstinence	Readiness to quit	Yes (every day)	Yes (10-minute videos)	Not measured	No	Self-reported

Burford et al [35], Australia	Successful quitting and quit attempts	Progression along the transtheoretical stages of change model and self-perceptions and attitudes toward smoking behavior	No	No	Not measured	No	Both

Quality of Reporting

The clarity of reporting was assessed for media role, dose and response measurement, and funding sources. The findings on clarity of reporting, study design, and bias are summarized in Table 3.

The role of media was clearly reported in all the studies (19/19, 100%). Behavior was clearly measured in all 15 studies that assessed behavioral outcomes. Among the 12 studies that assessed psychosocial outcomes, 11 (92%) reported them clearly, whereas 1 (8%) was unclear about its measurement.

Table 3. Clarity of measures and reporting.

Source	Clarity of media role	Response (outcomes)		Dose (exposure)			Study design	Bias	Funding source
		Behavior report	Psychosocial report	Intervention duration	Data collection duration	Engagement report			
Baskerville et al [17], Canada	Yes	Yes	Yes	Unclear	2 to <3 months	Yes	Quasi-experimental study	Generalizability and self-report	Yes

Burford et al [35], Australia	Yes	Yes	No	Not reported	4 to <6 months	N/A	Experimental study	No blinding	No

[a] N/A: not applicable.

The duration of intervention was unclear in 21% (4/19) of studies and was not reported in 16% (3/19) of studies. Of the 19 studies, 12 (63%) reported this explicitly. The intervention duration ranged from 10 minutes to 6 months. One of the studies (1/12, 8%) reported it in the range as it varied among participants because of the customization function of the digital intervention. Of the 19 studies, the intervention duration was 2 weeks to a month in 4 (33%) studies, 1 to 2 months in 2 (17%) studies, 2 to 3 months in 3 (25%) studies, and 4 to 6 months in 2 (17%) studies. The duration of data collection was unclear in 11% (2/19) of studies and was not reported in 11% (2/19) of studies. It ranged from 2 to 3 months in 47% (7/15) of studies, 6 months to a year in 20% (3/15) of studies, and >1 year in 13% (2/15) of studies. Approximately 7% (1/15) of studies each collected data for 2 weeks to a month, 1 to 2 months, and 4 to 6 months, respectively. The reporting of engagement was clear in 82% (9/11) of the studies that assessed engagement.

Of the 19 studies, 6 (32%) applied experimental study designs, 4 (21%) used quasi-experimental designs, and 9 (47%) used nonexperimental study designs. Quasi-experimental designs were defined as studies with a control group that did not involve random assignment. Of the 6 experimental studies, 3 (50%) reported representativeness and a biased sample as a potential source of bias. Quasi-experimental studies reported that self-reporting and aided recall were threats to bias (2/4, 50%). Lack of randomization, self-reporting, small sample size, and lower statistical power were frequently reported, in addition to generalizability and representativeness among nonexperimental studies. Of the 19 studies, 17 (89%) reported a source of funding, and 2 (11%) did not report this information.

Discussion

Principal Findings

This study identified the literature on digital behavior change interventions related to smoking and addressed the current practice of measuring and reporting intervention contents, channels, and dose and response outcomes. Data synthesis showed that both measurement and reporting were inconsistent across studies, illustrating the current challenges in this field of research.

This review revealed a lack of preventive studies on tobacco and nicotine use. Among 324 digital behavior change intervention papers, only 19 (5.9%) papers were relevant to smoking, and none centered on preventing its initiation. Although a literature search detected numerous prevention research papers, this review only included papers that assessed behavioral and psychosocial outcomes and did not include studies that focused on perceptions and engagement. This lack of research may reflect the fact that prevention studies for digital interventions remain at an early stage of identifying the basic conditions to make interventions engaging and effective rather than measuring the effectiveness of such interventions in achieving behavior change. This may also be because of a lack of funding in prevention research, as well as challenges in long-term follow-up to detect differences in smoking initiation rates.

Another gap in the literature on digital health identified in this review was the dose-response relationship. Although the effectiveness of interventions depends on the amount of exposure, only 16% of the literature has assessed the outcomes across different levels of doses.

The biggest issue was the inconsistency and vagueness of the reporting. Most studies paid attention to reporting outcomes and were relatively clear on their measurements in the methods sections. However, reporting of the amount of intervention offered to participants and the actual engagement was often unclear and not explicitly mentioned in a large proportion of studies. Insufficient details on the amount of exposure make it more difficult to compare outcomes across studies and conduct meta-analyses, which hinders the provision of evidence on effective digital interventions.

These findings were consistent with previous research on digital health interventions. Hu et al [3] found that only 10.6% of papers on digital health focused on health promotion and interventions, and only 2.6% centered on substance use, including tobacco use. Abad et al [4] pointed out that only 6.8% of the literature on digital health focused on smoking. Another review by Seiler et al [1] demonstrated that there have been relatively few rigorous studies on the effectiveness of digital behavior change interventions, and the reporting of design, measures, data collection, and other methods need to be improved [5].

The amount of exposure to an intervention can be divided into the intended dose planned by the intervention side and the enacted dose that was completed by the participant side. Dose can be expressed as the frequency multiplied by the length of the intended intervention dosage, and the amount of engagement can offer information about the enacted dosage. Clarifying these elements in the literature will lead to the promotion of comparable reporting and advancement of the evidence development of digital health interventions.

The types of behaviors used to report the outcomes were mixed. It can be divided into (1) targeted behavior (ie, smoking cessation), (2) surrogate behavior (ie, smoking reduction), and (3) behavior related to the improvement of the likelihood of conducting targeted behaviors (ie, use of cessation aid and smoking cessation information search). Although the measurement of these outcomes was predominantly self-reported, some studies combined objective measurements. The methods of objective measurement included (1) biochemical devices (eg, exhaled carbon monoxide tracker), (2) automatic digital tracking (eg, for information searches), (3) electronic health records, and (4) group-level psychological measures (eg, group-level awareness of campaigns). Leveraging these emerging methods will enhance the validity and reliability of measurements and advance evidence-based digital health interventions.

Strengths

To the best of our knowledge, this is the first study to review the dose and response measurements of digital smoking interventions. Dose measures were divided into the intended dose from the intervention side and the enacted dose that was actually completed by the participant side. The intended dose was separately assessed for frequency and length. Response measures were organized into behavioral and psychosocial outcomes, and measurement methods were assessed to determine their validity. The proportion of dose-response relationship studies was identified to determine the stage of current research in the field. The literature search combined general and journal-specific searches and yielded 2916 studies that showed high coverage.

Research gaps exist in assessing digital behavior change interventions with clear dose and response measurements and the dose-response relationship between the levels of intervention exposure and outcomes. More prospective studies are needed to examine the relationship between higher and lower dosages of interventions on smoking outcomes. For example, a well-designed dose-response relationship study on vaping outcomes among a specific population will identify the effective amount of digital intervention to prevent the initiation and decrease the amount of e-cigarette use. This will provide evidence for identifying the effective amount of intervention and offer grounds for conducting well-designed meta-analyses that synthesize evidence for digital behavior change interventions. This paper contributes to building a base for these studies.

Limitations

This review had several limitations. First, the number of studies included in this analysis was small. This was mainly because of the lack of digital behavior change intervention studies related to smoking and the measurement of behavioral and psychosocial outcomes in the current phase in the area. Second, the risk of bias assessment was omitted from the review. This was because of the nature of the mixed study designs in the included studies as there is little risk of bias assessment tools intended to apply to a variety of study designs. Instead, the quality of the papers was assessed by reviewing and evaluating the study design, theoretical model application, conceptual model application, cost, funding source, and bias source. In addition, the clarity of the media role and every measure of dose and response were assessed as part of the review for each study. When digital smoking behavior change interventions become more common and more literature can be included in the future, these limitations can be minimized.

Conclusions

There are challenges in every emerging area of scientific research. Digital smoking interventions are a new and growing area of research involving continuous and rapid advancements in technologies for health intervention delivery, implementation, and dissemination. This characteristic implies that it is essential to use consistent, standardized methods to evaluate the outcomes to accurately understand the efficacy and effectiveness of the interventions in rapid change, particularly in this area. For future improvement in this realm, this study assessed the consistency of measures used to quantify the dose and response in digital smoking interventions. These results suggest that both dose and response measures are often not clearly defined and are inconsistent across studies. This can imply that synthesizing the evidence on digital smoking interventions has been a challenge, and past studies could have been based on vague reporting and outcome evaluations. This is particularly an issue as interventions to date could be based on biased findings.

This study details and structures the composition of evaluation measures and assesses their use in digital smoking intervention studies. To the best of our knowledge, this is the first study to review dose and response measurements of digital smoking interventions. Although it has limitations such as the small number of papers included and the limited risk of bias assessment, the study successfully (1) reviewed and codified measures used for digital health interventions in tobacco and nicotine use research, (2) evaluated the quality of reporting of dose and response, and (3) identified areas for improvement in the field. More prospective studies that examine the clarity and consistency of measures among a larger number of studies are needed to develop further grounds for evidence-based digital smoking interventions. There is also a need for a clear and consistent reporting scheme for digital health interventions to accurately evaluate outcomes and conduct well-designed meta-analyses. Provision of clear and consistent reporting of both outcomes and exposures is needed to develop further evidence in this field that leads to protecting the lives and health of the public.

Acknowledgments

This study was supported by the National Cancer Institute (R01CA253013; principal investigator: WDE).

Authors' Contributions

MI and WDE conceived the study. MI designed the study protocol. WDE and JC contributed to the study design and provided expertise in digital media studies on tobacco control. MI, RG, SM, and AB performed the analyses. MI prepared the manuscript. All authors contributed to the final approval of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The RAND/UCLA Appropriateness Method (RAM), a variant of the Delphi Method, was developed to synthesize existing evidence and elicit the clinical judgement of medical experts on the appropriate treatment of specific clinical presentations. Technological advances now allow researchers to conduct expert panels on the internet, offering a cost-effective and convenient alternative to the traditional RAM. For example, the Department of Veterans Affairs recently used a web-based RAM to validate clinical recommendations for de-intensifying routine primary care services. A substantial literature describes and tests various aspects of the traditional RAM in health research; yet we know comparatively less about how researchers implement web-based expert panels.

Objective: The objectives of this study are twofold: (1) to understand how the web-based RAM process is currently used and reported in health research and (2) to provide preliminary reporting guidance for researchers to improve the transparency and reproducibility of reporting practices.

Methods: The PubMed database was searched to identify studies published between 2009 and 2019 that used a web-based RAM to measure the appropriateness of medical care. Methodological data from each article were abstracted. The following categories were assessed: composition and characteristics of the web-based expert panels, characteristics of panel procedures, results, and panel satisfaction and engagement.

Results: Of the 12 studies meeting the eligibility criteria and reviewed, only 42% (5/12) implemented the full RAM process with the remaining studies opting for a partial approach. Among those studies reporting, the median number of participants at first rating was 42. While 92% (11/12) of studies involved clinicians, 50% (6/12) involved multiple stakeholder types. Our review revealed that the studies failed to report on critical aspects of the RAM process. For example, no studies reported response rates with the denominator of previous rounds, 42% (5/12) did not provide panelists with feedback between rating periods, 50% (6/12) either did not have or did not report on the panel discussion period, and 25% (3/12) did not report on quality measures to assess aspects of the panel process (eg, satisfaction with the process).

Conclusions: Conducting web-based RAM panels will continue to be an appealing option for researchers seeking a safe, efficient, and democratic process of expert agreement. Our literature review uncovered inconsistent reporting frameworks and insufficient detail to evaluate study outcomes. We provide preliminary recommendations for reporting that are both timely and important for producing replicable, high-quality findings. The need for reporting standards is especially critical given that more people may prefer to participate in web-based rather than in-person panels due to the ongoing COVID-19 pandemic.

Introduction

The RAND/UCLA Appropriateness Method (RAM), a variant of the Delphi Method, was developed to synthesize existing evidence and the clinical judgement of a panel of medical experts. The goal of this method is to produce recommendations for appropriate treatment of specific clinical presentations, given current best evidence [1]. This method has been widely used to develop care recommendations and performance measures that define quality of care [2-6]; it provides a transparent and systematic approach that can garner trust and acceptance among physicians, other clinicians, patients, payers, and health systems [7].

The RAM classically involves engaging credible experts to evaluate specific clinical presentations in a 2-round rating process. In the initial round, experts independently rate each clinical scenario. During the second round, panelists participate in a 1 to 2-day in-person session where they have an opportunity to review and discuss each other’s first round ratings, revise the initial list of scenarios, and individually rerate each clinical indication. Indications are categorized as “appropriate,” “uncertain,” or “inappropriate” based on panelists’ median score and level of disagreement [1]. Compared to the standard Delphi Method, the RAM does not require panelists to reach group consensus after multiple rating rounds [1,8].

A difficulty in convening appropriate experts in person is their often-limited time and capacity to participate. Thus, there is a need to identify best practices for conducting expert panels via the internet not only to lower barriers to experts’ participation but also to reduce the costs involved with implementing traditional in-person RAMs. While the use of RAMs with a web-based component in health research was increasing prior to COVID-19, the pandemic has greatly accelerated the need for web-based alternatives with improved technology and end-user familiarity with these tools.

While there is a substantial body of literature describing and testing various aspects of the traditional in-person or hybrid RAMs, few studies report using a completely web-based RAM, and even fewer provide detailed descriptions on how the expert panels were conducted. There is often little information or guidance for designing approaches to meet the goals of specific studies. Boulkedid et al [9] published a systematic review of 80 articles published through 2009, finding that 63% used a “modified” Delphi Method but lacked enough detail to replicate or judge the quality of modified approaches to developing recommendations for quality health care indicators. Moreover, measures of process quality, such as consistent panelist engagement, are rarely reported. Because best practices for conducting virtual RAMs are unclear and reporting is inconsistent, we conducted a literature review to develop preliminary recommendations for implementing and reporting virtual RAMs.

Methods

Literature Search and Data Abstraction

In March 2019, we searched PubMed to identify studies published from 2009 to 2019 that reported using a virtual RAM to measure the appropriateness of medical care. The following search terms were used to identify relevant articles: “RAND/UCLA Appropriateness Method” OR “RAND Appropriateness Method” OR “Modified RAND” OR “RAND AND panel” AND “online OR e-delphi OR web OR virtual.” The full search strategy can be found in Multimedia Appendix 1. Two reviewers (JS and LD) screened each article and developed a list of inclusion and exclusion criteria, which are described in Multimedia Appendix 2. To be included, articles must have used the RAM to measure the appropriateness of medical care or focused on the development of clinical practice guidelines or performance measures. Moreover, the expert panel ratings must have been completed on the internet. Web-based ratings could include a teleconference component. Articles were included even if they did not report a rerate session or discussion period among panelists. Non-English articles and articles published prior to 2009 were excluded. Studies with goals not aimed toward providers (eg, improving support for patient caregivers) were also excluded. Additionally, articles were excluded if they were reviews or summaries of the literature. Relevant panel process data (ie, first author, year published, title, mode of administration, topic, and objectives) from each article included in our review were abstracted in a predefined matrix (Multimedia Appendix 3 [2,10-21]). Team members (JS, MK, and SS) independently abstracted the same sample of articles twice to (1) ensure that the basic data collected have been correctly entered in the spreadsheet and (2) verify that the selection criteria have been appropriately applied.

Subsequently, we expanded the Delphi reporting categories recommended by Boulkedid et al [9], which formed the basis of our article abstraction template. Specifically, we organized descriptions with respect to the following categories adapted from Boulkedid et al [9]: (1) composition and characteristics of the web-based RAM expert panels; (2) characteristics of the web-based RAM panel procedures; (3) results; and (4) panel satisfaction and engagement. Additional information abstracted into the matrix included the following: (1) descriptions of how quality indicators were selected; (2) the method used for participant recruitment; (3) whether materials were sent to participants prior to the first expert panel rating; (4) Delphi panel size and composition, as well as the duration of time the panel was convened; (5) purpose of convening the RAM panels; (6) criteria used to rate indications; (7) the web-based system used to host the panels; (8) the number of reported Delphi rounds; (9) description of feedback provided to panelists; and (10) descriptions of participation levels in the discussion rounds. Additionally, we captured information about second or third rounds of ratings and how the final list of indications was selected. Lastly, we captured information about panelist satisfaction and engagement. Four authors (JS, LD, MK, and SS) completed a second, more detailed, data abstraction. The authors independently reviewed each article and completed several rounds of data verification.

Ethics Approval

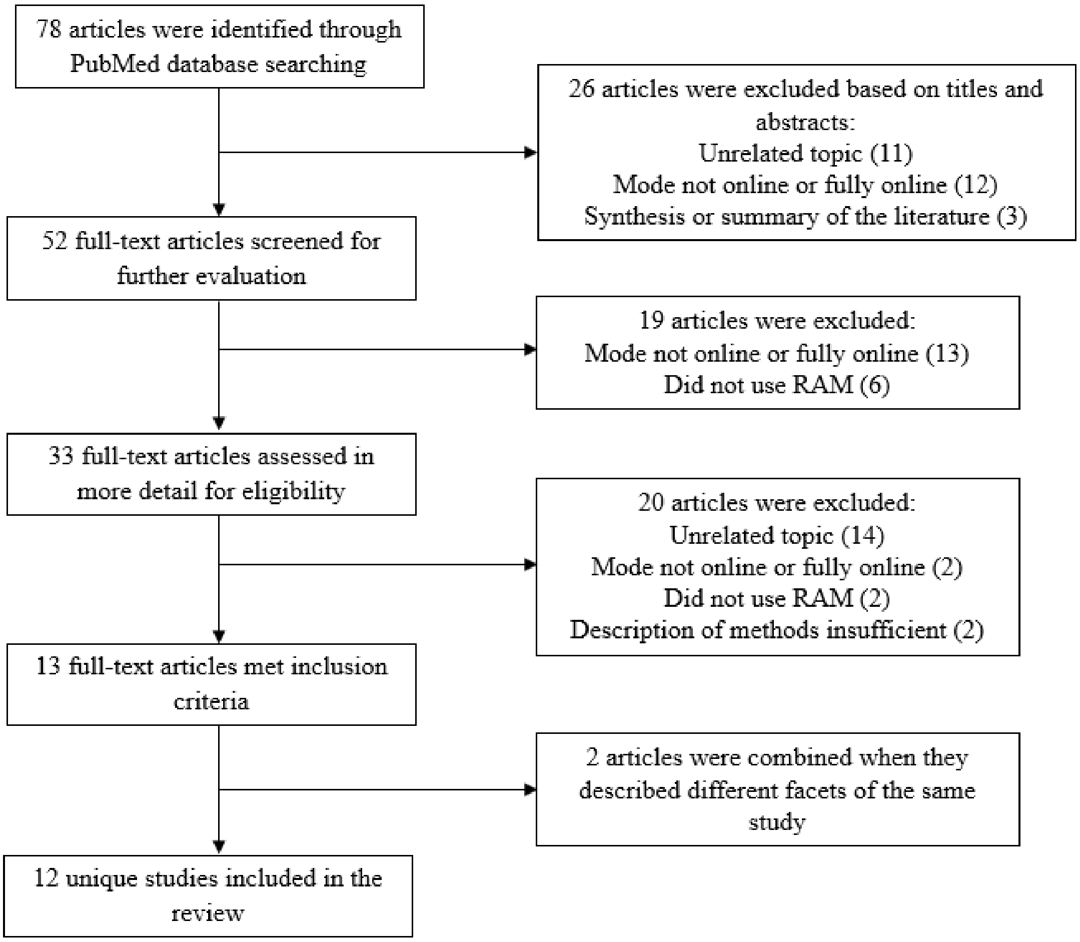
The ASSURES study was approved by the Ann Arbor VA Healthcare System IRB (project ID: 1597260).

Results

Article Selection

We identified 78 articles that reported using an “online” or “virtual” RAM from our narrative review; 26/78 (33%) articles were excluded based on the title or abstract (Figure 1). A full-text review of 52/78 (67%) articles was completed, resulting in the exclusion of an additional 39/52 (75%) articles; 13/52 (25%) articles were included in the review. We combined 2 published articles that met the inclusion criteria but described different facets of the same study, so the final review included 12/52 (23%) unique studies. Subsequent calculations are based on these 12 studies. The studies included in this literature review used completely web-based RAM approaches to accomplish their goals that ranged from developing quality performance measures or indicators to setting clinical practice standards. Throughout the manuscript, we use the term “indication” or “indicator” to standardize the description of statements panelists were asked to approve during the RAM process. Based on our narrative review, we developed foundational reporting recommendations from Boulkedid et al [9].

Figure 1. Article search and selection flowchart. RAM: RAND/UCLA Appropriateness Method.



Recruitment and Composition of Web-Based Expert Panels

Table 1 summarizes the characteristics of the RAM expert panels included in our review [2,10-21]. The methods for identifying and recruiting participants were not reported in 5/12 (42%) studies [13-15,18-20]. Of those who relied on professional networks or a snowball sampling approach, 3 (50%) reported inviting prospective participants via email [10,11,17].

The number of people invited to participate in the panels was reported in 9/12 (75%) of studies, ranging from 20 to 352 people with a median of 50 [2,10-13,16,17,20,21]. Of the 12 studies, 9 (75%) reported the number of panelists who participated in at least the first rating, ranging from 10 to 102 individuals, with a median of 42 [2,10-13,16-21]. In addition, all studies described included the types of stakeholders or experts who participated in the panels. In 11/12 (92%) studies, panelists were clinicians related to the topic studied [2,10-13,16-21]; 5 (42%) also included patients or people living with the condition studied [2,11,12,17,21]. Three-quarters of studies (9/12) had between one and two types of stakeholders. An additional 2 (17%) studies included three types of stakeholders; 1 (8%) study reported four or more types.

[a] Min-max: minimum-maximum.

[b] The total percentages may exceed 100% because some studies used more than one criterion.

[c] Clinicians include people who actively work in health care settings such as hospitals and clinics to deliver care to patients (ie, doctors, nurses, pharmacists, etc).

[d] RAND corporation.

[e] RAM: RAND/UCLA Appropriateness Method.

[f] REDCap: Research Electronic Data Capture.

[g] Quantitative: group median, minimum, and maximum ratings. Feedback may include panelists' own ratings to illustrate position versus group ratings.

[h] Qualitative: abstract of panelists' comments.

[i] IPR: interpercentile range.

[j] IRPAS: interpercentile range adjusted for symmetry.

Characteristics of Web-Based Expert Panel Procedures

Table 1 summarizes the RAM procedural characteristics across the 12 studies; 5 (42%) studies described the use of all the steps specified by the RAM method (ie, full RAM) [2,11,12,16,21]; the remaining 7 (58%) studies reported the use of some but not all the steps (ie, partial RAM) [10,13-15,17-20]. All studies reported between one and three rating rounds, with a median of 3 rounds. In 6/12 (50%) studies, the RAM was used to develop a set of performance indicators (ie, indicators of clinical care quality) [2,10,11,13,16,21], and the remaining studies focused on developing indications for documenting or describing specific conditions (eg, rheumatoid arthritis and dental caries) [12,14,15,17-20]. The type of web-based system used to conduct the expert panel was reported in 9 (75%) studies [2,11-13,16,17,19-21]. Of these, 4 (44%) studies used the ExpertLens platform [2,11,12,16], and 5 (56%) listed other survey software (eg, SurveyMonkey, Research Electronic Data Capture, and the Canadian Fluid Survey System) [13,17,19-21]; the type of web-based system was not reported in 3/12 (25%) studies [10,14,15,18].

The methods used to select indicators for the survey were reported in all 12 studies. The most common method was a literature review (alone or in addition to stakeholder feedback (8/12, 67%) [2,11-13,16,17,20,21]. The number of indicators in the first rating were reported in all 12 studies, and ranged from 6 to 524 items, with a median of 48 items. Only 1/12 (8%) studies reported sending materials to participants prior to the panel sessions and included a document with rationale, methods, and indicator specifications [2]. Duration of the consensus process was reported in 7/12 (58%) studies [2,10,11,13,16,17,21]; median duration was 12 weeks. The geographical scope of expert panel members was reported in all studies; 9 (75%) panels were classified as national [2,10,12,13,16,18-21], and 3 (25%) were classified as international [11,14,15,17].

All studies specified the criteria used to rate each indicator (ie, relevance, importance, feasibility, etc) [2,10-21]. Half of the studies (6/12, 50%) used between one and two types of selection criteria [12,16,17,19-21]; the remaining studies reported using three or more selection criteria [2,10,11,13-15,18]. After the first rating, 5/12 (42%) studies did not report providing feedback of results to panelists [13-15,18-20]. The remaining studies reported providing panelists with frequency distributions, medians, and interquartile ranges for the group, as well as panelists' own responses compared to the group [2,10-12,16,17,21]. Researchers in 1 (8%) study revised a list of clinical indications based on input from panelists in Rating 1 and distributed this information to participants after the first rating [17]. During this time, panelists review and discuss the ratings, focusing on indications with significant disagreement [1]. However, only 6/12 (50%) of the studies reported included a panelist discussion period after the first round of ratings [2,11,12,16,17,21]; the discussions in 5/6 (83%) studies were either asynchronous, anonymous, or moderated web-based discussions [2,11,12,16,21]; 1 (8%) study used a nonanonymous synchronous webinar format [17].

Web-Based Expert Panel Results

Most studies (8/12; 67%) reported a second round of ratings [2,10-12,16,18,20,21], with 1/8 (13%) study indicating a third rating was conducted (Table 1) [18]. All studies provided information about how indications were selected for the final list. In 8/12 (67%) studies, items were selected following the RAM criteria for disagreement (where the calculated interpercentile range is greater than the interpercentile range adjusted for symmetry, with a panel median score between 6 and 9) [1,2,10-12,16,18,20,21]. The methods used to select indicators differed in the 4 (33%) remaining studies. In the first study, indicators were included based on the following two conditions: (1) the median score for each item was between 8 and 9 and (2) at least 70% of the panelists rated an item in the top third of the scale [17]. In the second study, at least three-quarters of panelists had to agree on an item for it to be selected [14,15]. In the third study, if the average agreement was at least 70% or higher across all 4 criteria of preventability for each item, then the indication was selected [13]. In the last study, more than 50% of panelists had to rate an indicator "extremely important" (ie, 9) for it to be selected [19].

Web-Based Expert Panel Process Assessments and Satisfaction

Approaches for reporting process assessments and satisfaction were not included in recommendations from Boulkedid et al [9]. In our review, very few studies (3/12, 25%) reported process assessments (eg, level of engagement) or panelist satisfaction (Table 1) [11,14,15,21]. The 3 (25%) studies that did report an assessment of process quality focused on narrowly defined characteristics of satisfaction [11,14,15,21]. For example, one study reported that panelists would have liked more time to discuss ideas in a conference call [11]. In another study, it was reported that most panelists were satisfied with their degree of anonymity throughout the rating rounds [21]. The third study reported most panelists felt the web-based RAM process was "suitable for achieving consensus" [14,15].

Discussion

Principal Findings

Web-based RAM panels are increasingly used in health research as an effective, efficient, convenient, and acceptable alternative to traditional consensus processes [22,23]. Previous systematic reviews have assessed the implementation and reporting of the in-person or "modified" Delphi method in research settings [9]. Despite the growing prominence of the virtual RAM, there has been no literature review of design and conduct using completely virtual methods. Documentation, however, is vitally important for researchers to replicate RAM procedures and learn and improve the process across studies. It is also important to assess the validity and applicability of the process and to interpret the results of these studies. Our narrative review of the web-based RAM process in health research helps to fill this gap. Our results show that studies generally provide little information about how the web-based RAM was implemented, making it difficult to interpret and compare study results. After summarizing the main findings of our literature review, we suggest preliminary recommendations for ways to improve the implementation and reporting of virtual RAMs.

The first contribution of this study is to illustrate the underreporting of the web-based RAM process in health research. Our narrative review of 12 unique studies revealed that the vast majority provided only brief descriptions of how their virtual RAM process was implemented. For example, half of the studies did not report a discussion period between rating rounds even though this is a standard feature in the RAM panel process. Adequate time for discussion between rating rounds is necessary for reviewing the distribution of rating results and adjusting the list of clinical indications if necessary. Additionally, although all studies reported the number of panelists who participated in each round, no studies reported consistency of participation across rounds; this is important information to assess the quality and nature of recommendations, ideally generated by highly engaged panel members who consistently participated across the rounds.

Without a common framework for reporting results from web-based RAMs, it is difficult to compare the results across studies. Improved intentionality in designing and transparency in reporting would yield improved results for individual study teams while also allowing external researchers to learn, understand, and build on the process that was used to generate a given set of expert recommendations. Thus, we offer preliminary recommendations for ways the broader field could improve the consistency of the implementation of web-based RAND (RAND Corporation) processes and considerations for individual research teams in designing and reporting on their web-based expert panel studies. We hope these recommendations serve as a launching point for continued development to improve the implementation and reporting of web-based RAMs.

Preliminary Recommendation 1: Establish Data Collection and Reporting Standards for Web-Based RAM Panels

In the intervening decades since the RAM was developed, this method was continuously refined through its practical application in a wide variety of research settings. It was not until 2001 that the RAND Corporation issued a specific set of recommendations and guidelines for implementing the RAM [1]. However, the availability of this guidance alone does not ensure consistency.

As the systematic review of the Delphi Method by Boulkedid et al [9] revealed, there is still considerable variation in implementation and reporting among research teams using modified versions of the more established method. Thus, we recommend that a professional organization convene a group of experts (eg, journal editors, practitioners, RAM users, etc) to formulate a parallel set of best practices that mirror those developed for the in-person Delphi and Rand/UCLA Appropriateness expert panels. Research teams should clearly describe the data collected and any methodological modifications made to the standard RAM. Multimedia Appendix 3 can be used as a template to report these changes for a single study. Because of word limitations, it may be necessary for researchers to develop a separate protocol paper or to report details in appendices that accompany published findings. In our own work in which we conducted a technology-based RAND expert panel, we reported most of the suggested data elements in an extensive array of supplemental files [24]. Transparent and comprehensive reporting of web-based methods will promote the reproducibility of web-based RAM processes. Based on our own experience, and drawing on results from our literature review, we offer 2 additional recommendations.

Preliminary Recommendation 2: Establish Measures of Process Quality

We encourage researchers to develop and assess measures of process quality. Process quality can be assessed by asking expert participants to complete a survey at key points throughout the panel process or at its conclusion. Ideally, this would be carried out in the same web-based platform used to host the expert panel. Based on our own experience leading RAND panels, it is feasible to elicit this feedback. This feedback can yield useful quantitative and qualitative data (from numerical ratings and open-text feedback), which researchers can use to refine future rounds and evaluate ongoing processes, as well as using them for future planning purposes [24]. This review found scant reporting of such measures. Table 1 shows the few studies that reported facets of process quality (3/12, 25%), which did so for only narrowly defined assessments, including the need to discuss ideas over a conference call [13], satisfaction with rating anonymity [21], and the suitability of the process for "achieving consensus" [14,15]. Boulkedid et al [9] did not include these types of measures in their systematic review of the Delphi Method. We recommend eliciting and reporting panelist satisfaction as an indicator of process quality. Panel members may rate their satisfaction with all aspects of the RAM process, including the following: (1) background materials provided (if any); (2) process for revising indications; (3) meeting facilitation; (4) the web-based software used; and (5) their likelihood of participating in a similar process again. We also recommend reporting consistency of participation across rounds of the web-based RAM (eg, of the individuals participating in the first round, the percentage who also participated in subsequent rounds, and whether new participants were added across the rounds). Consistency is an important indicator of the depth of commitment and depth of thought as individuals consider and reconsider ratings across multiple rounds.

Preliminary Recommendation 3: Consider Other Viable Technical Platforms With Similar Levels of Functionality

Most studies included in our review used a web-based platform to conduct RAND panels. Although ExpertLens (RAND Corporation) was the most often used web-based platform among the studies in our review, our own experience using Group System's ThinkTank suggests there are other platforms with similar or perhaps expanded levels of functionality that could be considered [24,25]. A web-based hosting platform should have the following functions: (1) allow teams to engage, collaborate with, and capture and organize input from a large number of individuals; (2) allow for sharing, revising, organizing, and analyzing content in real time or asynchronously; and (3) allow teams to export session content (eg, ratings) to formats such as Microsoft Excel for further analysis.

Limitations

Although our review identified gaps in the literature, there are limitations. The PubMed database does not search full text, so we may have missed articles that reference using web-based RAM in the main text, but not in the title or abstract. This may have limited the number of articles included in our review. In addition, our article selection criteria were narrow, which again could have limited the number of articles included in our review. We also acknowledge that the time frame for our literature search stopped just before the start of the COVID-19 pandemic. Future work should include conducting an updated review, perhaps applying our preliminary recommendations to assess reporting in more recent studies. This study is, to our knowledge, the only investigation to formally review and summarize the literature on using completely web-based RAM approaches. We recommend further development of more formal reporting standards for running web-based RAM panels. Web-based approaches have undoubtedly grown during the pandemic as more and more research has moved to internet-based platforms, a trend that is likely to remain. Our preliminary reporting recommendations may encourage other researchers to report these details to increase research transparency and replicability. This methodological transparency is important for building and expanding knowledge of best practices for conducting RAMs virtually.

Conclusion

In conclusion, conducting research virtually has become particularly important within the context of the COVID-19 pandemic due to the prohibitions and safety concerns about in-person group meetings. This shift to web-based workplaces may outlast the pandemic [26]. We also anticipate that the multiple benefits associated with web-based collaboration will make the RAM with a web-based component an appealing and cost-effective option for researchers seeking an efficient process for incorporating expert opinion into developing recommendations. This narrative review reveals underreported yet important characteristics for conducting and reporting on web-based RAM expert panels. Without a common framework for reporting results from web-based RAMs, it is difficult to compare results across studies. In this way, intentionality in designing and transparency in reporting will yield improved results for individual study teams while also allowing external researchers to understand the process that was used to generate a given set of expert recommendations. We highlight preliminary recommendations for conducting and evaluating virtual RAM approaches that will contribute to replicable high-quality findings using web-based RAMs.

Acknowledgments

Abstract

Background: Extensive literature support telehealth as a supplement or adjunct to in-person care for the management of chronic conditions such as congestive heart failure (CHF) and type 2 diabetes mellitus (T2DM). Evidence is needed to support the use of telehealth as an equivalent and equitable replacement for in-person care and to assess potential adverse effects.

Objective: We conducted a systematic review to address the following question: among adults, what is the effect of synchronous telehealth (real-time response among individuals via phone or phone and video) compared with in-person care (or compared with phone, if synchronous video care) for chronic management of CHF, chronic obstructive pulmonary disease, and T2DM on key disease-specific clinical outcomes and health care use?

Methods: We followed systematic review methodologies and searched two databases (MEDLINE and Embase). We included randomized or quasi-experimental studies that evaluated the effect of synchronously delivered telehealth for relevant chronic conditions that occurred over ≥2 encounters and in which some or all in-person care was supplanted by care delivered via phone or video. We assessed the bias using the Cochrane Effective Practice and Organization of Care risk of bias (ROB) tool and the certainty of evidence using the Grading of Recommendations Assessment, Development, and Evaluation. We described the findings narratively and did not conduct meta-analysis owing to the small number of studies and the conceptual heterogeneity of the identified interventions.

Results: We identified 8662 studies, and 129 (1.49%) were reviewed at the full-text stage. In total, 3.9% (5/129) of the articles were retained for data extraction, all of which (5/5, 100%) were randomized controlled trials. The CHF study (1/5, 20%) was found to have high ROB and randomized patients (n=210) to receive quarterly automated asynchronous web-based review and follow-up of telemetry data versus synchronous personal follow-up (in-person vs phone-based) for 1 year. A 3-way comparison across study arms found no significant differences in clinical outcomes. Overall, 80% (4/5) of the studies (n=466) evaluated synchronous care for patients with T2DM (ROB was judged to be low for 2, 50% of studies and high for 2, 50% of studies). In total, 20% (1/5) of the studies were adequately powered to assess the difference in glycosylated hemoglobin level between groups; however, no significant difference was found. Intervention design varied greatly from remote monitoring of blood glucose combined with video versus in-person visits to an endocrinology clinic to a brief, 3-week remote intervention to stabilize uncontrolled diabetes. No articles were identified for chronic obstructive pulmonary disease.

Conclusions: This review found few studies with a variety of designs and interventions that used telehealth as a replacement for in-person care. Future research should consider including observational studies and studies on additional highly prevalent chronic diseases.

Introduction

Background

As a means to mitigate the risk of viral transmission for both patients and clinicians during the COVID-19 pandemic, many health systems have rapidly converted ≥70% of their outpatient visits to telehealth via phone or video delivery [1-5]. To support this shift, the Centers for Medicare and Medicaid Services in the United States issued an emergency ruling to decrease regulatory requirements for telehealth and created payment parity between in-person care and telehealth delivered via phone or video [6]. Increased telehealth use during the COVID-19 pandemic provided health systems, technology companies, and health care providers experience with telehealth at scale and raised the possibility that telehealth could become a standard option in the postpandemic period. However, concerns remain that care delivered via telehealth is potentially low in quality of care, is difficult to incorporate into workflows, and can exacerbate health disparities [7-10]. Specifically, evidence is needed regarding the efficacy of telehealth as a replacement for in-person care when treating patients.

Extensive literature supports telehealth as a supplement or adjunct to in-person care for the management of chronic conditions [11] such as congestive heart failure (CHF) and type 2 diabetes mellitus (T2DM) [12-14]. These 2 highly prevalent chronic diseases are among the most common and costly conditions affecting approximately 13.4% [15] and 10.5% [16] of all adults in the US, respectively. In addition, CHF and T2DM typically require physical assessment to establish disease status and assess the presence and extent of exacerbations. However, the effects of telehealth as a replacement for in-person health care delivery for CHF, T2DM, and other chronic illnesses remain uncertain [10,17,18] Before the COVID-19 pandemic, many patients with chronic medical conditions, such as CHF, chronic obstructive pulmonary disease (COPD), and T2DM, uniformly received in-person evaluation. During the pandemic, these patients often received telehealth to unknown effect. Although telehealth can increase accessibility to health care by lowering barriers to access [19-21], few studies exist to support the use of telehealth as an equivalent and equitable replacement for in-person care, and the potential adverse effects have not been well defined [18]. Assuming that telehealth can readily replace in-person care may be inappropriate, given the scarcity of evidence examining telehealth applied in this way.

A first step to address the question of equivalence of synchronous (real time) telehealth via phone or video as a replacement for in-person care for chronic diseases is a review focused specifically on evidence from the comparative literature. If there is moderate to strong evidence that telehealth is equivalent to in-person care for patients with chronic conditions, its promise should be developed more fully and incorporated as a standard option for delivering longitudinal care. Early during the COVID-19 pandemic, there was the first complete replacement of telehealth with in-person care [1-5]. However, since then, we have started to see the routine substitution of telehealth for in-person care visits across many specialties and contexts. This substitution (meaning only video) is not usually for all care, but rather can often be a replacement for part of in-person care (some phone visits replaced by video). In addition, currently, there are multiple commercial health care providers who provide only telehealth (Teledoc and CallonDoc). It is within this context that we formulated the questions for this review.

Objective

We conducted a systematic review to summarize and report the use of telehealth as a replacement or substitute for in-person care in the context of chronic management of CHF, COPD, and T2DM. The questions guiding this review were the following:

1. Question 1a—Among adults, what is the effect of synchronous (real time) telehealth (phone or phone and video) compared with in-person care (or compared with phone, if synchronous video care) for the chronic management of CHF, COPD, and T2DM on key disease-specific clinical outcomes and health care use (eg, hospital admission, hospital readmission, and emergency room visits)?
2. Question 1b—For each disease (CHF, COPD, and T2DM), does this effect differ by race and ethnicity, gender, age, and rural status?
3. Question 2—What are the adverse effects of synchronous telehealth for the chronic management of CHF, COPD, and T2DM as compared with in-person care (or compared with phone, if synchronous video care) on patients?

Methods

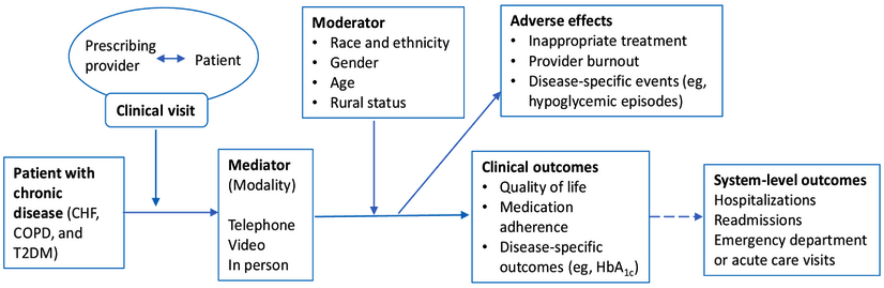
Overview

This systematic review was conducted as part of a Veterans Health Administration (VHA)–funded report [22] in response to a topic proposed by the VHA Office of Rural Health. For this review, similar to completed previous reviews and to meet the goals of the VHA as a learning health care system [23], (1) the partners from the Office of Rural Health were not involved in conducting the review, but informed topic and question development and provided contextual relevance for the study; (2) the partners from the Office of Rural Health were not involved in approving the final write-up of the report; and (3) a technical expert panel guided the conduct of the review and discussion of the findings. We developed and followed an a priori protocol for this review, and there were no significant deviations after registration (PROSPERO [International Prospective Register of Systematic Reviews] registration number CRD42021239756) [24]. Each step was pilot-tested to train and calibrate the study investigators. We adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [25].

Analytic Framework

We developed an analytic framework [26] (Figure 1) that outlined the population, outcomes, mediation effect of the care visit modality, moderation effect of patient characteristics, and any adverse effects. First, we identified clinical activities (medication management, symptom monitoring, and physical examination) for longitudinal follow-up and the ability to complete them via phone, video, or either of these for CHF, COPD, and T2DM. We determined the relevant aspects that should be abstracted from the eligible literature to obtain critical evidence about conducting a telehealth visit in any clinic setting. Then, with this foundation, we determined that the telehealth modality (eg, telephone, video, and in person) mediates the relationship between the clinical visit and prespecified clinical-level and system-level outcomes. The telehealth interventions matched with our operationalized definition of telehealth and included important contextual elements such as delivery mode (telephone, video, and in person), dose (duration and frequency of contact), and clinical context of care provision. In addition, we specified that care delivered via telehealth should be for clinical activities provided by the prescribing clinician such as for evaluation, diagnosis, or medication prescription and not for the provision of self-management education or other support provided adjunctively by a clinical team member other than the prescribing clinician (eg, nurse care manager), because such interventions have been previously evaluated [11].

Figure 1. Analytic framework to guide systematic review activities. CHF: congestive heart failure; COPD: chronic obstructive pulmonary disease; HbA_{1c}: glycosylated hemoglobin; T2DM: type 2 diabetes mellitus.



Search Strategy

In collaboration with an expert medical librarian, we conducted a primary literature search from inception to February 7, 2021, in 2 databases (MEDLINE [via Ovid] and Embase [via Elsevier]). We used database-specific subject headings and keywords to search for relevant titles and abstracts (Multimedia Appendix 1). The search strategies were peer-reviewed by a second expert medical librarian before execution using the Peer Review of Electronic Search Strategies Checklist [27]. In addition, we manually searched previous systematic reviews conducted on this or a related topic for potential inclusion.

Study Selection

Studies identified through our primary search were classified independently by 2 investigators from the study team for relevance to the questions based on the title and abstract from our a priori established eligibility criteria. Study eligibility criteria were organized by population, intervention, comparator, outcome, timing, and setting elements and other criteria such as study design, language, and publication type (Table 1). All studies classified for inclusion by at least one investigator were reviewed at the full-text level. The studies designated for exclusion by one investigator at the title and abstract level were screened by a second investigator. If both investigators agreed on exclusion, the study was excluded. Full-text review included 2 independent reviewers. Conflicts were resolved via discussion. All articles that met the eligibility criteria at the full-text level were included for data abstraction. All results were tracked in an electronic database (EndNote [Clarivate Analytics] for referencing and DistillerSR [Evidence Partners Inc] for data abstraction).

Table 1. Study eligibility.

Study characteristics	Inclusion criteria	Exclusion criteria

Population	• Adults (aged ≥18 years) with the following chronic conditions:
	  • CHF[a]
	  • COPD[b]
	  • T2DM[c]; at least 75% of the sample, if it is a mix of type 1 and type 2
	• Clinicians or clinics providing telehealth for chronic conditions, if relevant to adverse effects associated with CHF, COPD, and T2DM
		• Inpatient populations (eg, tele-ICU[d])
		• Patients receiving care in an ER[e] or tele–urgent care setting
		• Intervention limited only to the management of complications of CHF, COPD, and T2DM such as stroke, retinopathy, neuropathy, and foot ulcers

Intervention	• Synchronous care delivered over ≥2 encounters for the long-term management of relevant chronic conditions in which some or all in-person care is supplanted by telehealth (phone or video) and which is delivered remotely by an independently licensed clinician • May include asynchronous telehealth tools (eg, remote monitoring systems), if in both arms	• Supplemental nurse care management • Telehealth interventions that do not involve synchronous care delivered by a clinician to a patient (eg, 1-way SMS text messages and reminder systems) • Telecardiac or telepulmonary rehabilitation
Comparator	• In-person care without any telehealth delivery or care delivered via telephone, if compared with video	• No comparator

Outcome	• Key clinical outcomes (eg, medication adherence, quality of life, and depression) according to condition:
	  • CHF—for example, NYHA[f] functional classification
	  • COPD—for example, exercise tolerance and dyspnea
	  • T2DM—for example, HbA_{1c}[g] level
	• Clinical use (hospitalization, hospital readmissions, and ER visits or urgent care)
	• Adverse effects (eg, hypoglycemic episodes, inappropriate treatment, and clinician burnout)
		• Outcomes other than those listed in the inclusion criteria

Timing	• No limit	• N/A[h]
Setting	• Any outpatient setting (general medical or specialty care clinic)	• Intervention delivered primarily in hospital inpatient setting (including ER)
Study design	• Studies that meet the EPOC[i] criteria and have prospective data collection, such as the following: • Randomized controlled trials • Nonrandomized trials • Controlled before-after studies • Interrupted time series studies or repeated measures studies	• Not a clinical study (eg, editorial and letter to an editor) • Uncontrolled clinical study • Qualitative studies • Prospective or retrospective observational studies • Clinical guidelines • Measurement or validation studies • Studies that focus on mixed chronic conditions if results for specified conditions are not reported separately
Countries	• OECD[j]	• Non-OECD
Publication types	• Full publication in a peer-reviewed journal	• Letters, editorials, reviews, dissertations, meeting abstracts, and protocols without results

[a] CHF: congestive heart failure.

[b] COPD: chronic obstructive pulmonary disease.

[c] T2DM: type 2 diabetes mellitus.

[d] ICU: intensive care unit.

[e] ER: emergency room.

[f] NYHA: New York Heart Association.

[g] HbA_{1c}: glycosylated hemoglobin.

[h] N/A: not applicable.

[i] EPOC: Effective Practice and Organization of Care.

[j] OECD: Organisation for Economic Co-operation and Development includes Australia, Austria, Belgium, Canada, Chile, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Israel, Italy, Japan, Korea, Latvia, Luxembourg, Mexico, the Netherlands, New Zealand, Norway, Poland, Portugal, Slovak Republic, Slovenia, Spain, Sweden, Switzerland, Turkey, the United Kingdom, and the United States.

Data Extraction and Quality Assessment

Data from published reports were abstracted into a customized DistillerSR database by one reviewer and overread by a second reviewer. Disagreements were resolved by consensus or by obtaining a third reviewer's opinion. Data elements included descriptors to assess applicability, quality elements, intervention details, and outcomes including adverse events. Key characteristics that were abstracted included participant descriptors (eg, race and ethnicity, gender, age, and rural status), intervention characteristics (eg, clinician type and telehealth modality), comparator, and outcomes (eg, glycosylated hemoglobin [HbA_{1c}] level, hospital admission, emergency department visits, and New York Heart Association functional classification). We abstracted all outcomes that were used to evaluate telehealth, but prioritized outcomes identified a priori in collaboration with our partners from the Office of Rural Health and technical expert panel for analysis. Multiple reports from a single study were treated as a single data point, prioritizing results based on the most complete and appropriately analyzed data. When critical data were missing or unclear in the published reports, we requested supplemental data from the study authors. We emailed the authors of 1.6% (2/129) of the studies to obtain additional information and did not receive a reply from any of them. When we did not have sufficient information, we left the field blank.

The investigators who participated in data extraction also completed the quality assessment. Disagreements were resolved by consensus between the 2 investigators or, when needed, by arbitration by a third investigator. For randomized, nonrandomized, and controlled before-after studies, we used the criteria from the Cochrane Effective Practice and Organization of Care (EPOC) risk of bias (ROB) tool [28]. We assigned a summary ROB score (low, unclear, or high) to individual studies. Among the investigators, no ROB disagreements occurred owing to missing results in a synthesis.

The certainty of evidence for each question was assessed using the approach described by Grading of Recommendations Assessment, Development, and Evaluation [29]. We limited the Grading of Recommendations Assessment, Development, and Evaluation ratings to the questions that had at least two included studies. In brief, this approach requires the assessment of four domains: ROB, consistency, directness, and precision. Additional domains to be used when appropriate are coherence, dose-response association, impact of plausible residual confounders, strength of association (magnitude of effect), and publication bias. We considered these domains qualitatively and assigned a summary rating as high, moderate, or low strength of evidence after discussion by a subteam of 5 investigators. In some cases, high, moderate, or low ratings were impossible or imprudent to be provided. In these situations, a grade of *insufficient* was assigned.

Subgroups of Interest

The research questions guided our subgroup analysis. Prespecified potential effect modifiers included study design characteristics (eg, allocation concealment), disease context (CHF, COPD, or T2DM), and intervention type (eg, telehealth modality). Regarding patient-level characteristics of interest (race and ethnicity, gender, age, and rural status), we looked for analyses conducted within the primary literature that sought to identify effect modifications (eg, subgroup analyses and regression model explanatory variables). Manuscripts included in this review did not specify descriptions of gender or sex. For consistency, we use *gender* throughout the *Results* and *Discussion* sections because the interventions examined are more relevant to self-identity and not specific to one's biology at birth. However, we realize that this terminology may not reflect patients who would not have self-identified as such.

Data Synthesis and Analysis

We summarized the primary literature using relevant data abstracted from the eligible studies. Summary tables describe the key characteristics of the primary studies: study design, patient demographics, and details of the intervention and comparator. Owing to conceptual heterogeneity related to the structure, purpose, and delivery of telehealth visits, we did not conduct a meta-analysis, but rather described findings narratively, focusing on identifying patterns in the efficacy and safety of the interventions across conditions and outcome categories.

Continuous outcomes were summarized using the mean patient-level difference (follow-up minus baseline) when the outcome was reported using the same scale. For studies that did not directly report the mean and SD of patient differences, we used the difference in means between the follow-up and baseline. For 20% (1/5) of the studies [30], we computed the SD of the difference based on the reported *P* value for the difference between the 2 arms, assuming the same correlation between follow-up and baseline in each arm. When studies reported only medians and ranges, we translated them into means and SDs [31], and if a study reported only baseline SD, we assumed the same SD at follow-up. Finally, in the absence of other information, we assumed a conservative 0.5 correlation between the follow-up and baseline measures.

Ad hoc Horizon Scan to Identify Relevant Studies in Progress

Given the limited amount of existing literature we identified that addressed our questions, we sought to assess the pool of ongoing studies that would add relevant findings in the near future. To conduct such a scan of the literature on the horizon, we applied our previously developed search terms to the Cochrane Central Register of Controlled Trials. Notably, we did not apply the same rigor to this process as for our primary search process. At least one reviewer screened the studies identified through the horizon scan at the title and abstract level, and all the included studies were verified by a second reviewer.

Results

Overview

The search identified 11,245 studies from the 2 databases (Figure 2). After deduplication, 77.03% (8662/11,245) of the articles underwent the screening process. In total, 0.06% (5/8662) of the studies met the inclusion criteria. Of those 5 studies, 4 (80%) focused on diabetes and 1 (20%) focused on CHF. The details of the included studies are provided in Table 2. We have provided the details of study characteristics (Multimedia Appendix 2), intervention characteristics (Multimedia Appendix 3), all outcomes reported in the included studies (Multimedia Appendix 4), and excluded studies and the reason for exclusion (Multimedia Appendix 5). Common reasons for excluding studies by intervention included telehealth that supplemented rather than replaced in-person care, telehealth interventions delivered by nonprescribing clinicians, and telehealth delivered asynchronously only. In the following sections, we describe the results by chronic disease (CHF, COPD, and T2DM). The certainty of evidence for the included studies is presented in (Table 3).

Question 1a (Effect of Telehealth) and 1b (Differences by Special Population)

Findings for CHF

Question 1a: Effect of Telehealth

Overview

We identified only 20% (1/5) of studies that met the inclusion criteria for synchronous telehealth for chronic CHF management [33] and found it to have high ROB. The study was conducted in Germany, enrolled 210 patients, and had a duration of 12 months. The study incorporated phone-based appointments and follow-up in patients with CHF with recent placement of an implanted cardioverter defibrillator or cardiac resynchronization therapy defibrillator. Patients were randomized to receive asynchronous web-based automated review and follow-up of telemetry data alone every 3 months (n=102) or personal physician contact every 3 months in addition to remote monitoring. The personal contact group was further randomized to personal contact via telephone calls (n=53) or personal contact via in-person visits (n=55). In this study [33], the primary outcome was the proportion of patients with worse Packer Heart Failure Clinical Composite Response scores at 13 months compared with scores at 1 month after device placement. The Packer Heart Failure Clinical Composite Response score provides stepwise assessment and incorporates CHF death or hospitalization, change in New York Heart Association class, and self-assessed health status. The secondary outcomes in this study were all-cause mortality, CHF-related hospitalizations, arrhythmias, and changes in reported quality of life. We present the detailed results by outcome: (1) Packer Heart Failure Clinical Composite Response Score, (2) hospitalizations, (3) emergency department visits, and (4) number of contacts and use.

Packer Heart Failure Clinical Composite Response Score

The primary outcome of the study by Hansen et al [33] showed no significant differences in Packer scores in a 3-way comparison between the telemetry arm compared with the personal contact subgroups (remote monitoring and phone call vs remote monitoring and in-person visit; *P*=.97).

Hospitalizations

The authors found no significant differences between the subgroups in any of the outcomes that were measured. Outcomes between study arms included the following: mortality (*P*=.65), CHF-related hospitalization (*P*=.85), detection of supraventricular tachycardia (*P*=.22), detection of ventricular tachycardia (*P*=.75), and reported change in quality of life (*P*=.72).

Emergency Department Visits

The CHF study that was included did not report on emergency department visits [33].

Number of Contacts and Use

The CHF study compared the number of unscheduled follow-up visits conducted either via phone or in person among the telemetry only group, telemetry and phone visit group, and telemetry and in-person visit group [33]. In total, there were 219 unscheduled follow-ups among the 3 groups, involving 83 patients during the course of the study. However, there were no significant differences in the unscheduled follow-up rates among the 3 groups (*P*=.29).

Question 1b: Differences by Special Population

The 20% (1/5) studies that met the inclusion criteria [33] described the age (overall mean 63.8 years, SD was not reported by authors) and gender of their patient population (84.3% were men); however, details regarding race and ethnicity and rural status were not reported. Furthermore, the authors did not perform any subgroup analyses to examine the effect of age or gender on outcomes.

Findings for COPD

No studies that addressed the use of telehealth as a substitute for in-person chronic management of COPD were identified.

Findings for T2DM

Question 1a: Effect of Telehealth

Overview

We identified 80% (4/5) of studies—all of which were randomized controlled trials [30,32,34,35]—that evaluated the provision of synchronous telehealth compared with in-person care for the chronic management of T2DM. Of the 4 studies, 2 (50%) studies were conducted in the United States [30,35], 1 (25%) in South Korea [32], and 1 (25%) in Denmark [34]. Overall, 25% (1/4) of the studies were conducted with patients in the military [35]. Intervention duration varied across studies, from <8 weeks to 52 weeks. Intervention approach varied across all the studies (4/4, 100%) regarding duration and mode of incorporating telehealth into chronic diabetes management. Of the 4 studies, 3 (75%) studies included ≤60 patients [30,34,35] and 1 (25%) study included 338 patients [32]. Of the 4 studies, 3 (75%) studies used technology that facilitated synchronous bidirectional communication between the patient and clinician [32,34,35], and 1 (25%) study relied on telephone and email [30]. In total, 50% (2/4) of the studies included remote monitoring in addition to synchronous telehealth [32,35]. We present the detailed results by outcome: (1) HbA_{1c} level, (2) hospitalizations, (3) emergency department visits, and (4) number of contacts and use.

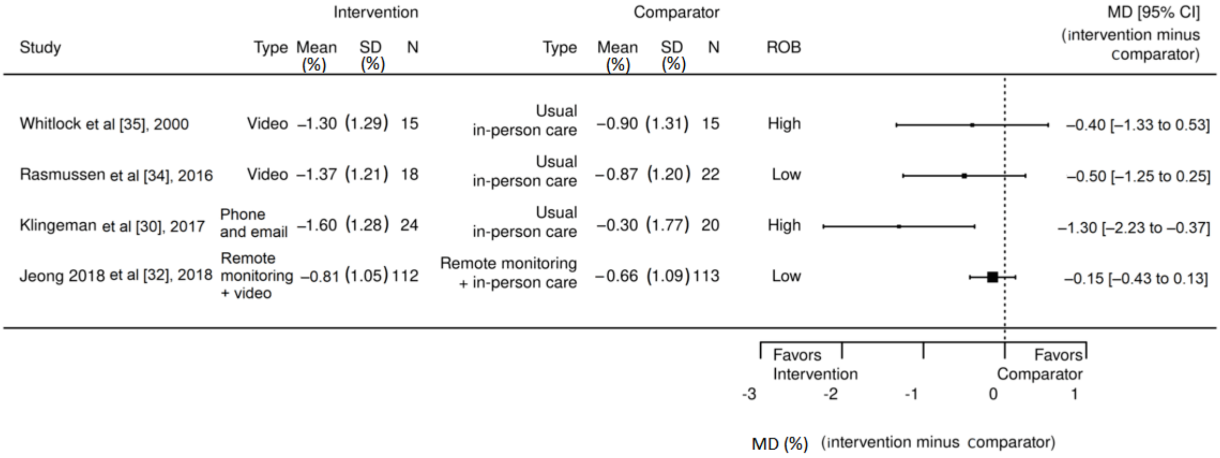
Change in Reduction of HbA_{1c} Level

All the studies (4/4, 100%) compared the change in reduction of HbA_{1c} level from baseline to the end of the study between synchronous telehealth and in-person study arms (Figure 3) [30,32,34,35]. The first study, by Jeong et al [32], was a 24-week 3-arm trial that compared usual care, telemonitoring (remote monitoring with automated clinical decision support with in-person endocrine follow-up appointments), and telemedicine (remote monitoring with automated clinical decision support with video-based endocrine follow-up appointments). Notably, that study was the largest study included and was rated as having low ROB. They enrolled 338 patients, with a baseline mean age of 53 years (SD was not reported by authors). No statistically significant difference was seen at baseline for HbA_{1c} level across groups: usual care (mean 8.39%, SD 1.10%), telemonitoring (mean 8.21%, SD 0.93%), and telemedicine (mean 8.39%, SD

1.10%). Statistically significant difference was seen for within-group reduction in HbA$_{1c}$ level from baseline to 24 weeks for all groups, ranging from −0.66% to −0.81% (P<.001). No statistically significant difference was noted for the extent of HbA$_{1c}$ reduction across groups: usual care versus telemonitoring groups (P=.61), usual care versus telemedicine groups (P=.16), and telemonitoring versus telemedicine groups (P=.34).

The second study, led by Klingeman et al [30], was a 52-week, 2-arm trial consisting of usual endocrine care versus an experimental endocrine clinic group that enrolled 60 patients with T2DM. The setting for the study was an endocrinology clinic at an academic medical center, where patient care was provided by endocrinologists. Patients who were not in the experimental arm received the usual care provided by the clinic's endocrinologists. The specialty clinic model in the experimental group included an endocrinologist and nurse educator who focused on patients with advanced diabetes; contact with the patients in this arm was designed to be variable and patient-specific. Preplanned contacts (via email and phone) were determined at baseline and amended over time, and ad hoc in-person visits occurred if clinically required. Contact was individually tailored based on each patient's outcomes, adverse reactions, and changes in the disease state. The control arm received the usual endocrine care, which included the ability for the patients to contact (via email and phone) clinicians as needed. HbA$_{1c}$ levels were compared between groups at baseline for usual care (mean 8.9%, SD 0.8%) versus specialty clinic model (mean 9.5%, SD 0.9%). In addition, high proportion of patients who were White were enrolled in the intervention group (96.6%) compared with the usual care group (76.8%). Analysis of data at 52 weeks found great reduction in HbA$_{1c}$ level in the specialty clinic model (−1.7%; from 9.6% to 7.9%) as compared with the usual endocrine care (0.3%; from 8.9% to 8.6%), with P=.004. Notably, sensitivity analysis was conducted that dropped data from a patient who was an outlier in the usual care group, with worsened HbA$_{1c}$ values (from 8.3% to 13.5%); however, this did not change the results.

Figure 3. Change in glycosylated hemoglobin levels between intervention and comparator arms across type 2 diabetes mellitus studies. MD: mean difference; ROB: risk of bias [30,32,34,35].



The third study, by Rasmussen et al [34], was a 2-arm trial comparing 3 weeks of brief standard in-person endocrine care versus telemedicine (video-based endocrine care) to stabilize patients with poorly controlled T2DM. They enrolled 40 patients with baseline HbA$_{1c}$ level of 8.1% (range 6.1%-10.7%) in standard care group and 9% (range 7.6%-12%) in the telemedicine group. At 6 months, the HbA$_{1c}$ level ranged from 8.1% to 7.2% in the standard care group and from 9.1% to 7.7% in the telemedicine group. The patients in the telemedicine arm experienced a larger decrease in HbA$_{1c}$ level (14.6%) than those in the standard care arm (10.6%), which was statistically significant (P=.02). Notably, although this study framed its hypothesis as "the treatment by telemedicine at home was similar to standard care," the analysis methods did not use noninferiority analytic approaches.

The fourth study, by Whitlock et al [35], which tested usual care and telemonitoring visits with a case manager and physician, enrolled 28 patients in a 36-week 2-arm trial consisting of a standard of care control versus experimental telemonitoring group. In this study, both groups were referred for multidisciplinary diabetic education classes. The experimental group received weekly telemonitoring via video from a case manager and, then, monthly telemonitoring via video from study physicians. Patients in the standard of care group received routine in-person care from their primary care clinician. Statistically significant within-group difference (P=.05) was noted for the experimental telemonitoring arm, from baseline HbA$_{1c}$ level of 9.5 (range 8.1-12.6) to week-36 HbA$_{1c}$ level of 8.2 (range 5.7-10.2). For the comparator, the mean baseline HbA$_{1c}$ level was 9.5 (range 8.1-11.9) and week-36 HbA$_{1c}$ level was 8.6 (range 7.1-11.9), which was not statistically significant.

Hospitalizations

In total, 50% (2/4) of the studies examined hospitalizations [30,32]. In the study by Jeong et al [32], only 1 patient in the telemonitoring arm experienced a diabetes complication–related hospitalization, and none of the patients in the control or telemedicine arms experienced diabetes-related hospitalizations. In the second study, by Klingeman et al [30], 10% (3/30) of the patients in the experimental arm and 23% (7/30) of the patients in the control arm experienced diabetes-related hospital admission.

Emergency Department Visits

Overall, 50% (2/4) of the studies examined emergency department visits [30,32]. In the first study, by Jeong et al [32], across the 3 study arms, none of the patients experienced diabetes-related visits to the emergency department out of the 338 patients enrolled in the study. In the second study, by Klingeman et al [30], none of the patients in the experimental arm and 1 patient in the control arm experienced a T2DM-related emergency department visit.

Number of Contacts and Use

In total, 75% (3/4) of the studies reported collecting data on number of contacts and use [30,34,35] among patients receiving in-person or telehealth. The study by Klingeman et al [30] reported on (1) diabetes education referrals, (2) diabetes-related visits, (3) use of modality, and (4) number of interactions and HbA_{1c} level. Klingeman et al [30] designed the experimental arm for variable frequency of contact using a specialty clinic model. Preplanned contacts (via email, phone call, or visit) were determined at baseline and amended over time; contact was tailored based on each patient's outcomes, adverse reactions, and changes in the disease state; and the control arm received usual endocrine care. Klingeman et al [30] reported that when diabetes education visits were combined with clinician's diabetes-related visits in the endocrinology clinic, the experimental group had fewer overall visits than the control group. Specifically, the experimental group had 1.5 (SD 0.7) visits and the control group had 3.6 (SD 4) visits over 12 months (*P*<.001). However, the experimental group had significantly more email contacts (mean 11.1, SD 6.4) than the control group with (mean 1.8, SD 3.5; *P*<.001; *note that email communication was a focus in the experimental group*).

The study by Rasmussen et al [34], which tested standard care and video consultation for home treatment of T2DM, reported on (1) number of visits and missed visits and (2) consultation time. The telemedicine group had an average of 4.1 visits, with no missed visits; however, the usual care group had an average of 3.8 visits, with 13% missed visits. Regarding consultation time, the telemedicine group had an average of 18 minutes and the usual care group had an average of 23 minutes. The study by Whitlock et al [35] reported no results on the number of contacts and use, despite describing collecting the number of clinic visits before and during the study in their Methods section.

Question 1b: Differences by Special Population

Only 25% (1/4) of the included studies reported on subgroup analysis [32] by patient characteristics. Jeong et al [32] analyzed two subgroups of a priori interest: gender and age. No statistically significant difference in reduction of HbA_{1c} level was found for men (mean −0.76%, SD 1.11% for telemonitoring vs mean −0.89%, SD 1.12% for telemedicine; *P*=.88) or women (mean −0.46%, SD 1.05% vs mean −0.63%, SD 0.87%; *P*=.16). No statistically significant difference in reduction of HbA_{1c} level was seen among people aged <55 years (mean −0.63%, SD 1.26% for telemonitoring vs mean −0.87%, SD 1.15% for telemedicine; *P*=.21) or among those aged ≥55 years (mean −0.68%, SD 0.88% for telemonitoring vs mean −0.73%, SD 0.93% for telemedicine; *P*=.83). Moreover, Jeong et al [32] reported on additional subgroups of potential interest. Users with high compliance (defined as users with >90% of number of records or data transmitted compared with recommended number of records) had no difference in reduction of HbA_{1c} level when compared with those with low compliance levels across the study arms of interest (mean −0.93%, SD 0.99% for telemonitoring vs mean −1.08%, SD 0.96% for telemedicine; *P*=.47). Similarly, there was no significant difference in the reduction of HbA_{1c} level between patients who had a high school education or less in the telemonitoring (mean −0.65%, SD 0.93%) and telemedicine (mean −0.94%, SD 1.1%) arms (*P*=.26).

Question 2: Adverse Events

The 20% (1/5) of the studies of CHF, by Hansen et al [33], did not report on adverse events. The 40% (2/5) of studies of T2DM reported adverse events [30,32]. Jeong et al [32] described four groups of adverse events: (1) general events, (2) diabetes-related events, (3) serious events, and (4) biochemical events. Adverse events were noted in the control (n=33 or 29.20%, in-person appointments at 8, 16, and 24 weeks), telemonitoring (n=30 or 26.55%, in-person appointments at 8, 16, and 24 weeks, with remote monitoring of blood glucose data), and telemedicine (n=23 or 20.54%, video visits at 8 and 16 weeks, in-person visits at 24 weeks) arms. Diabetes-related events were noted in the control (n=7 or 6.19%), telemonitoring (n=7 or 6.19%), and telemedicine (n=3 or 2.68%) arms. Serious reported adverse events were noted in the control (n=2 or 1.7%), telemonitoring (n=2 or 1.70%), and telemedicine (n=1 or 0.90%) arms, and it included angina pectoris, rotator cuff syndrome, malignant hepatic neoplasm, skin ulcer, and hematuria [32]. Biochemical parameters for serum alanine aminotransferase (ALT), aspartate aminotransferase, and creatinine levels were measured, and samples were obtained at baseline and 24 weeks [32]. Comparing the relative percentage of patients with worsened laboratory values, ALT was the only parameter that showed significant worsening between the telemedicine and telemonitoring groups. Specifically, none of the participants in the telemonitoring arm and 7 participants in the telemedicine arm (6.7%; *P*=.01) experienced worsening of ALT values. Klingeman et al [30] described two types of adverse events: (1) severe hypoglycemia and (2) foot ulcers. Severe hypoglycemia was noted in the experimental (n=1 or 3.3%) arm, but not in the control (n=0 or 0%) arm. Foot ulcer was noted in the experimental (n=1 or 3.3%) and control (n=3 or 10%) arms.

Quality of Evidence for Included Studies

The 20% (1/5) of the studies of CHF [33] that met our inclusion criteria was rated as having high ROB owing to low numbers of patients enrolled, unclear method for patient randomization, and poor description of both patient dropout and how primary outcomes were assessed. Among the 80% (4/5) of randomized T2DM studies, the ROB (Figure 4) for patient-reported outcomes was judged to be low for 1 (25%) study, unclear for 1 (25%) study, and high for 1 (25%) study and 1 (25%) study did not report this type of outcome [30,32,34,35]. For objective outcomes, ROB was judged to be low for 50% (2/4) of the studies [32,34] and high for 50% (2/4) of the studies [30,35]. Patterns that led to judgments of low ROB (Figure 5) included

(1) noting randomization of study participants, (2) collecting objective outcome data, and (3) generally limited expected impact of bias from patient knowledge of the treatment arm. Patterns that led to high ROB included (1) missing or unclear data on randomization methods, data collection, and analysis; (2) unblinded treatment arm; (3) absence of predetermined intervention assessment patterns in the protocol; (4) unclear primary outcomes; and (5) missing or unclear reporting of patient-reported outcomes.

Ad hoc Horizon Scan to Identify Relevant Studies in Progress

This search identified 1787 unique studies. We found only 0.17% (3/1787) of studies [36-38] in our horizon scan that reported on studies without published results (Multimedia Appendix 6) that may potentially meet the inclusion criteria of our systematic review. All of these studies (3/3, 100%) are randomized controlled trials that were designed before the COVID-19 pandemic. Of the 3 studies, 2 (67%) studies focus on T2DM [36,37], whereas the remaining 1 (33%) study is on CHF [38]. Although the noninferiority study [37] will not meet our inclusion criteria as it is conducted in Brazil (a non–Organisation for Economic Co-operation and Development [OECD] country) and the findings may not be applicable to the US population or setting, we mention it here given the low number of studies that otherwise met our inclusion criteria. The other T2DM study [36] is specifically focused on reducing emergency diabetes care for older (aged >50 years) African Americans. The CHF study by Komkov et al [38] has very limited detail available. Although using these registries to identify trials has limitations and there are likely other relevant studies, it appears that there are few trial-based studies currently in the pipeline to inform our questions in this review.

Discussion

This review aimed to summarize and report the use of telehealth as a replacement or substitute for all or a portion of in-person care in the context of chronic management of CHF, COPD, and T2DM.

Principal Findings

We found scant evidence examining chronic disease management delivered through synchronous telehealth compared with in-person delivery for T2DM (4/5, 80%), COPD (0/5, 0%), and CHF (1/5, 20%). This suggests that there is little evidence to help guide practice on when to use telehealth instead of traditional in-person visits while managing these chronic diseases. Our review sought to include studies that used telehealth to replace all or part of in-person care. In other words, some specific in-person visits in the intervention arm were replaced by telehealth visits, whereas the comparator arm maintained all visits as in-person. Note that we consider this to be different from using telehealth as a supplement or add-on to the usual in-person care. However, we did not find any studies that only partially substituted in-person visits. We did not attempt to include studies that used telehealth as an add-on to existing in-person care, as there are already existing high-quality, peer-reviewed publications on this question [11-13]. However, despite the paucity of evidence, telehealth modalities such as video or telephone have increasingly been used to replace in-person clinic visits for managing chronic conditions, particularly during the COVID-19 pandemic [1-5]. Understanding the benefits and risks associated with shifting in-person care to telehealth is critical in shaping how health systems deliver care going forward. Although in-person visits have since increased as more has become known about COVID-19 transmission and prevention practices, telehealth continues to play a much larger role in outpatient care than before the pandemic [39,40].

Comparison With Previous Studies

Evidence indicates that telehealth can be used effectively as an adjunctive or supplemental approach to in-person care. A recent review by Albritton et al [18] examined the impact of video teleconferencing visits on prevention and management of chronic illness. Results from that review indicated that video teleconferencing resulted in similar clinical effectiveness as in-person care for certain diseases [18]. The results from our review differ in indicating clinical effectiveness of telehealth from those of Albritton et al [18] owing to several differences in the review type (systematic vs rapid review), date limitations, search strategies, databases searched, and operationalization of telehealth. Our approach to identify relevant telehealth papers was broad and more comprehensive, which resulted in a large number of articles to review. Of the 7 papers included in the review by Albritton et al [18], only 1 (14%) was not captured in our search. Additional previous reviews have examined various ways of using telehealth modalities in the context of these conditions of interest, but none of them have focused on *replacing* in-person care with telehealth visits [11]. Although we found only 20% (1/5) of the studies on telehealth for chronic management of heart failure as a substitute for in-person care, previous reviews report mixed results for the impact of other supplemental types of telehealth on heart failure outcomes [41-43]. Several recent analyses on the impact of telehealth in T2DM indicated that health outcomes did not worsen because of switching to telehealth compared with those in-person clinic care [14,40,44,45]. However, there is evidence that telehealth as an *adjunctive* strategy to typical in-person care can be associated with a decrease in HbA_{1c} level in patients with both type 1 and type 2 diabetes [46-49].

Importance of Context in Telehealth Implementation

The successful incorporation of telehealth into health care delivery relies upon the fit between the telehealth modality, care delivery context, and disease management approaches [9,19,50]. Presumably, not all areas of health care delivery lend themselves equally well to telehealth, but management of certain chronic diseases (CHF, COPD, and T2DM) may provide good opportunity to replace routine in-person care with telehealth. In our review, we sought to address a critical evidence gap by examining the comparative literature on telehealth as a replacement for in-person care in chronic disease management. Interestingly, our findings came from studies that were conducted in specialty settings, and aspects of the studied telehealth interventions were often incompletely described. However, much of the long-term management of these chronic conditions occurs within the context of primary care settings. As primary care settings likely have different pressures and challenges with telehealth modalities, given the need to address multiple comorbidities during the same visit, the results from our review may not be directly applicable. Thus, we recommend future reviews to examine and provide evidence-based guidance about the effect of telehealth interventions to deliver high-quality care using the right modality for the right patients with the right clinical condition at the right time.

Additional Approaches to Examine Telehealth

A way to determine the effect telehealth is to use noninferiority analytic approaches when hypotheses focus on whether telehealth delivered care is equally effective to in-person care. Our eligibility criteria focused on randomized controlled trials and did not include observational study designs. Randomized controlled trials are the gold standard; however, conducting these trials is time-consuming and resource-intensive. Importantly, findings from randomized controlled trials take years to affect clinical practice, if they are implemented at all. Randomized controlled trials should not be expected to fill all the research gaps in the implementation and adoption of telehealth for chronic disease management. Thus, given the paucity of randomized controlled trials, we strongly recommend that future reviews focused on telehealth include what are likely to be rich and robust, but potentially biased; observational; and alternatively designed studies that emerge during and after the COVID-19 pandemic.

Future Directions

Overall, there are 5 key areas in which future studies on this topic can fill the existing gaps and improve the approach. First, and perhaps most critical, telehealth interventions should be thoroughly described to maximize reproducibility and generalizability in other clinical contexts. Guidance exists on mobile and web-based interventions, which may provide indirect suggestions about key characteristics for telehealth intervention description. Second, there is a need to evaluate how best to integrate telehealth as a replacement for in-person care. Furthermore, there is a need to assess which clinical settings are best suited to the telehealth environment (eg, primary care vs specialty care settings). Approaches to integrating telehealth can be expected to vary across settings with different workflow patterns, clinical resources, and competing clinical demands, which emphasizes the need for solid evidence. Third, outcomes varied across the included studies, and some important outcomes were not addressed by any study (eg, impact on clinical workflow, patient satisfaction with telehealth experience, and subsequent use). Fourth, investigators should be encouraged to consider a priori subgroup evaluations or make individual patient-level data available, so that future reviews can identify patient-level characteristics associated with better outcomes with telehealth. Finally, future studies should also actively solicit and report patient perspectives and feedback on telehealth interventions to better inform intervention design. Such information can guide clinics and health care systems to offer optimal patient-centered telehealth delivery and support efforts to ensure equitable benefits and access to telehealth.

Strengths and Limitations

Our review benefited from being protocol-driven, leveraging input from an expert panel consisting of clinicians and telehealth researchers, identifying disease-specific clinical outcomes, using an analytic framework to guide the understanding of telehealth modalities, and using a detailed approach to categorize and define telehealth components in chronic disease self-management. In addition, our review was based on a clear definition and use of telehealth. Notably, we acknowledge that individual patient characteristics (eg, race and ethnicity, gender, age, and rural status) may moderate the relationship between the modality in which the clinical visit occurs and any clinical-level and system-level outcomes.

Despite these strengths, our approach had some limitations. First, we included only the studies that met the EPOC criteria in this review; however, observational studies may have findings relevant to the provision of synchronous telehealth for chronic illness management. However, we do not believe that this limitation largely affected our findings. Second, we focused this review on 3 of the most prevalent chronic diseases, but there may be appropriately designed studies that targeted other conditions that we did not include. Third, we only included studies conducted in OECD countries, and thus, we may have missed relevant studies conducted in other countries. Fourth, given the small number of studies that we identified, statistical methods to detect publication bias were not conducted. Although it is possible that individual health systems or clinics have conducted quality improvement studies evaluating differences in experiences between synchronous and in-person care—especially during the COVID-19 pandemic—we suspect it to be unlikely that studies meeting EPOC criteria on this intervention have not been published, given the recent emphasis on the role of telehealth. Fifth, we identified few studies overall, and most studies had <100 patients and were assessed as having unclear or high ROB. Intervention core components, intervention fidelity, and impact of intervention on clinical workflow were not reported in any study. In addition, the interactions between clinicians and patients during telehealth episodes were not adequately or explicitly described, and most of our outcomes of interest were not consistently reported across the studies. These omissions limited the interpretation and replication of the evaluated interventions. Sixth, the included telehealth interventions used different telehealth modalities (email, phone, and video) with different hardware, delivered via different numbers of clinical interactions between patients and clinicians, over a wide range of intervention durations, and within different health care systems, which inherently make comparison between them challenging. Finally, the studies included in our review did not specify how they used or defined gender (man, woman, or nonbinary) or sex (male, female, or intersex) in their publications. Information on gender and sex is important to be captured and described for telehealth studies and research. Future studies should consider including observational studies; studies on additional, highly prevalent chronic diseases; studies conducted in non-OECD countries; and studies that do not meet the EPOC criteria especially, as those conducted since the onset of the COVID-19 pandemic may provide useful information.

Conclusions

The COVID-19 pandemic precipitated a rapid shift from in-person to telehealth delivery, without a clear understanding about the impacts of telehealth on important health outcomes. Previous studies have found that telehealth modalities can improve health outcomes through the supplementation of in-person management of certain chronic diseases, particularly with approaches such as remote monitoring and patient education. However, we found that, currently, there is very little evidence on the use of telehealth as a replacement for in-person care for several chronic conditions and that the studies in this area remain insufficient and methodologically inconsistent. In conclusion, our review builds on this existing body of literature by evaluating the comparative literature on the effectiveness of telehealth visits delivered as a substitute for in-person visits for chronic disease management and provides recommendations for future studies in this area.

Acknowledgments

The authors gratefully acknowledge their operational partner, Carolyn Turvey, PhD, for her telehealth expertise and Liz Wing and Sharon Thompson for editorial assistance. In addition, the authors would like to thank the following key partners and technical expert panel members for their feedback during the development and execution of this project: Bryan Batch, MD; Hayden Bosworth, PhD; Marla Clayman, PhD, Master of Public Health; Christopher Mosher, MD; and Scott Sherman, MD, Master of Public Health. Abstract

Background: Current evidence supports the use of wearable trackers by people with cardiometabolic conditions. However, as the health benefits are small and confounded by heterogeneity, there remains uncertainty as to which patient groups are most helped by wearable trackers.

Objective: This study examined the effects of wearable trackers in patients with cardiometabolic conditions to identify subgroups of patients who most benefited and to understand interventional differences.

Methods: We obtained individual participant data from randomized controlled trials of wearable trackers that were conducted before December 2020 and measured steps per day as the primary outcome in participants with cardiometabolic conditions including diabetes, overweight or obesity, and cardiovascular disease. We used statistical models to account for clustering of participants within trials and heterogeneity across trials to estimate mean differences with the 95% CI.

Results: Individual participant data were obtained from 9 of 25 eligible randomized controlled trials, which included 1481 of 3178 (47%) total participants. The wearable trackers revealed that over the median duration of 12 weeks, steps per day increased by 1656 (95% CI 918-2395), a significant change. Greater increases in steps per day from interventions using wearable trackers were observed in men (interaction coefficient –668, 95% CI –1157 to –180), patients in age categories over 50 years (50-59 years: interaction coefficient 1175, 95% CI 377-1973; 60-69 years: interaction coefficient 981, 95% CI 222-1740; 70-90 years: interaction coefficient 1060, 95% CI 200-1920), White patients (interaction coefficient 995, 95% CI 360-1631), and patients with fewer comorbidities (interaction coefficient –517, 95% CI –1188 to –11) compared to women, those aged below 50, non-White patients, and patients with multimorbidity. In terms of interventional differences, only face-to-face delivery of the tracker impacted the effectiveness of the interventions by increasing steps per day.

Conclusions: In patients with cardiometabolic conditions, interventions using wearable trackers to improve steps per day mostly benefited older White men without multimorbidity.

Introduction

Background

Cardiometabolic conditions are the leading cause of death worldwide, accounting for more than 41 million deaths annually [1]. These conditions include obesity, diabetes mellitus, and cardiovascular disease (CVD); these 3 common, intersecting noncommunicable diseases affect almost two-thirds of the global population [2,3].

The World Health Organization recently recognized physical inactivity as a serious and growing public health problem and has set out to reduce it by 10% before 2025 [4]. The United Kingdom's National Institute for Health and Care Excellence also highlights the importance of physical activity for obesity management, successful aging, CVD prevention, and weight management during pregnancy [5]. The consequences of being physically inactive include unhealthy weight gain, dyslipidemia, and elevated blood pressure and blood glucose levels, all of which heighten the risk of developing a cardiometabolic condition [6].

Wearable physical activity trackers, such as accelerometers, pedometers, and the Fitbit (Fitbit Inc), are portable electrical or electromechanical devices that count each step a person takes by detecting the motion of the person along the body's long axis [7,8]. They have become very popular for motivating and monitoring (thereby increasing) physical activity in general and in people with cardiometabolic conditions in particular [9,10]. Systematic reviews have suggested that the validity of various wearable trackers, especially those measuring steps, is high, and these reviews have found that they are useful for tracking ambulatory physical activity in clinical populations [11-13].

Since many wearable trackers are affordable and user-friendly, they are viewed as a good practical method for monitoring basic physical activity [14], such as the number of steps per day, in high-risk people with chronic cardiometabolic conditions [15-17]. However, their long-term effectiveness in achieving the desired behavior changes (ie, increasing steps per day) in specific patient subgroups with cardiometabolic conditions is unclear, and they may only succeed in the short term as "quick fixes" [18].

Our recent meta-analysis of 38 randomized trials [19] suggested that interventions using wearable trackers are moderately effective at increasing physical activity, including steps per day, in people with cardiometabolic conditions. The most promising interventions were those that focused on the number of steps per day. However, without individual participant data (IPD), we could not conduct an assessment of patient factors, baseline effects, and interventional differences, nor could we analyze their importance [20]. This was a major constraint of the review findings.

In IPD meta-analysis, rather than extracting summary (ie, aggregate) data from study publications or from investigators, original research data are obtained directly from the researchers responsible for each study. These data are then re-analyzed centrally and combined in the meta-analysis. The IPD approach is becoming an increasingly popular tool compared to traditional aggregate-data meta-analysis, especially as the IPD approach avoids reliance on published results and provides an opportunity to investigate individual-level interactions, such as treatment-effect modifiers [20].

Objectives

In the present study, we undertook an IPD meta-analysis to identify whether belonging to certain subgroups of patients with cardiometabolic conditions, including groups with differing age, sex, ethnicity, and number or combination of cardiometabolic conditions, moderated the effectiveness of interventions using wearable trackers in improving physical activity, measured by the number of steps per day. We also examined the impact of interventional differences, such as behavior change, device placement, delivery method, and performance over time, on the effectiveness of interventions using wearable trackers in improving steps per day.

Methods

This IPD meta-analysis followed a registered (PROSPERO CRD42019143012) protocol. A statistical analysis plan was produced in advance of analysis and the findings are reported in accordance with the PRISMA-IPD statement [21].

Literature Search and Study Identification

We searched MEDLINE (Ovid), EMBASE (EBSCO), CENTRAL, CINAHL, and PsycINFO from inception until August 2018, without language restriction; this was updated in December 2020 (Multimedia Appendix 1, pages 3-11). Additional studies were obtained by citation tracking, extraction from previous systematic reviews, and searches of trial registers (ie, ClinicalTrials.gov and ICTRP). A list of all the search sources and the data collection and management process are detailed in the protocol for this paper.

Two researchers (AH and MP) independently identified the citations and then fully screened the relevant manuscripts according to the eligibility criteria. We included randomized controlled trials (RCTs) or cluster RCTs involving adults (aged 16 years or older) with a cardiometabolic condition, defined as a diagnosis (or high risk) of type 2 diabetes, CVD, or obesity or overweight.

We included studies with an intervention program designed around the daily usage of wearable trackers, such as pedometers, accelerometers, and fitness trackers, rather than studies that only measured performance at the beginning and end of the study. Studies were required to have a usual-care comparator. Participants' steps per day in both intervention and usual-care groups were measured in parallel using the same device. We further required that studies reported a physical activity assessment (ie, step count) at baseline and follow up using a separate wearable tracker that all participants received independently of their allocation (ie, both the intervention and control groups). We adopted this eligibility criterion to be able to reliably pool the results across the studies.

The primary outcome was the number of steps per day, measured with any wearable tracker. Wearable trackers, either mechanical (eg, spring levered) or electronic (eg, using GPS or actigraph functionality), mostly monitored daily steps as the main outcome of interest; intervention programs involving wearable trackers often set goals for increasing the number of daily steps incrementally over time and estimated and logged the total distance travelled [22]. We excluded wearable trackers that used other types of measurement output, because these vary considerably in terms of their performance, choice of activity measurement (ie, light, moderate, or vigorous activity, energy expenditure, sedentary time, or stationary pattern) and intensity and frequency of the physical activity (ie, bouts of exercise). This would have made their pooling more problematic.

Secondary outcomes included anthropometric measures, glycated hemoglobin level (mmols/mol), blood pressure, and cholesterol level.

Risk of bias (RoB) was independently assessed by 2 reviewers (AH and MP) using the Cochrane RoB tool [23], alongside the completeness and quality of the provided IPD. Results of IPD studies were also compared with studies that did not supply IPD.

Data Extraction and Assessment of IPD Integrity

We used IPD (obtained from November 2019 to October 2021) to determine demographic characteristics that we chose a priori in the protocol, such as age, sex, ethnicity, and comorbidity; intervention characteristics, such as objective, duration, use of a behavior change framework, delivery method and placement of wearable tracker; and primary and secondary outcomes.

Continuous variables were kept continuous, but some were also categorized when this was considered to be more clinically meaningful. For instance, patient groups were split by median age and by age range (20-49, 50-59, 60-69, and 70-90 years); the total number of comorbidities, predefined as cardiometabolic conditions including type 2 diabetes, hypertension, obesity or overweight, metabolic syndrome, and any cardiovascular condition; and BMI (normal 18.5-24.9 kg/m^2; overweight, 25-29.9 kg/m^2; obese, ≥30 kg/m^2). Descriptive characteristics (eg, age, comorbidity, education, and ethnicity) were analyzed for intervention and control groups using ANOVA for continuous variables and the chi-square test for categorical variables. Following this, ethnicity was classified into 2 groups, White European/North American and other ethnicities, to improve the analysis of covariance (ANCOVA), due to the limited number of patients in other ethnic groups.

Since all the trials provided above 70% of the IPD for the corresponding primary outcome, we imputed any missing values using the R package MICE: Multivariate Imputation by Chained Equations [24], following Rubin's principle for imputation [25]. The range of imputed values was bounded by the observed values of the primary outcome, and baseline covariates (study, intervention, age, sex, and baseline) were used to predict missing data. The algorithms' convergence was assessed, and sensitivity analyses were performed using only cases with available data (ie, complete cases).

Data Synthesis

Primary analyses used a 1-stage linear mixed effect model that incorporated random effects to allow for heterogeneity across trials [20,26,27], fitted using the Stata (version 16.1; StataCorp LLC) commands mixed and ipdforest to summarize the evidence by study and obtain forest plots [28]. Restricted maximum likelihood was used for model estimation, and centering of covariates by study-specific means was performed to avoid aggregation bias [29].

As the primary outcomes were all objectively measured using the standard unit of steps per day, the analysis was performed using the mean difference (MD) between intervention and control groups with the 95% CI. Differential effects were then investigated by adding patient covariate parameters (ie, age, sex, ethnicity, and number of cardiometabolic conditions) and interactions between covariates (ie, treatment-covariate interaction terms) to the linear mixed model for the primary outcome. Important and significant differential effects were displayed through subgroup analysis plots.

Results from a 2-stage random-effects (DerSimonian-Laird) meta-analysis were compared to results from 1-stage analyses using the ipdmetan command, for consistency. The Hartung-Knapp CI was used to account for uncertainty in the variance estimate [30].

Heterogeneity was examined by visually inspecting forest plots and using the I^2 statistic with the 95% CI [31]. Publication bias was assessed visually by using contour-enhanced funnel plots and the statistical Egger test for asymmetry [32]. The Egger test is performed using the following hypothesis, testing by *P* value: the null hypothesis is symmetry in the funnel plot, and the alternative hypothesis is asymmetry in the funnel plot. If $P \leq .05$, we reject the null hypothesis. If $P > .05$, we accept the null hypothesis and reject the alternative hypothesis [33]. We assessed for availability bias by comparing summary results of the non-IPD studies with those from IPD studies [34].

Sensitivity analyses of study-level factors were performed by (1) comparing studies that used a social cognitive theory framework as a guide for behavior change, (2) comparing studies that used a goal or goals as part of the intervention, (3) comparing the placement of the wearable tracker (ie, on the waist or wrist), (4) comparing the delivery of the intervention (ie, face to face or self-managed), (5) removing studies with high or unclear RoB based on allocation concealment, and (6) assessing the long-term performance (ie, beyond 6 months).

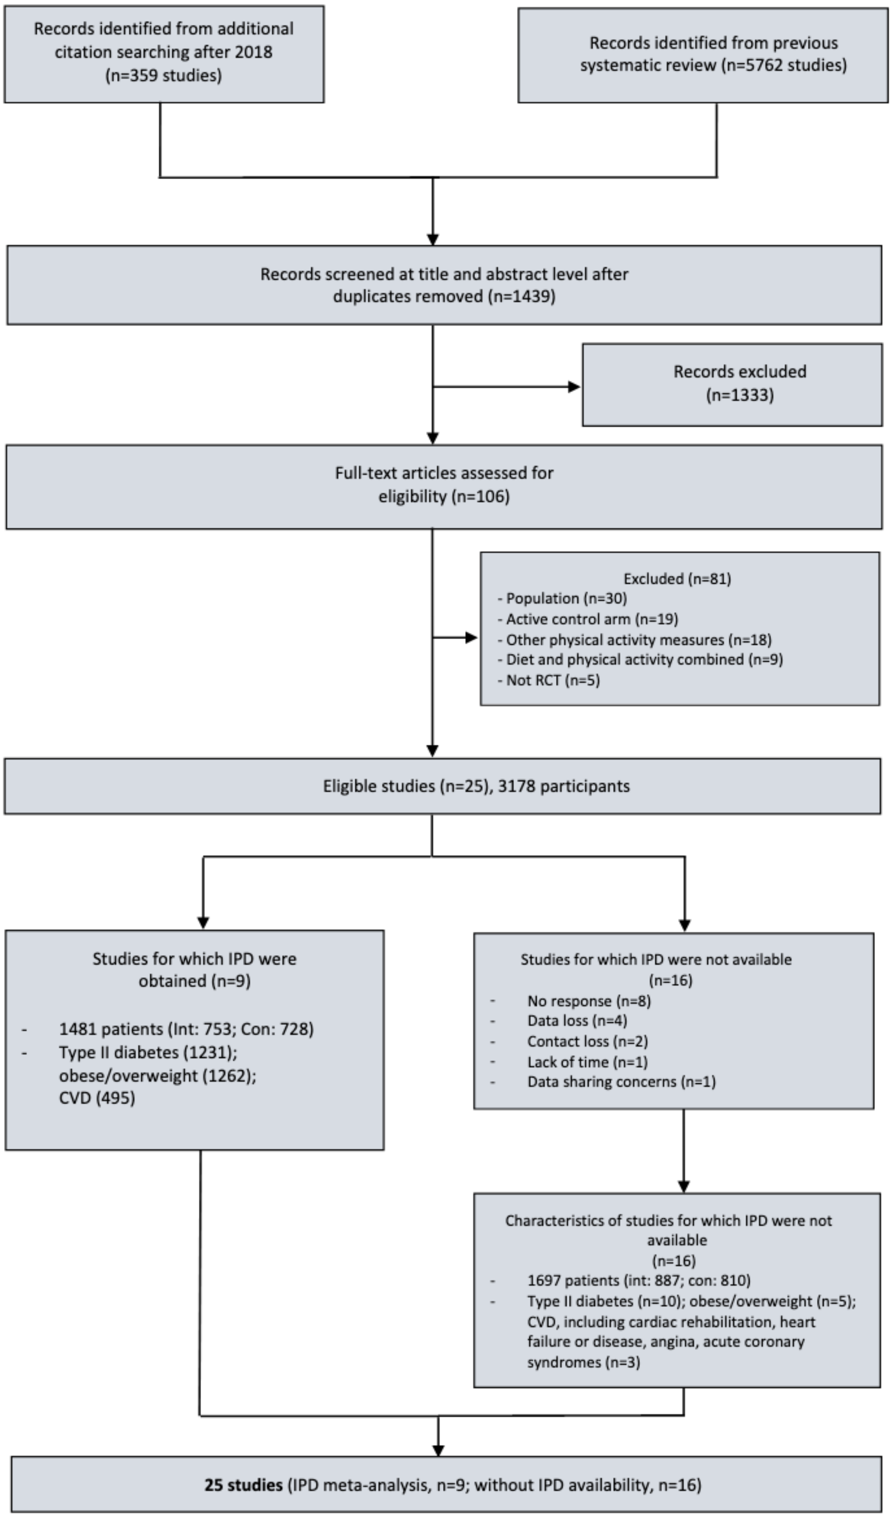
Ethical Considerations

Ethical approval and patient consent was not required as it had already been obtain from the primary authors during their trial period. Ethical waiver was provided and acknowledged by our University international review board.

Results

Of 25 eligible RCTs (including 3178 participants) that used wearable trackers and measured steps per day, we found that 9 studies (36%) had a median intervention duration of 12 (range 7-52) weeks, providing IPD for 47% of the total participants (1481/3178) (Figure 1). A list of the eligible studies is provided in Multimedia Appendix 1 (pages 12-14).

Figure 1. Identification and selection of studies providing individual participant data for meta-analysis of interventions involving wearable trackers for measuring steps per day in patients with cardiometabolic conditions. Con: control group; CVD: cardiovascular disease; int: intervention group; IPD: individual participant data; RCT: randomized controlled trial.



Characteristics of Studies

Of the 9 included IPD studies, 5 were from North America [35-40], 3 were from the United Kingdom [41-43], and 1 was from Nigeria [44]. Wearable trackers were used in all 9 studies [35,37-44] and the primary outcome was steps per day. Within the IPD sample, 822 of 1481 patients were men (56%) and 907 of 1481 were 60 years or older (61%; range 25-86 years). A total of 1231 of 1481 patients had (or were at risk of) type 2 diabetes (83%), 1262 of 1481 were obese or overweight (85%), and 495 of 1481 patients had CVD (33%). Characteristics of the studies that provided IPD and did not provide IPD are presented in Multimedia Appendix 1 (pages 15-22); baseline characteristics of the IPD are provided in Table 1.

Table 1. Baseline characteristics of the individual participant data and imbalance assessment between treatment arms. Percentages are proportions of observations to intervention or control arms, as applicable.

Characteristics	Intervention	Control	*P* value[a]
Steps per day (in 1481 patients in 9 studies) (n), mean (SD)	6071.25 (3060.72)	6072.11 (3064.40)	.99

Preexisting CVD (in 495 patients in 3 studies), n/N (%)	44/230 (19.1)	84/265 (32)	.07
Preexisting type 2 diabetes (in 1231 patients in 4 studies), n/N (%)	370/619 (59.8)	403/612 (65.8)	.21
Preexisting hypertension (in 642 patients in 3 studies), n/N (%)	250/311 (80.4)	264/331 (79.8)	.83
Preexisting metabolic syndrome (in 471 patients in 2 studies), n/N (%)	194/240 (80.8)	201/231 (87)	.73
Depression score (in 347 patients in 2 studies), mean (SD)	2.24 (4.13)	2.29 (4.10)	.99
Smokers (in 578 patients in 3 studies), n/N (%)	87/282 (30.9)	84/296 (28.4)	.48

[a] Mean values were compared with a 2-tailed *t* test and categorical covariates were compared with the chi-squared test or ANOVA.

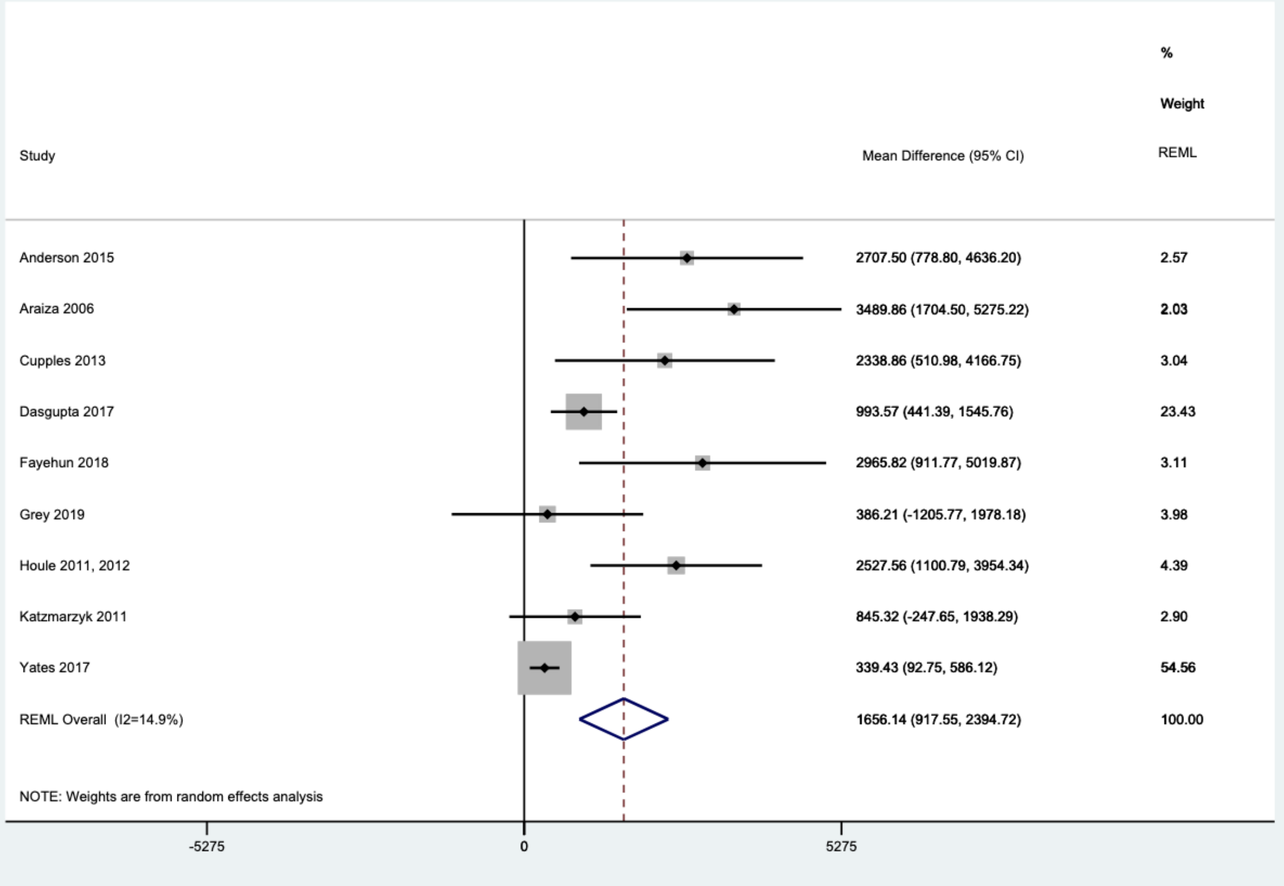
Risk of Bias Assessments

The RoB assessment of studies that contributed IPD compared with those that did not showed that the former had lower RoB across all domains (Multimedia Appendix 1, page 22). The assessments for each of the RoB domains of the IPD studies are available in Multimedia Appendix 1 (page 23), and the results of RoB assessments for non-IPD studies are available in our earlier systematic review [19].

Efficacy of Wearable Trackers on Increasing Steps per Day

In the 1-stage analysis involving all 9 studies and 1481 participants, wearable trackers were associated with small but significantly improved levels of physical activity over the median intervention duration of 12 (range 6-52) weeks. The number of steps was 1656 (95% CI 918-2395) greater in the intervention than the control group (Figure 2). These results are consistent with the 2-stage analysis (Multimedia Appendix 1, page 32). The mean number of steps per day at the end of treatment, without adjusting for baseline scores, was 6561 (SD 3336) in the wearable activity tracker intervention group and 6561 (SD 3340) in the control group; this was not a significant difference (*P*=.99). Visual and statistical evidence (*P*=.002; Egger test) of a small study effect was found in the funnel plots (Multimedia Appendix 1, pages 24-30). After removing the studies with high or unclear RoB from the analysis, the symmetry of the funnel plot improved somewhat (*P*=.06). Secondary outcomes showed insignificant differences (Multimedia Appendix 1, page 31).

Figure 2. Forest plot showing 1-stage meta-analysis of individual participant data from studies using wearable trackers to measure steps per day; the mean postintervention difference in steps per day is also shown. MD: mean difference; REML: restricted maximum likelihood.



Covariate interaction effects for the primary outcome showed that patients older than 50 years benefited more from using wearable trackers. The interaction coefficient for patients aged 50 to 59 years was 1175.16 (95% CI 377.46 to 1972.86) steps per day, with an individual group effect of 2006.83 (95% CI 1163.83 to 2849.82); in patients aged 60 to 69 years, the interaction coefficient was 981.37 (95% CI 222.39 to 1740.35), with an individual group effect of 1813.04 (95% CI 986.40 to 2639.68); and in patients aged 70 to 90 years, the interaction coefficient was 1059.98 (95% CI 200.29 to 1919.66), with an individual group effect of 1891.65 (95% CI 963.98 to 2819.31; I^2 15.5%). In contrast, for patients aged under 50 years the interaction coefficient was 831.67 (95% CI –97.00 to 1760.33) (Table 2).

The number of steps per day after using wearable trackers was greater among men than women (interaction coefficient –668.3, 95% CI –1156.8 to –179.93). For men, the mean number of steps per day was 2006 (95% CI 1204.4 to 2807.6), while for women, it was 1337.65 (95% CI 538.92 to 2136.37; I^2 16%) (Figure 3 and Figure 4). Patients with at least 2 comorbidities showed a significantly lower number of steps per day; the interaction coefficient for 2 comorbidities was –516.80 (95% CI –1188.34 to –10.74), and the mean number of steps was 1344.70 (95% CI 421.62 to 1843.87). For patients with 3 comorbidities, the interaction coefficient was –876.44 (95% CI –2071.88 to 509.41), and the mean number of steps was 570.17 (95% CI –304.66 to 870.08; I^2 15.7%). In contrast, for patients with only 1 comorbidity, the interaction coefficient was 1861.55 (95% CI 1061.6 to 2661.5). White patients also displayed a higher step count after using wearable trackers (2189, 95% CI 1276 to 3102) compared to other ethnic groups (1194, 95% CI 280 to 2107); the interaction coefficient was 995 (95% CI 360 to 1631) steps per day (I^2 21%).

Table 2. Differential effects of wearable trackers on physical activity measured by steps per day among specific subgroups of patients.

Characteristic	Mean difference in steps per day,[a] n (95% CI)	Treatment covariate interaction

Figure 3. Gender effect for women. Forest plot showing 1-stage meta-analysis of individual participant data from women only, derived from studies using wearable trackers to measure steps per day; the mean postintervention difference in steps per day is also shown. MD: mean difference; REML: restricted maximum likelihood.

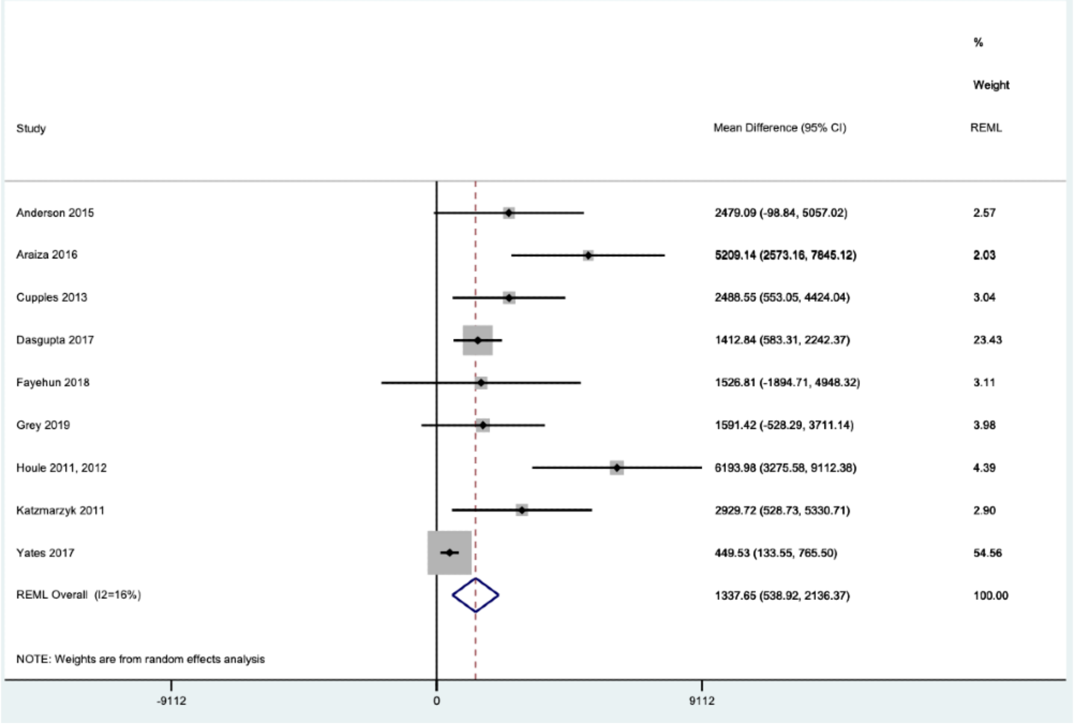

Figure 4. Gender effect for men. Forest plot showing 1-stage meta-analysis of individual participant data from men only, derived from studies using wearable trackers to measure steps per day; the mean postintervention difference in steps per day is also shown. MD: mean difference; REML: restricted maximum likelihood.

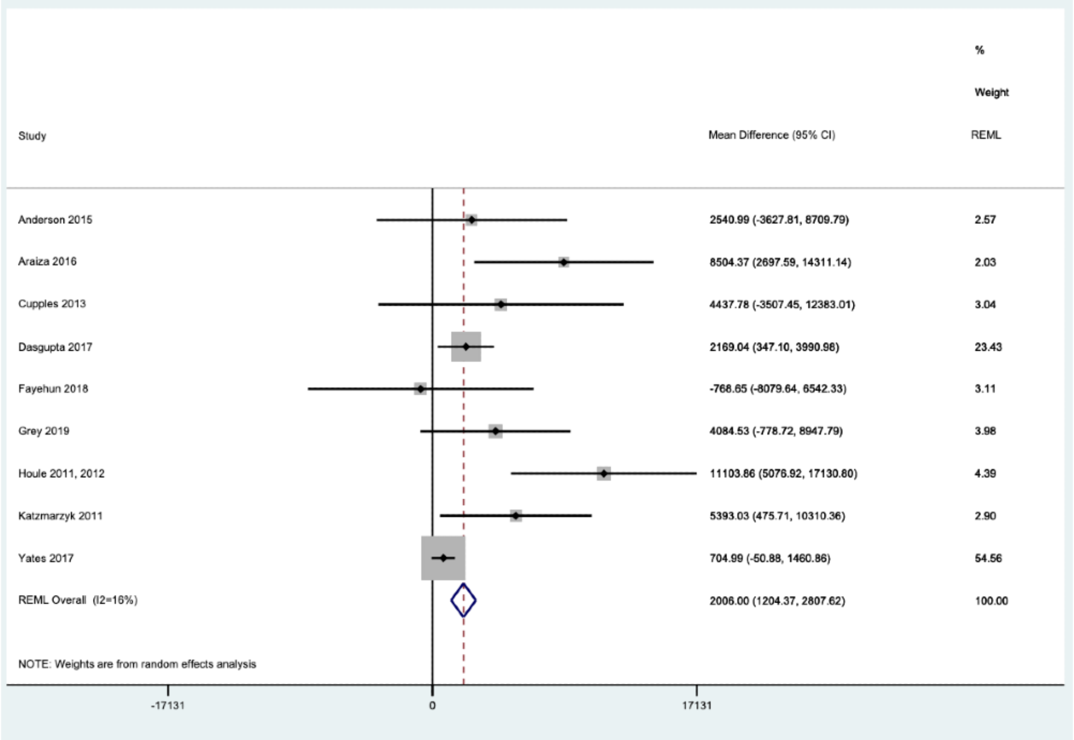

Further Sensitivity Analysis and Exploratory Analysis

Behavior change frameworks were used in 3 studies [35,37,38,45], but did not appear to improve the number of steps per day (the interaction coefficient was –1054, 95% CI –2785 to 677). Nevertheless, groups that did or did not use the program still showed a statistically significant change (part of program: 2476, 95% CI 935 to 4017; not part of program: 1422, 95% CI 634 to 2211). In addition, studies that set goals for reaching specific steps per day also did not appear to improve the number of steps per day, nor did the placement of the wearable tracker (ie, waist vs wrist) (Multimedia Appendix 1, page 33).

Small but nonsignificant improvements in steps per day were seen in studies with low RoB compared to studies with high or unclear RoB. Studies that assessed the number of steps per day beyond 26 weeks showed a lower (but nonsignificant) number of steps per day compared to studies that assessed performance in the short term (ie, less than 6 months). While both groups showed statistically significant changes (<26 weeks: 2000, 95% CI 1068 to 2932; ≥26 weeks: 1143, 95% CI 33 to 2254) when they used trackers over the longer term (ie, beyond 6 months) it was clear that performance waned by almost 1000 steps per day compared to short-term use (ie, up to 6 months). Studies that involved face-to-face delivery of the wearable tracker significantly improved the number of steps per day (2630, 95% CI 1835 to 3425) when compared to studies that involved only self-regulated use of the tracker (850, 95% CI 325 to 1375) (the interaction coefficient was 1780, 95% CI 826 to 2733).

Improvement in steps per day among the non-IPD studies was significantly higher with the wearable trackers; results showed almost double the number of steps per day (2854, 95% CI 1944 to 3763) compared to the IPD meta-analysis estimate (Multimedia Appendix 1, page 34). However, including the non-IPD studies in the meta-analysis increased bias from small studies and worsened the funnel plot asymmetry (Multimedia Appendix 1, pages 26-27).

Discussion

Principal Findings

This IPD meta-analysis confirms that interventions using wearable trackers were effective at increasing physical activity, as measured by total number of steps per day, in participants with cardiometabolic conditions, compared to control groups, over a median duration of 12 weeks. These improvements were slightly lower than estimated by our aggregate-data meta-analysis [19]. In this IPD meta-analysis, we identified differential effects in relation to age, sex, and ethnicity of the participants and the number of comorbidities present. Consistent with our aggregate-data meta-analysis [19], we observed that interventions that used wearable trackers with face-to-face delivery by a professional were more effective at increasing steps per day than patient self-managed interventions.

The benefits in terms of the mean difference in steps per day after using wearable trackers in the short term were not as large as seen in other meta-analyses [46,47], but at the end of treatment, the activity tracker mean score increased to 6561 steps per day, which does appear to meet the recommended number of daily steps as outlined in public health guidelines [48,49]. For example, the average daily steps recorded were just above the recommendation of 3000 to 6000 steps per day made by the United Kingdom's National Obesity Forum and the recommendation of 3000 steps per day made by Northern Ireland's Public Health Agency [50]. However, the large standard deviation (3336) from this mean score suggests that some patients were still underachieving and did not meet the goal for steps per day. Still, recent evidence [51] has shown that for each daily increase of 1000 steps in physically inactive individuals at baseline, the estimated risk reduction in all-cause mortality is 6% to 36%, while the reduction for CVD is 5% to 21%. An increase of 500 steps per day or the equivalent (eg, 5 minutes of brisk walking) is also considered the minimum clinically important difference in steps per day in inactive adults [52]. Further, a recent dose-response meta-analysis [53] of the association between steps per day and all-cause mortality risk indicated a strong inverse association; the risk decreased linearly from 2700 to 17,000 steps per day. More specifically, the hazard ratio for 10,000 steps per day was 0.44 (95% CI 0.31 to 0.63). Even the most extremely physically inactive patients, such as the ones in our study, are still likely to benefit from small gains in steps per day.

Wearable trackers were predominately more effective in White men, but were still somewhat effective in non-White men and women. Evidence gathered from various countries shows that women are less active than men (there is a global average of 31.7% inactive women vs 23.4% inactive men) and that barriers to women's involvement in sports are numerous and complex [54-56]. Men tend to have more intrinsic motivators linked to and leading to physical activity, such as the need or desire to improve health, prevent disease onset, and improve body shape, and are also more competitive [57]. In contrast, different stimuli appear to motivate women of various ages to undertake physical exercise, such as emotional involvement, socialization, mental and physical well-being, and the achievement and maintenance of a positive self-image [58]. Women may also have less time due to daily household chores. Therefore, policies that address the sex gap in physical activity could start with better access and investment and by altering sociocultural norms. In relation to ethnicity, there is evidence that non-White participants have lower levels of physical activity and that their participation in and benefit from physical activity programs are suboptimal, due to lower access and socioeconomic and sociocultural bias [59]. Our findings suggest that non-White women in particular are less likely to achieve significant benefits from interventions involving wearable trackers. This may be because of the increased likelihood that they encounter social, economic, and cultural barriers to physical activity that are unique to them.

Wearable trackers were also most effective for improving physical activity in participants aged 49 years or more, and were surprisingly ineffective in the 365 participants aged 50 years or less. Although this could be a sample size issue, there are some possible explanations for this finding. People under 50 years old may be less likely to engage with wearable trackers due to caring and work responsibilities, and they may have less time to participate in daily physical activity [60]. Conversely, patients aged between 50 and 60 years generally maintained better daily physical activity levels than those over the age of 60. This may be due to multiple comorbidities, which are likely to be the leading cause of reduced physical activity in the older age group [61].

Participants with a cardiometabolic condition have a relatively higher likelihood of developing additional comorbidities, meaning that many of these high-risk patients are often diagnosed with 2 or more diseases [62]. As we have clearly shown in this study, most patients do not meet the international clinical guidelines for recommended steps per day, and when cardiometabolic risk is combined with a comorbidity, the steps-per-day performance was reduced even further. This result reinforces several key studies and policy guidelines, which show that a worsening steps-per-day performance is highly associated with multimorbidity [1,2,5,6,63]. Moreover, it is well known that low physical activity increases weight, BMI, and waist circumference, which are all key predictors for further exacerbation of comorbid chronic diseases, including diabetes, hypertension, and dyslipidemia [64]. For health care professionals, effective and practical management of patients with multimorbidity is important. A more sensitive understanding of their lifestyles and their tendency toward extremely low levels of physical activity will facilitate the support of those most in need of it.

Secondary cardiometabolic biomarkers, such as blood sugar glucose, measured as hemoglobin A_{1c} (HbA_{1c}), blood pressure, cholesterol, and BMI or weight, were all found to not be statistically significant, which may be unsurprising given the short duration of the interventions (only 12 weeks). However, one study [65] did find small but significant reductions in BMI and systolic blood pressure when using pedometers, although the patient population in this study involved a variety of outpatients, who may not have been suffering from the same severe underlying cardiometabolic health conditions. Another study [47] investigated the effectiveness of setting physical activity goals in patients with type 2 diabetes who used step counters and did not report any significant reduction in HbA_{1c} level. Similarly, a meta-analysis [46] that compared accelerometers and pedometers for improving physical activity levels and HbA_{1c} levels in people with type 2 diabetes showed no significant differences between either type of tracker. While our original review [19] did show significant reductions in HbA_{1c} levels, this can only be considered a small reduction in effect size, and is not dissimilar to our findings based on IPD (–0.19 vs –0.13).

Strengths and Limitations

This is the first IPD meta-analysis to assess the differential effects of wearable trackers for important physical activity and clinically relevant outcomes in participants with cardiometabolic conditions. Strengths include a clear standardization of definitions and outcomes, imputation of missing data, a robust analysis that included ANCOVA [66], exploration of the potential for differential effects [29], extensive data checking and work with study investigators to ensure the quality of the data set, and the inclusion of studies that mostly had low RoB. Nevertheless, we were unable to obtain IPD from 16 studies, which meant that 1697 of 3178 (53%) of potential patients were missing. However, these studies were mainly small and generally had a higher RoB than the included studies. Over two-thirds of the IPD were from White participants, meaning that all other ethnic groups (Black African, Asian, Hispanic, and others) had to be combined into one category to allow for adequate power in the subgroup analysis. Nevertheless, we found that White patients had significantly higher step counts than other ethnic groups. This result is similar to findings from a recent prospective cohort study that assessed the association of steps per day with premature all-cause mortality among Black and White men and women with coronary artery risk and showed that Black participants took fewer steps than White participants (median 8670 steps/day, IQR 6810 to 10,811, vs median 9441 steps/day, IQR 7704 to 11,329, respectively; $P<.001$) [67]. As 83% of the patients had or were at risk of type 2 diabetes and 85% of the patients were at least overweight or obese, this meant that these 2 conditions largely overlapped in the patient population, meaning that it was not possible to properly adjust for this in the analysis. In addition, as only 33% of the patients had CVD, and no other condition data were provided in the IPD, these 2 conditions could only be compared with CVD. Thus, we urge that these results are interpreted with some caution and encourage better coding of condition data, which would allow for more detailed analyses. Only 3 studies [37,38,42,43] used a behavior change framework as part of their intervention design, and only 3 studies [36-38,43] collected data over the longer term (ie, at least 1 year). Both are clear weaknesses that limit our understanding of sustained effects over time, which is an important gap in knowledge [68]. Differences in tracker functionality may also have significant effects on their performance. For instance, trackers are often criticized for not measuring daily steps precisely enough, particularly when the tracker becomes tilted below the waistline in overweight or obese individuals [69-71]. However, some more expensive wearable trackers that can sense movement in a tilted position have shown promise [72]. Diversity in wearing time and self-monitoring across the studies made it impossible to effectively categorize this information for meaningful subgroup analyses.

Moreover, following an update to our aggregate review, we found that 8 studies, which included 414 participants, used wearable trackers to measure physical activity with variable measurement outputs rather than steps per day. We excluded these 8 studies from our IPD meta-analysis because the assessment of the differential effects would have been underpowered, with only 414 participants available. Once the evidence base is more developed, we strongly encourage future efforts to compare our findings with those of studies using additional measurement outputs or other wearable technologies (eg, smartphone apps, smartwatches, and wristbands). Finally, our last search update (in December 2020) could be considered marginally outdated for an aggregate-data meta-analysis. However, data acquisition, preparation, and analysis for IPD meta-analyses requires considerably more time and resources than aggregate-data meta-analyses. We strongly recommend universal open access to trial data to speed access to IPD in the future.

Conclusion

Interventions using wearable trackers were effective at providing a small mean improvement in steps per day over short periods of use in participants with a cardiometabolic condition. Interventions with wearable trackers that were delivered and guided by a professional were most effective in White men and in those aged 50 years and older with only one comorbidity. Future research should look at ways to extend the beneficial effects of interventions with wearable trackers to other patients (particularly women) with cardiometabolic conditions and for longer periods.

Acknowledgments

We thank the authors who agreed to participate and supply their individual participant data: CFE, MRB, HE, MEC, MAT, KD, SSD, ABC, AFF, EBG, JH, PP, TY, and JH. This study was funded by the Evidence Synthesis Working Group (project 390), which is supported by the National Institute for Health Research School for Primary Care Research. The National Institute for Health Research Greater Manchester Patient Safety Translational Research Centre has partly funded the time of MP.

Data Availability

A data sharing agreement form was completed by each participant that provided individual participant data; there has not been any agreement to share the data. Therefore, authors seeking individual participant data should contact the principal investigators from the individual trials if they desire access. However, we aim to discuss with the authors the possibility of making the individual participant data database publicly available.

Disclaimer

This paper presents independent research funded by the National Institute for Health Research School for Primary Care Research Project 390. The views expressed are those of the authors and not necessarily those of the National Institute for Health Research or the Department of Health and Social Care. The research team members were independent from the funding agencies. The funders had no role in the design and conduct of the study; the collection, management, analysis, and interpretation of the data; or the preparation, review, and approval of the manuscript.

Authors' Contributions

MP, EK, and PB developed the initial research idea and obtained funding for this study. AH, MP, EK, HVM, and PB formulated the research questions and designed the study. AH searched for published work, selected articles, extracted and analyzed data, and drafted the protocol, statistical analysis plan, and manuscript. MP, SSZ, and CG helped the article search, data extraction, and quality checking. MP substantially contributed to designing the searches and the statistical analysis plan, writing the manuscript, and interpreting the findings. EK provided statistical support for using the ipdforest command in Stata. MP, EK, PB, HVM, BM, SSZ, CG, DT, and all other authors substantially contributed to the manuscript by providing review comments and edits. All authors have read and approved the final manuscript. The manuscript’s guarantor (AH) affirms that the manuscript is an honest, accurate, and transparent account of the study being reported, that no important aspects of the study have been omitted, and that any discrepancies from the study as planned have been explained. The corresponding author attests that all listed authors meet the authorship criteria and that no others meeting the criteria have been omitted.

Conflicts of Interest

None declared.

Abstract

Background: Psychological therapy is an effective treatment method for mental illness; however, many people with mental illness do not seek treatment or drop out of treatment early. Increasing client uptake and engagement in therapy is key to addressing the escalating global problem of mental illness. Attitudinal barriers, such as a lack of motivation, are a leading cause of low engagement in therapy. Digital interventions to increase motivation and readiness for change hold promise as accessible and scalable solutions; however, little is known about the range of interventions being used and their feasibility as a means to increase engagement with therapy.

Objective: This review aimed to define the emerging field of digital interventions to enhance readiness for psychological therapy and detect gaps in the literature.

Methods: A literature search was conducted in PubMed, PsycINFO, PsycARTICLES, Scopus, Embase, ACM Guide to Computing Literature, and IEEE Xplore Digital Library from January 1, 2006, to November 30, 2021. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) methodology was applied. Publications were included when they concerned a digitally delivered intervention, a specific target of which was enhancing engagement with further psychological treatment, and when this intervention occurred before the target psychological treatment.

Results: A total of 45 publications met the inclusion criteria. The conditions included depression, unspecified general mental health, comorbid anxiety and depression, smoking, eating disorders, suicide, social anxiety, substance use, gambling, and psychosis. Almost half of the interventions (22/48, 46%) were web-based programs; the other formats included screening tools, videos, apps, and websites. The components of the interventions included psychoeducation, symptom assessment and feedback, information on treatment options and referrals, client testimonials, expectation management, and pro-con lists. Regarding feasibility, of the 16 controlled studies, 7 (44%) measuring actual behavior or action showed evidence of intervention effectiveness compared with controls, 7 (44%) found no differences, and 2 (12%) indicated worse behavioral outcomes. In general, the outcomes were mixed and inconclusive owing to variations in trial designs, control types, and outcome measures.

Conclusions: Digital interventions to enhance readiness for psychological therapy are broad and varied. Although these easily accessible digital approaches show potential as a means of preparing people for therapy, they are not without risks. The complex nature of stigma, motivation, and individual emotional responses toward engaging in treatment for mental health difficulties suggests that a careful approach is needed when developing and evaluating digital readiness interventions. Further qualitative, naturalistic, and longitudinal research is needed to deepen our knowledge in this area.

readiness for change; stages of change; digital; motivation; engagement; uptake; mental health; mental illness; mobile phone

Introduction

Background

Mental illness is a pervasive global problem, estimated to be the second most prominent cause of the global burden of disease, surpassed only by cardiovascular disease [1]. Psychological therapy is both an effective and acceptable treatment for common mental illnesses such as anxiety and depression [2,3], with comparable outcomes across all approaches (ie, cognitive behavioral therapy [CBT], psychodynamic, and person centered) [4] and delivery formats (ie, face-to-face [FTF] and digital format) [5]. Despite the demonstrated effectiveness of psychological therapy, there remains an alarming difference between the number of people with a mental illness and the number of people being treated, often referred to as the *mental health treatment gap* [6]. This gap is substantial and ever expanding, as prevalence rises without a corresponding rise in treatment outreach or provision [6].

One significant problem that perpetuates this treatment gap is *client engagement* in therapy [7,8]. Engagement is a term with many associated meanings [9,10]; for the purposes of this review, we use it as an overarching term to represent client uptake (ie, whether the client begins treatment), as well as the client's ongoing, active participation in treatment. Client engagement is essential for clients to obtain said favorable outcomes [11-13]; however, because it is an internal cognitive state, it is difficult to measure [9]. Consequently, engagement is often inferred from observing more easily quantifiable metrics, such as adherence, dropout, and use in the digital realm. The uptake rates of digital mental health treatments are estimated to range from 3% to 25% [14]. Low use and high dropout rates are persistent problems when it comes to digital solutions [15], although similar problems also affect FTF modalities; between 17% and 25% of clients are estimated to drop out of FTF psychotherapy [8,16,17]. Considering that only 20% of the people with mental health problems seek treatment in the first place [18], the problem becomes even more apparent. Therefore, increasing client engagement is a key focus area in the wider mental health sphere [10].

Barriers to Engagement

Many of the practical barriers that have historically impeded access to and engagement with FTF psychological therapy (eg, cost, accessibility, and time constraints) [19] have been reduced with the emergence of digitally delivered treatments. However, this new treatment modality introduces its own set of novel barriers, such as internet anxiety, privacy concerns, lack of confidence in using technology, and disbelief in the effectiveness of the treatments themselves [20-22].

Arguably, the most significant barriers to engagement across all types of therapy delivery stem from the client's attitude toward seeking help and engaging in therapy [23]. Among these attitudinal barriers, low perceived need, a preference to deal with the problem on one's own, and internalized self-stigma are the most common [21,23,24].

Motivation to Change

Motivation is a term used to describe the analytical and habitual processes that energize and direct behavior [25], thus encompassing the attitudinal barriers discussed earlier, among other factors. It is easy to assume that individuals presenting for treatment are motivated to engage in the process and make changes in their lives; however, research indicates that up to 80% of the people who seek treatment are not ready to change and that a leading cause of treatment dropout and low adherence is a lack of motivation [26,27].

The most prominent theory explaining motivation for therapy and readiness for change is the *Transtheoretical Model* (TTM), which posits that clients move through a series of stages on their journey toward and through the process of change [28]. This theory describes behavior change not only in terms of action but also as a wider contemplative process that begins before a person is even considering change [17]. The *stages of change* presented in the TTM are precontemplation, contemplation, preparation, action, and maintenance [28]; the stage a client is in before treatment positively correlates with their outcomes after treatment (ie, the further along they are in terms of the stages, the better their outcomes) [29,30].

The mechanism by which a client's stage of change affects their overall therapy outcomes could manifest in their initial experiences of treatment [31]. For example, if the client is in the action stage at the onset of treatment, they can fully engage with the process immediately rather than spending initial sessions or interactions in ambivalence, thus delaying improvements [32-34]. As symptom changes that occur early in treatment are linked to greater overall treatment success [11,33], targeting those clients who are not yet in the action stage of change *before* they commence treatment, with interventions designed to move them toward action, could mean that more clients begin therapy, stay engaged, and reach positive outcomes.

Motivational Interviewing

There are several FTF pretherapy interventions aimed at moving clients through the stages of change and preparing them for subsequent therapy. Examples of such pretherapy interventions include motivational interviewing (MI), role induction, and vicarious therapy pretraining [27]. MI is arguably the most established of these interventions due to its significant effects on client adherence to subsequent therapy as well as treatment outcomes [26,32,35]. MI is a collaborative, discursive therapeutic approach that aims to guide rather than direct clients, fostering autonomy through open questions and evoking the client's personal reasons for change [36,37]. The specific techniques or tools used by MI practitioners (we will refer to these as "components") include exploring reasons for change, weighing up the pros and cons of change, developing discrepancy between the client's ideal and current states, and building confidence and self-efficacy [38]. The key causal model of MI is that client speech affects client outcome [39], meaning that the more favorably a client talks about behavior change, the more likely they are to make the change. Helping clients achieve this "change talk" is a highly nuanced, conversational art undertaken by skilled practitioners over multiple sessions

[36]. Originally developed as a brief stand-alone intervention for alcohol misuse, MI is now used as a pretherapy intervention for a range of mental illnesses, including anxiety and depression [35]. However, owing to its current FTF delivery format, traditional MI is not a widely available or accessible option for millions of people experiencing mental health difficulties around the world. Finding a feasible way to deliver interventions, such as MI, in a more accessible format could help more clients become motivated and begin treatment ready to take action.

Digital Readiness Interventions

Digital methods of intervention delivery hold promise as a way of creating accessible and timely solutions that can be easily scaled to cover entire populations, including those who have not yet reached out for help [10]. A recent systematic review of technology-assisted MI indicated its potential in this area [38]. However, in most of the included studies, the MI components were integrated with other approaches (eg, CBT) and used as stand-alone digital treatments targeted at changing problem behaviors, such as alcohol use and smoking [38], rather than as motivational *pretherapy* interventions. The extent to which digitally delivered MI has been used as a readiness intervention to prepare clients for therapy is unclear. Furthermore, little is known about the feasibility of delivering such a conversational and highly tailored process via digital means [38].

Outside MI, other digital approaches have begun to emerge, such as engagement-facilitation interventions, which aim to increase both the uptake of and adherence to web-based mental health programs [40]. The components of these interventions differ from those used in MI; for example, engagement-facilitation interventions include components such as expectation setting, psychoeducation about symptoms and treatment, treatment belief enhancement, symptom assessment, and assessment feedback [20]. At present, little is known about the full range of different types of digital interventions that are being used to prepare clients for further therapy, the components of these interventions, or the design processes used in their development. Furthermore, research in this area is spread across the digital health, behavior change, and human-computer interaction fields. Thus, a review is needed to scope this topic and clarify the current dispersed and diverse body of research.

Collaboration with clinical professionals and human-centered design processes are key to developing effective mental health interventions, given their sensitive and complex nature [41,42]. As this is an emerging field, formative research exploring intervention design, development, and evaluation can provide insights into opportunities, barriers, and design strategies that can be used to create effective and acceptable solutions.

This Study

The aim of this study was to define the emerging field of digital interventions to enhance readiness for psychological therapy. By exploring the current state of research in this area, we hope to identify the conceptual boundaries of the topic and identify gaps in the literature. Our research questions were as follows:

1. What types of digital interventions have been used to prepare clients for psychological therapy?
2. What components have been used in these interventions and which of these show evidence of effectiveness?
3. What design processes have been used to develop these interventions?
4. Is the digital delivery of preparatory interventions to enhance readiness for psychological treatment feasible?

Methods

Protocol and Structure

The protocol for this review was registered with the Open Science Framework on March 26, 2021 [43]. We used the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses for Scoping Reviews) guidelines to structure our review [44].

Study Design

We chose a scoping review approach because the research studies in question are heterogeneous in nature and spread across multiple disciplines; they use different study designs to measure different outcomes, with different populations, in different contexts. As this is an emerging field, there are few boundaries on the extent, range, and nature of evidence [44], and the terminology used in the published literature is inconsistent and varied [45]. Therefore, this exploratory review type is well suited.

Eligibility Criteria

Publications were included for assessment if they met the following criteria: (1) the article concerns an intervention, a specific target of which is enhancing engagement with *further psychological* treatment or therapy; (2) the intervention is delivered *digitally* (ie, the primary active content of the intervention is digital), but studies that use technology solely as a means of synchronous communication (eg, web chat or video calls) were excluded; (3) the intervention took place *before* the target psychological treatment (ie, not combined or performed in tandem with the target treatment); (4) the article was written in English; (5) the article was published in a peer-reviewed publication between 2006 and 2021; and (6) the intervention was designed for adult or adolescent populations (ie, age ≥12 years).

The rationale for examining only recent evidence (past 15 years) is that digital technology is advancing rapidly; older studies may be out of date in terms of client attitudes and acceptance of technology [46]. Comparable time frames have been used in many recent reviews on digital mental health technologies [38,46,47]. We included adolescent populations in our review because research indicates that the main barriers to engagement with mental health treatments are comparable across adult and adolescent populations [48].

Search Strategy

The following electronic databases were searched: PubMed, PsycINFO, PsycARTICLES, Scopus, Embase, ACM Guide to Computing Literature, and IEEE Xplore Digital Library. Search terms reflected the 3 main eligibility criteria (Table 1).

Table 1. Search terms.

Criteria	MeSH[a] terms	Free-text terms
Target treatment (further psychological treatment or therapy)	"Mental Health" OR "Psychotherapy" OR "Stress, Psychological" OR "Anxiety Disorders" OR "Mood Disorders"	"CBT" OR "psychological" OR "mental ill-health" OR "anxiety" OR "depressi*" OR "stress" OR "wellbeing" OR "well-being" OR "resilience" OR "mood" OR "disorder*" OR "phobia*"
Digital delivery	"Therapy, Computer-Assisted" OR "Internet" OR "Digital Technology"	"digital" OR "technolog*" OR "comput*" OR "e-health" OR "ehealth" OR "m-health" OR "mhealth" OR "mobile" OR "online" OR "web" OR "web-based" OR "smartphone*"
Intervention type (readiness intervention; takes place before the target treatment)	"Transtheoretical Model" OR "Motivational Interviewing"	"readiness" OR "pre-therapy" OR "pre-treatment" OR prepar* OR "prelude" OR "prequel" OR "prior" OR "stage of change" OR "stages of change" OR "motivation to change" OR "motivational enhancement" OR "motivation interview" OR "motivational intervention"

[a] MeSH: Medical Subject Headings.

Data Collection

An initial exploratory search of PubMed and ACM databases was conducted, and words contained in the titles and abstracts of retrieved papers were analyzed. The search terms were adjusted based on the identified papers, and the final search strategy was decided. Once the protocol was registered with the Open Science Framework, a full search was undertaken across all included databases in March 2021; the search was updated in November 2021. Additional records were retrieved by checking the reference lists of included articles.

The first and second authors (JJ and RB) began by independently reviewing a subset (1300/9412, 15%) of the titles and abstracts against the eligibility criteria and comparing their findings. Discrepancies were found; hence, the eligibility criteria were clarified through discussion between the 2 authors by using relevant examples from the first sample reviewed. A further subset (1300/9412, 15%) was reviewed, the findings were compared, and consensus in decision-making about inclusion and exclusion was reached. The remaining articles were then split between the 2 reviewers (JJ and RB), who independently assessed the titles and abstracts. The final list of selected articles was reviewed by both reviewers. The first author (JJ) then retrieved the full text of the selected articles, and both reviewers independently evaluated them against the eligibility criteria. Reasons for exclusion were recorded, and where there were discrepancies, a discussion was held between the 2 reviewers, and a consensus was reached on the final selection of articles.

Data Analysis

Data charting was performed in Excel (Microsoft Corporation) by the first author (JJ), with checks and calibration by the second author (RB). The data charting form contained general study details as well as variables related to research questions, including target treatment, intervention type (eg, technology used, duration, and interaction level), intervention pathway (eg, how and when the intervention was delivered to clients and the relationship between the intervention and target treatment), intervention components, the model or framework used, measures and outcomes, user experience or acceptability, design process, critical appraisal (eg, limitations in the study, biases, strength of methodology, and generalizability of results), and key learnings.

Synthesis of Results

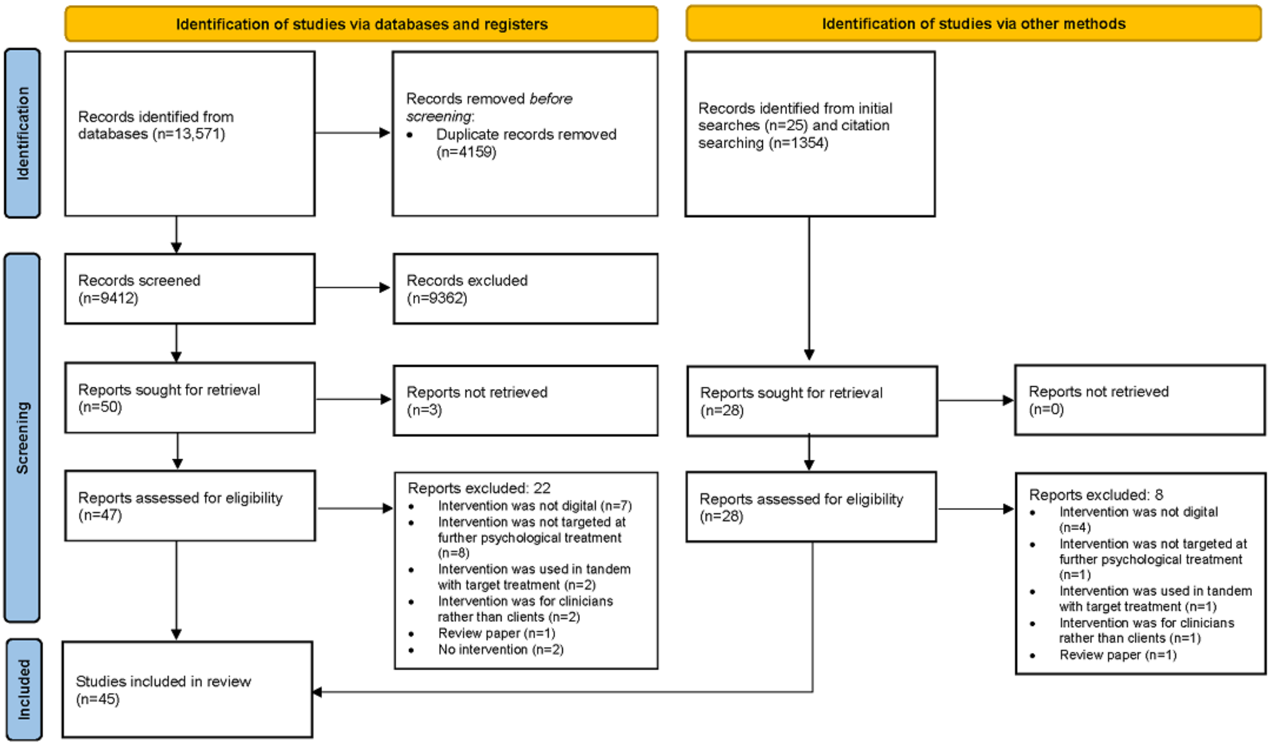
The charted data were further summarized based on the key characteristics of the data. For example, within a charted column such as *the target treatment* or *duration*, findings were assessed in relation to each other, and overarching categories were created based on the most common results. The frequency of occurrences was then examined, and result tables were created. In terms of more complex findings, such as components and outcomes, separate Excel worksheets were created, where individual studies or interventions could be explored in more detail. Frequent checks of the full paper were conducted to validate the initial charting.

Results

Study Selection

The search resulted in 13,571 hits. A further 1379 studies were identified via other sources. After removing duplicates and screening titles, abstracts, and full texts, 45 (0.30%) papers met the eligibility criteria (Figure 1).

Figure 1. Flow diagram of the study selection process.



Study Characteristics

The studies included in this review (Table 2) were mainly conducted in the United States (17/45, 38%), Australia (9/45, 20%), and Germany (7/45, 15%). Only 2% (1/45) of the studies included multiple countries [49]. In terms of study design, among the 45 studies, 19 (43%) were randomized controlled trials, 7 (16%) were observational studies, 6 (13%) were protocols, 4 (9%) were studies exploring the development process of interventions, 3 (7%) were pre-post designs, 2 (4%) were nonrandomized controlled trials, 2 (4%) were historically controlled studies, 1 (2%) was a qualitative evaluation, and 1 (2%) study presented the results of multiple studies (2 randomized controlled trials and 1 pre-post study). Only 26% (12/45) of the studies included qualitative data collection, 18% (8/45) used mixed methods [50-57], and 9% (4/45) were purely qualitative [58-61]. Depression (9/45, 20%) and unspecified general mental health (9/45, 20%) were the most common target conditions covered, with comorbid anxiety and depression being the next most frequent (6/45, 14%). The other conditions and problems targeted included smoking (5/45, 11%), eating disorders (5/45, 11%), suicide (3/45, 7%), social anxiety (3/45, 7%), substance use (2/45, 4%), gambling (2/45, 4%), and psychosis (1/45, 2%).

Table 2. Characteristics of the included papers.

Author, study, and year	Study design	Country	Condition
Christensen et al [62], 2006	RCT[a]	Australia	Depression

[a] RCT: randomized controlled trial.

[b] NRCT: nonrandomized controlled trial.

Types of Intervention

To assess the interventions analyzed in the included papers, we first distinguished the interventions themselves from the papers. A total of 6 studies in the sample [62,64,65,67,86,90] assessed 2 distinctly different interventions in their analysis (ie, the components of the interventions were distinct); therefore, we separated them into individual records. In all, 2 studies assessed slight variations in the same intervention [52,87]; however, we did not segregate these studies because they only reflected minor variations in what was essentially the same intervention. Furthermore, 3 sets of 2 studies in the sample analyzed the same interventions: [66,69], [54,58], and [51,89]; therefore, we grouped them together. The final list of 48 interventions is analyzed in this section and the subsequent one.

We explored the interventions under several categories: intervention format, target treatment or therapy for which the intervention was designed to prepare clients for, the level of support provided, whether the intervention was designed for repeated or once-off use, the duration of the intervention, the theoretical model used, and how the intervention was delivered to the client (Table 3). We found many variations in the types of interventions used to prepare people for psychological therapy. Almost half of the interventions (22/48, 46%) were web-based programs; the other formats included screening tools, videos, apps, and websites. Many of the included interventions were not designed to prepare clients for a specific treatment but instead to encourage general professional help seeking (27/48, 56%). Of those targeted at specific treatments, FTF therapy was the most common (14/48, 29%), followed by web-based therapy (6/48, 13%), and phone therapy (1/48, 2%). In terms of the duration of the interventions, those that specified a duration ranged from 15 seconds to 6 months, with most interventions taking <90 minutes to complete (23/48, 48%). We also investigated how and when the interventions were delivered to clients. Most of the interventions (32/48, 67%) were delivered to clients who had not already sought help via outreach methods such as social media, marketing, or email. Excluding a study that was unclear, the remaining 15 (31%) interventions were delivered to clients who had already sought help or were investigating help.

Table 3. Types of interventions in the selected studies (N=48).

Category	Studies, n (%)
Intervention format	
Web-based program	22 (46)
Screening tool	7 (15)
Video	6 (13)
App	4 (8)
Website	3 (6)

Self-selected (clients were interested in help)	3 (6)
Downloaded screening app	1 (2)
Via e-mental health portal	1 (2)
Via referral website for clinic	1 (2)
Unclear	1 (2)

[a] Other models used in only 1 or 2 studies: health belief model, acceptance and commitment therapy, self-determination theory, unified theory of acceptance and use of technology, screening brief intervention and referral to treatment, motivational enhancement therapy, theory of reasoned action, and extended parallel process model.

Intervention Components

The 48 interventions examined in the included studies all comprised several different topics and tools, which we refer to as components. The most prevalent component was general psychoeducation (40/48, 83%), followed by symptom assessment (23/48, 48%) and information on various treatment options (21/48, 44%). Refer Table 4 for a list of the 14 most common components. Other components included in <4 studies were self-monitoring, data security information, personal strengths, therapeutic alliance and roles in therapy, acceptance, imaginative exercises (eg, imagining ideal life or future with or without treatment), MI techniques (eg, importance and readiness rulers), and information about the effectiveness or advantages of a specific target treatment.

Identifying components that showed evidence of effectiveness was difficult owing to the variety of interventions and components covered in this review, as well as the diversity in the outcomes of the experimental studies (see the *Feasibility* section for a closer look at these outcomes). Some studies that compared 2 interventions with different components found no differences among the outcomes of these interventions [64,86]; however, other studies found the opposite (ie, different components in similarly delivered interventions resulted in significantly different outcomes [65,67,90]). In 2 studies aimed at social anxiety [65,90], the addition of components such as the pro-con list, goal setting, values, and planning led to significantly greater engagement with further treatment or help-seeking behaviors than did interventions without these components. Interestingly, another study found that the effectiveness of the components depended on the condition in question; in this case, providing tailored feedback on screening was detrimental when it came to social anxiety but not depression [75].

Table 4. Components used in the included interventions.

Component	Description	Frequency, n (%)
Psychoeducation	Information about condition, symptoms, risks, prevalence, treatment benefits, recovery chances, and myth busting	40 (83)
Assessments	Self-administered assessments of symptoms or behavior	23 (48)
Treatment options	Information about potential treatment options	21 (44)
Assessment feedback	Tailored or generic feedback on assessments; for example, severity relevant to the general population	18 (38)
Referral information	Direct contact information or guidance for further treatment	17 (35)
Testimonials	Videos or written stories from people with similar issues or from those who have been through treatment	16 (33)
Expectation management	Guiding expectations on treatment or help seeking and expectation setting	16 (33)
Pro-con list	Cost-benefit analysis of change, treatment, or help seeking	15 (31)
Coping skills	Cognitive behavioral therapy skills (eg, cognitive restructuring or behavioral activation), relaxation, mindfulness, and emotion regulation	10 (21)
Planning	Planning for change or treatment or planning for overcoming obstacles to change or treatment (implementation intentions)	8 (17)
Goal setting	Personal goals, life goals, and treatment goals	8 (17)
Values	Using values to develop discrepancy between ideal and actual self	5 (10)
Self-efficacy	Building belief in ability to change, self-esteem, and positive self-affirmations	4 (8)
Problem-solving	Identifying problems, brainstorming solutions, and solution planning	4 (8)

Design Processes

Only 18 of the 45 (40%) included papers discussed how the intervention was designed or developed. Of these 18 studies, only 4 (22%) mentioned the design approach: a study used a user-centered design [59], one used a person-based approach [58], another used a participatory design [40], and the final study used a participatory design, ethnography, and co-design [60]. In terms of the design methods used in the development of the interventions, 9 (20%) studies included consultation with experts or input from expert groups [56,58-60,63,77,84,89,91], 5 (11%) studies used expert or user surveys [50,55,58,60,84], 4 (22%) conducted focus groups with users [40,59,60,78], and 3 (7%) conducted interviews with either users or experts [55,59,60]. A total of 2 (4%) studies reported using working groups comprising users with lived experience and experts to cocreate the intervention [60,77], and 2 (4%) used expert-only working groups [56,63]. A total of 12 (27%) studies reported conducting user testing of their interventions, usually with an iterative process of implementing feedback. A study conducted feasibility testing with clinicians [56].

Feasibility

To better understand the effectiveness of the included interventions, we took the controlled studies (24/45, 53%) and charted their outcomes (Table 5). The outcome measures across the studies were diverse and ranged from behavior to intentions and attitudes toward further treatment. Other associated factors such as symptom improvement, mental health literacy, stigma, and acceptance were also used as proxy measures to infer subsequent behavior or action. Controls included treatment as usual, wait-list, no intervention, intervention control, and attention controls. For the attention controls, we distinguished between nonspecific treatment component controls and specific treatment component controls [92].

Of the 16 studies that measured actual behavior or action (eg, engagement with target treatment or help-seeking behavior), 7 (44%) showed evidence of intervention effectiveness compared with controls [63,65,66,74,87,89,90]. However, these results should be considered in the context of other findings in the studies. For example, a study of an MI-based program aimed at preparing clients for web-based CBT found that clients in the intervention group (IG) spent longer time using the target treatment than those in the control group (CG), but their symptoms were actually worse after the treatment [89]. The participants in this study were highly motivated to engage in treatment at screening, which should also be noted along with the results.

A further 7 studies found no differences between controls and interventions in terms of behavior [54,62,64,67,68,78,86]; however, the other results in these studies provide vital qualifying information. For example, Denison-Day et al [54] offered the intervention to clients in the IG but allowed for natural uptake, meaning that only 34% of the IG actually used the intervention. Hence, no differences were found among groups when 98% of those who actually used the intervention engaged in further treatment. The type of control also had a considerable impact on whether the interventions were found to be “effective” (eg, Brunette et al [86] found no differences among groups, but both groups were given interventions, and both had high subsequent use of target treatment). In some studies with no intervention controls, both groups were found to exhibit high adherence to the target treatment [68].

A total of 2 studies indicated worse behavioral outcomes for the IG compared with the CG [75,80]. Again, the control and other results need to be considered; in the study by Krampe et al [80], the “treatment-as-usual” CG received both the digital intervention and MI-based FTF psychotherapy sessions, whereas the IG received the digital intervention alone, and their results showed that the digital intervention was comparable with the FTF control for those with high readiness to change scores [80]. In the study by Batterham et al [75], the IG received tailored feedback after screening based on symptom severity, whereas the CG received generic, untailored feedback. For clients with social anxiety, tailored feedback led to lower treatment use and intentions to seek help rather than generic advice. Study attrition was lower in the IG than in the CG; however, this is another factor to consider along with these results [75].

Considering the other variables measured in these studies, the findings are mixed. Some indicated that the interventions increased help-seeking intentions [72,83], whereas others showed no effect on intentions [64,71,79], despite their effectiveness in improving attitudes toward treatment or motivation to change. Some indicated improved symptoms [62,71,78], whereas others reported reduced stigma or improved literacy [14,52,72,79]. In addition, all the pre-post studies in the review found that their interventions either reduced client symptoms [53,73] or increased client interest in further treatment [51,73], and all the observational studies in the sample indicated positively skewed effects of their interventions on help-seeking actions, behaviors, or intentions [49,57,69,76,77,82,84].

No obvious patterns were observed among intervention format, support level, duration, components (see the *Intervention Components* section), condition, target treatment or intervention delivery, and whether interventions were effective. Several studies that compared interactive and noninteractive interventions suggested that interactivity is important for effectiveness [62,87,90]; however, the opposite result was also found [86].

Table 5. Outcomes of the controlled studies in the sample (standardized measures are abbreviated).

Study	Study design	Control	Sample size, N	Intervention	Measures	Significant outcomes
Olson et al [56]	Historically controlled	TAU[a]	163	Screening tool	Acceptance and quality of physician appointment survey; qualitative physician feedback	IG[b] more likely to discuss alcohol and tobacco use with physician but not mood disorders. IG increased acceptance of subsequent physician appointment
Yoon et al [91]	Historically controlled	TAU	301	Screening tool	Screen for unhealthy drinking behaviors and alcohol use disorders; motivation to change and referral interest survey; acceptance survey	CG[c] used to compare response rate only (responses were comparable). Only 16% of the IG had unhealthy drinking habits. Of these, 14% were interested in further help, and 40% would cut back on their own
Bommelé et al [78]	NRCT[d]	NTCC[e]	757	WP[f]	PO[g]: receptivity to information, motivation to change, self-efficacy and referral interest survey; SO[h]: cigarettes per day and quit attempts	IG more receptive to information than CG after the intervention but not at the 2-week or 2-month follow-up. IG had reduced smoking at all time points. No differences in quit attempts or referral
Brunette et al [66]	NRCT	Wait-list	41	WP	PO: treatment seeking and motivation to change survey (verified by medical records); SO: FTND[i]; 1 item from SCS[j]; ATS[k]	IG more likely to have taken action toward change than CG (eg, attempting to quit, meeting with a clinician to discuss, or start treatment)
Strassle et al [68]	RCT	No intervention	68	Video	PO: return for second session of TT[l]; SO: SCL-90[m]; IIP-32[n]; CASF-P[o]; therapist measures: GAF[p]; CASF-T[q]	No differences between IG and CG in adherence to TT, therapeutic alliance, or TT outcomes (all clients had high adherence to TT)
Ebert et al [14]	RCT	No intervention	128	Video	PO: acceptance survey; SO: expectations, social opinions, internet concerns, help-seeking attitudes, and web-based therapy literacy survey	IG had higher acceptance, expectations, and literacy and lesser internet concerns than CG. No differences in social opinions or help-seeking attitudes
Ebert et al [83]	RCT	No intervention	1374	Screening tool	PO: intention to seek help survey; moderators: CIDIS[r]; AUDIT[s]; CSSR[t]; SITBI[u]; subjective health, lifetime and current treatment use, intention to use mental health services, barriers to treatment use, and readiness to change survey	IG had higher intentions to seek help than CG. Intervention was more effective for those with panic disorder and worse physical health and those who were nonheterosexual. No effect of intervention for those in the action stage of change
Soucy et al [89]	RCT	No intervention	231	WP	PO: CQ[v]; TT lessons accessed; GAD-7[w]; PHQ-9[x]; SO: motivation to engage in TT survey; acceptance survey; K10[y]; SDS[z]	IG spent longer in TT than did CG. IG had higher anxiety and perceived disability at post-TT period than did CG. No differences in motivation or acceptance
Christensen et al [62]	RCT	NTCC	414	2 IGs: W[aa] and WP	CES-D[ab]; help- and treatment-seeking survey	Both W and WP reduced depression symptoms compared with CG. W less likely to seek informal help than CG. WP more likely to use certain evidence-based treatments
Reis and Brown [63]	RCT	NTCC	125	Video	Therapist measure: TSQ[ac]	IG had lower dropout from TT than did CG
Costin et al [64]	RCT	NTCC	348	2 IGs: both automated emails and W	PO: AHSQ[ad]; informal help-seeking survey; SO: GHSQ[ae]; beliefs about help-seeking survey; depression and help-seeking literacy survey; CES-D; acceptance survey	No differences among IGs or between IGs and CG in help-seeking behavior, intentions, literacy, or depression symptoms. IGs had more positive beliefs about formal help than did CG
Johansen et al [67]	RCT	NTCC	105	2 IGs: WA[af] video and EA[ag] video	Acceptance survey; PANAS[ah]; WAI-S[ai] (client and therapist); return for second session of TT	WA had higher negative affect and lower therapist-rated alliance than CG. No difference in client-rated alliance among IGs. No differences in adherence to TT between IGs and CG

Study	Study design	Control	Sample size, N	Intervention	Measures	Significant outcomes
Taylor-Rodgers and Batterham [72]	RCT	NTCC	67	WP	PO: A-Lit[aj]; D-Lit[ak]; LSS[al]; DSS[am]; GASS[an]; SOSS[ao]; ATSPPH-SF[ap]; GHSQ; SO: PHQ-9; GAD-7; acceptance and adherence survey	IG had increased anxiety literacy, help-seeking attitudes and intentions, and reduced depression stigma compared with CG. No differences in symptoms, acceptance, or adherence
Griffiths et al [79]	RCT	NTCC	83	WP	PO: GHSQ; SO: ATSPPH-SF; SA-Lit[aq]; SASS-I[ar]; perceived need for treatment and interest in TT; acceptance survey	IG had higher literacy, perceived need, and positive attitudes toward treatment than did CG. No differences in help-seeking intentions or stigma
King et al [74]	RCT	STCC	76	Screening tool and messaging	Perceived need for help and treatment use survey; 2 items from DDS[as]; readiness to access help survey	IG had higher readiness to access help and use treatment and lower stigma than did CG at the 2-month follow-up
Batterham et al [75]	RCT	STCC	2773	Screening tool	PO: AHSQ; SO: PHQ-9; SOPHS[at] 2 items from GHSQ; AQoL-4D[au]; self-reported days out of role	IG had higher study attrition than did CG. For social anxiety, IG had lower treatment use and intentions to seek help than did CG, no differences found for depression
Peter et al [87]	RCT	STCC	805	2 IGs: screening tools—IM[av] and NM[aw]	PO: choice between BBGS[ax] and 3 items from GBQ[ay]; moderators: gambling history, psychological distress, and treatment interest survey	IM more likely to complete gambling screener than NM or CG
Titov et al [65]	RCT	Intervention control	108	2 IGs: WPs—Education and Education+Motivation	PO: SIAS[az]; SPS[ba]; SO: PHQ-9; K-10, SDS, and CEQ[bb]; literacy and motivation to change survey; time spent, log-ins, and homework downloads of TT	Education+Motivation had higher use of TT than Education. No differences in TT outcomes or acceptability. No differences in motivation to change
Tobias et al [90]	RCT	Intervention control	267	2 IGs: WPs—Education and Education+Motivation	Motivation for individual treatment steps, attitudes toward and intentions to seek treatment, perceived ability to engage in treatment seeking, and treatment use survey; CSQ-8[bc]	Education+Motivation had improved treatment-seeking attitudes and behaviors, compared with Education. Both groups improved on all outcomes
Brunette et al [86]	RCT	Intervention control	162	2 IGs: WPs—IWP[bd] and DEP[be]	PO: treatment use (verified by medical records); SO: expired carbon monoxide; TFB[bf] (quit attempts); PUEUS[bg]	No differences between IWP and DEP in TT use, quit attempts, or abstinence (both groups had high use of TT)
Denison-Day et al [54]	RCT	TAU	313	WP	PO: attendance at initial assessment appointment; SO: use of TT, acceptance, and motivation (interview)	No differences between IG and CG in attendance at initial appointment. Only 34% of the IG used the intervention, and of these, 98% attended the appointment
Krampe et al [80]	RCT	TAU	220	Screening tool	PO: treatment use; SO: URICA[bh]; BSI-GSI[bi]	IG had lower treatment use and worse symptoms than CG. IG and CG were comparable for those with high readiness to change scores
Keller et al [52]	RCT	Wait-list	320	3 IGs: videos—7 minutes, 13 minutes, and 17 minutes	SSOSH[bj]; stigma survey	Only the 17-minute IG reduced stigma compared with CG

Study	Study design	Control	Sample size, N	Intervention	Measures	Significant outcomes
Hötzel et al [71]	RCT	Wait-list	212	WP	PO: SOCQ-ED[bk]; SO: P-CED[bl]; SES[bm]; RSES[bn]; EDE-Q[bo]	IG had higher motivation to change, self-esteem, and symptom improvement than CG. No differences in motivation to begin treatment

[a] TAU: treatment as usual.

[b] IG: intervention group.

[c] CG: control group.

[d] NRCT: nonrandomized controlled trial.

[e] NTCC: nonspecific treatment component controls.

[f] WP: web-based program.

[g] PO: primary outcomes.

[h] SO: secondary outcomes.

[i] FTND: Fagerström test for nicotine dependence.

[j] SCS: Stage of Change Scale.

[k] ATS: Attitudes Toward Smoking Scale

[l] TT: target treatment.

[m] SCL-90: Symptom Checklist-90-Revised.

[n] IIP-32: Inventory of Interpersonal problems-32.

[o] CASF-P: Combined Alliance Short Form-Patient version.

[p] GAF: Global Assessment of Functioning Scale.

[q] CASF-T: Combined Alliance Short Form-Therapist version.

Discussion

Principal Findings

This scoping review explores digital interventions to enhance readiness for psychological therapy. These interventions are delivered most often as unsupported web-based programs designed for once-off use that takes <90 minutes. They are used to prepare clients for specific therapies or, more generally, to enhance readiness for professional treatment; they are provided to clients either via outreach methods for those who have not sought help, or they are inserted into the care pathway before the main treatment for those who have already reached out. Thus, these interventions appear to cater to clients across multiple stages of change, from those in precontemplation, who are not yet aware that they need help, to those in the preparation stage, who are taking initial steps toward change.

What is the most apparent from this review is the substantial variation not only in the types of digital readiness interventions that have been used but also in their development, delivery, and evaluation. When it comes to the feasibility of digitally delivering interventions, the included studies indicate that there is potential in this area. The current state of the literature, however, does not yet support the possibility of determining which components or types of interventions are effective or not effective; this is a complex undertaking with multiple factors to consider. For example, in some contexts, interactivity appears to be an important aspect of these interventions, which makes sense when considering the conversational nature of traditional FTF MI. However, many simple, noninteractive interventions such as videos and advertisements were also effective at improving variables related to further treatment seeking or engagement. Despite the variability among the studies included in this review, several common topics emerged: *tailoring to the stage of change*, *intervention pathways*, *risk*, and *evaluation*.

Tailoring to the Stage of Change

The existing literature indicates the effectiveness of tailoring psychosocial interventions to clients' stages of change [29]. Several studies in our review involved tailoring to the stage of change [58,69,73,84]. In 2 studies, tailoring involved a simple 2-way split, with different content for those who were interested in further treatment and those not interested [69,73]. In one of these studies, clients who were not yet interested in further treatment were given CBT coping techniques as a way to show them how treatment works and how effective it can be, rather than simply telling them this [73]. When clients are highly motivated, tailored interventions tend to focus on the practical aspects of engaging with further treatment (ie, choosing the right treatment, setting expectations, and planning).

The effective identification of a client's stage of change is a significant aspect of tailoring. This can be done by asking simple binary questions, such as those in the aforementioned studies (eg, Are you interested in treatment?) or more formally with readiness measures such as the General Help Seeking Questionnaire [93], Stage of Change Scale [94], or University of Rhode Island Change Assessment [95]. One interesting website intervention used the stages of change to frame the headings of the main website navigation (ie, "Do I have a problem?" "Should I get help?" "I want and need help?" "I have tried to get help"), giving the client agency in self-selecting their own stage and thus controlling and tailoring their own journey [84]. Outside the stages of change, information-based interventions can be tailored to the client's personal circumstances and needs at a broader level. For example, Dreier et al [50] provided suicide stigma interventions that were modified depending on whether clients had a suicide attempt in the past, had suicidal thoughts, had lost a close person by suicide, were fearing the loss of a close person by suicide, or were interested in the topic in general.

In all, 2 studies in this review illustrate the importance of effective stage identification and tailoring, with findings indicating negative or no effects of their inventions on those who already had high motivation or intentions to seek help [83,89]. Previous research also demonstrated that FTF MI is most beneficial for those who are not already motivated or engaged in treatment [96]. However, in contrast to this, Krampe et al [80] found that their brief digital intervention was as effective as FTF MI–based psychotherapy but only for clients who were already motivated. Tailored digital readiness interventions have the potential to bridge the divide between client and treatment, providing light-touch interactions for those who are already motivated as well as more detailed programs for those in earlier stages of change. For clients, these interventions could serve as stepping stones between information gathering and formal treatment, with layered interactions that support individuals on their journey through the stages of change [77].

Intervention Pathways

The implementation of digital readiness interventions involves both onboarding (ie, the uptake of the intervention itself) and off-boarding (ie, the link between the intervention and further treatment). In terms of onboarding, the first point of contact and framing of digital readiness interventions are crucial, as uptake issues can drastically impact their effectiveness in the real world. Denison-Day et al [54] found that although their intervention was highly effective for those who used it, only 34% of the IG actually used it (they offered participants the intervention but allowed for natural uptake). They noted that simply offering new interventions to address the problem of target treatment engagement may not be enough, and approaches focused on low engagement may need to be considered even earlier in the treatment pathway. An interesting aspect of their intervention (further detailed in the development process paper by Muir et al [58]) was that instead of aiming to prepare clients for the full extent of treatment, they framed it as preparation for the initial assessment appointment only. This removed some of the overwhelming aspects of thinking about full “recovery” and instead allowed clients to take their treatment journey 1 step at a time [58]. How the first step on a client’s journey is presented and by whom could have an impact on the client’s subsequent progress toward change.

Several studies included in this review were conducted in health care settings, where client trust has already been established [59,80,91]. Embedding readiness interventions within existing pathways, such as routine screening, general practitioner waiting rooms, or treatment waiting lists, can draw on this trust and help the client gain direct access to appropriate services. Regarding off-boarding, many studies in this review noted that access to the target treatment needs to be provided in a timely manner following the readiness intervention, as motivation wanes over time [66,74,78,82,86,90]. Moessner et al [76] included clinician monitoring of client deterioration as part of their intervention, allowing clients to take their time to become ready for treatment, while still being supported. In the intervention developed by Brown et al [55], the first session of the target treatment immediately followed the readiness intervention (if the client wanted to proceed), making the most of their motivation and removing any lag time between the interventions. Where digital readiness interventions fit within the wider context of client pathways appears to be an important consideration for both their development and evaluation.

Risk

An important aspect that surfaced while reviewing these studies was the potential risk of readiness interventions impairing treatment engagement, reducing help seeking, worsening symptoms, and increasing self-stigma. Batterham et al [75] found that tailored feedback on screening reduced help seeking for individuals with social anxiety compared with a control that was just generic information; the directive nature of this feedback may have come across as particularly confrontational to clients experiencing difficult emotions centered on their interactions with others. Similarly, Johansen et al [67] found that a video providing information on the working alliance between the client and therapist led to more negative emotions for the client and no improvement in working alliance ratings. Information designed simply to “prepare” clients for what is to come can potentially lead to negative emotions and apprehension, which can in turn affect readiness for treatment.

Stigma adds another layer of complexity to the help-seeking and treatment readiness process; Keller et al [52] found that informational videos on suicide prevention increased empathy, while simultaneously decreasing help seeking. Previous research shows that different types of stigma (eg, public stigma vs internalized self-stigma [97]) affect help seeking in different ways [98]. How we interpret the experiences and emotions of other people is distinct from how we perceive our own internal states. When addressing stigma with a digital readiness intervention, care should be taken as to which types of stigma are being targeted and the intricate relationships among them. Furthermore, stigma is not only complex, layered, and subjective, but even the act of measuring it can reproduce or reinforce stigmatizing attitudes [50]. Individual emotional responses to engaging in treatment for mental health difficulties are sensitive and differ from person to person; a delicate, cautious approach is clearly needed when developing and implementing readiness interventions.

Evaluation

The final discussion concerns the evaluation of readiness interventions and issues when conducting research in such a sensitive area. Several studies in this review found that clients in the control arms improved as much as those in the intervention arms [64,68,86]. Considering the large battery of measures used in several studies and the fact that screening was a core component in many of the included interventions, it is difficult to separate the effects of the interventions themselves from the overall effects of trial participation. Although this is often the case with research trials, the specific light-touch, preparatory nature of these interventions makes them more susceptible to this reactivity. Perhaps, in many cases, being included in a trial focused on help seeking constitutes a readiness intervention in itself.

In addition, the trial design has a significant influence on the “effectiveness” of a given intervention. Constrained processes that force engagement with an intervention may provide rigor in intervention effects but have little ecological validity. There is also potentially greater baseline motivation among people who are prepared to participate in clinical trials than among the general population [65]. The real-world uptake of digital readiness interventions is key to their effectiveness. Naturalistic studies could therefore be a more useful method of understanding how these interventions would function in practice.

Another aspect of evaluation involves the chosen research methodology, which not only has a fundamental impact on the outcomes of the study but also on how we come to understand complex social constructs such as stigma, motivation, and the stages of change. Using quantitative measures to isolate and examine phenomena such as attitudes and emotions is limited because these experiences are highly subjective and contextual [52]; we miss vital information when we detach these occurrences from what gives them meaning. Considering that only one-fourth of the studies in this review included qualitative data collection, there exists a significant gap in our understanding of the nuances of this process at the individual level. Furthermore, many of the studies in this review used proxy measures, such as intentions and attitudes, to infer potential future action although the attitude-intention-behavior models that underpin these inferences have been contested in research across several fields [99-101]. This review suggests that the measurement of digital readiness interventions requires careful consideration because of the many intricacies involved.

Limitations

There are several limitations to this study. First, we did not include help seeking as a search term (we decided to focus our search on the more general areas of readiness, preparation, and motivation); therefore, our coverage of help-seeking interventions was not comprehensive. Furthermore, our digital-only inclusion criteria excluded some interesting interventions that could easily be reproduced digitally (eg, a postal survey on implementation intentions [102] and an educational handout about the dose-effect relationship of therapy and expectation setting around treatment length [103]).

Implications for Research

Given the inconclusive nature of findings presented here, further research is needed to enhance our knowledge and shape the field of digital readiness interventions for psychological therapy. In-depth qualitative research is crucial to understanding individual differences in emotional responses to readiness interventions and how constructs such as self-stigma affect motivation. Longitudinal research could also provide insights into individual trajectories through the stages of change because the process of becoming ready for treatment can be a long-term one, involving many layers and influences [76]. Recent phenomenological research indicates that change is perhaps a more continuous, internal, and holistic process than the TTM allows [104], and therefore, mapping the process of change in relation to readiness for mental health treatment would add depth to our theoretical foundations. Naturalistic effectiveness studies that attempt to reduce confounding trial effects and examine intervention implementation would help us to ground our knowledge in ecologically valid data and thus improve the practical application of digital readiness interventions. In addition, few studies in this review reported on how the interventions in question were developed or the design strategies used; this is important information for advancing the field and building best practices for future development. Finally, to further understand the different types of readiness interventions being used, future reviews could use more specific search terms (eg, help seeking, screening, and wait-list) to explore these areas in more detail. They could also include quality assessments in their charting process; however, the methodological issues discussed earlier would need to be further unraveled to enable a useful discussion of quality.

Conclusions

Digital interventions to enhance readiness for psychological therapy are broad and varied. The interventions in question range from brief, simple videos and advertisements to supported web-based programs. They are used to help clients across multiple stages of change, from those in precontemplation who have not yet sought help to those already preparing to take action. Although these easily accessible digital approaches show potential as a means of preparing people for therapy and thus reducing the mental health treatment gap, they are not without risks. The complex nature of stigma, motivation, and individual emotional responses toward engaging in treatment for mental health difficulties suggests that a careful approach is needed when developing and measuring readiness interventions. The results of this review indicate that the implementation and uptake of these interventions are important elements to consider in design, delivery, and measurement and that further qualitative and longitudinal research is needed to deepen our knowledge of the process of change in relation to readiness for therapy. Overall, this review highlights the fact that the field of digital readiness interventions is an emerging one, and more research is needed in this area.

Abstract

Background: Acceptance and commitment therapy (ACT) is based on a psychological flexibility model that encompasses 6 processes: acceptance, cognitive defusion, self-as-context, being present, values, and committed action.

Objective: This systematic review and meta-analysis of randomized controlled trials (RCTs) aimed to examine the effects of internet-based ACT (iACT) on process measures.

Methods: A comprehensive search was conducted using 4 databases. The quality of the included RCTs was assessed using the Cochrane Collaboration Risk of Bias Tool. A random-effects or fixed-effects model was used. Subgroup analyses for each outcome were conducted according to the type of control group, use of therapist guidance, delivery modes, and use of targeted participants, when applicable.

Results: A total of 34 RCTs met the inclusion criteria. This meta-analysis found that iACT had a medium effect on psychological flexibility and small effects on mindfulness, valued living, and cognitive defusion at the immediate posttest. In addition, iACT had a small effect on psychological flexibility at follow-up. The overall risk of bias across studies was unclear.

Conclusions: Relatively few studies have compared the effects of iACT with active control groups and measured the effects on mindfulness, valued living, and cognitive defusion. These findings support the processes of change in iACT, which mental health practitioners can use to support the use of iACT.

Introduction

Background

Acceptance and commitment therapy (ACT), which is a type of mindfulness-based intervention, is an empirically supported transdiagnostic approach [1,2]. Mindfulness is defined as “awareness that arises through paying attention, on purpose, in the present moment, and nonjudgmentally” [3]. ACT aims to develop greater psychological flexibility, that is, the ability to face challenging experiences in an open, conscious manner and change one’s behaviors to participate in valued activities rather than avoiding or suppressing uncomfortable or painful experiences, emotions, and thoughts [1,2]. ACT is based on a psychological flexibility model involving 6 processes [2]. These six processes include (1) acceptance (ie, being open to unwanted thoughts and emotions as they are), (2) cognitive defusion (ie, stepping back from unhelpful thoughts and emotions to reduce their dominance over behaviors), (3) being present (ie, maintaining voluntary and flexible contact with the present moment), (4) observing self (ie, flexible self-conceptualization and perspective taking), (5) values (ie, identifying and connecting values to behaviors for a meaningful life), and (6) committed action (ie, establishing patterns of behaviors to live a meaningful life aligned with values) [2]. The first 2 processes (1 and 2) are conceptualized as *acceptance and mindfulness processes*, and the last 2 processes (5 and 6) are conceptualized as *commitment and behavior change processes*; the remaining 2 processes (3 and 4) are conceptualized to be shared by the *acceptance and mindfulness processes* and *commitment and behavior change processes* [4].

Studies have used ACT process measures to assess the effects of ACT on these process measures and to understand the processes of change [5,6]. Measuring psychological flexibility and its interrelated processes (eg, cognitive defusion, mindfulness, and valued living) has been emphasized to better understand why ACT works and how it directly affects these process measures [7]. Improvement of psychological flexibility and its interrelated processes is theorized to foster improvements in mental health outcomes, and this theory is supported by empirical studies to some extent [8]. For example, studies have found a significant predictive role of psychological flexibility in predicting mental health outcomes; negative associations of psychological flexibility with depressive symptoms, anxiety, and overall psychological distress; and positive associations of psychological flexibility with quality of life, emotional well-being, and resilience [9,10]. Studies have also shown negative relationships between cognitive defusion and psychological distress and a significant predictive role of cognitive fusion (ie, the opposite of cognitive defusion) for depressive symptoms, anxiety, distress, and lowered quality of life [11-14]. In addition, the literature suggests that personal values and mindfulness have a significant effect on psychological distress and quality of life [15,16].

Although a growing body of evidence shows that ACT can improve health and well-being outcomes in various populations [17,18], the synthesized evidence of ACT on process measures is lacking. For example, previous meta-analysis studies did not consider ACT process measures except for psychological flexibility, possibly because of the limited number of published studies and because previous meta-analysis studies often limited their review questions to specific populations [19]. Internet-based psychological interventions are easy to access and inexpensive; therefore, it is important to determine whether internet-based ACT (iACT) is an effective alternative option [20]. In particular, Brown et al [21] conducted a meta-analysis to measure the effects of iACT on outcomes related to mental health and well-being in any population, but none of the ACT process measures were addressed, possibly because of the limited number of included studies for meta-analyses of these outcomes at that time. In addition, Thompson et al [22] conducted a similar meta-analysis that involved only meta-analysis for psychological flexibility, with no meta-analyses for any other process measures.

Objectives

This systematic review and meta-analysis aimed to assess the effects of iACT on different process measures (eg, psychological flexibility, valued living, mindfulness, and cognitive defusion) in any population. In addition, this meta-analysis aimed to conduct subgroup analyses for each outcome according to the type of control group to determine whether the effects of iACT differed when compared with active control groups provided with other comparable interventions and passive control groups provided with no intervention. In addition, other subgroup analyses related to the characteristics of the included studies may be possible and may provide useful information. For example, studies have found that iACT with therapist guidance showed larger effects on psychological flexibility compared with iACT without therapist guidance, and populations with psychological distress symptoms showed larger effects on mental health outcomes compared with nonclinical populations [22]. As studies have also found negative associations of psychological flexibility and cognitive defusion with psychological distress as well as a significant effect of personal values and mindfulness on psychological distress, studies that directly targeted people with psychological distress symptoms might show greater effects on ACT process measures [10-12,14-16]. Outcomes may differ based on how iACT was delivered (eg, web-based ACT modules, iACT accompanied by in-person ACT sessions, and videoconferencing ACT). Therefore, this study aimed to conduct additional subgroup analyses according to the use of therapist guidance, delivery modes, and the use of targeted participants with psychological distress symptoms, when applicable.

Methods

The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [23] and the Cochrane Handbook for Systematic Reviews of Interventions (version 5.1.0) [24] were used as guides for conducting and reporting this systematic review and meta-analysis. This study was not preregistered.

Inclusion and Exclusion Criteria

Studies were selected based on the following inclusion criteria: (1) the study must be a randomized controlled trial (RCT), (2) ACT must be delivered mainly on the web (ie, iACT), (3) the study must have pre-post test results in ACT process measures (eg, psychological flexibility, mindfulness, valued living, and cognitive defusion), (4) the study must compare iACT with a non-ACT condition or with a control condition, and (5) the study must be written in English. Studies were excluded if they compared ACT groups only with different delivery modes without any other comparison or control condition (eg, ACT delivered on the web vs ACT delivered in person).

Search Strategy

Relevant articles were identified by searching 4 electronic databases from the date of inception of each database to June 5, 2021. The databases were PubMed (1966-2021), CINAHL (1981-2021), PsycINFO (1935-2021), and Scopus (1966-2021). Key search terms were combined to identify the relevant literature using keywords for iACT. To broaden the database search, keywords relevant to the outcomes were not entered as search terms. The full search strategies for all databases can be found in Multimedia Appendix 1. Articles were also searched manually using the reference lists of the identified articles and related article features in the databases.

Data Extraction and Quality Assessment

The characteristics of the included RCTs, such as the country of origin, characteristics of participants, description of intervention and control groups, outcome measures, and results (ie, between-group differences with *P* values), were extracted into a table. The mean and SDs at each data collection time point and sample sizes of the intervention and control groups in the included studies were entered into a Microsoft Excel file. The methodological quality of the included RCTs was assessed using the Cochrane Collaboration Risk of Bias Tool [24]. The domains in the tool include random sequence generation, allocation concealment, blinding of participants and personnel, blinding of outcome assessment, incomplete outcome data, and selective reporting. Risk of bias in each of the domains was judged as *low risk* of bias, *high risk* of bias, or *unclear risk* of bias following the criteria provided in the Cochrane Collaboration’s handbook [24]. Summary assessments of the risk of bias within a study and across studies were also determined based on the handbook’s criteria [24]. One author with extensive experience in conducting systematic reviews and expertise in ACT completed the process for data extraction and quality assessment.

Meta-analysis

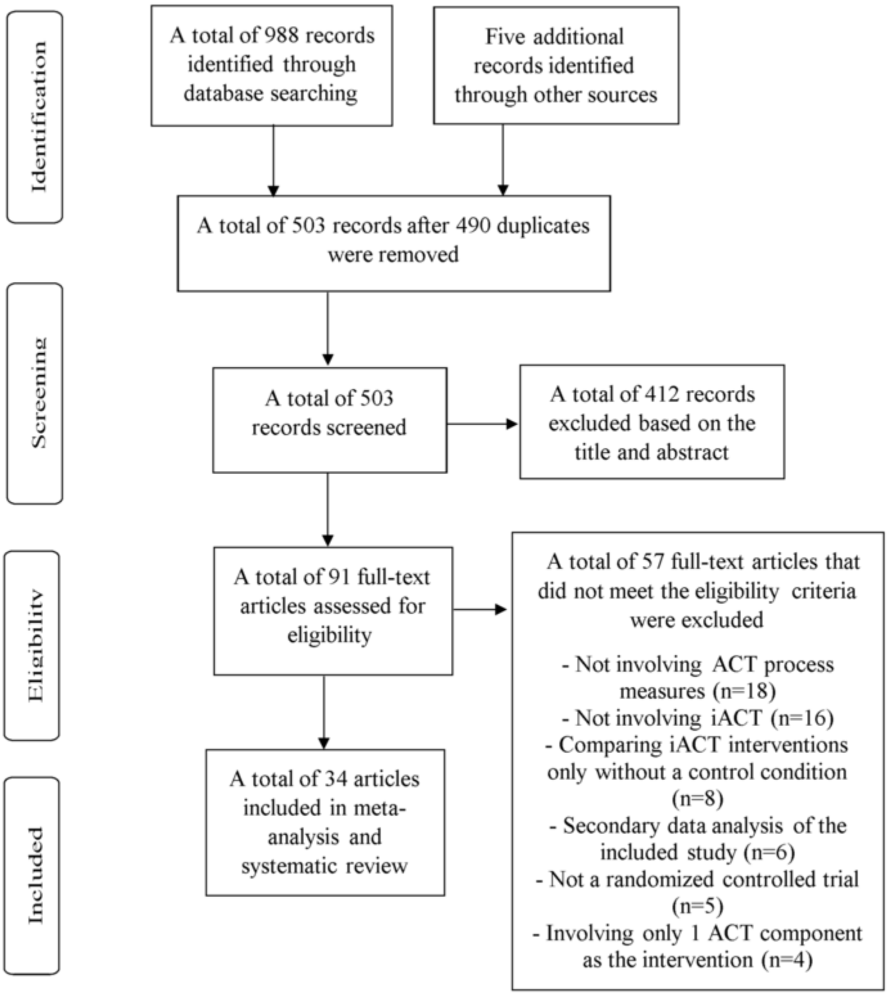
Means, SDs, and sample sizes of intervention and control groups in the included studies were entered into RevMan (version 5.4; Cochrane Collaboration) for meta-analyses and pooled for each outcome at the immediate posttest and at follow-up. The I^2 statistic was used to indicate statistical heterogeneity across studies, and $I^2>60\%$ might indicate substantial heterogeneity [24]. The decision to use either a random-effects model or a fixed-effects model with the inverse variance method was determined using I^2 statistic values for each outcome. In other words, a random-effects model was used when the I^2 statistic for each variable was >60%; otherwise, a fixed-effects model was used. The standardized mean difference (SMD) with 95% CIs was used as a summary statistic for the size of the intervention effect to account for outcomes measured using different assessment tools [24]. SMDs<0.4 indicate a small effect, SMDs between 0.4 and 0.7 indicate a medium effect, and SMDs>0.7 indicate a large effect [24]. The mean difference, rather than SMD, was used when the studies used the same assessment tool [24]. Subgroup analyses for each outcome were performed according to the type of control group, if applicable, to see whether the effects of iACT differed compared with active control groups provided with other comparable interventions and compared with passive control groups provided with no intervention (ie, treatment as usual control groups and wait-list control groups). Additional subgroup analyses for each outcome were conducted according to the use of therapist guidance, delivery modes, and the use of targeted participants with psychological distress symptoms, when applicable. Funnel plot analysis was used to test for possible publication bias (ie, studies with positive findings are more likely to be published) [24]. A possible publication bias was suggested if the inverted funnel shape was asymmetrical [24].

Results

Selection of Studies

Figure 1 illustrates the study selection process. A total of 988 articles were identified through database searching, and 5 additional articles were identified through hand searching. After removing 490 duplicates, 503 articles were screened based on their titles and abstracts. A total of 412 articles were excluded based on title and abstract screening, and 91 articles were assessed for eligibility by reading the full text. A total of 57 articles were excluded after reading the full text because of the following reasons: not involving any ACT process measures (18 studies), not involving iACT (16 studies), comparing iACT interventions delivered differently without a control condition (8 studies), involving secondary data analysis (6 studies), not an RCT (5 studies), and involving only 1 ACT component for the intervention (4 studies). A total of 34 articles met the eligibility criteria [8,25-57].

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the study selection process. ACT: acceptance and commitment therapy; iACT: internet-based acceptance and commitment therapy.



Characteristics of the Included Studies

The main characteristics of the included RCTs are summarized in Multimedia Appendix 2. The average number of ACT modules (sessions) in the included studies was 6.4 (SD 2.5), ranging from 2 to 12 modules in total. The average duration of ACT modules (sessions) delivered in the included studies was 7.9 (SD 3.2) weeks, ranging from 2 to 15 weeks in total. ACT was delivered on the web with therapist guidance in 26 studies (eg, via videoconferencing, phone calls, written feedback, and a mobile app) and without therapist guidance in 8 studies [25-32]. A total of 7 studies used a blended ACT program, which involved both iACT and in-person sessions [33-40]. A total of 3 studies involved videoconferencing ACT [41,42]. The remaining 24 RCTs used web-based ACT modules. Out of a total of 34 studies, 11 (32%) involved active control groups, including web-based cognitive behavioral therapy (CBT) [25], web-based smoking cessation interventions [26,27], web-based discussion forums [44,45,57], web-based mental health education [30], in-person behavioral support [35], web-based expressive writing [48,55], and in-person documentary discussion [38]. The population of the included studies varied widely, including college students [8,29-32,36,47,54], adults with chronic pain [37,39,52,55-57], family caregivers of people with chronic conditions [42,49,50,53], adults with insomnia [28,33,41], and smokers [26,27,35] (refer to Multimedia Appendix 2 for these different participant characteristics in the included studies). A total of 14 studies directly targeted people with certain types of psychological distress, such as depressive symptoms, anxiety, stress, and overall psychological distress [8,27,33,36-39,42,44-49].

The average sample size of participants in the included RCTs was 141 (SD 196), ranging from 24 to 1162. The mean age of the participants was 37.8 (SD 13.2) years, ranging from 13.9 to 55.9 years, and the average percentage of female participants was 68.1% (SD 19.7%), ranging from 0% to 98.5%. The included RCTs were conducted in the United States (10 studies), Finland (5 studies), Sweden (4 studies), the Netherlands (4 studies), the United Kingdom (2 studies), Australia (2 studies), Ireland (2 studies), Canada (1 study), Belgium (1 study), France (1 study), Denmark (1 study), and Germany (1 study). Of the 34 included studies, 26 (76%) were published between 2016 and 2021 and the remaining 8 (24%) were published between 2012 and 2015.

The following sections describe the results of the meta-analysis of the efficacy of iACT for psychological flexibility, mindfulness, valued living, and cognitive defusion at the immediate posttest and at follow-up, with findings of subgroup analyses listed according to the type of control group (ie, subgroup 1: iACT vs active control groups and subgroup 2: iACT vs passive control groups), when applicable.

Effects of iACT on Improving Psychological Flexibility at the Immediate Posttest

A meta-analysis of 30 RCTs (n=3743 participants) found that iACT had a medium effect on improving psychological flexibility at the immediate posttest compared with control groups overall (SMD=0.43, 95% CI 0.30-0.55; Figure 2). There was no significant subgroup difference at the immediate posttest (χ^2_1=1.26; *P*=.26), indicating that the effects of the 2 subgroups (ie, subgroup 1: iACT vs active control groups and subgroup 2: iACT vs passive control groups) at the immediate posttest were not statistically different from one another. The iACT had a medium effect on psychological flexibility compared with active control groups at the immediate posttest (7 studies that involved 841 participants; SMD=0.60, 95% CI 0.25-0.95), whereas iACT had a small effect compared with passive control groups (23 studies that involved 2902 participants; SMD=0.38, 95% CI 0.25-0.51).

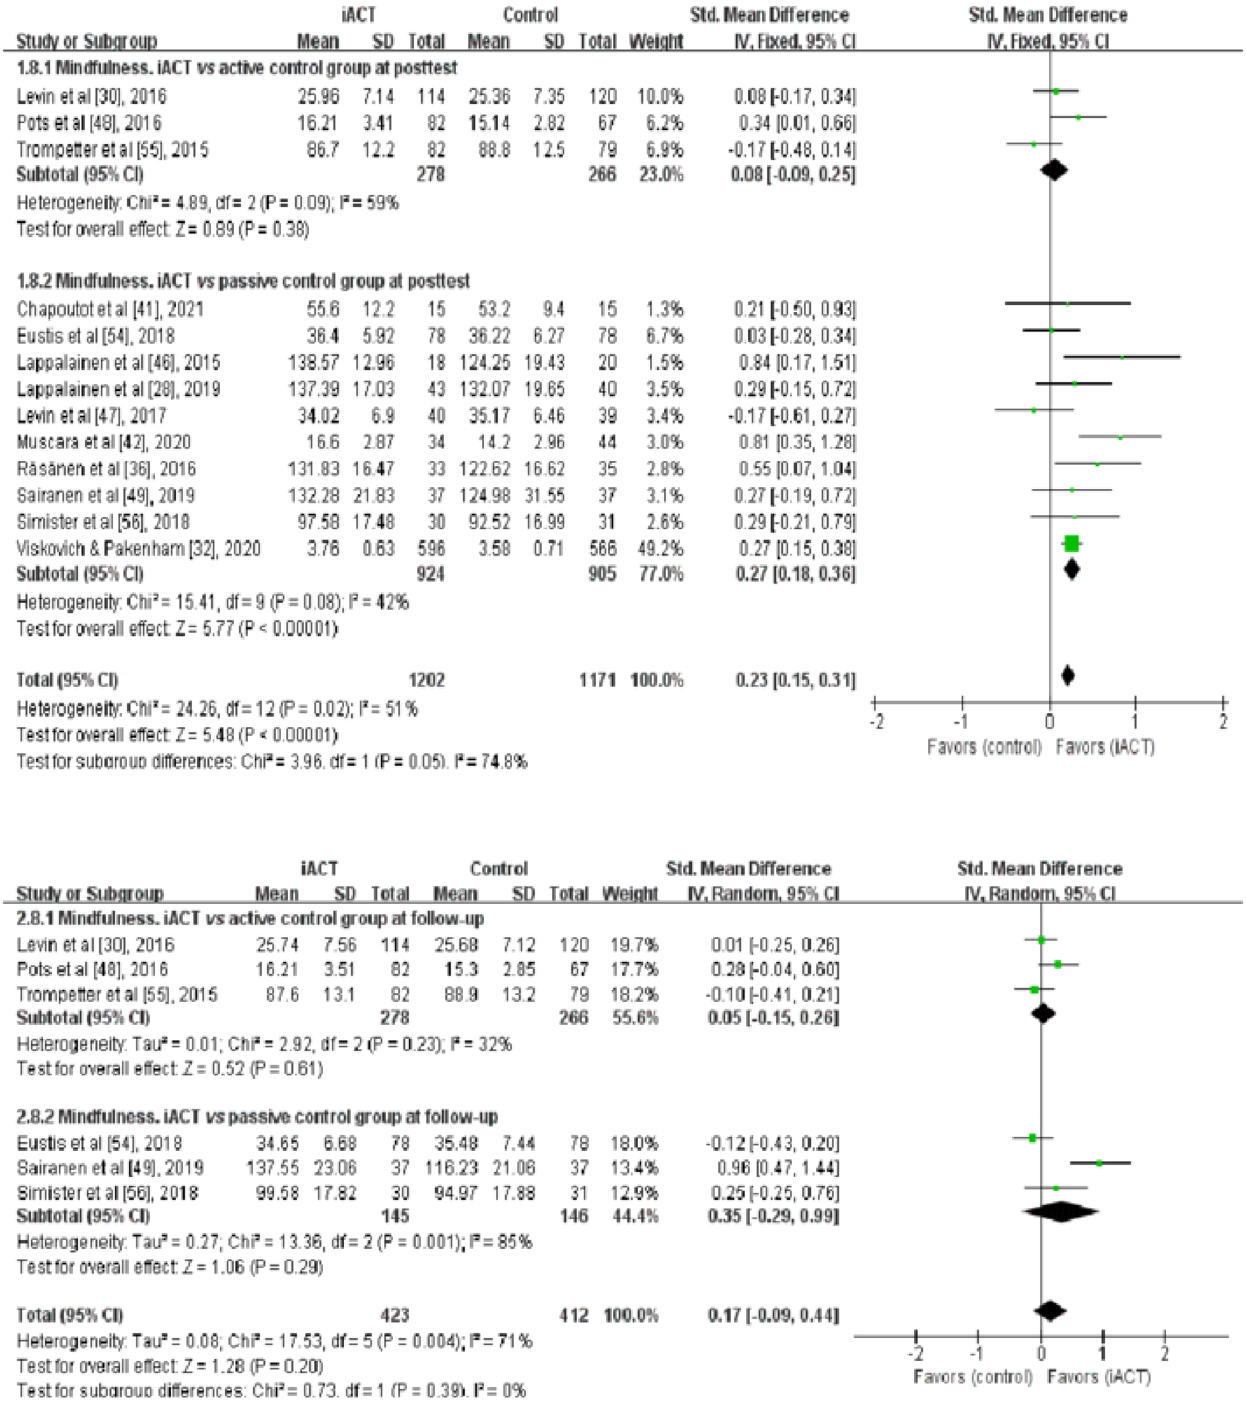
Effects of iACT on Improving Psychological Flexibility at Follow-up

A meta-analysis of 12 RCTs with follow-up data (n=1366 participants) revealed that iACT had a small effect on improving psychological flexibility at follow-up compared with control groups overall (SMD=0.35, 95% CI 0.16-0.54; Figure 2). There was no significant subgroup difference at follow-up (χ^2_1=0.91; *P*=.34), indicating that the effects of the 2 subgroups (ie, subgroup 1: iACT vs active control groups and subgroup 2: iACT vs passive control groups) at follow-up were not statistically different from one another. The iACT had a medium effect on improving psychological flexibility compared with passive control groups at follow-up (9 studies that involved 822 participants; SMD=0.41, 95% CI 0.19-0.62), but iACT was not significantly different from active control groups (3 studies that involved 544 participants; SMD=0.21, 95% CI −0.13 to 0.55).

Effects of iACT on Improving Mindfulness at the Immediate Posttest

A meta-analysis of 13 RCTs (n=2373 participants) showed that iACT had a small effect on improving mindfulness at the immediate posttest compared with control groups overall (SMD=0.23, 95% CI 0.15-0.31; Figure 3). There was a significant subgroup difference at the immediate posttest (χ^2_1=2.96; *P*=.05), indicating that the effects of the 2 subgroups (ie, subgroup 1: iACT vs active control groups and subgroup 2: iACT vs passive control groups) at the immediate posttest were statistically different from one another. The iACT had a small effect on improving mindfulness compared with passive control groups at the immediate posttest (10 studies that involved 1829 participants; SMD=0.27, 95% CI 0.18-0.36), but iACT was not significantly different from active control groups (3 studies that involved 544 participants; SMD=0.08, 95% CI −0.09 to 0.25).

Figure 3. Forest plots showing the effects of internet-based acceptance and commitment therapy on mindfulness at the immediate posttest and at follow-up. iACT: internet-based acceptance and commitment therapy.



Effects of iACT on Improving Mindfulness at Follow-up

A meta-analysis of 6 RCTs with follow-up data (n=835 participants) found that iACT was not significantly different overall from control groups in improving mindfulness at follow-up (SMD=0.17, 95% CI −0.09 to 0.44; Figure 3). There was no significant subgroup difference at follow-up (χ^2_1=0.73; *P*=.39), indicating that the effects of the 2 subgroups (ie, subgroup 1: iACT vs active control groups and subgroup 2: iACT vs passive control groups) at follow-up were not statistically different from one another. No significant between-group difference in improving mindfulness was found at follow-up, regardless of control group conditions, including 3 studies (n=544 participants) that compared iACT with active control groups (SMD=0.05, 95% CI −0.15 to 0.26) and 3 studies (n=291) that compared iACT with passive control conditions (SMD=0.35, 95% CI −0.29 to 0.99).

Effects of iACT on Improving Valued Living at the Immediate Posttest

A meta-analysis of 9 RCTs (n=2079 participants) revealed that iACT had a small effect on improving valued living at the immediate posttest compared with control groups overall (SMD=0.28, 95% CI 0.19-0.36; Figure 4). There was a statistically significant subgroup difference at the immediate posttest (χ^2_1=14.88; P<.001), indicating that the effects of the 2 subgroups (ie, subgroup 1: iACT vs active control groups and subgroup 2: iACT vs passive control groups) at the immediate posttest were statistically different from one another. The iACT had a small effect on improving valued living compared with passive control groups at the immediate posttest (7 studies that involved 1684 participants; SMD=0.36, 95% CI 0.26-0.46), but iACT was not significantly different from active control groups (2 studies that involved 395 participants; SMD=−0.07, 95% CI −0.27 to 0.12).

Figure 4. Forest plots showing the effects of internet-based acceptance and commitment therapy on valued living at the immediate posttest and at follow-up. iACT: internet-based acceptance and commitment therapy.

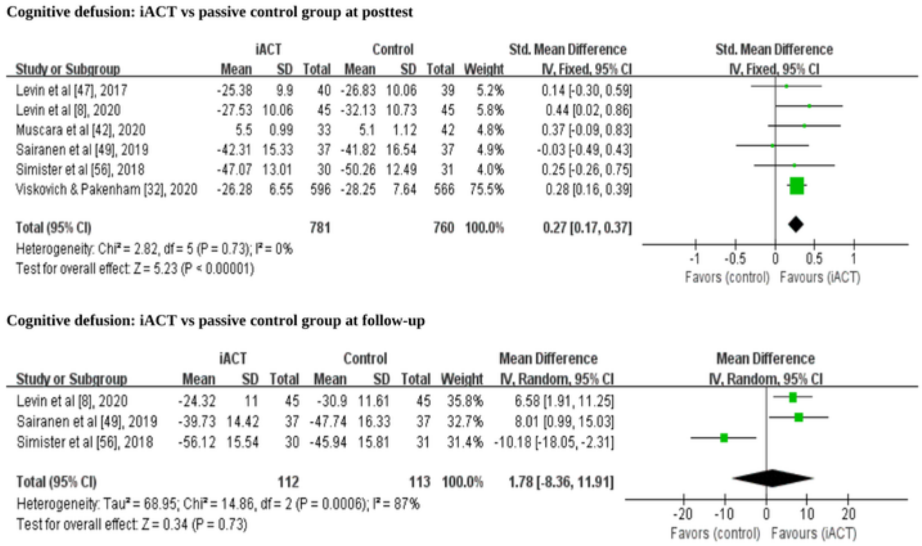
Effects of iACT on Improving Valued Living at Follow-up

A meta-analysis of 7 RCTs with follow-up data (n=841 participants) showed that iACT did not differ from control groups in improving valued living at follow-up (SMD=0.08, 95% CI −0.14 to 0.30; Figure 4). There was no statistically significant subgroup difference at follow-up (χ^2_1=0.49; *P*=.48), indicating that the effects of the 2 subgroups (ie, subgroup 1: iACT vs active control groups and subgroup 2: iACT vs passive control groups) at follow-up were not statistically different from one another. No significant between-group difference in improving valued living was found at follow-up, regardless of control group conditions, including 2 studies (n=395 participants) that compared iACT with active control groups (SMD=−0.02, 95% CI −0.25 to 0.22) and 5 studies (n=446 participants) that compared iACT with passive control conditions (SMD=0.12, 95% CI −0.19 to 0.44).

Effects of iACT on Improving Cognitive Defusion at the Immediate Posttest

All studies that measured cognitive defusion compared iACT with passive control groups only; therefore, a subgroup analysis was not conducted. A meta-analysis of 6 RCTs (n=1541 participants) found that iACT had a small effect on improving cognitive defusion at the immediate posttest compared with passive control groups (SMD=0.27, 95% CI 0.17-0.37; Figure 5). A meta-analysis of 3 RCTs with follow-up data (n=225 participants) revealed that iACT was not different from passive control groups in improving cognitive defusion at follow-up (SMD=1.78, 95% CI −8.36 to 11.91; Figure 5).

Figure 5. Forest plots showing the effects of internet-based acceptance and commitment therapy on cognitive defusion at the immediate posttest and at follow-up. iACT: internet-based acceptance and commitment therapy.



Subgroup Analyses According to the Use of Therapist Guidance

Subgroup analyses showed medium effects of iACT with therapist guidance on psychological flexibility at the immediate posttest (25 studies that involved 2085 participants; SMD=0.50, 95% CI 0.34-0.65) and at follow-up (10 studies that involved 1056 participants; SMD=0.40, 95% CI 0.21-0.58) and small effects of iACT with therapist guidance on mindfulness (10 studies that involved 894 participants; SMD=0.20, 95% CI 0.07-0.34) and valued living (7 studies that involved 686 participants; SMD=0.26, 95% CI 0.04-0.48) at the immediate posttest compared with control groups. The iACT with therapist guidance was not significantly different from the control groups in valued living at follow-up (5 studies that involved 531 participants, SMD=0.14, 95% CI −0.15 to 0.43). Conversely, subgroup analyses revealed small effects of iACT without therapist guidance on psychological flexibility (6 studies that involved 1700 participants, SMD=0.18, 95% CI 0.03-0.32) and mindfulness (3 studies that involved 1479 participants, SMD=0.24, 95% CI 0.14-0.34) at the immediate posttest only. The iACT without therapist guidance was not significantly different from control groups in psychological flexibility at follow-up (2 studies that involved 310 participants; SMD=0.17, 95% CI −0.38 to 0.71) and valued living at the immediate posttest (3 studies that involved 1472 participants; SMD=0.20, 95% CI −0.10 to 0.49) and follow-up (2 studies that involved 310 participants; SMD=−0.08, 95% CI −0.30 to 0.14). In particular, the pooled effect size of studies that involved iACT with therapist guidance was greater than that of studies that involved iACT without therapist guidance in psychological flexibility at the immediate posttest. In addition, although there was a statistically significant pooled effect of iACT with therapist guidance on valued living at the immediate posttest, iACT without therapist guidance was not significantly different from the control groups. There was no statistically significant subgroup difference in any of the outcomes (*P*>.05), except for psychological flexibility at the immediate posttest (*P*=.003). These findings indicate that there was no statistically significant difference among studies according to the use of therapist guidance in all outcomes, except for psychological flexibility at the immediate posttest, in which a statistically significant larger effect of iACT was found when iACT studies involved therapist guidance (ie, SMD=0.50 vs SMD=0.18). Forest plots of these subgroup analyses are illustrated in Multimedia Appendices 3-7.

Subgroup Analyses According to the Delivery Modes

Subgroup analyses showed small effects of web-based ACT on psychological flexibility (22 studies that involved 3257 participants; SMD=0.38, 95% CI 0.26-0.49) and mindfulness at the immediate posttest (10 studies that involved 2197 participants; SMD=0.20, 95% CI 0.11-0.28) compared with control groups. Subgroup analyses revealed medium effects of iACT accompanied by in-person ACT sessions on psychological flexibility (6 studies that involved 394 participants; SMD=0.61, 95% CI 0.02-1.20) and mindfulness (1 study that involved 68 participants; SMD=0.55, 95% CI 0.07-1.04) at the immediate posttest compared with control groups. Although videoconferencing ACT was not significantly different from control groups in psychological flexibility at the immediate posttest (3 studies that involved 134 participants; SMD=0.43, 95% CI −0.25 to 1.11), subgroup analyses found medium effects of videoconferencing ACT on mindfulness at the immediate posttest compared with control groups (2 studies that involved 108 participants; SMD=0.64, 95% CI 0.24-1.03). There was no statistically significant subgroup difference in psychological flexibility at the immediate posttest (*P*>.05), indicating that there was no statistically significant difference among studies according to delivery modes. However, there was a statistically significant subgroup difference in mindfulness at the immediate posttest (*P*=.04), suggesting a statistically significant difference among studies according to their delivery modes, in which medium effects of iACT with in-person sessions and videoconferencing ACT were found, whereas web-based ACT showed small effects. Subgroup analyses according to the delivery modes were not conducted for the other outcomes because of the lack of studies on any other outcomes. Forest plots of these subgroup analyses are illustrated in Multimedia Appendices 8 and 9.

Subgroup Analyses According to the Targeted Participants With Psychological Distress Symptoms

Subgroup analyses found a medium effect of iACT on psychological flexibility at the immediate posttest (13 studies that involved 919 participants; SMD=0.55, 95% CI 0.31-0.79) and small effects of iACT on psychological flexibility at follow-up (5 studies that involved 414 participants; SMD=0.29, 95% CI 0.09-0.49) and on mindfulness (6 studies that involved 486 participants; SMD=0.38, 95% CI 0.20-0.56), valued living (4 studies that involved 308 participants; SMD=0.35, 95% CI 0.02-0.69), and cognitive defusion (4 studies that involved 318 participants; SMD=0.24, 95% CI 0.02-0.46) at the immediate posttest compared with control groups when studies directly targeted participants with some type of psychological distress. Subgroup analyses, however, showed small effects of iACT on psychological flexibility at the immediate posttest (18 studies that involved 2866 participants; SMD=0.33, 95% CI 0.19-0.48) and at follow-up (7 studies that involved 952 participants; SMD=0.38, 95% CI 0.10-0.67), mindfulness at the immediate posttest (7 studies that involved 1887 participants; SMD=0.19, 95% CI 0.10-0.28), and cognitive defusion at the immediate posttest (2 studies that involved 1223 participants; SMD=0.28, 95% CI 0.16-0.39) compared with control groups in studies that did not involve targeted participants with some type of psychological distress. However, there was no statistically significant difference in iACT among control groups in mindfulness and valued living at follow-up when studies did or did not directly target participants with some type of psychological distress, or in valued living at the immediate posttest when studies did not involve targeted participants with some type of psychological distress. There were no statistically significant subgroup differences in any of the outcomes (*P*>.05), indicating that there was no statistically significant difference among studies according to the use of targeted participants with some type of psychological distress in all the outcomes. Forest plots of these subgroup analyses are illustrated in Multimedia Appendices 10-16.

Risk of Bias and Publications Bias of the Included Studies

Out of the 34 included studies, 18 (53%) had an unclear risk of bias, 10 (29%) had a low risk of bias, and 6 (18%) had a high overall risk of bias (Multimedia Appendix 17). A domain regarding blinding of participants and personnel was not regarded as the key domain for the overall risk of bias within a study because studies that involved passive control conditions were less able to conceal the group allocation from participants. The overall risk of bias across the 34 studies was interpreted as unclear because most information was from studies with an unclear risk of bias [24]. The risk of bias in each domain for each study is reported in Multimedia Appendix 17, and the risk of bias summary graph and chart are reported in Multimedia Appendix 18 [8,25-57] and Multimedia Appendix 19.

As at least 10 studies have suggested using the funnel plot asymmetry analysis, possible publication bias was tested for psychological flexibility and mindfulness at posttest only [24]. Overall, the funnel plots tend to be symmetrical, although more studies are needed to better interpret such visual inspection, especially for mindfulness. Funnel plots are reported in Multimedia Appendix 20.

Discussion

This systematic review and meta-analysis identified 34 RCTs that assessed the efficacy of iACT for process measures (ie, psychological flexibility, mindfulness, valued living, and cognitive defusion). This meta-analysis found that iACT had a medium effect on improving psychological flexibility and small effects on improving mindfulness, valued living, and cognitive defusion at the immediate posttest. A small effect of iACT on psychological flexibility was also observed at follow-up.

Previous meta-analysis studies that involved ACT (ie, not iACT in particular) found similar findings to this meta-analysis study that included a medium effect of ACT on psychological flexibility in family caregivers [6] and a small effect of self-help ACT on psychological flexibility in adult populations [58]. A total of 26 studies that assessed the effects of iACT on process measures were conducted from 2016 to the end date of the search for this meta-analysis (June 5, 2021), whereas only 8 studies were published before 2016. This may explain why a previous meta-analysis study of iACT in particular did not include process measures [21]. Thompson et al [22] conducted a meta-analysis for psychological flexibility only among process measures and found small effects of iACT on psychological flexibility at the immediate posttest and at follow-up. These findings by Thompson et al [22] were based on 23 studies at immediate posttest and 11 studies at follow-up. This meta-analysis found a medium effect at the immediate posttest (based on 30 studies) and a small effect at follow-up (based on 12 studies). The larger effect size of iACT on psychological flexibility at the immediate posttest found in this study may be because of the inclusion of 7 more studies than the meta-analysis by Thompson et al [22]. Unlike previous meta-analysis studies for iACT [21,22], this meta-analysis study conducted meta-analyses in other process measures, such as mindfulness, valued living, and cognitive defusion, and found small effects on these measures at the immediate posttest. Thus, the findings of this meta-analysis contribute to the body of evidence on the efficacy of iACT for different process measures, which could be applicable to both clinical and nonclinical populations, as ACT is a transdiagnostic approach [1].

Subgroup analyses for each outcome were conducted in this meta-analysis study according to the type of control group, unlike previous iACT meta-analysis studies [21,22]. Subgroup analyses showed small effects of iACT on psychological flexibility, mindfulness, valued living, and cognitive defusion at the immediate posttest compared with passive control groups. In contrast, subgroup analyses that compared iACT with active control groups found no significant between-group differences in mindfulness and valued living at the immediate posttest and follow-up and in psychological flexibility at follow-up. Such findings indicate that iACT was not significantly more effective than active control conditions (eg, CBT and mental health education). However, relatively few studies have compared the effects of iACT with active control conditions. There were 3 times more studies that compared iACT with passive control conditions than those that compared iACT with active control conditions in all the process measures, except for mindfulness at follow-up. Such a gap in the literature suggests a need for studies that compare iACT with active control conditions, such as CBT, psychoeducational interventions, and support groups, to better understand whether iACT is comparable or superior to other evidence-based treatments in improving process measures such as mindfulness and cognitive defusion.

This study conducted subgroup analyses according to the use of therapist guidance, delivery modes, and targeted participants with symptoms of psychological distress. This study found no statistically significant subgroup difference among studies of these 3 characteristics in all the outcomes, except for the subgroup difference among studies according to the use of therapist guidance for psychological flexibility at the immediate posttest (ie, a larger effect of iACT when iACT was provided with therapist guidance compared with iACT without therapist guidance) and for the subgroup difference among studies according to the delivery modes for mindfulness at the immediate posttest (ie, a larger effect of iACT when iACT was delivered with in-person sessions or videoconferencing ACT compared with web-based ACT modules). Thompson et al [22] also found larger effects of iACT with therapist guidance on psychological flexibility compared with iACT without therapist guidance. However, more studies are needed to confirm these findings, especially in subgroup analyses according to delivery modes, because only a few studies have involved delivery modes other than web-based ACT modules.

This review had several limitations that should be considered when interpreting the findings. A total of 4 electronic databases were used to search the literature, and some relevant articles could have been missed if they were published only in other databases. Only studies written in English were searched and included in this review, which could create a publication bias. One author with extensive experience in comprehensive literature reviews and expertise in ACT searched the literature; therefore, this review did not include 2 independent reviewers in the search process. A recent systematic review found that single screening for study selection in systematic reviews conducted by experienced reviewers had no impact on the findings of the meta-analysis [59]. The overall risk of bias across the included RCTs was interpreted as unclear, indicating the need for high-quality studies to better determine the effects of iACT on process measures.

According to this meta-analysis study, there were 2 to 5 times more studies that assessed psychological flexibility than studies that assessed mindfulness, valued living, and cognitive defusion. Investigators of further studies should consider assessing diverse ACT process measures to better understand the processes of change. In addition, relatively few studies have been conducted to compare the effects of iACT with active control groups. Future high-quality studies that compare iACT with active control conditions are needed to better understand whether iACT is comparable or superior to other evidence-based treatments in process measures. The findings of this review contribute to the literature by showing the direct effects of iACT on ACT processes, which are theorized to foster improvements in mental health outcomes. These synthesized findings support the processes of change in iACT, which mental health practitioners can use to support the use of iACT.

Acknowledgments

This research was supported by a grant from the Korea Health Technology Research and Development Project through the Korea Health Industry Development Institute and funded by the Ministry of Health and Welfare, Republic of Korea (grant number HR21C0885040021). The funder had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Authors' Contributions

AH was responsible for the conceptualization, methodology, formal analysis, investigation, resources, data curation, writing the original draft, visualization, and project administration. THK was responsible for the conceptualization, validation, resources, writing the review and editing, supervision, project administration, and funding acquisition. All the authors have read and approved the final manuscript.

Abstract

Background: Publishing identifiable patient data in scientific journals may jeopardize patient privacy and confidentiality if best ethical practices are not followed. Current journal practices show considerable diversity in the publication of identifiable patient photographs, and different stakeholders may have different opinions of and practices in publishing patient photographs.

Objective: This scoping review aimed to identify existing evidence and map knowledge gaps in medical research on the policies and practices of publishing identifiable photographs in scientific articles.

Methods: We performed a comprehensive search of the Cochrane Central Register of Controlled Trials, Cochrane Database of Systematic Reviews, CINAHL with Full Text, Database of Abstracts of Reviews of Effects, Ovid MEDLINE, and Scopus. The Open Science Framework, PROSPERO, BASE, Google Scholar, OpenGrey, ClinicalTrials.gov, the Campbell Collaboration Library, and Science.gov were also searched.

Results: After screening the initial 15,949 titles and abstracts, 98 (0.61%) publications were assessed for eligibility at the full-text level, and 30 (0.19%) publications were included in this review. The studies were published between 1994 and 2020; most had a cross-sectional design and were published in journals covering different medical disciplines. We identified 3 main topics. The first included ethical aspects of the use of facial photographs in publications. In different clinical settings, the consent process was not conducted properly, and health professionals did not recognize the importance of obtaining written patient consent for taking and using patient medical photographs. They often considered verbal consent sufficient or even used the photographs without consent. The second topic included studies that investigated the practices and use of medical photography in publishing. Both patients and doctors asked for confidential storage and maintenance of medical photographs. Patients preferred to be photographed by their physicians using an institutional camera and preferred nonidentifiable medical photographs not only for publication but also in general. Conventional methods of deidentification of facial photographs concealing the eye area were recognized as unsuccessful in protecting patient privacy. The third topic emerged from studies investigating medical photography in journal articles. These studies showed great diversity in publishing practices regarding consent for publication of medical photographs. Journal policies regarding the consent process and consent forms were insufficient, and existing ethical professional guidelines were not fully implemented in actual practices. Patients' photographs from open-access medical journals were found on public web-based platforms.

Conclusions: This scoping review showed a diversity of practices in publishing identifiable patient photographs and an unsatisfactory level of knowledge of this issue among different stakeholders despite existing standards. Emerging issues include the availability of patients' photographs from open-access journals or preprints in the digital environment. There is a need to improve standards and processes to obtain proper consent to fully protect the privacy of patients in published articles.

Introduction

Background

Scientific publications are considered to be the most important formal elements of scholarly communication, translating new evidence in practice and increasing relevant stakeholders' knowledge. Publishing identifiable patient photographs in journals, such as photographs of the face, is a challenging ethical issue, not only because it requires consent but also because many research participants as well as researchers are not aware of what happens when identifying photographs of individual persons are published. This is of particular importance in digital publishing, especially when open publishing licenses such as the Creative Commons license CC BY are used [1]. Many medical journals that publish articles identifying patient photographs are in open access and under open licenses [2], which means that identifiable patient data are widely available and can be easily abused [3].

It is not always clear how patient data are classified as identifiable, nonidentifiable, or anonymized. The scoping review by Chevrier et al [4] on the use and understanding of terms of anonymization and deidentification in biomedical literature showed that there is large variability in the use of these as well as the need for clearer definitions and better education. Current publication standards on the use of patient identifiable data proposed by the International Committee of Medical Journal Editors (ICMJE) recommend avoiding publication of identifiable photographs or marks and the necessity of obtaining written consent from the patient [5]. However, in some clinical disciplines such as those involving the head and neck, it is necessary to show the patients' faces to illustrate study findings. The most used methods of deidentification to protect patient identity—covering the eye area in facial photographs—have been recognized as insufficient and should not be published without the patient's written consent [6-8]. Consent for the publication of an identifiable photograph should be obtained after the patient is informed of all the potential consequences of a publication even if the publication results from routine health care and is written up as a case report [9-12]. Patients should also be aware of the impossibility of withdrawing or controlling any future use of photographs once they have been published on the web [1,13]. This means that consent for the publication of an identifying patient photograph is separate from and additional to the general consent for research [2,8,14-16].

Objectives

Despite these recommendations, there is diversity among medical journals in their policies on patient consent for the publication of identifying photographs and their implementation in practice [2,17]. There are also varying opinions and practices among different stakeholders—patients, professionals, journals, and professional societies. To identify the existing evidence and map knowledge gaps in research on the policies and practices of publishing identifiable photographs in medicine, we performed a scoping review of the published literature on this topic. The research question of this scoping review was as follows: what are the opinions, standards, and practices of different stakeholders (patients, health professionals, policy makers, journals, editors, and publishers) regarding consent for publishing potentially identifiable medical photographs?

Methods

Methodological Approach

We used the methodology for scoping reviews from the Joanna Briggs Institute [18]. The protocol of this scoping review was registered at the Open Science Framework [19]. Study results are presented following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist (Multimedia Appendix 1) [20].

Study Selection (Eligibility Criteria)

We performed a sensitive search without language, time, or geographical limitations to identify studies that investigated the conditions of publication of patient facial photographs regardless of whether they were identifiable or not; articles that addressed only body parts other than the face were excluded. Publications that reported the results of conducted studies were included in the analysis. All other types of publications, such as editorials, opinion letters, reviews, and book chapters, were excluded.

Information Sources and Search

Search strategies for bibliographical databases were designed by an experienced librarian (AU; Multimedia Appendix 2). We searched the Cochrane Central Register of Controlled Trials, Cochrane Database of Systematic Reviews, CINAHL with Full Text, Database of Abstracts of Reviews of Effects, Ovid MEDLINE, and Scopus in September 2018 and updated the search in December 2020. In January 2021, we also searched registries and gray literature sources: ClinicalTrials.gov, Campbell Collaboration Library, Open Science Framework, PROSPERO, BASE, Google Scholar, OpenGrey, and Science.gov. These sources were searched using variations of the terms “medical” and “photography.” The reference lists of all studies included in the full-text assessment were also searched.

Screening

The retrieved articles were exported to and deduplicated in EndNote (Clarivate Analytics). Owing to the large number of articles for screening using a sensitive strategy that retrieved many nonrelevant articles, 2 authors (MR and TPP) screened the titles and abstracts of separate sets of articles. Articles identified in the screening were then jointly assessed by 2 authors (DŠ and MR), who discussed each article. Independent assessment by the 2 authors was not performed, and agreement indexes were not calculated as reporting in many articles was not always clear and significant disagreement was expected. The 2 assessors reached a joint conclusion on the inclusion of an article during their discussion based on the article’s full text.

Data Charting Process

Two authors (MR and MV) created the charting form for the variables to be extracted. The form was reviewed by another author (AM) and tested by 2 authors (DŠ and MR), who extracted the data for the first 10 articles and discussed the coding for each variable. They confirmed the inclusion and exclusion criteria and then each independently extracted the data for half of the articles in the final sample. The data from 2 articles authored by some of the authors of this review were collected by the author who did not participate in the study (MV). AM checked the quality of data extraction.

Data Items

Data were collected for the following variables: authors, article title, year of publication, source origin and country of origin, World Bank ranking of the country, publication type, journal title, journal access status, study design, study population, setting, sample size and response rate, age of the participants, gender, aim of the study, methodology, key outcomes, philosophical approach, key findings, limitations, future study ideas, and recommendations.

Summarizing Data and Reporting Results

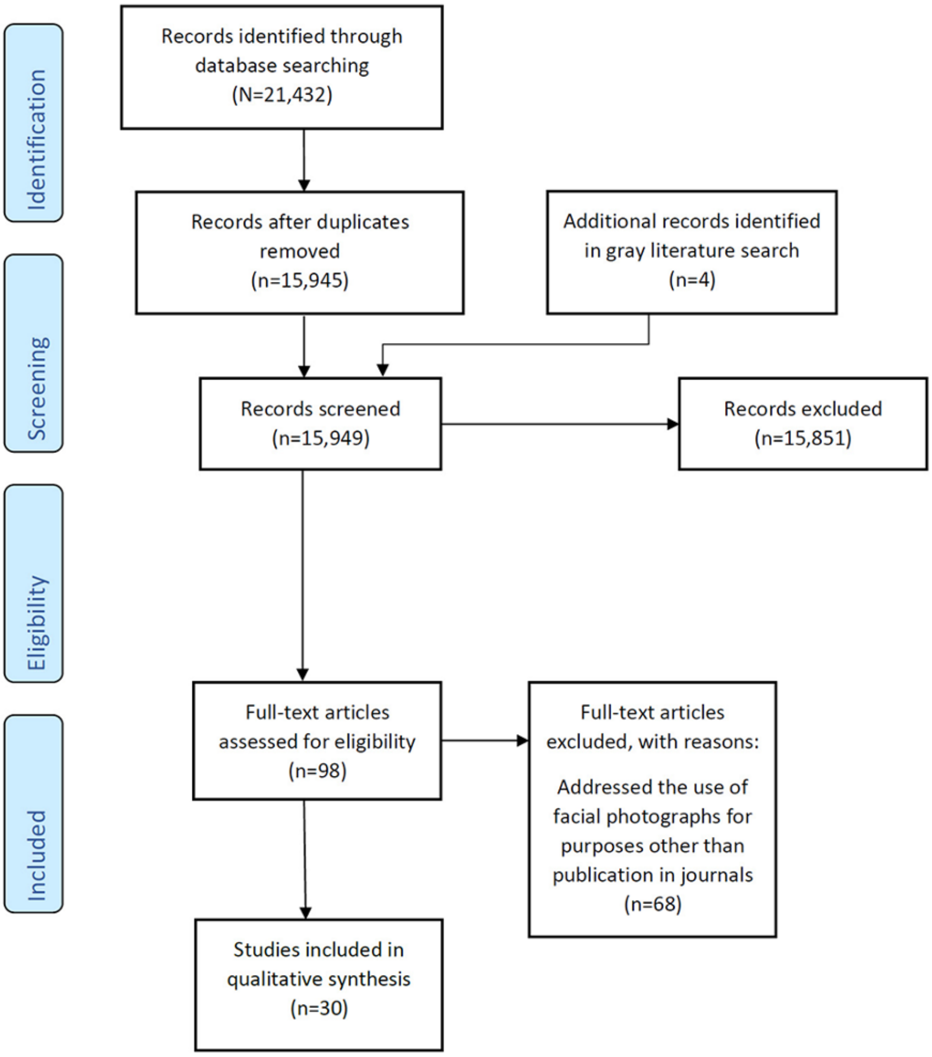
We summarized the data quantitatively for the description of the included studies. In the qualitative analysis, we grouped the results of the studies into main themes. According to the PRISMA-ScR guidance, we did not formally assess the methodological quality, including risk of bias, of the studies from which data were extracted as the scoping review method is not intended to be used to appraise the risk of bias of a cumulative body of evidence [20].

Results

Selection of Sources of Evidence

The search of bibliographical database literature retrieved a total of 21,432 published items, leaving 15,945 (74.4%) items after deduplication. The search of registries and gray literature yielded 4 additional items. After screening titles and abstracts, of the 15,949 items, 98 (0.61%) references were screened at the full-text level. We excluded 69% (68/98) of the studies as they addressed uses of facial photographs other than for publication in journals. This left 31% (30/98) of articles for analysis [2,3,6-12,14-16,21-38]. The flow diagram of the literature review is shown in Figure 1.

Figure 1. Flowchart of the literature review.



Characteristics of the Sources of Evidence

Of the 30 articles included in the analysis, 6 (20%) investigated the publication of facial photographs in scientific journals as the main topic [2,3,7,32,35,36]. Other studies (24/30, 80%) had the publication of medical photography as one of the topics, so only those results were included in this review.

The included studies were published between 1994 and 2020. Almost half of the studies (13/30, 43%) were published in open access [3,6,7,11,15,21-23,25,30,31,36]. The studies were performed in countries from all continents, from both high– and low–research-intensive countries. Of the 30 studies, 29 (97%) were published in English, and 1 (3%) was published in French. Most of the studies (5/30, 17%) were conducted internationally in scientific journals, followed by studies from the United Kingdom (5/30, 17%); the United States (4/30, 13%); Australia (3/30, 10%); Brazil, Canada, France, and India (2/30, 7% each); and China, Croatia, Ireland, Nigeria, and Saudi Arabia (1/30, 3% each). The studies were published in journals from different disciplines: ethics (4/30, 13%), surgery (10/30, 33%), general medicine and education (3/30, 10%), and clinical dermatology (13/30, 43%). Most of the studies (26/30, 87%) had an observational or cross-sectional design (Table 1), 3% (1/30) were randomized controlled trials [6], 3% (1/30) used another experimental design [28], and 7% (2/30) used qualitative approaches [23,25]. Reported limitations were the small number of participants [8,12,26,27,34], pilot studies [22], a single type of health professional included [6,8,9,25,29], years of clinical practice for specialists [9], poor response rate [26,27,33,34], possibility of socially desirable answers [29,35], and a single study setting [21,22,25,29]. The limitations of the studies performed on data or journals were the small number of journals [7,36], small number of analyzed journal issues [2], filters for web-based image search, and the fluctuating number of available web-based images from academic journals [3].

There were 25 studies involving different stakeholders (Table 1): patients (n=11, 44%), legal representatives (parents) of minors (n=1, 4%), undergraduate and postgraduate students of medicine and dental medicine (n=5, 20%), nurses and other hospital health professionals (n=1, 4%), and medical doctors and doctors of dental medicine (n=11, 44%; Table 1). Another 17% (5/30) of studies involved editorial policies or published articles in journals (Table 1). The studies that involved human participants were conducted in clinical settings (17/30, 57%), at universities (3/30, 10%), and on the web (5/30, 17%). The median number of study participants was 153 (range 12-945), and the median response rate was 70% (range 17%-90%). All participants were adults, with a median age of 40 (range 27-57) years. The median percentage of women involved in the studies was 55% (range 33%-84%). The remaining 17% (5/30) of studies analyzed data on journals and articles [2,3,7,32,36].

The studies included in this review addressed three general topics: (1) ethical aspects of the use of medical photography in publications (Table 2), (2) practices and use of medical photography in journals (Table 3), and (3) characteristics of medical photographs in published articles (Table 4).

Table 1. Description of the studies included in the scoping review (N=30).

Study, year	Country where the study was performed	Study design	Study population	Setting or data sources	Sample size	Response rate	Age (years)
Jones [14], 1994	United Kingdom	Cross-sectional	Patients	Teaching and university hospitals or large district general hospitals (44 medical illustration departments)	35	79%	NR[a]
Cheung et al [22], 2005	United Kingdom	Cross-sectional	Patients	Emergency department	100	N/A[b]	>18
Windsor et al [38], 2006	Australia	Cross-sectional	Digital images (photographs and video clips)	Adult emergency department in Australia	493	N/A	N/A
Taylor et al [8], 2007	United Kingdom	Cross-sectional	All surgical staff	Plastic surgery units in the hospital	42	70%	NR
Clover et al [6], 2010	Ireland	Randomized controlled trial	Medical students	Medical school	126	96%	NR
Lau et al [15], 2010	United Kingdom	Cross-sectional	Patients	Department of plastic and reconstructive surgery	205	NR	>18
Engelstad et al [28], 2011	United States	Experimental study	Dental students	School of Dentistry	12	NR	Median 27 (range 24-29)
Adeyemo et al [10], 2012	Nigeria	Cross-sectional	Patients	Oral, maxillofacial, and plastic surgery clinics	338	NR	Mean 32.5 (SD 12.2; range 16-79)
Shintani and Williams [36], 2012	International	Cross-sectional	Journals	Medical journals in oral surgery	3	N/A	N/A
Devakumar et al [25], 2013	United Kingdom	Qualitative (focus groups)	Pediatricians	Teleconference via Skype	13	NR	NR
Hacard et al [29], 2013	France	Cross-sectional	Patients	Department of dermatology	272	NR	Adults: mean 57.5 (SD 17.6), children: median 1.5 (IQR 0.6-7.0), and accompanying parents: mean 35.0 (SD 6.8)
Kunde et al [31], 2013	Australia	Cross-sectional	Dermatology registrars and insurance providers	N/A	13	65%	NR
De Runz et al [24], 2014	France	Cross-sectional	Plastic surgeons and patients	Department of maxillofacial, plastic, and esthetic surgery in the hospital	176 surgeons and 93 patients	Surgeons: 42% and patients: NR	NR
Leger et al [12], 2014	United States	Cross-sectional	Patients	Hospital	398	NR	>18
Caires et al [11], 2015	Brazil	Cross-sectional	Nurses, nursing technicians, residents working at inpatient units, and physical therapists	Teaching hospital	360	Nurses: 31.4% and residents: 43.9%; regarding the place of work in the hospital, 3% worked in inpatient units	>40
Indu et al [30], 2015	India	Cross-sectional	Postgraduate students and teaching staff	Oral pathology departments	60	44%	NR

Study, year	Country where the study was performed	Study design	Study population	Setting or data sources	Sample size	Response rate	Age (years)
Rimoin et al [34], 2016	United States	Cross-sectional	Surgeons	Members of the American College of Mohs Surgery	158	17%	NR
Roberts et al [7], 2016	International	Cross-sectional	Journals	Medical journals that frequently publish facial photographs	13	N/A	N/A
Abbott et al [9], 2017	Australia	Cross-sectional	Dermatologists and dermatologic trainers	Australian College of Dermatologists	101	96%	NR
Dumestre and Fraulin [26], 2017	Canada	Cross-sectional	Patients, plastic surgeons, and residents	Section of plastic surgery	86 patients, 3 plastic surgeons, and 12 residents	57% of patients, 67% of surgeons, and 92% of residents	NR
Wang et al [37], 2017	China	Cross-sectional	Patients	Dermatology clinic	474	89%	Mean 31.9 (SD 11.7)
Marshall et al [3], 2018	International	Cross-sectional	Journals	Google Images and open-access articles	94	N/A	N/A
Milam and Leger [33], 2018	United States	Cross-sectional	Dermatologists	Board-certified dermatologists practicing in the United States	107	69%	Mean 47.2 (SD 11.7)
Nair et al [16], 2018	India	Cross-sectional	Patients	Ophthalmic plastic surgery clinic	280	NR	Mean 40.2 (range 18-82)
Dumestre and Fraulin [27], 2020	Canada	Cross-sectional	Plastic surgeons, residents, and patients	Section of plastic surgery	16 plastic surgeons, 24 residents, and 84 patients and parents	51% of surgeons and residents and 56% of patients	NR
Lessing et al [32], 2019	International	Cross-sectional	Journals	Top 10 impact factor general medical journals	10	N/A	N/A

Table 2. Ethical aspects of medical photography for publications.

Study, year	Study aim	Key findings
Jones [14], 1994	To determine common practices and attitudes toward medical photography among hospital patients	Most departments insist on written informed consent. When releasing clinical slides for publication, most departments insist that patient consent is obtained.
Cheung et al [22], 2005	To investigate patients' attitudes toward medical photography and consent use at an emergency department	Most participants gave consent for publication of images in a medical journal or books but were more likely to refuse consent for use of images on internet medical sites.
Taylor et al [8], 2007	To investigate awareness of and compliance with present regulations regarding clinicians taking digital photographs of patients	Less than half of the surgeons reported always obtaining consent, more often verbal than written for different purposes. The process of consent must include the option that consent may be withdrawn at any time before the information has passed irretrievably into the public domain.
Lau et al [15], 2010	To explore patient perception of digital photography	Approximately half of the patients would consent for each purpose of use.
Adeyemo et al [10], 2012	To determine acceptance and perception of medical photography among Nigerian patients	Most respondents indicated that their consent should be sought for each purpose.
Kunde et al [31], 2012	To review ethical and legal considerations of clinical photography in dermatology and present a hypothetical medicolegal scenario	Verbal consent would be commonly obtained for different purposes, including publication.
Devakumar et al [25], 2013	To explore the issues around photography in low-resource settings by conducting discussions with medical doctors and researchers who are currently working or have recently worked in low-resource settings with children	Participants considered that informed consent is required, but its form may vary depending on the context. Protection of the rights of children is especially important in relation to photographs.
Hacard et al [29], 2013	To evaluate patients' perceptions of medical photographs	Written consent was considered necessary for adult and pediatric patients.
De Runz et al [24], 2014	To analyze the use of photography by plastic surgeons, the perception of this use by the patients, and medicolegal and ethical consequences	Most of the surgeons considered that verbal consent or no consent is sufficient for taking patient photographs.
Leger et al [12], 2014	To investigate patient opinions on clinical photography	Respondents preferred permission for photographs to be obtained in written form.
Caires et al [11], 2015	To evaluate the knowledge of health care professionals regarding taking medical photographs within the hospital environment among hospital staff	Verbal and written consent for taking the photographs was lacking.
Indu et al [30], 2015	To assess the awareness of oral pathologists regarding various aspects of medical photographs	Most students and faculty members informed the patients of the purpose of the photograph and took verbal consent. Most of them mentioned to the patient their right to withdraw consent.
Rimoin et al [34], 2016	To elucidate the nature of use, storage, and informed consent for digital photography among Mohs surgeons	A very small number of responders pursued some form of consent before taking photographs, with most preferring verbal consent over written consent. They considered that consent should be obtained for different purposes.
Abbott et al [9], 2017	To evaluate the understanding of the use of smartphones in clinical practice regarding professional and legal risks	Patient consent was not often documented regarding different uses of patient photographs; respondents mostly did not receive information on relevant guidelines.
Dumestre and Fraulin [26], 2017	To evaluate a smartphone app for clinical photography regarding patient security among plastic surgeons, plastic surgery residents, and patients who had undergone plastic surgery	The app ensured adequate consent for educational and research purposes but was inadequate for publication and disclosure to the public.
Wang et al [37], 2017	To assess the perception and acceptability of medical photography in patients of dermatology	Almost half of the respondents considered that oral consent only should be obtained before taking medical photographs, whereas the other half of the respondents answered that written consent should be obtained. Most of the respondents argued that all possible image uses should be detailed in the consent form.
Milam and Leger [33], 2018	To examine dermatologists' current practices in medical photography	Most respondents agreed that patients should be allowed to withdraw consent and should be informed of the use of their photographs on each occasion, including publication.

Study, year	Study aim	Key findings
Dumestre and Fraulin [27], 2020	To evaluate a smartphone app for clinical photography that prioritizes and facilitates patient security	Patients considered the consent process acceptable in the app. Surgeons and residents felt that the consent process was superior or equivalent to previous methods.
Costa et al [23], 2020	To evaluate the behavior of dentists on the use of patients' images	Participants considered that informed consent for sharing patients' images, including in publications, can be verbal or absent when the patient cannot be identified.
Roguljić et al [35], 2020	To explore opinions of patients, students, and doctors on the acceptability of different levels of deidentification and the informed consent needed for publication in academic journals	All respondents reported increased preference for more stringent forms of permission as the level of identifiability in photographs increased.

Table 3. Practices and use of medical photography for research publications.

Study, year	Study aim	Key findings
Jones [14], 1994	To determine common practices and attitudes toward medical photography among hospital patients	Most respondents felt that, even though the patient was consenting to treatment by being in hospital, they still had a right to refuse to be photographed.
Windsor et al [38], 2006	To summarize 3 months of digital photography taking in an adult emergency department	The use of digital photographs and video clips in clinical settings is very useful in creating a database of confidential medical records that can be used for medical teaching and publication.
Taylor et al [8], 2007	To investigate awareness of and compliance with present regulations regarding clinicians taking digital photographs of patients	Patients considered themselves insufficiently informed of their right to withdraw consent. Surgeons used methods of deidentification for patient photographs for teaching and publication purposes. They stored password-protected photographs in PCs and personal cameras.
Clover et al [6], 2010	To analyze the effectiveness of blacking out the eyes in facial photographs through alternative techniques	Deidentification failed most in the group with a covered eye area in a photograph, followed by covering the eye and nose and covering the eyes, nose, and mouth.
Lau et al [15], 2010	To explore patients' perception of digital photography	Patients preferred the use of hospital cameras and nonidentifiable photographs for all purposes.
Engelstad et al [28], 2011	To test the hypothesis that unaltered features from an original full-face patient image could be blended with other facial images to create a unique facial composite that deidentifies the patient	Facial composites were more effective at deidentification than traditional methods.
Adeyemo et al [10], 2012	To determine acceptance and perception of medical photography among Nigerian patients	Patients had high acceptance of medical photography, especially of nonidentifiable photographs. The use of institutional cameras operated and stored by the patients' physicians was the preferred method.
Kunde et al [31], 2012	To explore ethical and legal considerations of clinical photography in dermatology and present a hypothetical medicolegal scenario	Dermatologic registrars used personal smartphones for taking photographs for different purposes, such as to obtain advice from peers, teaching, sharing with colleagues, treatment and disease monitoring, and publication.
Devakumar et al [25], 2013	To explore the issues around photography in low-resource settings	Photographs of children in medical and research settings are useful as they enrich teaching, research, and advocacy.
Hacard et al [29], 2013	To evaluate patients' perceptions of medical photography	Low acceptability of the use of the images in professional emails, health magazines, television health programs, and medical websites. Publication in medical scientific articles was significantly more acceptable for adults than for children.
De Runz et al [24], 2014	To analyze the use of medical photography by plastic surgeons and perception of this use by the patients	Patients and surgeons had high acceptance of taking medical photographs for diagnosis and treatment follow-up and lower acceptance for publication purposes.
Leger et al [12], 2014	To investigate patients' opinions of clinical photography	Nonidentifiable photographs taken by their physician with clinic-owned cameras within the institution for all purposes were preferred. Race and ethnicity, income level, and age influenced the patients' answers.
Abbott et al [9], 2017	To evaluate the understanding of the use of smartphones in clinical practice regarding professional and legal risks	Most respondents had and used smartphones for taking medical photographs for different purposes.
Dumestre and Fraulin [26], 2017	To evaluate a smartphone app for clinical photography regarding patient security among plastic surgeons, plastic surgery residents, and patients who had undergone plastic surgery	Patients: high acceptance of use for educational, research, communication, and medical documentation purposes and less acceptance for publication in a public medium; surgeons and residents: the app will be suitable for use when certain issues regarding consent and protection of confidentiality are overcome
Wang et al [37], 2017	To assess the perception and acceptability of medical photography in patients of dermatology	Patients' physicians using clinic-owned cameras were the most accepted as photographers. Low acceptability of use was reported for medical websites and televised health programs.
Milam and Leger [33], 2018	To examine the current medical photography practices of dermatologists	Respondents reported the use of medical photographs for different purposes, including research and publication. They used digital cameras, personal phones, and electronic medical record applications. Photographs were stored in the office computer with various security measures and shared via email with colleagues and patients.
Nair et al [16], 2018	To assess patient perceptions regarding medical photography and smart devices	Most patients accepted the use of smartphones for medical photography, but only a third approved the use of medical photographs in presentations and medical journals. Patients preferred to be photographed by their physician with their own camera or an institutional camera at the institution.

Study, year	Study aim	Key findings
Dumestre and Fraulin [27], 2020	To evaluate a smartphone app for clinical photography that prioritizes and facilitates patient security	Patients: the purpose of the app was well explained, and it was perceived as safe; surgeons and residents: respondents believed the app was suitable for broad implementation to receive and send patient photographs
Abouzeid et al [21], 2020	To evaluate the awareness of practice, opportunity, and morals of dental photography among undergraduate dental students	Almost all students take photographs on a regular basis. Phone cameras were the most commonly used device, followed by digital single-lens reflex cameras. Verbal consent was obtained before taking photographs. For research publication, they edited the photographs using specific software or by covering the eye area. More training in photography techniques was perceived to be necessary.
Costa et al [23], 2020	To evaluate the behavior of dentists in using patients' images	The most common purposes of the use of photographs were didactic or academic. Discussion groups on social media may increase the knowledge of the use of patient photographs.

Table 4. Medical photography in research publications.

Study, year	Study aim	Key findings
Shintani and Williams [36], 2012	To investigate how guidelines on the protection of patient anonymity are actually implemented and how effective such methods of protection are in 3 oral surgery journals	Most of the published photographs were of the entire face or a part of the face. Masking the eye area was observed in half of the facial photographs, and deidentification failed.
Marshall et al [3], 2018	To analyze current practices used in patient facial photograph deidentification	Sensitive medical photographs from articles freely available were found on Google Images. A small number of articles reported obtaining written informed consent for publication of medical images from patients undergoing transgender surgery.
Roberts et al [7], 2016	To analyze the current practices used in patient facial photograph deidentification and set forth standardized guidelines for improving patient autonomy that are congruent with medical ethics and health insurance	Facial image anonymization guidelines varied across journals. When anonymization was attempted, 87% of the images were inadequately concealed. The most common technique used was masking the eyes alone with a black box.
Lessing et al [32], 2019	To assess consent requirements in a sample of 10 top impact factor general medicine journals that publish clinical images	All journals had web-based information regarding clinical image consent requirements. Written consent was required for all identifiable photographs. No journals were fully compliant with ICMJE[a] consent recommendations.
Roguljić et al [2], 2022	To analyze policies of journals that publish research and their implementation regarding patient consent for facial image publication	Only approximately half of the analyzed journals had a specific policy on clinical images. A small number of articles that published recognizable patient facial images included a statement on consent for image publication.

[a] ICMJE: International Committee of Medical Journal Editors.

Ethical Aspects of Medical Photography for Research Publications

Almost all studies that analyzed the ethical aspects of medical photography in research publications (19/20, 95%; Table 2) reported that the consent process was not conducted properly for different uses of patients' photographs, including for journal publications. A total of 5% (1/20) of the studies stated that they addressed medicolegal issues [31], but the study findings were not put in the context of privacy protection legal regulations. Studies that included patients and health professionals (13/20, 65%) were affirmative of the practice of obtaining informed consent for the use of patient medical photographs. However, relevant stakeholders recognized different levels of potential risks if patient medical photographs were used for different purposes, from treatment planning and follow-up in medical documentation to education and different forms of publication.

Studies that investigated patients' perspectives on the importance of informed consent (8/20, 40%) showed that patients were aware of the increased risks of being recognized after the publication of their medical photographs by anyone who has access to the publication [10,12,14-16,22,35,37]. Patients in an emergency medicine department were more likely to refuse consent for the use of images on internet sites, but they would provide consent for the purposes of medical education, medical books, or journals [22]. Patients in that study were not aware that medical books or journals could also be accessed on internet sites [22]. Patients in a plastic surgery department were more likely to approve the use of medical photography for diagnosis and treatment follow-up but were also less likely to consent for publication purposes [24]. A total of 10% (2/20) of the studies showed that patients preferred to be offered consent for a specific purpose and not a general consent for any type of use of their medical photographs, including identifiable and nonidentifiable photographs [10,14]. Furthermore, patients preferred being offered a written consent form rather than being offered oral consent [12,14,29].

Studies that involved plastic surgeons and dentists showed diversity in written informed consent for taking photographs of patients. A total of 17% (5/30) of the studies showed that patient consent was not always obtained for taking and using patient medical photographs and that the prevalent opinion was that verbal consent was sufficient [3,8,23,24,26]. Studies that involved dermatologists (2/20, 10%) [9,33] showed that most of them did obtain consent for patients' photographs, but they did not consider it necessary. In addition, dermatologists emphasized the need for better education on this issue and the need to create more realistic and practical policies for everyday practice. They also asked for better policies and tools for patients to exercise their right to withdraw their consent at a later time.

A small number of studies (4/20, 20%) investigated other health professionals' opinions regarding ethical publishing of medical photography, involving residents, students, nurses, nursing technicians, and physical therapists [11,30,31,35]. These studies reported that health professionals in general had a lack of knowledge regarding the need to obtain patient written consent and the use of patient medical photographs in general. A survey of nursing staff, physical therapists, and physicians reported a lack of knowledge of both verbal and written consent for taking patient photographs [11], whereas undergraduate and postgraduate students considered that verbal consent was sufficient for medical image publication [30,35]. Similarly, in the study by Kunde et al [31], 4 out of 13 dermatology registrars reported that they used verbal consent for taking photographs of patients for publishing purposes.

In total, 7% (2/30) of the studies investigated the issues of taking and using medical photographs of children [25,29]. In the focus group study by Devakumar et al [25], pediatricians emphasized that, although photographs are valuable resources, they might be potentially harmful. Thus, written informed consent was considered mandatory. In addition, they thought that the publication of photographs from this patient population required more stringent forms of informed consent to protect children. Similarly, a questionnaire survey by Hacard et al [29] included patients from a dermatology department and parents or legal guardians from the pediatric department and showed that acceptance of medical photographs was high among both groups. They considered that written informed consent was required for each purpose of use, with participants from the pediatric department being stricter in this aspect.

Practices and Use of Medical Photography for Research Publications

Studies addressing practices for taking medical photographs (20/30, 67%; Table 3) were conducted among different stakeholders: patients, medical staff, graduate and postgraduate students of medicine and dental medicine, residents, dermatologists, dentists, and plastic surgeons. The devices used for taking medical photographs included institutional cameras, personal cameras, and smartphones [9,29,38]. The device most often used for taking patient photographs was a personal camera (smartphone) [8,9,16,21,29,33], but 10% (3/30) of the studies showed that patients preferred to be photographed by their physicians using institutional cameras and in an institutional setting [10,15,37]. Patients considered that the use of personal devices, particularly smartphones, for taking medical photographs constituted a potential breach of patient-physician confidentiality [16].

Patients and physicians showed a high level of acceptance of medical photography for different purposes, such as medical documentation, research, communication, and education, but less for their publication in a public medium such as medical websites, professional emails, health magazines, and television health programs [24,26,29,37]. Furthermore, they preferred nonidentifiable over identifiable photographs for all types of use [10,12,15,35]. However, the studies also showed that conventional methods of deidentification of facial photographs concealing the eye area are not sufficient to achieve nonidentifiability [6,7]. The exception was the study by Engelstad et al [28], which demonstrated successful deidentification using a blended facial composite technique. This technique combined significant components of the original patient's photograph with cropped parts of the head and neck from other photographs using a computer software program to create nonidentifiable photographs that still presented patient details relevant to the clinical findings.

Several studies (8/20, 40%) reported that both patients and physicians considered important to ensure secure data storage, maintenance of privacy, and controlled access to the images [8,9,14,16,26,29,30,37]. A total of 7% (2/30) of the studies reported that dental students and dentists lacked knowledge and training regarding the techniques of taking and managing patient photographs, including for the purpose of publishing [21,23].

Medical Photography in Journal Articles

Studies addressing practices of publishing medical photographs in medical journals (5/30, 17%; Table 4) demonstrated a large diversity in publishing practices regarding consent for publication. Studies that analyzed high-impact general medical journals [32] or journals publishing dentistry and otorhinolaryngology research [2] showed that journal policies regarding the consent process and consent forms were insufficient and that existing ethical professional guidelines were not fully implemented in actual practices. A total of 40% (2/5) of the studies analyzed the deidentification of facial photographs published in medical journals and showed that the most common techniques, such as concealing the eye area, were not sufficient to protect the patient's identity [7,36]. The authors of these studies emphasized the importance of improving the policies regarding consent for publication of patient facial photographs. All facial photographs, with or without the applied deidentification technique, should require separate written consent for publication from the patient.

The only study that analyzed web access to patient-sensitive data published in open-access journals and platforms was the study by Marshall et al [3]. This study showed that patient medical photographs, including the face (8.1% of the photographs), were published in open-access formats and could be accessed easily via a Google Image browser, indicating a serious lack of protection of patient-sensitive data.

Discussion

Principal Findings

Our scoping review identified 30 studies that investigated different aspects of publishing identifiable patient photographs in research journals over a period of >25 years. It seems that, despite existing legal and professional guidelines regarding the use of patient photographs, obtaining informed consent properly is a challenge for many health professionals not only for scientific publications but also for other purposes. Relevant stakeholders did not always consider that only written informed consent was necessary for the publication of a patient photograph, and they also considered that it was possible to use patient photographs after obtaining oral consent or even without consent. Although relevant stakeholders were aware of the potential issues of using patients' medical photographs in terms of violating privacy and confidentiality, they did not have a satisfactory level of knowledge, skills, or tools to put existing guidance on medical photography in research into practice. Finally, there was little awareness of the current challenges, such as the protection of patients' clinical images and their permanence and availability in a digital environment.

Our study had some limitations. Most of the studies included in this scoping review (22/30, 73%) did not investigate medical photography publishing as the primary topic but as one of several purposes and aspects of medical photography. In addition, the studies did not define clear criteria for the deidentification of facial photographs. Although our search strategy did not have language restrictions, 97% (29/30) of the included studies were in English, and it is possible that there are studies in other languages that were not captured by the search of standard databases, registries, and gray literature sources. The methodological issues of the studies, such as questionnaire survey designs and insufficient reporting of methods and results, which might influence the validity of the studies, also limit the comparisons and generalizability of the findings.

We also did not assess the compliance of practices with legal standards as they varied in the countries in which the studies were performed. We presumed that the studies considered the contemporary legal regulations and investigated the compliance, practices, and opinions of the participants in relation to these regulations. The protection of patients' personal data is ensured by strict legal regulations such as the Health Insurance Portability and Accountability Act in the United States [39]. In Europe, the General Data Protection Regulation (GDPR) provides the strictest protection of patient personal data, including for research purposes [40,41]. According to the GDPR, consent is one of the legal bases for lawful processing of personal data and is most relevant for publications in scientific journals. Accordingly, a research participant consents to have the right to be informed, withdraw consent, have access to data, rectify the data or erase them, restrict data processing, and obtain and reuse their data (data portability) [40,41].

The problem of following procedures for obtaining valid patient consent in clinical practice is not limited to the purposes of publication but is a part of the general challenge in medical practice. A recent updated systematic review by Glaser et al [42] regarding interventions to improve patient comprehension in obtaining informed consent for medical procedures showed that, although progress was achieved, the consent process does not always meet 4 key elements of valid informed consent—decision capacity, documentation of consent, disclosure, and competency. The findings of our scoping review focused on the ethical publication of patient photographs in scientific journals and also showed that there are problems not only with the existing guidance, such as successful deidentification of published photographs, but even more with implementing existing guidance in practice, particularly in relation to proper and adequate informed consent. For example, despite the existence of ethical guidelines created by relevant professional or governmental organizations on the importance of obtaining patient consent in written form [5,43], studies that investigated the practices of obtaining informed consent for different uses of medical photographs (7/30, 23%) showed that even high-profile academic clinicians still considered verbal consent sufficient [8,9,23,26,33,35,37]. In another study, dermatologists reported that they did not always document patient consent for a specific purpose [9], indicating the need for better education at all career stages as well as the creation of more practical guidance for the implementation of standards for consent procedures in everyday practice. An unsatisfactory level of knowledge was also present among other health professionals as well as among patients [9,11,24,30,35]. Inasmuch as most of the analyzed studies in our scoping review used cross-sectional designs (26/30, 87%), future studies should have an interventional or qualitative design to investigate possible solutions for increasing the level of knowledge of all relevant stakeholders. We also did not identify studies that investigated whether consent for a research study included consent for publication and whether that consent provided sufficient information to the participants regarding how their photographs would be published and under which publishing license.

As open-access publishing has become a common format for medical research, patients' informed consent for identifiable photographs in open-access journals deserves special attention. Considering that patients can be a very heterogeneous group regarding educational level and socioeconomic background, health professionals should be able to explain to them that scientific articles published in open-access journals could be as accessible as any other information on the internet. It seems that patients do not always perceive that scientific journals are available on the web in the same way as any other content on the internet. For example, patients in an emergency department were more likely to consent to the use of their medical photographs in medical publications than on websites [22]. Thus, it is important that patients are fully informed of the implications of publishing photographs in a web-based medium before signing the consent form. They should be warned that open-access formats allow access to their photographs without any safeguards, leaving no possibility to withdraw or control their future use.

Generally, both patients and health professionals had high acceptance of medical photography and found it useful for many purposes, but patients preferred the use of nonidentifiable photographs [10,12,15]. Several studies that analyzed methods of deidentification of facial photographs (4/30, 13%) showed that conventional techniques were insufficient, and such photographs cannot be considered as nonidentifiable [6,7,35,36]. Such photographs should be considered as potentially reidentifiable, which leads to the conclusion that, in many situations, it is not possible to determine whether the photograph is identifiable. Furthermore, different computer programs have been developed to identify a person from a photograph (eg, DeepFace, Visual Search, Social Mapper, and Amazon Rekognition) with high levels of accuracy [44]. Patients may not be aware of this issue, but physicians should anticipate such situations and protect patients by providing proper informed consent. Although health care professionals commonly use medical photography in medical documentation, patient privacy becomes jeopardized when such photographs are used for other purposes such as communication with colleagues, lectures, presentations, or publications [43]. Patients were more likely to allow the use of their photographs for medical documentation, treatment follow-up, and education than for publications, websites, social media, and televised programs [26,29,37]. These findings suggest that patients recognize the increased risk of violating their privacy in a public environment regardless of their general affirmative attitudes toward medical photographs.

The studies included in this review addressed not only fully identifiable photographs but also potentially reidentifiable photographs as well as those that were considered to be nonidentifiable. The distinction between these types of photographs is very difficult [6-8], and it has been shown that patients and their families or social environment can recognize them even if the photograph that was published was considered to be fully nonidentifiable [45]. It would be safe to consider that all photographs of a patient's body are potentially identifiable or reidentifiable and that consent for the publication of such photographs should be sought.

The full maintenance of medical photography integrity requires practical protocols that should be in accordance with current guidelines and best ethical practices [5,46]. However, there are still different practices for taking and storing photographs, so it seems that the process of taking patient photographs has not yet been standardized and might be one of the reasons why the consent processes for their different uses are not often performed and reported in line with best ethical practices. Studies that analyzed the clinical practices of taking medical photographs (20/30, 67%) showed that patients were more likely to be photographed by their physicians than by other health personnel. In addition, patients were more consenting of being photographed with institutional cameras than with personal devices. These findings indicate that taking an identifying photograph is a sensitive procedure in which patients expect a high level of confidentiality and privacy. Following established guidelines such as those from the ICMJE would be a good beginning toward the responsible publishing of medical photography.

The analysis of medical journals also demonstrated the problem of an insufficient consent process for the publication of patient photographs. As journals have been shown not to be fully compliant with ICMJE consent recommendations, it was recommended that standard consent forms for the publication of identifiable images in medical journals should be developed [32]. Studies that investigated the ethical publication of identifiable photographs of patients (5/30, 17%) came to a very similar conclusion: there is a lack of consensus from journal editors and publishers, and uniform publishing policies are needed. The aforementioned recommendation seems reasonable and actionable as editorial organizations have created similar standards for other declarations in published studies, such as competing interest declarations from the ICMJE [47]. As previously mentioned, the digital environment represents a new challenge for publishing practices, especially with the growing trend of open-access publications. Journal editors and publishers should make clear what their publishing practices involve with regard to the use and sharing of published patient photographs, develop appropriate procedures for adequate and responsible declaration of obtaining informed consent for photograph publication that are separate from declaring and describing informed consent for research, and incorporate the submission of relevant declarations in web-based manuscript submission systems. They also have to protect the identity of the patients and not receive or publish consent forms from patients but rather ensure that authors provide declarations that appropriate procedures were followed and that patients gave informed consent for publishing their (identifying) photographs. If journals advise authors to provide proof of consent for persons mentioned in the acknowledgments [5], then they have to ensure the integrity of publishing patient photographs.

Gaps in Knowledge

This scoping review provided information about the attitudes, opinions, and practices regarding medical photography among relevant stakeholders and showed that they recognized the issues of privacy protection when medical photographs are used, particularly in publications. The impact of recent legal regulations related to personal data protection, such as the GDPR [40,41], on the publication of potentially identifiable photographs of research participants needs also to be further investigated. As it was shown that all stakeholders lack knowledge regarding the ethical publication of patient medical photographs, interventional studies are needed to address effective education and training. In addition, there is no evidence in the literature of the knowledge of stakeholders regarding published medical photographs in freely available web-based formats, particularly those published under licenses for wide use. An emerging issue that has not yet been addressed is the publication of medical photographs in preprints. Preprints, as "complete and public drafts of scientific documents, not yet certified by peer review" [48], do not pass the same scrutiny as regular journal publications, but their number and importance have enormously increased [49,50]. The latest update of the ICMJE Recommendations for the Conduct, Reporting, Editing, and Publication of Scholarly Work in Medical Journals [5] in 2021 emphasized the need for appropriate declarations regarding published articles in preprint archives, such as disclosure of funding sources and disclosure of interest, but ethical issues about consent for patients' photographs were not mentioned. As one of the main aims of preprints is to increase the discoverability of research, the openness of such publications may be a facilitator for the research community but a threat and concern for patients whose photographs may be published in a way that will hinder the protection of their privacy. A recent study of editorial policies in preprint archives did not report on patient privacy protection, and only 20% of the archives in health sciences stated that they followed the ICMJE recommendations [51]. Future studies should investigate the practices of publishing patient photographs in preprints.

Conclusions

This scoping review of opinions, standards, and practices in publishing identifiable patient photographs in almost a 30-year period leads to the conclusion that all stakeholders in this issue have not fully developed and implemented best-practice standards for publishing medical images, particularly identifiable photographs of individuals. They are also not ready for the challenges of new developments in how we communicate research. In a digital environment, the protection of patient privacy is especially difficult because of how research information is shared on the web and on social media. Furthermore, newly developed digital tools for the deidentification of photographs are not commonly used, although it is clear that a standard black tape across the eyes on a photo does not make the person nonidentifiable. Despite the existence of legal, governmental, and professional policies and guidelines, the consent process and obtaining informed consent for publication are often not properly conducted or adequately reported in scientific literature. Relevant professional and ethics organizations, as well as journals and publishers, should address the emerging challenges in privacy protection by developing and updating guidance, protocols, and tools to ensure best practices in publishing patient photographs in medical literature.

Acknowledgments

This study was funded by the Croatian Science Foundation (*Professionalism in Health—Decision making in practice and research, ProDeM*) under grant agreement IP-2019-04-4882. The funder had no role in the design of the study; the collection, analysis, and interpretation of the data; or the decision to approve the publication of the finished manuscript.

Data Availability

The data sets used and analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

MR, MM, and AM generated the idea and designed the study. MR, AU, and AM created the search strategy, and AU executed the search. MR, DŠ, TPP, MV, and AM participated in the screening or extraction and analysis of the data. All authors contributed to the interpretation of the results. MR and AM drafted the manuscript, and all authors critically revised it for important intellectual content. All authors approved the submitted version. All authors agreed to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved.

Abstract

Background: As the need for digital health care based on mobile devices is increasing, with the rapid development of digital technologies, especially in the face of the COVID-19 pandemic, gaining a better understanding of the industrial structure is needed to activate the use of digital health care.

Objective: The aim of this study was to suggest measures to revitalize the digital health care industry by deriving the stakeholders and major issues with respect to the ecosystem of the industry.

Methods: A total of 1822 newspaper articles were collected using Big Kings, a big data system for news, for a limited period from 2016 to August 2021, when the mobile health care project was promoted in Korea centered on public health centers. The R and NetMiner programs were used for network analysis.

Results: The Korean government and the Ministry of Health and Welfare showed the highest centrality and appeared as major stakeholders, and their common major issues were "reviewing the introduction of telemedicine," "concerns about bankruptcy of local clinics," and "building an integrated platform for precision medicine." In addition, the major stakeholders of medical institutions and companies were Seoul National University Hospital, Kangbuk Samsung Hospital, Ajou University Hospital, Samsung, and Vuno Inc.

Conclusions: This analysis confirmed that the issues related to digital health care are largely composed of telemedicine, data, and health care business. For digital health care to develop as a national innovative growth engine and to be institutionalized, the development of a digital health care fee model that can improve the regulatory system and the cost-effectiveness of patient care, centering on the Ministry of Health and Welfare as a key stakeholder, is essential.

KEYWORDS

digital health care; industrial ecosystem; network analysis; topic modeling; South Korea

Introduction

In the 21st century, epidemics, including Severe Acute Respiratory Syndrome and Middle East Respiratory Syndrome, spread rampantly, causing enormous social and economic losses and casualties. Above all else, pandemics such as COVID-19 are directly threatening our health and life, and modern society is entering a situation in which forecasting is more difficult than ever before [1,2]. Due to the prolonged COVID-19 pandemic, the amount of physical activity has decreased by 2%-30%. Measures such as quarantine and social distancing have only highlighted the importance of mental well-being and health care. The disconnection of communication in daily life due to social distancing has a great impact on the happiness and health of individuals. Social and economic factors such as unemployment and loss of income, depression, anxiety, and lack of social communication due to COVID-19 and associated restrictions on physical contact seem to have a negative impact on health. Accordingly, digital health care is being used to compensate for the collapse of the medical system due to the increase in infection and to manage health during disconnection. Digital health care is accessible regardless of location, enabling communication between users. Therefore, it is judged that more digital solutions will be essential not only for health care but also to solve the continuing COVID-19 pandemic and future pandemics.

As digital smart technologies such as smartphones, Internet of Things (IoT), wearable devices, and cloud computing, which were previously outside of the existing medical system area, are rapidly being grafted into the medical field, the utilization of digital health care has been emerging, through which health care can be received anytime and anywhere via various advanced information and communication technologies (ICTs) [3,4]. Digital health care technology is attracting attention as an effective untact (ie, without face-to-face encounters) treatment method in the COVID-19 crisis, which is recognized as an alternative that can be applied to patient evaluation and management [5]. Amid such changes, the medical environment is also expected to undergo a major change; the perception of telemedicine is changing due to the expansion of untact services and treatment caused by self-quarantine [6,7].

Digital health care was first mentioned by Seth R Frank in 2000 [8], which is defined as a service formed by the convergence of the internet and health care, combining health care with the core technologies of the so-called “4th industrial revolution,” including ICT, IoT, cloud computing, big data, and artificial intelligence (AI) [9,10]. In addition, digital health care provides a personalized health management process based on information, including health information, biorhythms, and health behaviors, collected through personal devices and health-related apps [11]. Restricted medical access and other unresolved problems in the medical field have traditionally limited access to medical data; however, a movement has recently emerged to foster the digital health care industry due to the revision of the 3 Data Acts and others [12,13]. A great feature of digital health care is that it enables the treatment and prediction of diseases by utilizing patient big data. Toward this end, it is necessary to effectively utilize big data while maintaining the security of personal information.

In Korea, regulations on data use have prevented digital health care companies from becoming active. However, with revision of the 3 Data Act, big data analysis using pseudonymized data became possible, and this is expected to be a turning point in digital health care innovation using AI and big data. Accordingly, as the development speed of digital technology has become rapidly high and various types of health care services based on mobile devices have been increasing, research is being actively conducted to expand the application of digital health care.

To date, studies on digital health care have mainly focused on user acceptance, intention, and willingness for continuous use. Becker [14] investigated the acceptance intention of mobile health (mHealth) apps, targeting German adults aged 18-35 years, finding that the leakage and loss of personal information in the medical sector is the most sensitive matter to users. In addition, Kim et al [15] analyzed the determinants of the intention to use wearable device products in a middle-aged and elderly population, with the goal of suggesting alternatives to the increase in health care demand and costs due to aging of the population. Moreover, studies on smart health care systems to expand the use of digital health care through big data case studies and providing patient-oriented services are being actively conducted. However, digital health care products involve many stakeholders before they are delivered to users. In the existing health care system, hospitals, pharmaceutical and medical device companies, and patients represent the main stakeholders, whereas the primary stakeholders in the digital health care industry are insurance companies, health care professional services, telecommunication companies, manufacturers of wearable devices (eg, biosensors), and health care app solution providers; thus, a new ecosystem is being formed.

In this changing paradigm, to activate and promote the utilization of digital health care, it is necessary to first understand the industry structure; however, the research in this field remains insufficient. In particular, digital health care products are closely associated with regulations and related policies because they affect the human body. For digital health care products to be practically used, it is necessary to establish future policy directions by grasping the relationship between stakeholders and issues regarding the industry.

Therefore, the aim of this study was to analyze the network of the digital health care industry using newspaper articles that form the basis of social debates on specific issues. Through this approach, we intend to suggest measures to revitalize the industry by deriving the stakeholders and major issues with respect to the ecosystem of the digital health care industry. In other words, by analyzing the ecosystem surrounding the current digital health care industry and identifying key stakeholders and major issues, we can propose policy alternatives for the future development of the industry. The ultimate goal is to provide personalized medical services through digital health care, thereby contributing to reducing social costs through preventive treatment.

Methods

Korean Digital Health Care

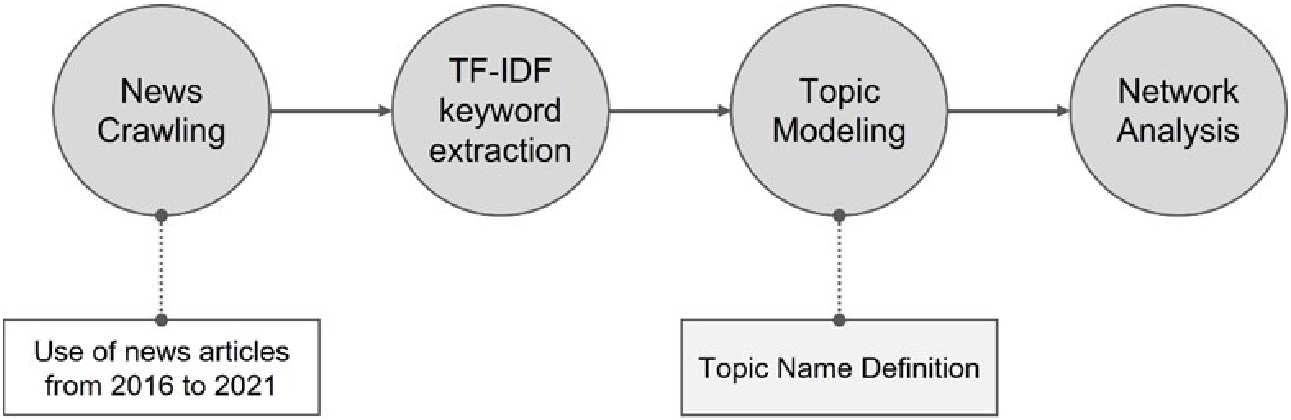
The major subject of digital health care in South Korea can be classified into a telemedicine pilot project and a mobile health care project. The former started with a remote image diagnosis pilot project as a collaboration between Seoul National University Hospital and Yeoncheon Public Health Center in 1988, which was promoted until the mid-1990s, but could not be activated due to factors such as limitations in ICT, an insufficient socioeconomic environment, and no supporting laws and systems [16]. Subsequently, after revision of the Medical Act to allow telemedicine between doctors and patients in 2003, digital health care has been used for health service accessibility, chronic disease management, and other health care services, centered on both local and public health centers [17]. In the telemedicine pilot that ran from 2014 to 2017, various types of pilot projects were applied for patients with chronic illnesses and visiting nursing systems to offer digital health care services for the disabled, elderly, and other vulnerable groups with access difficulty. A social consensus was not reached due to the risk of misdiagnosis and legal disputes in telemedicine. From this negative perspective, there were limits to the provision of telemedicine, which also limits the use of digital health care. Meanwhile, with the emergence of COVID-19, South Korea has temporarily allowed telemedicine, and has thus been able to provide patient-oriented medical services based on data obtained through digital health care. Through telemedicine, medical services were provided to patients who had difficulty visiting hospitals, improving health service accessibility. In the midst of such changes, even citizens who previously expressed negative views on telemedicine also empathize with the need for telemedicine, resulting in a trend of expansion in the utilization of digital health care in the country [18].

To overcome the limitations of the existing health care service and verify the effectiveness of mHealth, a mobile health care project has been promoted since 2016, centered on public health centers. For this purpose, an mHealth platform was developed, providing health care services by interlocking mobile apps and devices. To meet the demand for preventive health care, customized health care services are provided by utilizing digital health care based on ICT, big data, and other applications in health centers belonging to the public sector. For those with health risk factors for metabolic syndrome, doctors, nurses, nutritionists, exercise specialists, and other professionals are providing customized health counseling for 6 months. Digital health care is being utilized to reduce medical expenses and effectively help national health promotion by continuously managing and preventing chronic diseases and other conditions [19]. However, a health care service delivery system through digital health care has not yet been established owing to limitations in data utilization and related factors. Accordingly, to overcome such limitations and build an effective health management system utilizing digital health care, we performed an analysis on the stakeholders related to the digital health care industry.

Research Model

The purpose of this study was to derive measures to activate digital health care through network analysis. To this end, we used newspaper articles to identify trends in the related industries and analyze associated issues. Newspaper articles reflect public perceptions and industrial opinions on specific topics, enabling broader ecosystem analysis than possible with academic papers. In addition, as newspaper articles can reflect expert opinions, there is an added advantage of including the opinions of more professional stakeholders than possible when analyzing data from social networking sites (SNSs) such as Twitter and Google. The analysis period was set from 2016 to August 2021, when the mobile health care project was promoted, being centered on public health centers. For data collection, we used the news big data system BIG Kinds [20]. BIG Kinds is the largest search engine in Korea, providing articles from 11 central, 8 economic, 28 regional, 5 broadcasting, and 2 specialized magazines. To ensure data reliability, articles were collected using 11 domestic metropolitan newspapers, excluding economic magazines, regional comprehensive magazines, broadcasting companies, and specialized magazines. The search keyword was set to “digital health care,” and a total of 1822 articles were used for analysis. The study flow then followed the order term frequency-inverse document frequency (TF-IDF) keyword extraction, topic modeling, and network analysis (Figure 1).

Figure 1. Research model. TF-IDF: term frequency-inverse document frequency.



Analysis Method

The collected text data were analyzed using programs of R 4.1.1 (RStudio, Inc, Boston, MA, USA) and NetMiner 4.4.1 (Cyram Inc, Seoul, Korea). First, for data preprocessing, we used the “KoNLP” package, a Korean morpheme analysis function of R, and the “koRpus” package, which can extract language samples with a specific purpose for natural language research. Second, TF-IDF weights were extracted from the extracted text, and then major topics were derived using topic modeling. Third, network analysis was performed with NetMiner. Major stakeholders in the digital health care industry and related issues were analyzed through 2-mode network analysis, which can analyze the dual structure of data, such as the relationship between organizations and the relationship between an organization and its members. In other words, the 2-mode network was used because it enabled elucidating the relationships between stakeholders in the digital health care industry, between issues, and between stakeholders and issues.

The TF-IDF weight model is a statistical index to investigate the importance of keywords, which is the weight generated by multiplying the reciprocals of keyword and document frequencies. The larger the TF-IDF value, the more likely it is to determine the meaning or topic of the document to which the relevant word belongs; thus, it is utilized as a measure to extract major keywords from text data [21,22]. TF-IDF analysis is useful for analyzing issues frequently mentioned in SNS or news articles, through which we can discover the main content, information, network relationships, and other aspects regarding the issues of interest [23]. With topic modeling, all keywords included in text are organized by topic, where values within topics are automatically arranged in descending order. Since a large number of keywords are summarized into analysis units referred to as “topics,” the arranged topic can be considered a cluster representing the keywords that constitute the topic. Through this approach, it is possible to understand what topics the keywords are composed of, the importance between keywords, and similar characteristics [24,25]. Since topic modeling has the advantage of considering and identifying all of the multiple topics included in a single document, it has recently become more widely used in studies related to the fields of management, policy, and industry [26,27].

Network analysis is a method used to quantitatively analyze the relationship of individualized nodes, and is also a technique to identify the regular and stylized patterns that are consequently induced by interactions between actors [28]. Network analysis can find various hidden relationship types that are not normally recognized, and can structurally grasp the expression of specific relationship types [29,30]. Network analysis is divided into a 1-mode and 2-mode network according to the analysis target. One-mode network analysis is performed to analyze the relationship between objects when there is an n number of objects of the same nature, and the associative relation is analyzed after organizing the objects into an $n \times n$ matrix. When two objects with different properties exist, 2-mode network analysis is used to analyze the relation between them [31].

In addition, to interpret the network analysis, the degree of centrality is measured by using concepts such as the node, link, and connection degree [32]. Centrality is an index expressing the degree to which an actor is centrally located in the entire network; through centrality analysis, it is possible to identify key actors in the network and to determine how close each actor is to the center, along with similar metrics [33]. By showing the position each actor (nodes, keywords) occupies in the overall network and mathematically presenting their size, the actors can be separated into the core part and the periphery of the network. This approach can therefore enable searching for actors playing a central role in the network [34].

There are various types of centrality indices, including degree centrality, betweenness centrality, closeness centrality, and others. In this study, we used degree centrality, which is the most commonly used index in network analysis. Degree centrality refers to the degree of how many neighboring words are connected to a specific keyword; a higher number of connected words indicates higher centrality [35-37]. In degree centrality, the connection degree with other nodes is emphasized, which enables identifying how many relationships the node is involved in [38]. In other words, when using nodes with a high degree of connection, it will be easier to obtain information through their relationships with other nodes. If the nodes disappear in the network, interactions with connected neighboring nodes will be lost, resulting in loss of network function; thus, they are more likely to be key nodes in the network [39,40]. Therefore, in this study, we derived stakeholders and issues regarding the digital health care industry through 2-mode network analysis, also aiming to identify key stakeholders and corresponding major issues with respect to their relationship through evaluation of the degree centrality.

Results

TF-IDF Analysis

TF-IDF analysis to identify keywords that have been frequently utilized in the articles analyzed showed that the word with the highest importance among the top 25 keywords (Table 1) was “Medical Care,” indicating that discussions related to the application of digital health care in the medical field have been continuously ongoing. This highest-ranking word was followed by “Government,” “Hospitals,” “COVID-19,” “Care,” and “Insurance,” as the terms with the highest weight values. As a state of public health emergency has been declared in accordance with the spread of COVID-19 and telemedicine services have consequently expanded, it can be seen that the government is promoting precision medicine, smart hospital construction, and so forth. Conversely, keywords with relatively lower weight values were found to be “Regulation,” “Innovation,” “Samsung,” “Seoul National University,” and “Venture” (Table 1). These terms with lower weight demonstrate that discussion is insufficient on the regulatory policy that could be the basis for the activation of digital health care, and that cooperation between companies and universities for product development is not yet active.

Table 1. Top 25 ranking keywords based on term frequency-inverse document frequency (TF-IDF) analysis.

Rank	Keywords	TF-IDF
1	Medical care	60.75
2	Government	55.69
3	Hospital	48.76
4	COVID-19	46.52
5	Care	45.61
6	Insurance	44.98
7	Health	42.01
8	Information	40.43
9	Bio	39.92
10	Remote	37.15
11	Data	36.60
12	Company	36.29
13	USA	34.58
14	Seoul	33.84
15	Startup	33.23
16	Technology	31.70
17	Health	31.49
18	Digital	30.22
19	Communication	30.02
20	Economy	27.54
21	Regulation	27.41
22	Innovation	27.13
23	Samsung	26.48
24	Seoul National University	24.31
25	Venture	23.33

Topic Modeling Analysis

Topic modeling analysis identified a total of 7 topics; we directly assigned the topic name after identifying the correlation between keywords in the topic. Topics 2, 3, and 4 were assigned to "Government"; Topics 1 and 6 were assigned to "Medical Institution"; and Topics 5 and 7 were assigned the topic name "Company." Keywords belonging to the "Government" topic included Digital, Data, Support, Government, Regulation, COVID-19, and Platform, reflecting the recent movement to invigorate the digital health care industry through the government's vitalization of the usage of medical data, including the My Data project and the Bio-Health promotion policy. With COVID-19, the demand for untact medical care will further increase continuously in the future; thus, it seems that the necessity to vitalize related industries will be further highlighted. In addition, the government is preparing a foothold for nurturing the digital health care industry via related projects such as establishment of a big data platform, which has limitations in the private capacity.

The keywords belonging to the topic "Medical Institution" included Medical Treatment, Patient, Remote, Smart, Medical Care, and Policy. In the case of medical institutions, it is judged that since the number of outpatients has decreased due to COVID-19, the importance of telemedicine is expanding. In addition, this finding seems to reflect attempts to realize the effective management of patients with chronic diseases and the improvement of health service accessibility by building smart medical care using digital health care products. Conversely, the top keywords belonging to the topic "Company" were Service, Innovation, Device, Startup, Company, and Insurance. In the case of digital health care, those who have access to digital technologies such as AI, ICT, and IoT, even if not belonging to the existing digital health care industry, can readily enter the industry; accordingly, startups are actively being established. Furthermore, to develop digital health care products, cooperation with doctors and hospitals is required; thus, it seems necessary to establish a cooperative company-hospital-doctor system (Table 2).

Table 2. Topic modeling analysis.

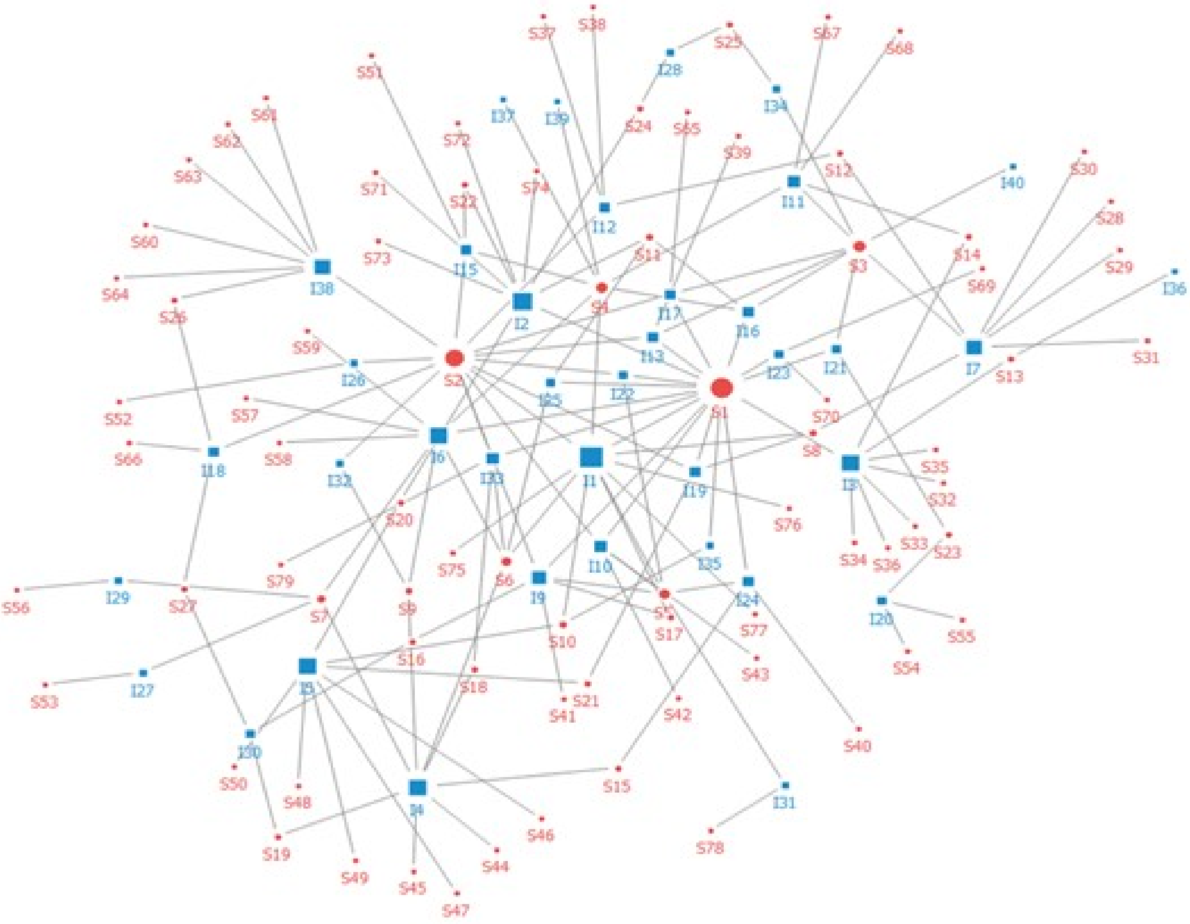
Themes and topics	Keywords
Government	
Topic 2	Digital, Health, Korea, Field, Support, Provision, Representative, Company, Communication
Topic 3	Health, Data, Market, Utilization, Investment, Cooperation, Nurturing, Research, Driving, Change
Topic 4	Government, Regulation, COVID-19, Bio, World, Platform, Plan, Individual, Data
Medical institution	
Topic 1	Government, Patient, Economy, Health, Technology, Medical Treatment, Construction, Cure, Region, Policy
Topic 6	Medical Care, Remote, Management, Smart, Seoul, Possibility, Special Zone, Country, Strategy, Apple
Company	
Topic 5	Service, Innovation, Device, Growth, Future, Startup, Center, Promotion, Diagnosis, Global
Topic 7	Industry, Company, Business, Hospital, Insurance, AI[a], Institution, Doctor, Expansion, Development

[a] AI: artificial intelligence.

Network Analysis

Network analysis was performed to analyze the ecosystem of the digital health care industry, and the relationship between nodes was identified according to the degree centrality (Figure 2). A total of 79 stakeholders and 40 key issues constituted the industrial ecosystem network. The major stakeholders included (1) government and regulatory agencies, represented by the government, Ministry of Health and Welfare, Ministry of Science and ICT, and Regulatory Reform Committee, and (2) medical institutions such as Seoul National University Hospital, Ajou University Hospital, and Gachon University Gil Medical Hospital. Stakeholders also included industrial and maintenance organizations such as the Korea Digital Health Industry Association, Asan Nanum Foundation, Samsung, LG Electronics, and KB Insurance.

Figure 2. Network analysis. Red indicates stakeholders (circles, S) and blue indicates the main issues (squares, I).



The stakeholder showing the greatest centrality was the Ministry of Health and Welfare. In other words, the Ministry of Health and Welfare raises core issues with respect to the network of the digital health care industry ecosystem, representing the actor connected with major issues and other actors in the industry. The government had the second highest centrality value, followed by the Ministry of Food and Drug Safety, Ministry of Science and ICT, and Korean Medical Association in descending order. Thus, the majority of government and regulatory agencies showed higher centrality, except for the three actors ranking in the top 10 with high centrality: the Korean Medical Association, Seoul National University Hospital, and SK Telecom. This seems to be because the digital health care industry ecosystem network became structured, led by the government, on the key issues and actors as the government-centered discussion on the activation of digital health care progressed (Table 3).

Next, we examined the major issues regarding stakeholders. The key issue in the digital health care industry ecosystem network was telemedicine introduction review, followed by passing of the 3 Data Acts, accuracy of AI technology in health care, deregulation of the health care sector, and smart health business (Table 4). Although South Korea has a strong personal information act, the development possibility of telemedicine has increased since revision of the 3 Data Acts was passed in the National Assembly. Particularly, telemedicine services have largely expanded in recent years since the state of public health emergency was declared according to the spread of COVID-19. Our findings further confirmed that deregulation in the health care sector, platform construction, and personnel training in related fields are emerging as major issues due to the expansion of private participation in digital health care. Moreover, other issues have been discussed, such as smart care policy, job creation, and AI real-time prediction of disease diagnosis and infection route (Table 4).

Table 3. Centrality of stakeholders.

Rank	Stakeholder	Number of nodes	Centrality
1	Ministry of Health and Welfare	17	0.425

Discussion

Principal Findings

As a result of network analysis on the digital health care industry, the government and the Ministry of Health and Welfare of Korea showed the highest centrality and were thus found to be major stakeholders; the major issues they had in common were review of telemedicine introduction, concerns over village doctors going bankrupt, and establishment of precision medicine–integrated platforms. Currently, the government is temporarily allowing telemedicine to respond to the spread of COVID-19, and intends to apply digital health care for remote patient monitoring and disease treatment to cope with insufficient medical demand. In addition, the issue of telemedicine is related to not only government agencies, including the National Assembly and Ministry of Science and ICT; but also medical institutions such as Seoul National University Hospital; and medical industry groups such as SK Telecom, Asan Nanum Foundation, and the Korean Medical Association.

In South Korea, telemedicine has been continuously discussed since the doctor/health care provider pilot project in 2002, but was not institutionalized due to the possibility of misdiagnosis, concerns over village doctors going bankrupt owing to the concentration of patients in large hospitals, and other related issues. As the digital health care industry has developed owing to the development of AI diagnosis technology, popularization of smart devices, and expansion of the utilization of medical data, the possibility of introducing telemedicine has also increased, and citizens' perception of telemedicine is changing owing to COVID-19. Therefore, the government, industrial sector, and medical care–related organizations should create institutional measures that could support digital health care through continuous discussions on the introduction of telemedicine that can contribute to improving public health. In particular, to prevent the concentration of large hospitals, which is a concern of medical institutions, it seems that patient convenience will improve, which could in turn improve the quality of medical care if primary medical institutions treat chronic diseases. Represcription of patients with mild conditions and patient monitoring for disease prevention could be achieved through the multidisciplinary treatment of primary medical institutions and large hospitals by utilizing digital health care products such as wearable devices. In this regard, an emergency medical system that can provide optimal treatment by collecting vital signs and images of patients in a severe emergency condition using digital health care in real time is being applied to the medical field.

Currently, there are only a few regional trauma and emergency medical centers in South Korea located in county areas, with the majority of such centers located in large cities such as Seoul and Gyeonggi. For emergency and trauma patients, the time required for treatment is important; thus, a balanced arrangement between regions is required. Therefore, digital health care can help to reduce the gap in medical infrastructure between rural and urban areas to better treat and manage patients with severe diseases. Expanding the functions of regional medical institutions by providing appropriate treatment for each emergency patient is expected to lay the foundation for expanding the utility of digital health care.

The major stakeholders of medical institutions and companies were found to be Seoul National University Hospital, Kangbuk Samsung Hospital, Ajou University Hospital, Samsung, and Vuno Inc, and their main issues were accuracy of health care AI technology and smart health business. Safety issues with respect to the utilization of digital health care have been constantly raised. Poor technical accuracy may lead to medical accidents; therefore, institutional strategies must be established in preparation of the possibility of misdiagnosis caused by product defects. It is necessary to improve the performance of digital health care products used for diagnosis and prescription, and to train professional personnel to develop and use the products appropriately. Furthermore, since data measurement must be accurate so as to increase the accuracy of diagnosis, it is judged thereby that periodic education for patients and medical staff in using the product will be necessary. Meanwhile, digital health care is an industry requiring medical information and continuous clinical data; with the increase in the use of digital health care, medical institutions are changing their position from a consumer to a supplier. Accordingly, if digital health care product development is accomplished through industry-university collaboration, it will be possible to develop safe digital health care products through continuously provided data, and in turn establish a smart health care business that can vitalize the industry.

Conclusion

This analysis confirmed that the major stakeholders in the digital health care industry of South Korea are largely composed of the government, medical institutions, and industrial companies, and that the issues related to digital health care largely consist of telemedicine, data, and health care business. We considered that all government, medical institutions, and industrial companies need to apply digital health care to the medical system through telemedicine and health care business establishment, and that cooperation is necessary among the government, medical institutions, corporations, research institutes, and related stakeholders. For practical cooperation, efficient use of data between institutions is required. Currently, medical data are stored in different ways between institutions, and there is a limit to the use of these data as there is no integrated management. Therefore, it is necessary to enable the use of integrated medical data for the commercialization of digital health care through standardized data linkage. This will not only revitalize the digital health care industry but will also lay the foundation for providing patient-tailored medical services, enabling the realization of precision medicine.

Meanwhile, for digital health care products to be effectively incorporated into the medical system, deregulation and the preparation for health insurance fees are necessary; however, there seems to be insufficient discussion on this aspect. The Ministry of Health and Welfare, a key stakeholder in the digital health care industry, is trying to vitalize the digital health care industry by preparing telemedicine health insurance rates; however, this analysis showed no connection of the Ministry with deregulation in the health care sector, the designation of regulation-free special zones, and other related issues. To vitalize the digital health care industry, it is necessary to expand the usability of patients through deregulation in related fields and application of health insurance fees; however, it seems that there has been no substantial institutional improvement on these aspects, as the discussion has mainly involved only government agencies, civic groups, and interest groups belonging to the related fields. Therefore, to promote the development of digital health care as a national innovative growth engine and its institutionalization, the development of a digital health care fee model that can improve the regulatory system and enhance the cost-effectiveness of patient treatment is essential, which will need to be centered on the Ministry of Health and Welfare as a key stakeholder. To revitalize the digital health care industry, as a national strategic project, the regulatory paradigm should be rationally established and centered on the market economy. This is expected to have a positive impact on the development of related industries by expanding into digital health care–related software, the medical service industry, and the insurance industry in the future, and ultimately enable a preventive-centered medical format through innovative medical service provision.

There are some limitations of this study that should be mentioned. Although newspaper articles have the advantage of providing a large amount of information, including opinions from various stakeholders on a specific topic, they also have a limitation in presenting data reflecting the popular experience on digital health care. Accordingly, future work exploring the issues regarding the digital health care industry by subdividing and analyzing data from SNS such as Twitter, blogs, and Facebook could better reflect the direct experience of digital health care and the views of the government, medical institutions, companies, and general consumers. In addition, we did not perform an analysis of the ecosystem according to the change in digital health care technology. In future research, it will be necessary to prepare a plan to provide digital health care for each patient type by analyzing the ecosystem according to technological change over time, which can help to identify issues and the structure of technology.

Abstract

A paradigm shift is underway in the patient-clinician relationship, driven by irreversible changes in information access, yet the model under which clinicians are trained, care is conducted, and care delivery is designed has not changed significantly even though we call it "patient centered." Humanity endured centuries in which even doctors had little idea what the patient's problem really was. Science slowly solved that, and for a century, only doctors could know what was worth knowing. Today, the rise of the internet and digital health has led to the end of that era. We are already witnessing early signs of the era of participatory health: genuinely empowered people living their lives and managing their health according to their own priorities, in partnership and consultation with physicians as needed. This may feel like a threat to the physician's sacred role, but it is no more so than when physicians adopted informed consent and then shared decision-making. In the 2010s, many pharmaceutical, medical, and health care companies started to use patient centricity as a mantra. We argue that to drive this paradigm change fully into existence, we need to shift "patient centricity" from a relatively passive process, driven by industry needs, into a far more active, collaborative process driven by both parties' needs and preferences. To build this new world of practice and workflow, we simply must engage with patients as true partners. To achieve medicine's new potential, it must be optimized around the wants and priorities of the ultimate stakeholder—the party that has the most at stake in how it all plays out: the patient. Patient design is the approach that can make it happen.

(J Med Internet Res 2022;24(8):e39178) doi:10.2196/39178

The Short History of Patient Empowerment

Health care has been going through a paradigm shift in the 21st century, as per Thomas Kuhn's 1962 classic, *The Structure of Scientific Revolutions* [1]. Kuhn was an American philosopher who was influential in both academic and popular circles, introducing the term "paradigm shift." His "blockbuster" book claimed that sometimes a scientific field discovers it was wrong about something important.

Kuhn [1] wrote that "perhaps science does not develop by the accumulation of individual discoveries and inventions," but that "discovery commences with the awareness of anomaly, i.e., with the recognition that nature has somehow violated the paradigm-induced expectations that govern normal science."

We are at the point of detecting such anomalies in health care. For centuries, the dominant paradigm has been that patients do not and cannot contribute to their care, especially medical decisions concerning their case. However, as the ivory tower of medicine started breaking down in the early 21st century, empowered patients started bringing real value to their own cases, violating the paradigm-induced expectations that dictate the culture of medicine [1].

Kuhn [1] wrote that when too many anomalies accumulate, a field goes into crisis mode until a new paradigm is developed and accepted. We assert that the current paradigm cannot explain nor cope with the cluster of anomalies in which patients are genuinely creating value in health care, and to ignore this is to suboptimize health care in a way we can no longer afford.

Thus, this crisis stage has arrived, but as often happens, the causes of the anomalies are poorly understood, which leads to confusion. No new paradigm can arise, letting the field advance, while confusion reigns. Here, we present those causes—the factors that did not exist a generation ago, and now do:

- Consumerism: the cultural willingness of consumers to pursue their own priorities
- Information liquidity brought by the internet, which eradicated the belief that only people from the “priesthood” could know certain facts
- Advanced consumer health technologies putting unprecedented knowledge in the hands of consumers who had previously been uninformed
- Global supply chains making it possible for new products and technologies to reach patients worldwide
- The rise of social media enabling peer-to-peer communication among patients about needs and solutions

In truth, patient empowerment has been evolving for decades, but information liquidity and access to technology made it explode in this century—and become visible to the naked eye. At the time of his death in 2006, “Doc Tom” Ferguson, MD, was working on a white paper funded by the Robert Wood Johnson Foundation, “e-Patients: How They Can Help Heal Healthcare,” documenting what empowered and engaged patients had been doing as far back as the 1980s. His colleagues published the paper in 2007, and, in 2009, founded the Society for Participatory Medicine [2].

The cultural transformation we call digital health represents this paradigm shift and is a continuation of that vision [3].

The Practical Reality of Patient Empowerment

Today, except for the commercial obstacle inserted by paywalls, patients can have access to the same online health care resources, studies, and data as medical professionals [4]. Empowered patients want to get engaged in their health or disease management. There are many examples of how patients take their lives into their own hands. From joining patient communities online to using a range of digital health sensors, they bring new value to the table. In doing so, they violate the paradigm’s cultural expectation that only doctors know anything useful [5].

Empowered patients also put pressure on regulators. The #WeAreNotWaiting movement is a community of patients with diabetes taking disease management into their own hands by organizing themselves and developing applications, platforms, and other solutions to help each other beat their disease. They even created the “DIY pancreas” software, which automatically provides patients with the right doses of insulin based on their blood glucose level [6]. The software was created entirely by the patient community with no contribution from medical professionals.

It should be noted that this OpenAPS (Open Artificial Pancreas System) software is the second most-forked item on all of GitHub (Microsoft Corp) because almost all patients tweak the code to suit their own biological response. In other words, the app is designed from the ground up to be fully configurable to suit individual needs. This is the most advanced example of patient design we have seen.

Patient scholars have published in prestigious medical journals [7-9]. The #PatientsIncluded movement has led to involving patients in medical events either as speakers or cohosts. Governments such as that of New Zealand have started developing digital health policies featuring empowered patients.

These examples further underscore that a more patient-inclusive design approach is already emerging and will inevitably be the norm. The only thing holding it back is cultural resistance, which is why we say digital health is a cultural transformation.

The Rise of Patient Centricity and Patient Design

In the 2010s, myriad pharmaceutical, medical, and health care companies started to use patient centricity as a mantra. Each claimed that their company is patient centric and thus ahead of the others. Pharmaceutical company executives started making “putting patients first” part of their slogans and internal documents. A 2020 survey revealed that 85% of companies were raising their investment in patient-centric capabilities over the next 18 months [10].

Patients want more reliable and relatable health information from the companies that make their medication, so this was an obvious step forward for the industry. A 2019 survey indicated that 76% of patients expect pharmaceutical organizations to provide them with tools and support services [11].

At the same time, policy makers started adopting this theme too. The US Food and Drug Administration (FDA) launched the Patient Engagement Advisory Committee in 2017. The committee provides advice to the FDA commissioner or designee on complex issues relating to medical devices, the regulation of devices, and their use by patients.

The Need for a New Level of Patient Centricity: Patient Design

To drive this paradigm change fully into existence, we call for changing patient centricity from a relatively passive process, driven by industry needs, into a far more active, collaborative process driven by both parties’ needs and preferences. In short, it is no longer viable for patient centricity to mean, “We were *thinking about you* while *we* made *our* decisions.”

From the patient’s perspective, patient centricity has been a passive process since the inclusion of their opinion in the final design depends solely on those who invite the patient's opinion. That approach may sound patient centric, but in this scenario, patients' voices literally have no power since all decisions are still made by the project organizers. Sociologist Sherry Arnstein bluntly called this tokenism [12].

In contrast to this, patient design means patients are involved in the highest level of decision-making in the organization, essentially having patients advise the chief executive officer of a company or the head of a health care organization.

Patient design is a so-called "co-design" approach. Co-design is defined as "a creative practice that can be used to improve customer experience and enhance value" [13]. The approach involves a wide range of people who are the experts of their experience and therefore make creative contributions that come from the perspective of the person who has the need. This is only possible by admitting to ourselves that the cared-for person just might know what they want and be well-informed! On what basis would someone assert otherwise?

The short-term benefits of such a co-design approach could include:

- More original ideas arising from more diverse perspectives and priorities
- Better achievement of consumer value (by incorporating the voice of the person for whom the project exists)
- Improved knowledge of patient needs
- Immediate validation of ideas
- More efficient decision-making
- Reduced development time
- Generally better cooperation between patients and companies or organizations.

The long-term benefits of such a co-design approach could include higher degrees of patient satisfaction, increased levels of support and enthusiasm for innovation, and a better relationship between patients and companies (Table 1).

Table 1. Comparison of patients' role and power in token patient centricity versus patients as empowered design partners.

	Token "patient centricity"	Patients as design partners
Involvement of patients	Passive; when asked by the power holders	Active at all times
Patients' decision power	None; their opinions are sought but need not be heeded. The system is free to continue not responding	Shared
Type of input provided by patients	Share their opinions when invited	Actively influence design decisions, including what gets worked on
Mode of involvement	Through surveys, questionnaires, and focus groups, all organized by the power holders	By sitting on project committees and advisory boards that set agendas
What level of decision-making patients influence	Any level within the organization	The highest level of decision-making

Real-life Practical Examples of How Patient Designs Work

This social movement has already progressed to where examples exist to illustrate the shift in thinking—the paradigm change.

Physical Products

For physical products, the Patient Innovation website [14] shares innovations developed by patients. Some focus on a disease, some are just for a symptom, while others enable a particular activity. What they have in common is that they all feature patient-centered thinking: they are expressions of what patients *want* to improve.

Research

In research, patient voices are calling for researchers to change priorities to match patients' urgent needs. The father of a son with suicide ideation told Dr Thomas Insel after a speech [15], "Our house is on fire, and you're telling us what you learned about the chemistry of the paint." The scientific literature may contain volumes about "the paint," but Insel realized "this gap between our scientific progress and our public health failure." He left academia to pursue product development to solve real-world problems.

The urgency articulated so powerfully by Insel's audience member precisely echoes the urgency of AIDS activists in the last century who demanded that science respond more to patients' immediate needs, not just long-term science.

When the husband of Bettina Ryll, MD, PhD, was dying of melanoma, she switched hats and observed the clinical trials process as a family stakeholder and was incensed to discover that researchers chose their work priorities without consulting the people who were dying. Today, she advocates in *Nature* for researchers to do just that [16].

Clinical Design

In clinical design, the Oral and Maxillofacial Surgery Department of Radboud University Medical Centre Nijmegen in the Netherlands redesigned the whole department's rooms based on advice from patients. This involved changes that enabled a more balanced patient-physician relationship and a comfortable atmosphere. They prioritized round tables over square ones for more friendly conversations and suggested brightly lit rooms with warm colors.

These examples merely illustrate how differently things can play out when, in fact, the patient truly has agency in influencing the nature of care.

While it may seem that we portray patient design in an almost utopian manner, we must note that such transitions—like all cultural changes—are time-consuming and complicated. An analogy is Title IX, a law introduced in the United States in 1972 that required schools to provide sports for girls, not just boys. It took a generation before the US women's soccer team won the World Cup in 1991. A major consequence of an incorrect paradigm is that if we do not let women onto the pitch (or patients into the executive world), we have no chance of discovering their actual suppressed potential.

Conclusion

We are at the end of the only period in history where physicians knew important scientific facts and medical insights that patients could not. For health care to achieve its potential in this new era, our methods, along with our paradigm, must change.

Before 1900, medical practice mostly lacked any scientific basis. Doctors were not even exposed to patients in medical school (patients were merely called "clinical material" in the Flexner Report!). Yet by the end of the 20th century, the internet let knowledge flow.

Now in the 21st century, a plethora of personal health devices gives patients access to *more* information than their physicians have. The possibility of true participatory medicine is on the horizon—patients with increasing autonomy living their lives according to their own priorities, in partnership and consultation with physicians *as needed*.

To build this new world of practice and workflow, we simply must engage with patients as true partners. To achieve medicine's new potential, it must be optimized around the wants and priorities of the ultimate stakeholder—the party that has the most at stake in how it all plays out: the patient. Patient design is the approach that can make it happen.

Abstract

Background: Efficacious mental health interventions for sexual and gender minority youth have had limited reach, given their delivery as time-intensive, in-person sessions. Internet-based interventions may facilitate reach to sexual and gender minority youth; however, there is little research examining their efficacy.

Objective: This study aims to describe the results of a pilot randomized controlled trial of *imi*, a web application designed to improve mental health by supporting lesbian, gay, bisexual, transgender, queer, and other sexual and gender minority identity affirmation, coping self-efficacy, and coping skill practice.

Methods: Sexual and gender minority youth (N=270) aged 13 to 19 (mean 16.5, SD 1.5) years and living in the United States were recruited through Instagram advertisements. Approximately 78% (210/270) of the sample identified as racial or ethnic minorities. Participants were randomized in a 1:1 fashion to the full *imi* intervention web application (treatment; 135/270, 50%) or a resource page–only version of the *imi* site (control; 135/270, 50%). The *imi* application covered four topical areas: gender identity; lesbian, gay, bisexual, transgender, queer, and other sexual and gender minority identity; stress and coping; and internalized homophobia and transphobia. Participants explored these areas by engaging with informational resources, exercises, and peer stories at a self-guided pace. Both arms were assessed via web-based surveys at baseline and 4-week follow-up for intervention satisfaction, stress appraisals (ie, challenge, threat, and resource), coping skills (ie, instrumental support, positive reframing, and planning), and mental health symptoms among other outcomes. Main *intent-to-treat* analyses compared the arms at week 4, controlling for baseline values on each outcome.

Results: Survey retention was 90.4% (244/270) at week 4. Participants in the treatment arm reported greater satisfaction with the intervention than participants in the control arm (t_{241}=–2.98; *P*=.003). The treatment arm showed significantly greater improvement in challenge appraisals (ie, belief in one's coping abilities) than the control (Cohen *d*=0.26; *P*=.008). There were no differences between the arms for threat (*d*=0.10; *P*=.37) or resource (*d*=0.15; *P*=.14) appraisals. The treatment arm showed greater increases in coping skills than the control arm (instrumental support: *d*=0.24, *P*=.005; positive reframing: *d*=0.27, *P*=.02; planning: *d*=0.26, *P*=.02). Mental health symptoms improved across both the treatment and control arms; however, there were no differences between arms. Within the treatment arm, higher engagement with *imi* (≥5 sessions, >10 minutes, or >10 pages) predicted greater improvement in stress appraisals (all *P* values <.05).

Conclusions: The results provide initial evidence that asynchronous psychosocial interventions delivered via a web application to sexual and gender minority youth can support their ability to cope with minority stress. Further research is needed to examine the long-term effects of the *imi* application.

KEYWORDS

lesbian, gay, bisexual, transgender, queer, and other sexual and gender minority; LGBTQ+; youth; adolescence; discrimination; minority stress; mental health; resilience; sexual and gender minority; SGM; intersectionality

Introduction

Background

Compared with their cisgender, heterosexual peers, sexual and gender minority (SGM) youth are at increased risk of experiencing a wide variety of negative mental health outcomes [1]. In a recent national surveillance survey conducted by the Centers for Disease Control and Prevention, 55% of gay, lesbian, or bisexual youth reported poor mental health during the prior 30 days. SGM youth were also twice as likely as their non–SGM youth counterparts to report feeling sad or hopeless and nearly 3 times as likely to have considered attempting suicide [2]. These disparities may vary further by race and ethnicity. A 2021 national survey of SGM youth (aged 13-24 years) in the United States sponsored by the Trevor Project found that racial and ethnic minority SGM youth were more likely than White non-Hispanic SGM youth to have seriously considered suicide in the prior year [3]. Taken together, these data underscore the need to address the well-being of diverse SGM youth populations through innovative mental health interventions [4].

The minority stress model [5,6] provides a framework for understanding the higher prevalence of psychological distress and negative mental health outcomes for SGM youth, as well as for identifying interventions to improve SGM individuals' mental health [7]. The minority stress theory proposes that SGM health disparities can be explained in large part by discrimination from a hostile homophobic and transphobic culture, which creates stressors unique to minority identity [8]. These stressors include harassment, victimization, internalized homophobia and transphobia, and expectations of rejection. These disparities may be further compounded if individuals experience multiple minority stressors because of having >1 minority identity (eg, discrimination because of sexuality, gender, racial, and ethnic identity) [9-12]. For instance, racial and ethnic minority SGM youth may experience sexual or gender minority stress within their racial and ethnic communities while also experiencing racial and ethnic minority stress within lesbian, gay, bisexual, transgender, queer, and other SGM (LGBTQ+) communities.

The transactional model of stress and coping [13] notes that individuals' ability to respond to stress and reduce its impact on their well-being begins with an assessment of the stressor (ie, primary appraisal) and their confidence and ability to respond to the stressor (ie, secondary appraisal). Interventions designed to target and transform appraisals of stress from that of a threat to more of a challenge through cognitive and behavioral coping strategies have been shown to support the mental health and well-being of adolescents [14-16]. Efficacious mental health interventions for SGM youth have focused on providing resources that scaffold the ability of SGM youth to perceive minority stressors as a challenge to be faced and overcome rather than as a threat, including strengthening the coping skills of SGM youth, affirming SGM identities, and strengthening supportive social connections [17-19].

Although prior research suggests that face-to-face interventions that include these components may improve the mental health of SGM youth [20], the reach and scalability of these programs have been challenging, given their time intensity and need for synchronous interactions, which have become increasingly difficult to coordinate amidst the COVID-19 pandemic [21,22]. At the same time, the need for scalable mental health resources has become particularly acute in recent years. For example, data from a large US survey of teenagers conducted by Common Sense Media [23] indicated that the amount of time SGM youth spent searching for mental health information on the web substantially increased during the pandemic.

In recent years, technology-assisted interventions have been posited to help decrease implementation challenges by serving as supplemental strategies to face-to-face psychotherapy. For example, Lucassen et al [24] found that their modular computer-delivered cognitive behavioral therapy program was feasible, acceptable, and effective in their pilot study with 21 sexual minority adolescents, aged 13 and 19 years, in New Zealand. Other programs have sought to use web-based interventions to circumvent barriers to accessing affirming in-person services. For example, Craig et al [18] found that SGM youth in Canada (N=46; age 14-29 years) who participated in their 8-session, manualized, and synchronous pilot telehealth group intervention found the program to be acceptable. Although their design did not allow for randomization, preliminary efficacy analyses noted improvements in stress appraisals, cognitive and behavioral coping skills, and depressive symptomatology in the web-based group program when compared with youth in the wait-list control group. Taken together, these findings are promising and highlight technology's potential as a modality to deliver mental health interventions for SGM youth.

To date, there is limited research examining the efficacy of web-based platforms for helping SGM youth cope with minority stress asynchronously. For instance, in a pilot randomized trial, Schwinn et al [25] found that their tailored, 3-session web-based intervention resulted in decreases in perceived stress and increases in coping and problem-solving skills when compared with youth in the control arm at a 3-month follow-up. Egan et al [26] designed an innovative, web-accessible role-playing game intervention. Although they found high acceptability for their program among SGM youth participating in their randomized trial, they did not observe any improvements at the 1- or 2-month follow-up across coping skills, depression and anxiety symptoms, or knowledge and use of web resources.

Study Objectives

Although these findings suggest that SGM youth perceive web-based asynchronous interventions to be acceptable, there is a need to increase the empirical evidence base for the efficacy of these interventions [27]. Moreover, the generalizability of the aforementioned findings to racial and ethnic minority populations has been constrained, given the limited representation of these groups in prior research. Given the current state of the science, this study sought to test the acceptability and preliminary efficacy of an asynchronous web application—*imi*—among a predominantly racial and ethnic minority sample of SGM youth aged between 13 and 19 years living in the United States. The *imi* application was designed to facilitate SGM identity affirmation, promote a sense of connectedness to the LGBTQ+ community, and encourage cognitive and behavioral coping skill practice. In partnership with a racially and ethnically diverse group of SGM youth, we co-designed the *imi* application to be directly responsive to their needs by leveraging the visual, aesthetic, and interactive capacities of a web-based interface to deliver identity-affirming experiences that could support the intervention's engagement and efficacy.

Our study had 4 main objectives. First, we examined the acceptability of the *imi* application in a diverse sample of 270 SGM youth. Given our use of human-centered design principles and the involvement of SGM youth in the design of the *imi* application, we expected that participants randomized to receive the *imi* application would report greater acceptability and satisfaction than participants assigned to a resource-only version of the *imi* application (the control arm), which did not contain any of the newly created interactive coping and identity-affirming content designed with LGBTQ+ youth. Second, we examined the preliminary efficacy of the *imi* application as a digital tool for increasing adaptive stress appraisals among SGM youth (primary outcome). Given the *imi* application's focus on teaching cognitive and behavioral coping skills, we hypothesized that participants assigned to receive the *imi* application would be more likely to appraise stress as a surmountable challenge and less likely to appraise stress as threatening by the 4-week follow-up relative to the control arm. Third, we examined the preliminary efficacy of the *imi* application across five secondary outcomes related to the mental health of SGM youth: cognitive and behavioral coping skills, identity affirmation and connectedness to the LGBTQ+ community, internalization of blame for minority stress, sense of belonging, and anxiety and depression symptoms. We predicted that the *imi* application would be more likely to improve SGM youth's outcomes across these domains relative to the control arm. Finally, as exploratory analyses, we examined participants' engagement with the *imi* application relative to the control arm. We also explored whether participant engagement with the *imi* application (ie, counts of user sessions, time spent, and the number of pages visited) predicted improvement in primary and secondary outcomes.

Methods

Study Design

This pilot randomized controlled trial evaluated the acceptability and initial efficacy of the *imi* application at the end of the 4-week active study period. Participants were randomly assigned in a 1:1 fashion to receive either the *imi* application (treatment arm) or a resource page–only version of the *imi* site called "asterix," which linked out to a series of LGBTQ+-specific external mental health resources (resource-only control arm). We collected survey data via web-based self-completed Qualtrics surveys administered at baseline and at a 4-week follow-up.

Ethics Approval

The University of Pennsylvania Institutional Review Board approved all study procedures (protocol 849509), and the study was registered on ClinicalTrials.gov (NCT05061966). A waiver of parental consent was granted to ensure that youth who might not yet be out to their parents or have less parental support, and thus could benefit from an identity-affirming tool, could participate in the study.

Participants and Recruitment

Participants were SGM youth recruited through Instagram between October and November 2021. To be eligible for this study, the youth had to (1) be aged 13 to 19 years (inclusive); (2) identify as a sexual or gender minority; (3) reside within the United States; (4) have English literacy; (5) have access to a device with internet access, a web browser, and SMS text messaging capabilities; and (6) be willing to participate in study activities for 4 weeks.

A target sample size of 250 participants was selected to allow for the detection of arm differences in week 4 outcomes, which were medium to small in size or larger (Cohen $d \geq 0.35$) after accounting for the potential loss of participants because of attrition or noncompliance. These effect sizes are consistent with those observed in previous research on digital mental health tools for SGM youth [18,25].

Study Procedures

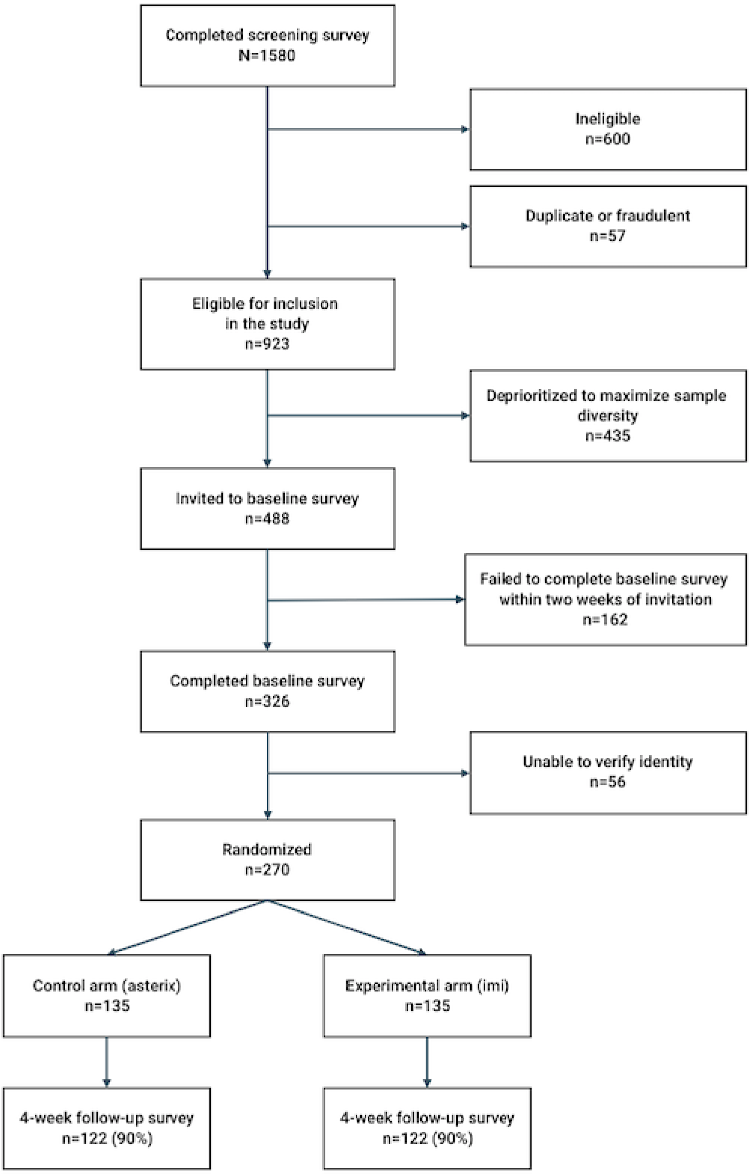
All study activities were conducted remotely, and web-based screening and survey assessments were delivered through the Qualtrics software. Prospective participants clicked on a paid advertisement and completed a brief screening survey. Individuals were emailed a link to the baseline survey, which contained the informed consent form (Multimedia Appendix 1), and participants were given 2 weeks to complete the survey. The baseline survey contained 8 of the same or similar questions as were asked in the screener. Following the established best practices for participant verification [28-30], the staff compared each applicant's screener and baseline data for these 8 questions, in addition to the metadata (eg, IP addresses registered in the United States, review of the time taken to complete the survey, and answers in hidden "honey pot" fields). The study staff also manually checked all screeners that met basic eligibility criteria to eliminate duplicate and fraudulent entries. If any significant inconsistencies were identified, applicants were emailed and asked to respond via email or phone to resolve the issue.

Once participants completed the baseline survey and passed the verification procedure, they were considered to be enrolled in the study. Enrolled participants were randomized in a 1:1 ratio into the *imi* (treatment; received full intervention content) or *asterix* (control; received pared-down resources-only version of the *imi* application) arm. Within 1 business day of completing the baseline survey, each participant was emailed a unique link to the *imi* or *asterix* web application. Participants were compensated with a US $30 Amazon e-gift card once they registered for an account on *imi* or *asterix*. The informed consent form encouraged participants to log into their digital resource at least twice a week and informed them that the study team would be able to track where they went within the web application, what features they used, what content they saw, and the duration of time they spent on the web application. Depending on their communication preferences, participants were emailed or texted every 7 days after enrollment to remind them to use the web application. On day 28, participants were sent a link to the follow-up survey, which they had 14 days to complete. Once completed, they received a US $40 Amazon e-gift card. Authors were not blind to participants' conditions during data collection or analysis; however, as all intervention activities were self-guided and all outcome measures were self-assessed by participants, there was no interaction between study staff and participants that could have led to response biases on the part of participants because of demand characteristics. No adverse events were reported during the trial.

Intervention Development Study Procedures

The *imi* application was built by Hopelab, a nonprofit social innovation laboratory, in collaboration with CenterLink, an international nonprofit organization and member-based association of LGBTQ+ centers serving their local and regional communities. Before launching the pilot trial, Hopelab conducted formative work through interviews, focus groups, co-design sessions, and surveys of SGM youth. The *imi* web application content and visual elements were tailored based on youth feedback and contributions. Screenshots containing example content are presented in Figure 1. The core intervention modules or "guides" in the *imi* application were designed based on a review of the existing efficacious minority stress interventions in the literature and honed through feedback with scientific advisors during a 6-month iterative design phase. This included extracting evidence-based exercises from the literature to support key psychosocial targets (eg, cognitive and behavioral coping skills and identity affirmation) that could be adapted to a digital platform and prototyping digital "mini-interventions" that would be further developed in the final *imi* application content.

Figure 1. CONSORT (Consolidated Standards for Reporting Trials) diagram.



Intervention Description

Experimental Arm

imi is a web application designed to facilitate LGBTQ+ identity affirmation, promote a feeling of connectedness to the LGBTQ+ community, and encourage cognitive and behavioral coping skill practice (Multimedia Appendix 2). The name *imi* (pronounced *eye-me*) is a nod to the idea that no matter who you are, you are you (ie, “I’m me”). The logo, designed as an ambigram that can be read in many orientations, represents the belief that even as one changes and evolves, they are exactly as they are. The *imi* application delivers fully automated information and skill practice across guides covering four content areas: (1) gender identity exploration (the *gender* guide), (2) sexual orientation and broader LGBTQ+ identity exploration (the *queerness* guide), (3) stress and coping (the *stress* guide), and (4) internalized homophobia and transphobia (the *stigma* guide). Examples of each guide’s goals and sample activities are as follows:

1. The *gender* guide allows youth to explore and affirm their gender identity and expression. For example, one activity uses a chat interface that allows users to experiment with different names and pronouns that fit their gender identity.
2. The *queerness* guide encourages youth to examine their LGBTQ+ identity through an intersectional lens and reflect upon what *queerness* means to them. For instance, one activity provides examples of the ways other LGBTQ+ youth define their queerness and guides the user through the creation of their own definition.
3. The *stress* guide provides psychoeducation on LGBTQ+ sources of minority stress (eg, discrimination, prejudice, and microaggressions) and teaches cognitive and behavioral coping skills through activities such as guided breathing, positive reframing exercises, and social support resources. Users are encouraged to select coping skills that work for them most effectively.
4. The *stigma* guide explains how negative and stereotypical messages become internalized and encourages users to examine and challenge their own internalized homophobia

and transphobia. For example, one activity scaffolds users in developing a personalized affirmation to help them combat negative self-talk.

Each of the four guides comprises four types of content: (1) learning segments, (2) activities, (3) community content, and (4) external resources. Learning segments provide information about LGBTQ+ relevant vocabulary (eg, pronouns and commonly used terms for sexual and gender identity), queer history, and psychoeducation on minority stress and internalized stigma. Activities include interactive exercises, such as chat interfaces, drawing activities, and guided relaxation and mindfulness practices. Community content includes video, audio, and written stories and images of LGBTQ+ youth. External resources connect youth to externally linked content designed for LGBTQ+ youth, such as the Trevor Project and the Gay, Lesbian, and Straight Education Network's *coming out* guides.

Both Arms

Participants in both arms received access to resource webpages that linked to freely accessible, preexisting crisis and noncrisis resources. Crisis resources included the National Suicide Prevention Lifeline, as well as resources specific to LGBTQ+ youth, such as TrevorChat. The noncrisis resources included moderated social networking and web-based chat spaces (eg, TrevorSpace and Q Chat Space), local LGBTQ+ centers (eg, CenterLink's center-finder tool), self-guided web resources (eg, The "It Gets Better Project"), databases of LGBTQ+-affirming therapists (eg, Gaylista), and a guide to free digital mental health tools (One Mind PsyberGuide). The resource section also contains *safer browsing tips*, which provide web-based privacy and safety advice specific to LGBTQ+ youth.

The control arm only received access to the resource webpages described previously and did not have access to any of the other content in the *imi* application. This pared-down, resources-only version of the *imi* site that was provided to the control group was named *asterix* This control allowed for a test of whether the learning, interactive, and community content of *imi* guides had benefits above and beyond any benefit that might be derived from simply having a curated, unified access point for existing, freely available web-based resources for SGM youth.

Participants in both arms were instructed to try to visit their respective web applications at least twice a week during the 4-week active trial period but could engage with the content available to them however they wished, in any order, at their discretion. On the basis of their preferences, participants received either weekly texts or emails reminding them to log into their web application.

Measures

Primary Outcomes: Stress Appraisals

The Stress Appraisal Measure for Adolescents [15] captures stress appraisals across 3 dimensions (challenge, threat, and resources). The 3-item Challenge subscale assesses perceptions of stress as a surmountable challenge (Cronbach α=.67). The 7-item Threat subscale measures perceptions of stress as having lasting, negative repercussions (α=.83). The 3-item Resources subscale assesses the belief that one has the necessary internal and external resources to cope with stress (α=.81). Responses to all items are recorded on a 5-point scale (1=*strongly disagree* to 5=*strongly agree*). A mean score was computed for each subscale, with higher values indicating greater endorsement of each respective stress appraisal.

Secondary Outcomes

Cognitive and Behavioral Coping Skills

Participants' use of specific cognitive and behavioral coping skills were measured with items adapted from the brief 2-item Coping Orientation to Problems Experienced (COPE) inventory by Carver [31], specifically the self-distraction (α=.46), active coping (α=.70), emotional support (α=.79), instrumental support (α=.78), venting (α=.66), positive reframing (α=.61), planning (α=.71), acceptance (α=.65), self-blame (α=.79), substance use (α=.96), and behavioral disengagement (α=.75) subscales. Instructions were modified such that participants indicated how they had been coping with stress in their lives over the past 2 weeks on a 4-point scale (1="I haven't been doing this at all" to 4="I've been doing this a lot"). A mean score was computed for each subscale, with higher values indicating greater use of that respective strategy.

Positive LGBTQ+ Identity

Two 5-item subscales from the Lesbian, Gay, and Bisexual (LGB) Positive Identity Measure [32] were used to measure positive LGBTQ+ identity factors. The first subscale, the *authenticity subscale* (α=.87), measured comfort with one's own LGBTQ+ identity (eg, "I am honest with myself about my LGBTQ+ identity"). The second subscale, the community subscale (α=.87), measured a sense of connection to the broader LGBTQ+ community (eg, "I feel supported by the LGBTQ+ community"). Items were modified from LGB to LGBTQ+ to be inclusive of a range of SGM identities. Participants responded on a 7-point scale (1=*strongly disagree* to 7=*strongly agree*), and a mean score was computed for each subscale, with higher scores indicating greater authenticity and connection, respectively.

Internalization of Blame for Minority Stress

The 5-item Coping with Discrimination Scale–Internalization subscale [33] assesses the tendency to blame oneself for instances of SGM-related discrimination (eg, "I tend to wonder if I did something to offend the others involved"). Participants responded on a 6-point scale (1=*never* to 6=*always*), and positively worded items were reverse coded. We computed a mean internalization score, where higher scores indicate greater internalization of blame for minority stress (α=.84).

Sense of Belonging

A 5-item version of the Thwarted Belongingness subscale of the Interpersonal Needs Questionnaire [34] was used to measure perceived belonging. Participants responded to the items (eg, "These days, I feel disconnected from other people.") on a 7-point scale (1=*not at all true*" to 7=*very true for me*). Positively worded items were reverse coded. We computed a sum score ranging from 5 to 35, where higher scores indicate a lack of sense of belonging (α=.81).

Anxiety and Depression Symptoms

The 7-item General Anxiety Disorder Scale [35] was used to examine symptoms of anxiety (eg, “Feeling nervous, anxious, or on edge”), and the 8-item Patient Health Questionnaire [36] was used to assess depressive symptoms (eg, “Feeling tired or having little energy”). These brief clinical measures have been used to screen for generalized anxiety and depression across a wide range of populations, including adolescents [37-39]. For both measures, participants rated the frequency of their symptoms over the past 2 weeks using a 4-point scale (0=*not at all* to 3=*nearly every day*). Items were summed to compute total scores for each construct, with higher scores indicating greater symptoms of anxiety and depression, respectively (General Anxiety Disorder-7 α=.88; Patient Health Questionnaire-8 α=.83).

Intervention Acceptability and Satisfaction

Participants rated the acceptability and their satisfaction with the *imi* and *asterix* applications at the 4-week follow-up. A modified version of the LGBTQ Appropriateness Scale [40] was used to assess the perceived relevancy and appropriateness of the web resources to SGM youth (eg, “This product appears to be relevant to people who identify as LGBTQ+”) using a 7-point scale (1=*strongly disagree* to 7=*strongly agree*). These questions were tailored for each web application’s features; we asked 12 items for the treatment arm (α=.91) and 9 items for the control arm (α=.86). Items were averaged, with a higher score indicating greater perceived appropriateness.

A measure of intervention satisfaction and suggestions for improvement created for this study were also included. The measure comprises a multiple-choice question (eg, “How would you rate your overall experience of this product?”; 1=*very bad* to 7=*excellent*) that was analyzed as a continuous variable and free-text responses (eg, “How could this product be more helpful to you?” [text box]).

A net promoter score (NPS; eg, “How likely would you be to recommend [*imi/asterix*] to a LGBTQ+ friend?”) was administered to further assess the perceived value of the interventions. Respondents answered on an 11-point scale (0=*not at all likely* to 10=*extremely likely*). Following established industry conventions for NPS, responses were recoded such that respondents who selected 9 or 10 were categorized as “Promoters,” those selecting 7 or 8 as “Passives,” and all others as “Detractors.”

Web Application Engagement

Participants’ actions in the *imi* and *asterix* applications were collected as paradata over the trial period. Each participant was provided with a unique link to their respective intervention. This link embedded participants’ study IDs as metadata within their individual accounts, allowing us to track how much time each participant spent in their web application, which pages they viewed, and which links they clicked. These paradata were transformed to characterize the amount, frequency, duration, and depth of engagement with the web-based intervention [41].

In this study, we derived four paradata metrics: (1) counts of user sessions, (2) time spent on each intervention, (3) the number of pages visited, and (4) external links clicked. Sessions were counted whenever there was a period of activity within the app, with a participant having the same session ID until they had a period of ≥15 minutes or more of inactivity with the application. We derived the variable *number of sessions* by counting the number of discrete sessions in which the participant engaged during the 4-week active trial period.

To measure time spent on the intervention, we tracked the number of minutes and seconds participants spent logged into their respective web resources during the active trial period. Each time a participant visited a page within the app, there was a record of their activity. We derived the variable *number of unique pages viewed* by summing the number of distinct pages a participant visited during the active trial period. Finally, each time a participant clicked on a link, a unique record of the click was generated. We summed the number of unique external links a participant clicked on during the active trial period to derive this value.

Analytic Strategy

Overview

Descriptive analyses were conducted to summarize demographic characteristics among the study arms at baseline. Preliminary analyses tested baseline equivalence between the study arms on demographics, assessment of attrition, and differential attrition by study arm. We used SAS (version 9.4; SAS Institute) to conduct all analyses.

Intervention Acceptability

To test the interventions’ acceptability, we compared participants’ ratings of the 2 web resources (eg, intervention satisfaction and NPSs) using chi-square tests for categorical variables and Student *t* tests for continuous variables. Within the treatment arm, open-ended feedback was coded by 2 coders using rapid qualitative analysis methods [42]. Core questions guiding the coding included “What did you find most helpful about *imi*?” and “If you could change anything about *imi* or the guides in it, what would you change and why?” Quotes were chosen to illustrate salient themes.

Preliminary Efficacy

Analyses of all primary and secondary outcome variables were performed using an intention-to-treat approach, which included all available data from participants randomly assigned to the 2 arms, regardless of whether participants created an account within their respective web resources. Our primary efficacy analysis sought to examine whether there were differences in our primary and secondary outcomes between the 2 arms. We used linear regression to test the main effect of arm (treatment=1 vs control=0) on week 4 outcomes, adjusting for the baseline value of each respective outcome as a covariate. Recognizing that we were testing 2 versions of a web application (the resource-only version of *imi* called *asterix* and the full interactive *imi* intervention), we also tested for changes over time within each web application. For these within-arm analyses, we examined the mean changes from baseline to follow-up using paired *t* tests.

Engagement

Given the absence of standardized and generalizable threshold indicators to suggest adequate engagement across digital health interventions, we adopted an exploratory approach to the analysis of these data and created thresholds to define participants' engagement with the intervention. After examining the distribution of the engagement data, we selected the following to define thresholds of use: ≥4 sessions, ≥10 minutes, ≥10 unique pages viewed, and ≥1 external link clicked. Given the high bivariate correlations between these indicators of engagement (Spearman $\rho>0.65$), as well as the exploratory nature of these analyses, we compared each engagement indicator separately by study arm using chi-square tests. Of note, treating the nonnormal data as continuous (with and without transformation of these data) yielded similar results.

Finally, we explored whether reaching these thresholds of use within the *imi* arm predicted differential gains across primary and secondary outcomes. We focused these analyses on three indicators capturing participants' engagement within *imi*: time spent on site, number of sessions completed, and number of pages viewed, which captured the depth of participant engagement with that content which was unique to the treatment arm. We ran separate regression models because of the high multicollinearity among engagement metrics and the importance of examining the different scopes of paradata (eg, the amount, frequency, duration, and depth of engagement). All models accounted for the baseline value of each respective outcome as a covariate.

Results

Screening and Enrollment

Of the 1580 individuals who completed the screening survey, 923 (58.4%) met all inclusion criteria and passed the duplicate and fraudulent entry checks (Multimedia Appendix 3). From this pool of 923 eligible participants, racial, ethnic, and gender minority youth were selectively invited to access the baseline survey to achieve a diverse participant pool.

We invited 488 participants in total to complete the baseline survey to ensure that the target enrollment of 250 participants would be reached, with the expectation that not all participants who expressed interest in participating would respond to further outreach or pass identity verification checks.

Of the 488 participants who were invited to complete the baseline survey, 162 (33.2%) failed to do so within the 2-week window, and another 56 (11.5%) participants did not pass the participant verification procedure (ie, there were discrepancies between information entered on screener and baseline surveys); thus, in total, 270 (55.3%) participants completed the baseline survey and were enrolled in the study.

Sample Characteristics

Participants had a mean age of 16.49 (SD 1.49) years. Most of the participants resided in a metropolitan area, with the majority residing in the Southern or Western regions of the United States. A large proportion of participants identified with multiple races, gender identities, and sexual orientations. To represent the diversity and heterogeneity of the sample, we report these variables in a nonmutually exclusive fashion in Table 1. The sample was racially and ethnically diverse, with 77.8% (210/270) of participants identifying as racial or ethnic minorities. Similarly, 41.9% (113/270) and 39.6% (107/270) of the sample identified with multiple gender identities and sexual orientations, respectively. Nonbinary (94/270, 34.8%) and bisexual (96/270, 35.6%) were the response options selected most frequently. Participants expressed various levels of outness about their sexual orientation, with 26.3% (71/270) of participants noting that they were completely or mostly in the closet, whereas 39.3% (106/270) were mostly or fully out.

Table 1. Sociodemographic characteristics by study arm (N=270).

Completely out of the closet	30 (11.1)	20 (14.8)	10 (7.4)

[a] The highest level of education completed.

[b] SES: socioeconomic status.

[c] Nonmutually exclusive categories; participants were allowed to select all that apply.

Baseline Equivalence, Attrition, and Differential Attrition

Randomization resulted in baseline equivalence between the treatment and control arms on all demographics, primary and secondary outcomes. Our survey retention rate at the 4-week follow-up was 90.4% (244/270). In attrition analyses, comparing those who completed the follow-up survey (244/270, 90.4%) with those who did not (26/270, 9.6%), we found no significant condition differences in attrition linked to demographic characteristics or baseline scores on primary or secondary outcomes. Collapsing across the arms, participants who did not complete the follow-up survey were more likely to be younger (mean 15.42, SD 1.53 years vs mean 16.60, SD 1.44 years; 2-tailed $t_{268}=–3.95$; $P<.001$) and reported fewer cognitive and behavioral coping skills at baseline (Multimedia Appendix 4; all *P* values <.01).

Intervention Acceptability

Participants perceived the content of the intervention as appropriate to LGBTQ+ individuals, both in the treatment (mean 6.01, SD 0.85) and control arm (mean 5.85, SD 0.83; $t_{241}=–1.45$; $P=.15$). Participants in the treatment arm rated their overall experience with the *imi* application (mean 6.01, SD 1.06) more positively than participants in the control arm (mean 5.59, SD 1.14; $t_{241}=–2.98$; $P=.003$) and were also more likely to report that they would recommend the *imi* application to a friend ("Detractors" treatment: 26/121, 21.5%; "Detractors" control: 45/121, 37.2%; $\chi^2_2=8.9$; $P=.01$).

When asked what they liked and found most useful about the *imi* application, participants remarked on the benefits of hearing the stories and seeing the images of other LGBTQ+ youth:

> *I liked being able to read other queer folks' stories—no matter how many friends I have, it's always nice to hear about other people with experiences or identities similar to my own and learn from what they've done.*

Additional themes included being taught concrete strategies for managing stress and engaging with the activities (eg, the interactive chats and questionnaires) that encouraged identity exploration:

> *It gave lots of suggestions for stress relief, so I could focus on tackling stress myself. I don't like turning to other people for help that much, so the self-aspect of it was helpful.*
>
> *I really liked the activities—especially the one where I got to test out a new name. It made me feel seen.*

When asked what they would change or improve about the *imi* application, participants expressed a desire for more content and content on additional topics:

> *I'd add more content, the content is slightly lacking for now.*
>
> *I would also add a relationship section. Being in a relationship as a person in the LGBT community, there is a great need for knowledge on having thriving romantic, sexual, and even platonic relationships*

They also expressed interest in the addition of social networking and other interactive features:

> *I'd like to be able to interact with more people, not just the automatic responses...*
>
> *It would be cool if imi could track your location and find support groups in my area or a group chat to join with fellow lgbt people my age.*

Another common critique was that the *imi* application felt tailored to youth beginning to explore their identities and less suitable for those who are already more affirmed:

> *I believe this resource is excellent for someone part of the LGBT community who is questioning themselves and actively needs help or would benefit from it. If you're already out of the closet and comfortable with who you are, it may not be very beneficial.*

Preliminary Efficacy of the Intervention

Primary Outcome: Stress Appraisals

Stress appraisal improved over time across both arms. The treatment arm experienced significant improvements in challenge ($t_{121}=4.51$; $P<.001$), threat ($t_{121}=–2.73$; $P=.007$) and resource appraisals ($t_{121}=4.24$; $P<.001$) from baseline to the end of the follow-up. The control arm also showed improvements in challenge ($t_{121}=1.96$; $P=.052$) and resource appraisals ($t_{121}=2.83$; $P=.005$; Table 2).

Controlling for baseline scores (Table 3), the treatment arm reported significantly higher challenge appraisals at follow-up than the control arm (Cohen $d=0.25$; coefficient for treatment arm $b=0.26$; $P=.008$). We did not observe a difference between the study arms for threat appraisals ($d=0.10$; $b=–0.06$; $P=.37$) or resource appraisals ($d=0.15$; $b=0.14$; $P=.14$).

Table 2. Within-arm changes in primary and secondary outcomes from baseline to the 4-week follow-up (N=244).

Secondary Outcomes

Cognitive and Behavioral Coping Skills

At the 4-week follow-up, the treatment arm showed significant improvements in emotional support (t_{121}=2.30; *P*=.02), instrumental support (t_{121}=3.15; *P*=.002), positive reframing (t_{121}=2.98; *P*=.003), and planning to cope (t_{121}=2.80; *P*=.006). We observed no other changes over time in the other COPE subscales within the treatment arm. The control arm had significant reductions in self-blame (t_{121}=–3.73; *P*=.003). We observed no other changes over time in the other COPE subscales within the control arm.

The effect of the intervention on cognitive and behavioral coping skills was greater among the treatment arm than the control arm (instrumental support: *d*=0.24, *b*=0.29, *P*=.005; positive reframing: *d*=0.27, *b*=0.22, *P*=.02; planning: *d*=0.26, *b*=0.23, *P*=.02). However, we observed no differences in emotional support (*d*=0.04; *b*=0.09; *P*=.37) or self-blame (*d*=0.13; *b*=0.13; *P*=.18) between the arms. We observed no other differences between the arms in the COPE subscales.

Positive LGBTQ+ Identity

We did not observe any significant changes over time in the authenticity or the community subscales of the LGB Positive Identity Measure in either arm, nor did we observe differences in improvements between the arms.

Internalization of Blame for Minority Stress

We did not observe reductions in internalization of blame for minority stress over time in either arm or differences between the two arms.

Sense of Belonging

At the 4-week follow-up, both the treatment arm (t_{121}=–3.53; *P*<.001) and the control arm (t_{121}=–2.53; *P*=.01) showed significant reductions in thwarted belongingness. We did not observe differences in reductions of thwarted belongingness between the arms (*d*=–0.08; *b*=–0.64; *P*=.34).

Anxiety and Depression Symptoms

We also observed reductions in anxiety and depression symptoms for both arms. Among the treatment arm, we found significant reductions in anxiety (t_{121}=–4.42; *P*<.001) and depression (t_{121}=–3.33; *P*=.001) from baseline to week 4. We found similar results among control arm participants (reductions in anxiety: t_{121}=–2.55, *P*=.01; reductions in depression: t_{121}=–2.35, *P*=.01). However, the treatment arm did not report significantly lower anxiety (*d*=0.14; *b*=–0.55; *P*=.31) or depression (*d*=0.07; *b*=–0.17; *P*=.74) at the follow-up than the control arm.

Intervention Engagement

Approximately 98.5% (133/135) of the participants in the treatment arm and 97.8% (132/135) of the participants in the control arm created an account in their respective web resource within 4 weeks of being invited to access it. Participants in the treatment arm did not log significantly more sessions than participants in the control arm (t_{268}=–1.84; *P*=.07); however, they spent significantly more time in the product (t_{268}=–7.08; *P*<.001) and viewed more pages (t_{268}=–10.30; *P*<.001). Similarly, although there were no significant differences between the treatment and control arms in thresholds of use for the number of sessions logged (≥5 sessions; χ^2_1=1.0; *P*=.39), significantly more participants in the treatment arm spent ≥10 minutes in the product (χ^2_1=49.2; *P*<.001) and viewed >10 unique pages (χ^2_1=101.9; *P*<.001) than participants in the control arm (Table 4). Although the treatment arm showed higher engagement than the control overall, the control arm participants clicked on more unique external links than the treatment arm (t_{268}=4.51; *P*<.001) and were more likely to click on at least one external link (χ^2_1=13.1; *P*<.001).

Table 4. Engagement metrics by arm (N=270).

[b] Compares dichotomized engagement (high vs low) and study arm (control vs intervention).

[c] N/A: not applicable. Refer to the *P* value for low engagement for a statistical comparison of high and low engagement by study arm.

[d] The maximum number of unique pages in the control web application (*asterix*) was 8 and the maximum for the *imi* application was 73.

Engagement and Outcome Improvements Within the *imi* Application Arm

Exploratory analyses examining outcomes within the treatment arm revealed a positive relationship between the 3 engagement indicators and several of the primary and secondary outcomes (Table 5).

Table 5. Linear regressions examining differences in primary and secondary outcomes by engagement indicators among participants assigned to the *imi* application (n=122).

Outcomes	The number of sessions (high [≥5] vs low[a])		Total minutes (high [>10] vs low[a])		The number of unique pages viewed (high [>10] vs low[a])

[a] The effect of engagement (reached thresholds of use vs not reached) on the outcome at follow-up, controlling for outcome at baseline.

[b] LGBTQ+: lesbian, gay, bisexual, transgender, queer, and other sexual and gender minority.

[c] Considered as continuous variables in the analyses.

Sessions

Controlling for baseline scores, participants in the treatment group who engaged in ≥5 sessions during the intervention period had greater improvements in resource appraisals (*b*=0.33; *P*=.03) at follow-up than those who engaged in <5 sessions.

Total Minutes

Controlling for respective baseline scores, participants who spent >10 minutes in the *imi* application during the intervention period had significantly greater improvements in challenge appraisals (*b*=0.42, *P*=.003), resource appraisals (*b*=0.50;

P=.001), and emotional support coping skills (*b*=0.32; *P*=.03) at follow-up than those who spent ≤10 minutes.

Unique Pages

Participants who viewed >10 unique pages within the *imi* application during the intervention period had significantly greater improvements in challenge appraisals (*b*=0.38, *P*=.008) and resource appraisals (*b*=0.51; *P*=.001) at follow-up than those who viewed ≤10 pages, controlling for baseline scores.

Discussion

Principal Findings

Digital interventions show promise in supporting the mental health of SGM youth, given the appeal of the modality, their suitability to deliver engaging asynchronous content, and their unique capacity to reach large numbers of SGM youth, including youth who may be unable to access in-person services because of transportation concerns, availability of local services, or concerns about privacy and stigma. In this study, we found high acceptability for both the full *imi* intervention web application and the resource page–only control, with participants reporting greater satisfaction and engagement with the *imi* web application. SGM youth assigned to the *imi* web application also had greater improvements in stress appraisals and coping skills. Given the potential for digital interventions such as the *imi* application to support the mental health needs of SGM youth, we discuss our findings in detail in the following sections and note opportunities to advance work in this area.

Participants indicated that the *imi* application's content was acceptable and well-suited for SGM youth populations. Consistent with our hypothesis, participants randomly assigned to receive the *imi* application were more likely than those assigned to the resource-only control arm to report a positive experience with the intervention and to recommend it to SGM youth friends. These sentiments were echoed in the qualitative feedback, in which participants highlighted the benefits of viewing the stories of other SGM youth and learning approaches for coping with stress. Participants also offered several ways of improving the *imi* application, including developing greater breadth (eg, more overall content) and depth (eg, expansion to include a section focused on LGBTQ+ relationships) of content, and the addition of new features (eg, the ability to interact with other SGM youth through the web application). Collectively, these findings align with the growing body of evidence suggesting that SGM youth consider digital interventions to be acceptable modalities through which to receive mental health support [18,19,24]. They also point to concrete directions for intervention improvement.

For individuals to respond effectively against a stressor, they must be able to feel confident in their ability to address it [43]. Consistent with our hypothesis, SGM youth in the *imi* application arm were more likely than their peers in the control arm to appraise stressful situations as a surmountable challenge at the 4-week follow-up. The *imi* application arm was also less likely to report appraising stressful events as having lasting, negative repercussions. Participants in both study arms reported gains in having the internal and external resources to deal with stressful situations. The absence of a significant difference in resource appraisals between the 2 arms may be explained by the fact that both sites contained the same *imi*-based curated list of resources tailored to SGM youth. Taken together, these findings are promising and suggest that the *imi* application may help SGM youth situate stressors in their lives as transient and addressable, which, in turn, may reduce the acuity of these experiences on their mental health.

We also observed important initial changes in SGM youth's coping skills after the 4-week follow-up period. Compared with the control arm, participants in the *imi* application arm reported greater gains in their ability to seek out instrumental support, positively reframe challenging situations, and engage in planning as coping skills. Interestingly, we observed improvements in measured areas of mental health across both arms (eg, anxiety and depression symptoms), suggesting that web applications of varying scope tailored to SGM youth are promising sources of mental health support. Unfortunately, the absence of a no-treatment control group prevents us from inferring whether both interventions are efficacious relative to the absence of any program. Although comparing the full *imi* intervention with a resource-only subset of the *imi* website (ie, *asterix*) makes it harder to detect differences between the arms, we felt that withholding referrals to care for SGM youth would be unethical. We also selected this control as we wished to examine whether the full, interactive *imi* intervention provides benefits to SGM youth that go above and beyond what might be gained by being given access to a unified, vetted list of freely available existing resources. Previous studies suggest that SGM youth are increasingly and disproportionately searching for support on the web; however, this opens them to increased experiences of encountering homophobic and transphobic content and other hate speech [23]. It may be the case that gathering vetted resources in a single safe site designed specifically for them (ie, the resources section of the *imi* application) supports the well-being of SGM youth in and of itself. Although our design lacked a no-treatment control and, therefore, was unable to test this hypothesis, it does highlight the additive benefit of interactive identity affirmation and coping content contained in the full *imi* intervention; that is, although participants who were assigned both versions of the web application (the resource-only version of *imi* called *asterix* and the full interactive *imi* intervention) experienced decreased feelings of anxiety and depression after 4 weeks, only those given the full intervention experienced the additional benefit of greater stress appraisal and cognitive and behavioral coping skill improvements.

Future Directions

The lack of observed differences between the arms across other domains (eg, identity affirmation and connectedness to the LGBTQ+ community, internalization of minority stress, and sense of belonging) may be related to several additional considerations. First, it is possible that the 4-week study period may be too short to allow for meaningful changes to emerge in certain types of outcomes. For example, it may be that identity-related shifts require more time to manifest. Second, consistent with participants' qualitative feedback, it is possible that SGM youth require a greater amount of content and activities in a web application to, for example, feel more connected to the broader LGBTQ+ community. Third, some participants noted in their qualitative recommendations that the *imi* application may be most useful for SGM youth who are earlier in the exploration and affirmation of their identities. However, it remains unclear whether the intervention's effects may be greater for SGM youth earlier in their coming out process or those questioning their identities, a question which this study was not statistically powered to address. Future research is needed to examine whether the intervention's effect on the outcomes requires greater content to be developed within the web application, whether the intervention effects are moderated by how comfortable users are with their identities, or whether a longer follow-up period may allow for changes in distal outcomes to be observed.

Participants' engagement with the web application also offers insights into its acceptability and preliminary efficacy. Most participants across both arms created an account on their assigned web application, with participants reporting a comparable number of log-ins over the 4-week follow-up period. As expected, participants in the *imi* application arm viewed more unique pages than participants in the control arm. In and of itself, this finding does not indicate greater engagement with the *imi* application, as the control web application contained only a small subset of pages from the *imi* application. Consistent with our hypothesis, participants in the *imi* application arm also spent more time logged into the intervention than their peers in the control arm. However, *imi* participants were less likely than their control counterparts to click on external links. When taken together, these findings may be explained by two alternate (but complementary) possibilities: *imi* participants may have been more likely to spend time on the web application and less likely to require clicking on external links as the created content and activities were engaging and sufficiently helpful. Alternatively, given the limited content available to SGM youth in the control arm, participants assigned to *asterix* may have spent their time reviewing the content offered through the links to curated LGBTQ+-affirming resources, a possibility we could not assess in this study as we could not track participants' behavior on external websites. Future research examining participants' experiences within and outside of the web application may be warranted.

As an exploratory analysis, we examined whether SGM youth's engagement with the *imi* application could affect the strength of the intervention's effect. Consistent with our hypothesis, and in alignment with prior research examining the role of engagement on a digital intervention's efficacy [41,44,45], higher engagement with the *imi* application (eg, ≥10 minutes spent on the tool; >10 unique pages viewed) was linked to greater improvement on our primary outcome variables. This finding supports the interpretation that engaging with the *imi* application's content improves coping abilities. On the basis of our engagement data, it is promising to see that more than half of the participants assigned to the full *imi* intervention achieved these thresholds. However, it is worthwhile noting that SGM youth were incentivized for creating an account within the tool and sent reminders by the study team to log back in over time. It remains crucial to understand whether these thresholds and their associated benefits persist outside of the clinical trial setting. Efforts to explore engagement in a naturalistic study may be worthwhile to examine and affirm external validity.

Strengths and Limitations

Several limitations are worth noting. First, although the intervention effects moved in favor of the *imi* application arm in primary and secondary outcomes, our ability to detect these effects with statistical precision was limited by our small sample size and short follow-up period. Future scaled-up versions of the *imi* intervention with larger sample sizes, a longer duration, and a greater number of follow-up periods may be warranted to examine efficacy and effectiveness with greater precision. Second, some of the indicators used to measure our outcomes (eg, authenticity and LGBTQ+ community connectedness) were originally developed with adult populations. Given the unique needs of SGM youth, it is possible that the measures used in our study were not optimal for use with SGM youth populations. Future research examining the psychometric appropriateness of these measures with SGM youth populations may be warranted. Third, our ability to recruit youth from the lowest end of the age spectrum was somewhat limited. Only 11.1% (30/270) of the sample was aged 13 to 14 years. This is a common limitation in studies of SGM youth [46]. However, given the qualitative feedback that youth earlier in the journey of identity exploration may benefit more from the tool, future implementation research should explore pathways for making the tool more accessible to both younger youth and youth who may be in the earlier stages of identity exploration or questioning their identities. Similarly, although the diversity of race and ethnicities, as well as sexual and gender identities represented in our sample, is a strength, this initial pilot study was not powered to assess whether the intervention has differential efficacy based on these demographic characteristics. Finally, we weighed the advantages and disadvantages of enforcing a type I error (ie, false positive) correction relative to a type II error (ie, false negative). Given the exploratory nature of our trial and the small sample size of this pilot study, we did not include a family-wise error rate correction, which is justified in early exploration [47]. Future research examining the effects of both the *imi* and *asterix* applications with larger and population-representative samples may be warranted.

Our study also has several strengths worth emphasizing. First, it is one of the few clinical trials examining how to design and deliver a coping intervention that may reduce the negative effects of minority stress on SGM youth. Second, compared with face-to-face programs for SGM youth and synchronous digital interventions, our findings underscore the feasibility and acceptability of an asynchronous digital intervention that overcomes access and engagement barriers by being freely accessible on demand, scalable, confidential, and not requiring a significant time commitment. Our study demonstrated that a brief (as little as 10 minutes), self-guided intervention may have significant benefits for coping with stress. Finally, compared with prior trials, our study increases the likelihood that the findings are generalizable, given our commitment to recruiting and retaining a diverse group of SGM youth across races, ethnicities, sexual orientations and gender identities, geographies, and socioeconomic backgrounds.

Conclusions

This study demonstrated that a brief web-based intervention can provide self-guided, asynchronous, and confidential support that improves the ability of SGM youth to cope with minority stress. As a tool, the *imi* application may provide public health utility and value by expanding the reach and scalability of mental health programs, particularly for SGM youth who may be unable to participate in time-intensive, synchronous interactions. It may also serve as an ancillary tool for community-based agencies seeking to engage their SGM youth clients via the internet. Further research is needed to examine the long-term effects of the *imi* application and its potential for scalability and population health impact.

Acknowledgments

The authors are grateful to all their partners who participated in the co-design of the *imi* application and the study reported herein. In particular, the authors would like to thank Chris McCarthy, Denise Ho, Danielle Ramo, Janise Chan, Grace Greene, Cassandra Marzke, Primo Lagaso Goldberg, Griffin Somaratne, Starr Jiang, Rayan Madjidi, Adriana Allman, Sam Dinga, Will Coleman, Jett Allen, Amanda Keller, Lauren Jacobs, Katie Suppes, Meryl Franklin, Sam Aguilar, Kevin McCloskey, Forrest Marie Linsell, David Biele, Tess Allen, Audrey Ford, Brooks Banker, Deborah Levine, and Justin Tindall, who were instrumental in the design and development of the *imi* application. The authors would also like to thank their scientific advisors Annesa Flentje, Shelley Craig, Edward Alessi, Ashley Austin, Alison Cerezo, and Amaranta Ramirez for their thoughtful input and feedback.

Conflicts of Interest

imi is a progressive web application codeveloped by Hopelab, CenterLink, and It Gets Better Project. Although all 3 organizations were involved in the development of the product, CenterLink will ultimately be responsible for the operation and distribution of the *imi* application. As a free digital tool created and distributed by nonprofit organizations, none of the organizations involved stand to profit financially from the product. The research reported here, as well as the development of the *imi* application, were supported by the nonprofit Hopelab Foundation. Hopelab develops behavioral interventions to improve the health and well-being of young people. The design, conduct, analysis, and reporting of this study represent a scientific collaboration between Hopelab and the Program on Sexuality, Technology, and Action Research at the University of Pennsylvania School of Nursing. EBS, FD, AT, JL, LR, and JH are employed by Hopelab Foundation. The study sponsor was involved in the study design; collection, analysis, and interpretation of data; writing of the article; and decision to submit it for publication.

Abstract

Background: The efficacy of pre-exposure prophylaxis (PrEP) is highly dependent on adherence, and one of the main reasons for poor adherence is forgetfulness. Therefore, it is important to explore how to remind users to take their medicine on time.

Objective: This study aims to explore the effect of a reminder system on PrEP adherence in men who have sex with men (MSM) to improve adherence. The main function of the reminder system based on the WeChat social media app is to send daily messages to PrEP users reminding them to take their medicine.

Methods: An open-label, multicenter, prospective cohort study of PrEP in HIV-negative MSM was conducted from November 2019 to June 2021. Study participants who met the criteria were randomly divided into 2 groups: no-reminder group and reminder group. Both groups received daily oral PrEP with follow-up every 3 months. Adherence was measured on the basis of self-report and was defined as the percentage of medications taken on time. Participants in the reminder group scanned a WeChat QR code and received a reminder message every day. Participants in the no-reminder group took daily oral medicines without reminders. The longitudinal trajectories of adherence for both groups were displayed to compare the variability in adherence at each time point. The association between the changes in adherence (no change, improvement, decline) at each time point and the use of the reminder system was analyzed by multinomial logistic regression models to further explore the effectiveness of the system.

Results: A total of 716 MSM were included in the analysis, that is, 372 MSM in the no-reminder group and 344 MSM in the reminder group. Adherence in the no-reminder group fluctuated between 0.75 and 0.80 and that in the reminder group gradually increased over time from 0.76 to 0.88. Adherence at each time point was not statistically different between the 2 groups. Further analysis showed that an improvement in adherence in the early stage was associated with the use of the reminder system (odds ratio [OR] 1.65, 95% CI 1.01-2.70; *P*=.04). An improvement in average adherence compared to initial adherence was positively associated with the use of the reminder system (OR 1.82, 95% CI 1.10-3.01; *P*=.02).

Conclusions: The effect of the reminder system on PrEP adherence in MSM was more significant in the early stage, which is related to the increased motivation of users and the development of medicine-taking habits. The reminder system is potentially effective for early-stage medicine management, encouraging users to develop healthy medicine-taking habits and to increase their adherence.

Introduction

Globally, men who have sex with men (MSM) bear a disproportionate burden of HIV, and they are a high-risk group for infection [1]. In China, more than a quarter of new HIV diagnoses can be attributed to MSM [2]. Despite various interventions, the risk of HIV infections among MSM in China is increasing, with the proportion of new HIV infections rising from 2.5% to 25.5% [3,4]. Given the existing circumstances, several studies have been exploring ways to prevent HIV infection in MSM populations, including biomedical interventions such as oral pre-exposure prophylaxis (PrEP) [5,6]. PrEP is a biological HIV prevention intervention that focuses on reducing the risk of HIV infection through daily (or event-based) oral antiretroviral medication [7]. In fact, several clinical trials and cohort studies have demonstrated the safety and efficacy of oral PrEP in reducing the risk of HIV infection in MSM [8]. However, the efficacy of PrEP for HIV prevention is highly dependent on adherence [9,10].

PrEP advocates and researchers agree that one of the important issues that needs to be addressed before PrEP can be scaled up is the concern about nonadherence [11,12]. As a result, researchers have focused their attention on PrEP adherence and the factors that influence it. Prior studies have shown that the potential barriers to daily oral PrEP include living arrangement, side effects, stigma, and forgetfulness [13,14]. In addition, another study found that forgetting to take medicines is the most common objective reason for nonadherence, accounting for 70.21% [15]. Taken together, forgetfulness is one of the main reasons for poor adherence, and reminding users to take medicines is an important way to improve adherence. Exploring how to obtain and maintain high adherence in MSM populations is crucial for promoting the effective implementation of PrEP intervention strategies and reducing new HIV infections.

Different methods can be considered to remind MSM to take their medicines on time. Many attempts have been made in this direction by researchers. Mobile health (mHealth) technologies are effective and cost-effective strategies to improve individual and public health [16,17]. Among them, SMS text messaging is often used to help remind users to take their medicines, which can improve adherence, owing to its ubiquity and ease of use in mobile devices. The feasibility and acceptability of SMS text messaging as a potential tool for primary HIV prevention has been demonstrated [18,19]. Meanwhile, other studies have also developed a novel mobile app to support PrEP adherence through artificial intelligence and an electronic sexual diary, which have received positive feedback from users, thereby providing a further basis for future effectiveness studies [20]. These studies of improving adherence through a “reminder function” have been tested in Africa, Thailand, Peru, and the United States, but implementation in China is uncommon [21,22].

Like Facebook and Twitter, WeChat is a popular social media app in China. According to the data analysis, WeChat is the most popular social media platform with over 1 billion registered users [23]. Approximately 93% of the residents in the major Chinese cities log on to WeChat every day [24]. The high ownership of mobile phones and the widespread popularity of the WeChat app suggest that this is a promising platform for providing low-cost interventions. Moreover, WeChat-based interventions have shown feasibility and acceptability in HIV prevention and control in China [25,26], which includes MSM [23]. However, studies using the WeChat app to remind MSM to take their medicine daily during PrEP use are limited in China.

Therefore, we conducted a prospective cohort study of PrEP adherence in the MSM population in Western China. Our reminder system is based on the WeChat app for mobile phones that scans individual QR codes and connects to the backend management system to send daily reminder messages. We compared the variability of adherence between the no-reminder group and the reminder group at each time point by plotting the longitudinal trajectory of adherence. At the same time, the relationship between changes in adherence (no change, improvement, decline) and the use of the reminder system was investigated to confirm the influence of the reminder system on adherence and to provide a theoretical foundation for the improvement of the reminder system in the future so as to improve adherence and increase the effectiveness of PrEP.

Methods

Ethics Approval

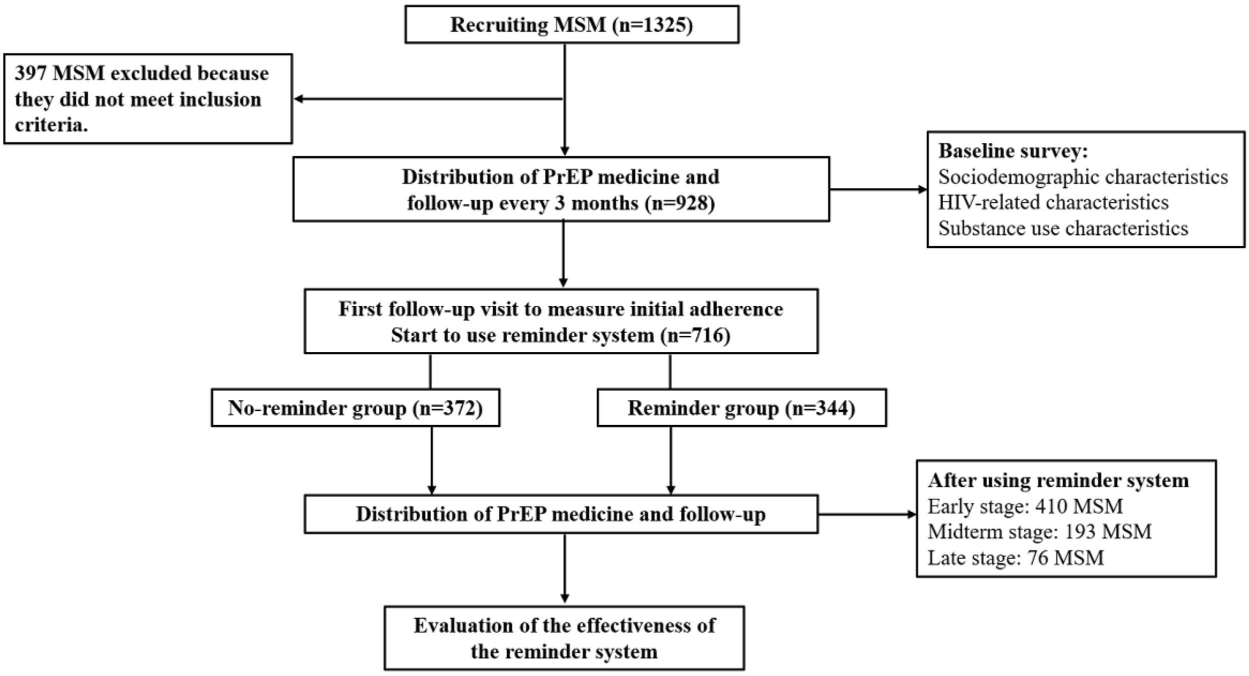
All procedures of this study were in accordance with the ethics approval granted by the ethics committee of Chongqing Medical University (2019001). The ethics committee of Chongqing Medical University has reviewed the proposed use of human participants in the abovementioned project.

Data Collection

This study was a PrEP open-label, multicenter, prospective cohort study conducted from November 2019 to June 2021 in 3 regions of Western China: Chongqing, Sichuan, and Xinjiang (Chinese clinical trial registration ChiCTR190026414). MSM who met the criteria were recruited through collaboration with local nongovernment organizations and peer recommendations. Inclusion criteria for the study population were (1) physiological male (assigned male sex at birth), (2) older than 18 years, (3) had engaged in sex with male partners in the past 6 months, (4) negative HIV antigen-antibody test, (5) willing to use medicines under guidance and subject to follow-up arrangements, and (6) signed informed consent form.

The MSM population was screened for inclusion criteria and then divided into 2 groups: no-reminder group and reminder group. After completing the baseline survey, participants were followed up every 3 months and given their medicines by our study researchers. They received daily oral dose of Lamivudine and Tenofovir Disoproxil Fumarate tablets (300 mg/tablet). The first 3 months after joining the cohort were considered as an observation period with no use of the reminder system. The initial adherence of the study participants was measured and the reminder system was started at the first follow-up visit. Participants in the reminder group scanned a WeChat QR code (unique identity QR code, scanned only once) to receive daily medicine reminder messages, while the no-reminder group took daily oral medicines without reminders. We designated the intervals corresponding to each follow-up time point as early, midterm, and late stages after the initial follow-up visit (beginning to employ the reminder system). A total of 716 MSM were included in the analysis: 372 MSM in the no-reminder group and 344 MSM in the reminder group. Figure 1 presents the flow chart of the recruitment, survey, and follow-up of the study participants.

Figure 1. Flowchart of the recruitment, survey, and follow-up of the study participants. MSM: men who have sex with men. PrEP: pre-exposure prophylaxis.



Reminder System of PrEP

Our study developed a PrEP reminder system in conjunction with Chongqing Future Health Management Company Limited. This system relies on the internet and intelligent medicine information tracking management system using cloud computing, big data, intelligent hardware, and other new generation information technology products to provide effective medicine management for the study participants through the process of medicine-taking plan, medicine reminder, and health knowledge promotion to achieve the expected prevention effect. Our researchers typed in the basic information of the reminder group into the background management system and generated an independent personal QR code. Participants were bound to the backend system after scanning the QR code using their WeChat apps. Daily reminders were sent from the next day, and users could set the time according to their request. In order to protect the privacy of the users, the content of our messages was relatively obscure. For example, when users received a “You need to learn” message from Future Health Management, it is a reminder that they should take the medicine that day. When users received a “Time for examination” message from Future Health Management, it is a reminder that they should visit the study center for the 3-month follow-up (Figure 2).

Figure 2. A: reminds users that they should take their medicine that day and B: reminds users that they should go for a follow-up visit.

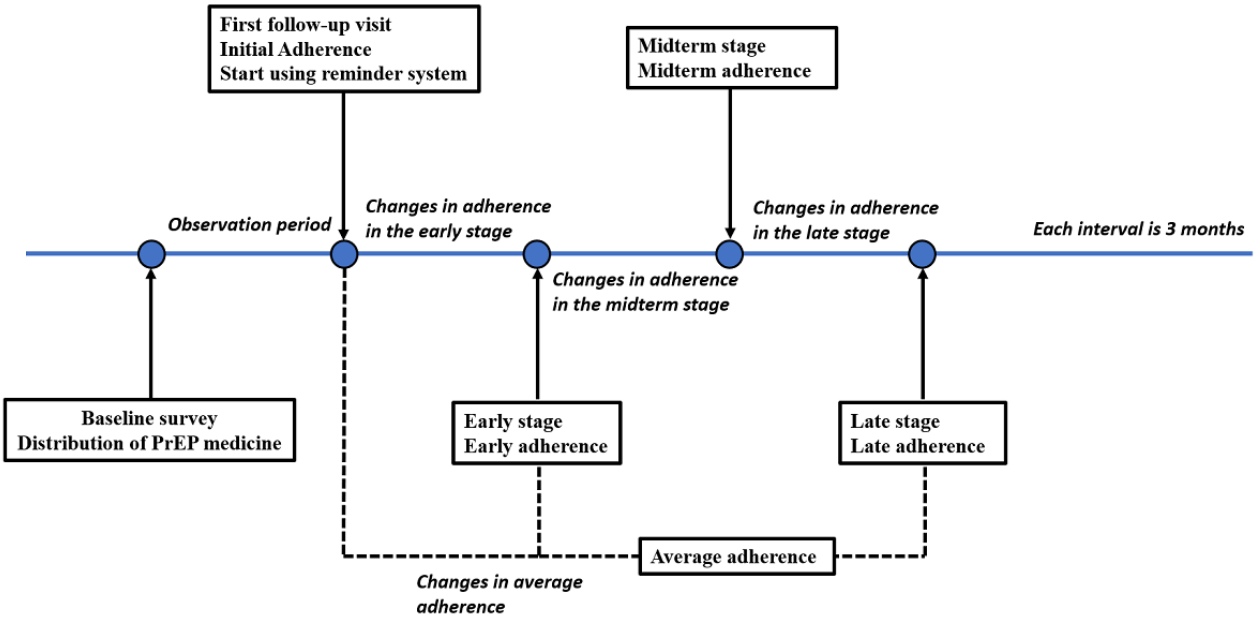
Baseline Variables

The baseline survey included demographic characteristics, HIV-related characteristics, and substance use characteristics. Among them, the demographic characteristics include age, household register location, education attainment, employment status, marital status, and monthly personal income. HIV-related characteristics mainly included HIV testing and counseling, number of sexual partners, condom use, and HIV risk perception. Participants were asked, “In the last month, how many male sexual partners (casual and regular) have you had? How many times did you have sex with a male sexual partner? How many of these times did you use a condom?” These questions were used to measure the number of male sexual partners and condom use during sex. We defined that condoms were used at each sexual intercourse and if the number of condom use was greater than or equal to the number of sexual intercourses. At the same time, participants were asked, “How likely do you think you are to get AIDS?” We used this question to measure the participants’ perceived HIV risk. Participants responded on a scale of 1-5, with a score of 1 indicating very small and 5 indicating very large. We defined a score ≥3 as the subgroup with higher perceived HIV risk. Substance use mainly included alcohol use. Participants were asked, “in the last month, how often did you drink alcohol?” Participants responded, “basically every day,” “at least 3 times a week,” “at least 1 time a week,” “less than 1 time a week,” or “never drink alcohol.” We divided the alcohol use into 2 categories: one for never drinking and one for ever drinking.

Adherence

At each follow-up visit, adherence was measured by self-report. Study participants were asked, “in the last two weeks, have you missed any doses? how many days did you miss?” Participants answered “yes” or “no” and the number of days missed (0-14 days). Adherence was equal to the percentage of days adhered. All answers were checked by our researchers. If illogical answers occurred, quality control and corrections were made in the study site. After completing the baseline survey, participants entered an observation period, taking their medicines without reminders. The participants arrived for the first follow-up visit 3 months later, at which point adherence was referred to as “initial adherence.” In the meantime, study participants in the reminder group began using the reminder system. After this, adherence during the follow-up period was defined as early stage adherence, midterm adherence, and late stage adherence. Changes in adherence at each follow-up time point (no change, improvement, decline) were compared to the adherence in the previous period. For example, the changes in adherence in the early stage is defined as early stage adherence minus initial adherence. Average adherence is the mean of adherence in the early, midterm, and late periods, and changes in average adherence is defined as average adherence minus initial adherence. The definition of adherence in each period is shown in Figure 3.

Figure 3. Explanation of adherence (initial adherence, early stage adherence, midterm adherence, late stage adherence, average adherence) and changes in adherence by period. PrEP: pre-exposure prophylaxis.



Statistical Analyses

We compared the variability of the baseline demographic characteristics, HIV-related characteristics, and substance use characteristics between the no-reminder group and reminder group of the MSM population. Trajectories of adherence were plotted for the 2 groups. The nonparametric test (Kruskal-Wallis test) was used to compare the variability of adherence between the 2 groups at each follow-up time point. A multinomial logistic regression model was developed using the changes in adherence (no change, improvement, decline) in each period of follow-up as the dependent variable, and the relationship between the reminder system and the changes in adherence was further assessed by odds ratio (OR) and 95% CI. Variables with $P \leq .15$ were first screened by one-way analysis of variance, which was included in the multinomial logistic regression model. The efficacy of the reminder system was assessed by exploring the factors influencing the improvement and decline of adherence, using no change in adherence as the reference. $P<.05$ indicated a statistical difference. All statistical analyses were performed with SAS software (SAS Institute).

Results

A total of 716 MSM were included in the analysis, with 372 in the no-reminder group and 344 in the reminder group. The baseline demographic characteristics, HIV-related characteristics, and substance use characteristics of the 2 groups were not statistically different in one-way analysis of variance. The results of the descriptive analyses and chi-square tests for each variable are shown in Table 1.

Adherence trajectories were plotted for the no-reminder group and reminder group (Figure 4). The median of initial adherence was 1.00 (IQR 0.64-1.00) in the no-reminder group and 1.00 (IQR 0.47-1.00) in the reminder group, with no statistical difference in initial adherence between the 2 groups (P=.48). After using the reminder system, adherence in the no-reminder group fluctuated between 0.75 and 0.80; adherence in the reminder group gradually increased over time from 0.76 to 0.88. There was no statistical difference in adherence between the 2 groups at the early (P=.69), midterm (P=.96), and late (P=.37) stages of follow-up. After using the reminder system, the mean adherence for the 3 periods in the no-reminder group was 0.79 and the mean adherence in the reminder group was 0.78, which was not statistically different (P=.82) (Table 2).

[a] Kruskal-Wallis test was used.

To further explore the effect of the reminder system on adherence, the percentage of changes in adherence (no change, improvement, decline) at each time point in the MSM population is shown in Figure 5. A percentage bar graph was used to show the distribution of the changes in adherence. No change in adherence was used as a reference for the dependent variable, and the no-reminder group was used as a reference for the independent variable. After the one-way analysis of variance, variables with $P \leq .15$ were included in a multinomial logistic regression model for adjusting. The adjusted variables in the early stage included age, HIV counseling, and male sexual partners’ attitude. The adjusted variables in the midterm stage included age, household register location, education attainment, male sex partners, and their attitudes. The adjusted variables in the late stage included household register location and male sexual partners’ attitude. In the model for changes in the average adherence, the adjusted variables included age, HIV testing, HIV risk perception, alcohol use, and male sexual partners’ attitude. After adjusting for basic demographic characteristics, HIV-related characteristics, and substance use characteristics with no change in adherence as a reference, analysis based on multinomial logistic regression models was obtained (Table 3). An improvement in adherence in the early stage was positively associated with the use of the reminder system (OR 1.65, 95% CI 1.01-2.70; *P*=.04). The result showed that the reminder system was not able to prevent a decline in adherence in the early stage, and the difference was not statistically significant (*P*=.78). The changes in adherence in both the midterm and late stages were not statistically associated with the reminder system (*P*>.05). An improvement in the average adherence compared to the initial adherence was associated with the use of the reminder system (OR 1.82, 95% CI 1.10-3.01; *P*=.02); a decline in the average adherence was not associated with the reminder system (*P*=.67).

Figure 5. Distribution of changes in adherence.

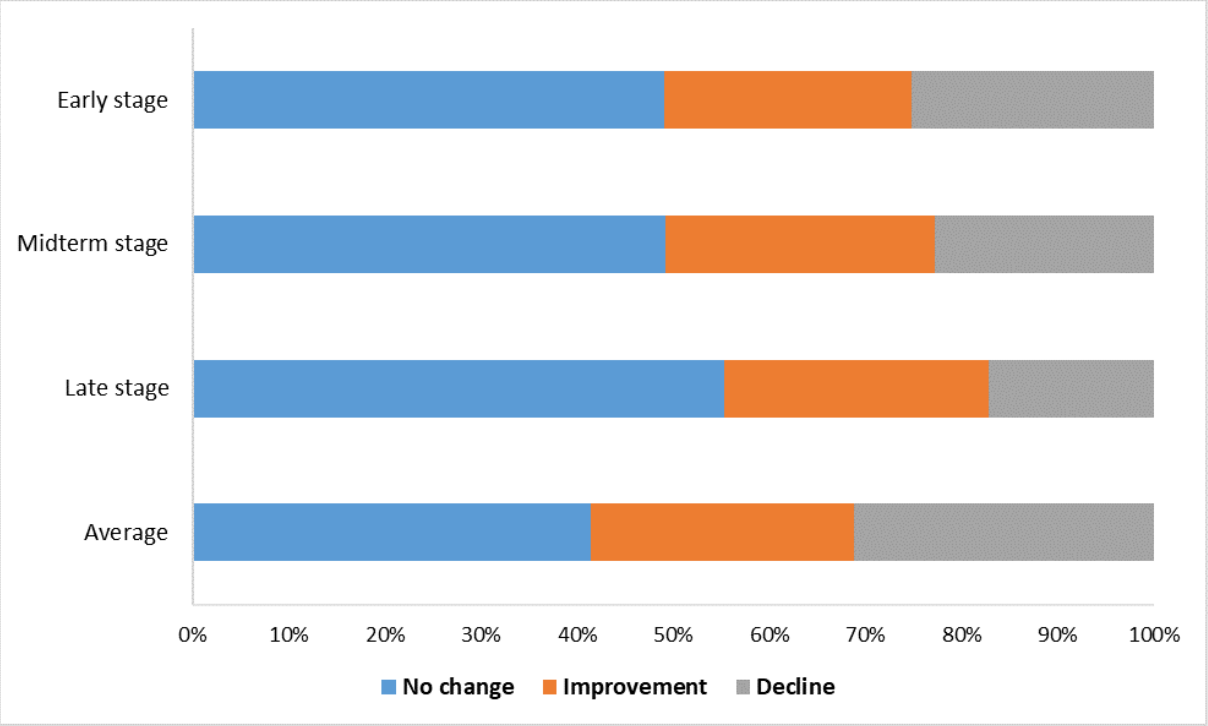

Table 3. Multinomial logistic regression analysis of the changes in adherence at each time point after using the reminder system.

Time point, variables	Improvement versus no change		Decline versus no change	
	Odds ratio (95% CI)	*P* value	Odds ratio (95% CI)	*P* value

No-reminder group	Reference	Reference	Reference	Reference

Discussion

Principal Findings

Our study explored the effect of a reminder system on PrEP adherence to promote adherence and support HIV prevention efforts in the MSM population. We found that the reminder system contributed to an improvement in adherence in the early stage. Previous studies have mentioned that text message reminders are one of the interventions that can improve adherence [27]. Two pilot studies and a PrEP demonstration project in Kenya and Brazil have also demonstrated that incorporating text message reminders into PrEP practices is an acceptable method [28-30]. These reminder methods have been found to be effective in improving adherence by increasing the user's knowledge of the medicine, motivation, and perceived support through text messages [31]. Meanwhile, according to Rogers' Protective Motivation Theory, users' motivation factors may be the driving force for individual behavior change [32]. A prior study has also confirmed that the Protective Motivation Theory can provide a valuable reference for the study of PrEP adherence in the MSM population [33]. The newly developed reminder system in our study was based on text message, and the presentation of this information can increase users' motivation to take their medicines and encourage them to change their behavior, especially in relation to PrEP adherence.

We believe that the use of the reminder system can encourage users to form medicine-taking habits. Habit is defined as behavior that is performed subconsciously without thought [34]. In the book of "The Power of Habit," Charles Duhigg defines habit as a 3-step loop of cue, routine, and reward [35]. Habits are behaviors that are induced by situational cues, and our reminder system serves as a cue. Previous findings have shown that habit formation interventions have the potential to improve adherence to antiretroviral therapy [36]. In the meanwhile, as mentioned in the previously published review, the idea of "habit" has been applied to the Medication Usage Skills for Effectiveness program [35]. In their program, users selected cues to help them remember to take their medicine, such as a specific time, a meal, or a reliable daily ritual. According to the findings of that study, the reminder system provided daily cues to users, motivating them to develop the habit of taking medicine and improving their adherence. However, the reminder system was ineffective in preventing adherence declines in the early stage as well as changes in adherence in the midterm and late stages of follow-up. We believe that there are several main reasons for this.

First, according to previous survey results, 70.21% of MSM did not take their medicines because they forgot, while 29.08% said they were too busy, 28.01% were worried about the side effects, and 18.44% thought it was troublesome to take medicine [15]. Forgetting to take medicine is the main factor affecting adherence, but there are still other factors that can potentially impact adherence. Reminder systems are primarily targeted at MSM who forget to take their medicine, and the effect of reminder systems on adherence may not be significant for those users with low willingness to take medicine. Therefore, reminder systems are ineffective in stopping the decline in adherence in MSM in the early stage.

Second, as we mentioned before, practice over many repetitions can help develop habits. The increased level of early stage adherence may be related to the reminder system that motivates users to develop the habit of taking medicine. However, repetitive activity eventually transforms the individual's cognitive control from a conscious to an automatic process [37]. This suggests that once a habit is formed, the act of taking medicines shifts from a conscious motivated behavior to an unconscious automatic one, which does not require external reminders. This may lead to a less effective reminder system in the midterm and late stages. Therefore, if the reminder system is used for medicine management in the early stage, it can not only promote the formation of medicine habits and improve adherence among users but also make the use of reminder systems more targeted and effective.

In addition, while most participants expressed positive attitude toward using the reminder system, a few expressed concerns about this approach. Fear of privacy disclosure was the main reason. For example, it is still possible for others to see the messages after receiving it. Owing to the special nature of MSM population, the difference in public awareness, and the complexity of the public opinion environment, privacy disclosure in this population may cause physical and psychological harm and negative impact on personal life. Once their privacy is leaked, they may face problems such as discrimination, stigma, breakdown of social relationships, and even experience anxiety, depression, and other psychological disorders [38-40]. After receiving a reminder message, users may be likely to quickly close the page to prevent it from being seen by others. There are also some users who may unbind with the backend system in order not to be discovered by their family and friends. However, this may reduce the reminder system's effectiveness, resulting in poor performances in the midterm and late stages. Thus, one of the most important aspects of system optimization is the privacy protection of the users.

Moreover, as a new developed reminder system for improving PrEP adherence, it does have some problems that were not considered. For instance, what are the attitudes of users toward this daily reminder? We do not have any surveys on this. Is the frequency of the daily reminders feasible? Would it be more effective to have a weekly reminder instead? It emphasizes the necessity for more personalization. Administrators can communicate with users face-to-face, design reminders to their individual needs, set reminder frequency, and provide feedback and corrections. It was also mentioned in an in-depth qualitative interview that most users showed a strong preference for feedback mechanisms [19]. The ability to respond and receive information may help increase users' motivation to participate in the program and improve health outcomes. For example, users can interact with the system, and the system will send encouraging words like "Good job" after taking the medicine. In addition, we can try to include health information and education in the WeChat reminder messages, for example, the risk of HIV infection if you do not use PrEP consistently. In this way, we can increase the feedback from the system to the users. The comments and suggestions provided by users provide an important basis for understanding messaging preferences and operating procedures, which further help managers optimize text messages and overall implementation methods.

The reminder system has several advantages. First, although the development and management of the reminder system is challenging, the issue of message costs is fully considered compared to SMS text messaging. Many literatures on SMS text messaging usage do not focus on reducing message costs [41,42], while the reminder system we use does not incur any cost as long as it is bound to the backend system for the first time. Second, according to previous studies, users prefer WeChat as a platform for receiving information and interacting with each other [25]. Compared to receiving text messages, app-based reminders are visually and formally more vivid and interesting, which provide a more convenient platform for our reminder system and are more likely to inspire interest and confidence in users. At the same time, preliminary experience with reminder system practice suggests that given the widespread use of the WeChat app compared to smartphones and other internet resources, this reminder method may be a relatively simple, convenient, and a quick tool to support HIV prevention efforts among high-risk populations [17,43,44]. MSM may benefit from a technology-based intervention that can also be integrated into routine HIV education for high-risk populations. In addition to PrEP, adherence also plays an important role in areas such as HIV antiretroviral therapy, clinical research in traditional Chinese medicine, and chronic diseases [45-47]. Therefore, there is no denying the importance and potential applicability of this reminder system for medicine adherence. The usage of a reminder system not only promotes healthy medicine-taking habits but also decreases the possibility of privacy breaches and costs associated with long-term use. This system is expected to be used on a broader scale after the improvements and upgrades, with a focus on evaluating social and economic benefits as well as targeted dissemination of health education.

Limitations

There were some limitations in this study. First, adherence was measured by self-report. Owing to recall bias, inaccurate reporting of adherence may occur [48,49]. However, it may also have a social desirability bias, which will cause adherence to be overestimated [50,51]. A previous study has also pointed out that self-reported data may be reliable [52]. Second, the initial design protocol for our study was a prospective cohort study based on a randomized controlled trial in which study participants were randomized to a no-reminder group and a reminder group, and they started using the reminder system once they entered the cohort. However, owing to the impact of COVID-19, the reminder system's development was delayed, and a portion of the MSM was already recruited. Because of the particularity and privacy of the MSM, finding eligible participants was very difficult. To avoid attrition of the study participants, we had to change the protocol to include the first 3 months of follow-up as the observation period without using a reminder system. When the first 3-month follow-up visit was conducted, the reminder system was initiated, which addressed the problem of the reminder system's development delay. Nevertheless, this could have a potential impact on our results. Since the study participants took the medicine 3 months in advance, the efficacy of the reminder system was underestimated as they may have developed good adherence during this time. In addition, for the reminder group, we did not ask more questions about the reminder messages. For example, did the participants read the reminder messages every day? Therefore, we were unable to perform a subgroup analysis to assess the effect of different groups. Future studies could focus on more detailed subgroups. Lastly, the specificity of MSM population and the impact of COVID-19 posed significant challenges in recruitment and the follow-up for our study; therefore, longitudinal cohort maintenance in this population was not optimistic.

Conclusions

Our study constructed a longitudinal cohort of PrEP adherence, explored the factors associated with changes in adherence, and further confirmed the effect of the WeChat-based reminder system on improving PrEP adherence in the MSM population in Western China. The effectiveness of the reminder system in improving adherence is currently significant in the early stage, which is considered to be related to the increased motivation of the users and the development of medicine-taking habits. Although it still can be improved and upgraded, there is no denying the importance and potential applicability of this reminder system for early-stage medicine management, which can help users build medicine-taking habits and increase adherence. Meanwhile, enhancing the privacy protection of reminder system and providing more personalized services and informative feedback are priorities for future studies, which will help improve adherence in the MSM population and promote PrEP implementation.

Acknowledgments

The authors thank all men who have sex with men participants in this study. In addition, the authors thank the following persons for their support to this study: Ailong Huang, Jianghong Dai, Yuwen Gao, Ruibin Deng, and Cuie Kong. Furthermore, the authors thank the members of the nongovernment organizations and the doctors working in the First Hospital of Chongqing Medical University.

Abstract

Background: Mental illness stigma has been a global concern, owing to its adverse effects on the recovery of people with mental illness, and may delay help-seeking for mental health because of the concern of being stigmatized. With technological advancement, internet-based interventions for the reduction of mental illness stigma have been developed, and these effects have been promising.

Objective: This study aimed to examine the differential effects of internet-based storytelling programs, which varied in the levels of interactivity and stigma content, in reducing mental illness stigma.

Methods: Using an experimental design, this study compared the effects of 4 storytelling websites that varied in the levels of interactivity and stigma content. Specifically, the conditions included an interactive website with stigma-related content (*combo* condition), a noninteractive website with stigma-related content (*stigma* condition), an interactive website without stigma-related content (*interact* condition), and a noninteractive website without stigma-related content (*control* condition). Participants were recruited via mass emails to all students and staff of a public university and via social networking sites. Eligible participants were randomized into the following four conditions: *combo* (n=67), *stigma* (n=65), *interact* (n=64), or *control* (n=67). The participants of each group viewed the respective web pages at their own pace. Public stigma, microaggression, and social distance were measured on the web before the experiment, after the experiment, and at the 1-week follow-up. Perceived autonomy and immersiveness, as mediators, were assessed after the experiment.

Results: Both the *combo* (n=66) and *stigma* (n=65) conditions were effective in reducing public stigma and microaggression toward people with mental illness after the experiment and at the 1-week follow-up. However, none of the conditions had significant time×condition effects in reducing the social distance from people with mental illness. The *interact* condition (n=64) significantly reduced public stigma after the experiment (P=.02) but not at the 1-week follow-up (P=.22). The *control* condition (n=67) did not significantly reduce all outcomes associated with mental illness stigma. Perceived autonomy was found to mediate the effect of public stigma (P=.56), and immersiveness mediated the effect of microaggression (P=.99).

Conclusions: Internet-based storytelling programs with stigma-related content and interactivity elicited the largest effects in stigma reduction, including reductions in public stigma and microaggression, although only its difference with internet-based storytelling programs with stigma-related content was not statistically significant. In other words, although interactivity could strengthen the stigma reduction effect, stigma-related content was more critical than interactivity in reducing stigma. Future stigma reduction efforts should prioritize the production of effective stigma content on their web pages, followed by considering the value of incorporating interactivity in future internet-based storytelling programs.

Trial Registration: ClinicalTrials.gov NCT05333848; https://clinicaltrials.gov/ct2/show/NCT05333848

KEYWORDS

mental illness stigma; internet-based; interactivity; storytelling; social distance; microaggression

Introduction

Mental Illness Stigma

According to the social cognitive model of stigma, mental illness stigma is defined as having stereotypical thoughts, prejudicial feelings, and discriminatory actions against people with mental illness in situations with power differentials [1]. Mental illness stigma is a global concern owing to its detrimental effects imposed on people with mental illness across various life domains (eg, education, housing, employment, and health care) during their recovery and their willingness to seek help [1-3].

Given the possible negative impacts of mental illness stigma, various approaches have been proposed to reduce it, with education and contact being identified as the 2 most common and effective approaches in inducing positive attitudinal changes and reducing public stigma [4-7]. Knowledge enhancement through psychoeducation can improve mental health literacy, which corrects misunderstanding of mental health–related issues, challenges stigmatizing beliefs, and supports recovery from mental illness [7]. Contact is effective in confronting stigmatization through an equal, interpersonal exchange that fosters perspective taking and empathy [4]. The primary form of contact is an in vivo one, which requires the person with lived experience to share his or her experiences of mental illness and stigmatization with an audience live. However, it can be costly and taxing for speakers to share their experiences repeatedly [8]. Hence, researchers have investigated the possibilities of using parasocial contacts, which include video-based, filmed, and web-based contacts [4,8-11]. These have exhibited similar effects as were found with in vivo contacts [4,11].

Internet-Based Stigma Reduction Interventions

Recently, internet-based programs addressing mental illness stigma have been established worldwide owing to their low cost, accessibility, and scalability [12-14]. Studies have shown the effectiveness of internet-based stigma reduction programs in the form of social media platforms, digital games, webinars, filmed social contact, and websites [9,15-19]. Research has also shown that internet-based and face-to-face stigma reduction programs are equally effective [20,21]. Research has also found increased empathy and reduced intergroup anxiety to be significant mediators explaining the effects of interventions on the reduction of mental illness stigma [22,23]. However, the content and design of these internet-based stigma reduction programs vary greatly, and limited efforts have been made to investigate the common factors contributing to their effectiveness.

In addition to incorporating the critical determinants, namely education and contact, in stigma reduction, many internet-based interventions have made use of interactivity and storytelling in their designs and have demonstrated positive results in reducing mental illness stigma [24-28]. However, the types of interactivity are diverse, and it is unknown whether the addition of interactivity induces significant positive attitudinal changes that should be valued. Despite the popularity of incorporating elements of interactivity into websites to enhance the engagement of users, there is minimal empirical work investigating the effect of interactivity on stigma reduction. Thus, rather than focusing on psychological variables (ie, empathy and intergroup anxiety) as mediators (the effects of which have been established), this study focused on the mediators related to the form of interventions and aimed to examine the differential effects of internet-based storytelling programs with the presence or absence of interactivity and stigma content in reducing mental illness stigma.

Stigma-Related Content

As previously mentioned, educating about mental illness and fostering an understanding toward people with mental illnesses helps individuals to clear misunderstandings and empathize with their experiences [7]. Hence, it is pivotal to introduce stigma-related content into stigma reduction programs. However, research has shown significant positive attitudinal changes in *control* conditions where stigma-related content is not present [28,29]. Although the situation is rare, it is proposed that the effect might be attributed to the social desirability effect and priming effect in which people have been prompted to answer questions related to mental illness attitudes at preassessment [28,29]. In this study, stigma-related content was one of the independent variables that accounted for this possible effect. Despite some cases of stigma reduction in the absence of stigma content, we hypothesized that the reduction of stigma will only manifest in conditions with the presence of stigma content.

Storytelling

In previous research related to interventions aimed at reducing mental illness stigma, the use of storytelling has demonstrated significant reduction in stigma [24,28,30]. Corrigan and Kosyluk [31,32] have identified three crucial components that make storytelling effective in reducing mental illness stigma, namely people with lived experience as storytellers, in-person story delivery, and descriptions encompassing both ups and downs on the recovery journey of mental illness. Disclosure from storytellers enables people to understand the experience shared in a deeper way with the aid of contexts and connection with the storytellers [33]. Storytelling was found to be positively related to people’s reflection, motivation, and engagement, which not only allows people to have a better understanding of people with mental illnesses cognitively but also cultivates empathy in people [30].

Interactivity

Empirically, few studies have shown that communication using interactive media could exert synergistic effects with education in reducing stigmatizing attitudes toward people with mental illness [26,27,34]. However, past efforts investigating internet-based stigma reduction programs that have incorporated interactivity have mainly used interactivity in different delivery formats. For instance, a study allowed participants to choose the sequence of reading materials but not the content [26]. Another study allowed individuals to undergo simulated contact by using web-based interactions with avatars who shared their emotional distress [27]. There is still a dearth of empirical studies investigating the effects of interactivity in internet-based stigma reduction programs.

Scholars have proposed that the effect might be attributed to the inducement of positive affect during the processing of mental illness information on the internet [26,35]. According to the Systemic Thinking Model, in interactive environments, interactivity allows individuals to be the agent and effect physical environmental changes that best align with their thinking needs and flow [36]. Individuals actively manipulate information and receive contingent feedback, which facilitates the encoding of new information [37]. In turn, information processing and learning are facilitated [36]. Empirical research has found that interactivity induces positive affect, including increased satisfaction and pleasure [38]. Individuals tend to favor interactive information through attitude transfer mechanisms [39]. In addition, research shows that incidental positive affect can reduce complex affective judgments toward outgroup members and lead to more prosocial orientations [40]. These findings suggest that interactivity could lead to positive affect and reduced stigmatizing attitudes toward people with mental illness even without the presence of stigma content aiming to correct misconceptions.

Interactivity is a favorable element in learning. McMillan proposed four main types of interaction, namely user-to-user, user-to-content, user-to-medium, and medium-to-medium interactions [41]. Most internet-based programs have used user-to-content interaction, where individuals can interact with information on the internet [42]. Kim and Stout [26] examined a type of user-to-content interaction by allowing individuals to control the navigation sequence of web pages. In this study, individuals interacted with the contents of web pages by choosing their actions and responses, and the possible factors mediating the interactivity effect were analyzed.

Possible Mechanisms of Change

Research has found interactivity to have a significant role in improving information processing through enhanced motivation, which facilitates stigma reduction [26]. Perceived autonomy and immersiveness have been found to enhance motivation [43,44]. Thus, they might be possible mediators of the effect of interactivity although their relationships remain untapped.

Perceived autonomy refers to the perception of being the agent, which makes one consider the experience and behavior as concordant with one's integrated sense of the self [45]. When perceived autonomy is high, autonomy need satisfaction is achieved and cognitive changes are facilitated [46]. By allowing individuals to select their responses as an avatar on the website, the heightened perceived autonomy might facilitate the endorsement of responses and actions selected, which may foster cognitive changes. Therefore, perceived autonomy might be a possible mediator of cognitive changes that correct misbeliefs about mental illnesses.

Immersiveness indicates the subjective feelings of participating in a comprehensive and realistic experience [47]. Storytelling has been evident in inducing immersiveness [48]. With higher levels of immersiveness, individuals are driven to take in messages conveyed in the story [49], which in turn leads to cognitive and affective changes related to mental illness stigma [50-53]. Interactivity also allows people to engage with the content, which is also considered an immersive medium [47]. Thus, immersiveness was proposed to be another possible mediator leading to stigma reduction.

Aims and Hypotheses

This experimental study aimed to investigate the effect of internet-based storytelling programs on the manipulation of stigma-related content and interactivity. We hypothesized that an internet-based storytelling program with a combination of interactivity and stigma content would lead to the most significant reduction in public stigma, microaggression, and social distance from people with mental illnesses, followed by an internet-based storytelling program with stigma content only and interactivity only, compared with the control group. Second, we hypothesized that the effects observed in stigma reduction would be mediated by perceived autonomy and immersiveness owing to the presence of interactivity.

Methods

Study Design

This experimental study compared the following four internet-based storytelling programs: an interactive stigma content website (*combo* condition), a noninteractive stigma content website (*stigma* condition), an interactive nonstigma content website (*interact* condition), and a noninteractive nonstigma content website (*control* condition).

Ethics Approval

Ethics approval for behavioral research was obtained from the Survey and Behavioral Research Ethics Committee of the Chinese University of Hong Kong, and the study was registered on ClinicalTrials. gov (NCT05333848). The findings of this study were reported in accordance with the recommendations of the CONSORT (Consolidated Standards of Reporting Trials) guidelines.

Participants

This study targeted people who were aged ≥18 years and able to read and understand Chinese. Recruitment was performed by sending mass emails to students and staff of a public university in Hong Kong and by posting advertisements on social media. Individuals who were interested in participating in the study visited the registration link, where they were screened through a web-based survey on basic contact information and age. The experimenter (THCF) then provided eligible individuals a Zoom (Zoom Video Communications Inc) appointment link, where individuals indicated their preferred day and time to participate in the experiment. A Zoom link was provided to individuals upon the completion of their booking. At the scheduled Zoom experimental session, participants were given detailed information about the study aims, length of the program, and participant involvement. Participants provided informed consent by checking the *I agree* button at the end of the study description page. Afterward, participants received another web-based questionnaire link to complete the pre-experiment questionnaire. The participants were randomly assigned to 1 of the 4 experimental conditions through block randomization. Participants completed the pre-experiment, postexperiment, and 1-week follow-up questionnaires on the web.

Storytelling Programs

The four internet-based storytelling programs were administered via the internet with 4 different web pages that were displayed in the Chinese language. The design of the web pages, including the story content and the use of graphics, was created to appeal widely to the adult population without catering specifically to a certain gender or age group. The Amazing Adventure Against Stigma website [54] was used in the experimental study for the *combo* and *stigma* conditions. Animation with fictional backgrounds (eg, mountains, canyons, and safari) and avatars of diverse body types, height, skin color, and gender-neutral hairstyle and clothing were used to minimize the effect of cultural and environmental effects that may be more prominent in using real persons and real settings on the participants and to maximize the possibility of adults with diverse backgrounds relating to the avatars. It is also easier and more economical to create control animations by using existing software than to produce videos with real people in real-life settings. Each web page took approximately 20 minutes to browse through. The presence or absence of interactivity and the presence or absence of stigma content were manipulated on the four web pages. All web pages involved a story. For the *combo* and *stigma* conditions, the story was identical, which was about the journey of a person experiencing mental illness stigma. For the *interact* and *control* conditions, the story was also identical and nonstigma related, illustrating the typical day of a person. Interactivity was manipulated by adding interactive elements to the *combo* and *interact* conditions, where participants could choose their actions and responses on web pages. In these 2 conditions, the participants had internet-based contact with the protagonist in the story, where they learned about the life experiences of the protagonist through the story portrayed on the web pages. Contact and interaction with the protagonist were in the moment as the story regarding the lived experience of the protagonist unfolded along the journey and the participants chose their responses to continue their interaction with the protagonist. The story content in the *combo* and *stigma* conditions was organized based on the disclosure of a person with a lived experience of mental illness. The person with a lived experience of mental illness accompanied participants to visualize their microaggressive encounters in various life domains (eg, work, family, and social circle) and the public's misunderstanding of mental illness with the aid of visual images on the web page. The story also incorporated messages about the interconnection between people with or without mental illness. The selection of the aforementioned story content was based on the previous identification of both education and contact as the most effective approaches for inducing stigma reduction [4-7].

The story content in the *interact* and *control* conditions formulated a typical day for a person, which began with the morning routine, followed by having breakfast, going to work, working encounters, and ending the day. The ordinary storyline was created to minimize affective arousal and, in turn, minimize influences on judgment and decision-making according to the affect-as-information framework proposed by Storbeck and Clore [55]. At the end of each web page experience, participants were provided with a questionnaire link that measured microaggression, public stigma, social distance from people with mental illness, perceived autonomy, and immersiveness. One week after the experimental session, participants completed a follow-up questionnaire assessing microaggression, public stigma, and social distance from people with mental illness. Finally, participants were debriefed. Participants could not reaccess the contents of the web pages after the experimental session. Screenshots of the web page interventions are provided in Multimedia Appendix 1.

Measures

Baseline Measures

At baseline, participants provided demographic and background information, including age, gender, education level, religion, and previous experience with mental illness.

Contact With People Having Mental Illness

To assess one's previous experience with mental illness, the Level of Contact Report [56] was used, where participants indicated whether they had the experiences reported in the 12 items such as "I have watched a movie or television show in which a character depicted a person with mental illness" and "I have observed persons with a severe mental illness on a frequent basis." Higher scores indicated higher levels of previous contact with people with mental illnesses.

Mental Illness Stigma Measures

Public Stigma Toward People With Mental Illness

The 21-item Public Stigma Scale-Mental Illness-Short Version [57] was used to assess public stigma regarding mental illness and personal advocacy. Each item was rated on a 6-point Likert scale ranging from 1 (strongly disagree) to 6 (strongly agree). Sample items included "People with mental illness are a burden to society" (public stigma) and "I wholeheartedly fight for the rights of people with mental illness" (personal advocacy). Reverse scoring was performed for personal advocacy items. Higher scores indicate higher levels of public stigma. In this study, its Cronbach α values were .93, .95, and .94 at baseline, after the experiment, and at the 1-week follow-up, respectively.

Microaggression

Microaggression was measured using the 17-item Mental Illness Microaggressions Scale [58], which covers the assumption of inferiority, patronization, and fear of mental illness. Each item was rated on a 4-point Likert scale ranging from 1 (strongly disagree) to 4 (strongly agree). Sample items included "If someone I'm close to told me that they had a mental illness diagnosis, I would expect them to have trouble understanding some things" (assumption of inferiority), "If someone I'm close to told me that they had a mental illness diagnosis, I would give them advice on how to remain stable" (patronization), and "If I saw a person who I thought had a mental illness in public, I would keep my distance from them" (fear of mental illness). Higher scores indicate higher levels of microaggression. In this study, the Cronbach α values of the Mental Illness Microaggressions Scale were .78, .86, and .87 at baseline, after the experiment, and at the 1-week follow-up, respectively.

Social Distance From People With Mental Illness

The 8-item Social Distancing Scale [57] was used to measure the behavioral intention to maintain social distance from people with mental illness. Participants rated the extent to which they endorsed each item from 1 (very willing) to 6 (very unwilling) on items such as "Assuming you have children, you will let persons with mental illnesses take care of your children" and "You will work with persons with mental illnesses in the same institution." In this study, its Cronbach α values were .83, .88, and .86, at baseline, after the experiment, and at the 1-week follow-up, respectively.

Mediators Measures

Perceived Autonomy

To assess the perceived autonomy of the web page experience, the 10-item Self-Determination Scale [59] was used in the postexperiment questionnaire. Each item was a pair of opposite statements, in which participants rated their level of perceived choice and self-awareness with a slider from 1 (only A feels true) to 5 (only B feels true). Sample items included item—"A. During this web page experience, I always feel like I choose the things I do. B. During this web page experience, I sometimes feel that it's not really me choosing the things I do" (perceived choice)—and item 2—"A. During this web page experience, my emotions sometimes seem alien to me. B. During this web page experience, my emotions always seem to belong to me" (self-awareness). Reverse scoring was performed for perceived choice items. In this study, its Cronbach α was .89 after the experiment.

Immersiveness

The 15-item Transportation Scale [60] was used to assess participants' immersiveness in the web experience. It used a 4-point Likert scale ranging from 1 (very much) to 4 (not at all) for items such as "I could picture myself in the scene of the events described in the web page." The last 4 items were adapted to suit the experimental conditions. In the *combo* and *stigma* conditions, the last four items were "While reading the web page, I had a vivid image of the avatar representing me"; "While reading the web page, I had a vivid image of the host"; "While reading the web page, I had a vivid image of the journey"; and "While reading the web page, I had a vivid image of the dialogue." In the *interact* and *control* conditions, the last four items were "While reading the web page, I had a vivid image of the avatar representing me"; "While reading the web page, I had a vivid image of my home"; "While reading the web page, I had a vivid image of my breakfast"; and "While reading the web page, I had a vivid image of my office." Items 2, 5, and 9 were framed negatively. All the items were scored in the direction that higher scores indicate higher levels of immersiveness. In this study, its Cronbach α was .84 after the experiment.

Data Analysis

All analyses were conducted using SPSS (version 27.0; IBM Corporation) and the moderation and mediation plug-in PROCESS. Categorical chi-square and 1-way ANOVA were used to examine baseline differences among the experimental conditions. Repeated measures ANOVA with Bonferroni adjustment and post hoc analysis were conducted to detect significant interaction effects between condition and time to see if conditions showed significant reduction in all mental illness stigma outcomes across the 3 time points. Mediation analysis was conducted using PROCESS model 4 to investigate the relationship of possible mediators, perceived autonomy, and immersiveness, with all outcomes at follow-up assessment.

Results

Participant Characteristics

A total of 263 participants were recruited for this study and completed the experimental session, pre-experiment and postexperiment questionnaires. All but 1 participant (262/263, 99.6%) completed the 1-week follow-up questionnaire. The procedure of the study is illustrated in Figure 1. Demographics and baseline characteristics of 263 participants were analyzed, and data from 262 participants were analyzed using repeated measures ANOVA and mediation analyses. The mean age of the participants was 22.56 (SD 6.16) years. Most of the study participants were women (182/263, 69.2%). The participants were predominantly university students (227/263, 86.3%), with 74.9% (197/263) being undergraduates. Among the 197 undergraduate students, 11.8% (31/197) were in year 1, 17.1% (45/197) in year 2, 22.8% (60/197) in year 3, 20.5% (54/197) in year 4, 1.9% (5/197) in year 5, and 0.8% (2/197) in year 6. The other detailed demographics and baseline characteristics of the participants are presented in Table 1.

Across the four conditions, significant gender differences were found (χ^2_3=10.0; *P*=.02). The *control* condition had a higher women-to-men ratio than the other 3 conditions. A significant difference in age across conditions was also found in the 1-way ANOVA ($F_{3,259}$=3.28; *P*=.02). A correlation analysis was performed to investigate whether gender and age were correlated with mental illness stigma outcomes. Age was not correlated with any of the outcomes, including public stigma (*r*=−0.02; *P*=.81), microaggression (*r*=−0.02; *P*=.74), and social distance (*r*=0.08; *P*=.18). Gender was weakly correlated with public stigma (*r*=−0.14; *P*=.02) and microaggression (*r*=−0.12; *P*=.05) but not with social distance (*r*=−0.01; *P*=.84). No other significant differences in demographic characteristics were found. In terms of participants' previous experiences with mental illness, no significant differences were found across the conditions. Given the baseline difference in gender across conditions, gender was included as a covariate in subsequent analyses.

Mental Illness Stigma Measures

Public Stigma Toward People With Mental Illness

Results from the repeated measures ANOVA indicated a significant time×condition effect (*P*=.002; η^2=0.04), and a post hoc analysis was conducted. In the *combo* condition, public stigma significantly decreased from baseline to after the assessment (mean difference 0.61, 95% CI 0.49-0.74; *P*<.001; η^2=0.37), and the decrease was maintained at the 1-week follow-up (mean difference 0.53, 95% CI 0.37-0.69; *P*<.001; η^2=0.37). In the *stigma* condition, public stigma also significantly decreased from baseline to after the assessment (mean difference 0.42, 95% CI 0.30-0.55; *P*<.001; η^2=0.22), and the decrease was maintained at the 1-week follow-up (mean difference 0.34, 95% CI 0.18-0.50; *P*<.001; η^2=0.22). In the *interact* condition, public stigma significantly decreased from baseline to after the assessment (mean difference 0.14, 95% CI 0.02-0.26; *P*=.02; η^2=0.03), but the effect was not sustained at the 1-week follow-up (mean difference 0.12, 95% CI −0.04 to 0.28; *P*=.22; η^2=0.03). In the *control* condition, the effect was not significant from baseline to after the assessment (mean difference 0.07, 95% CI −0.06 to 0.20; *P*=.56; η^2=0.01) and from baseline to 1-week follow-up (mean difference 0.09, 95% CI −0.08 to 0.26; *P*=.57; η^2=0.01). In terms of mean difference values, the results indicated that the effect was the strongest in the *combo* condition, followed by the *stigma* and *interact* conditions. An additional post hoc analysis was carried out to compare *combo* and *stigma* conditions; the interaction effect between interactivity and stigma content was not significant (*P*=.09).

Microaggression

The results showed a significant time×condition effect (*P*<.001; η^2=0.06), and a post hoc analysis was carried out. Microaggression significantly decreased from baseline to after the assessment in both the *combo* (mean difference 0.34, 95% CI 0.25-0.42; *P*<.001; η^2=0.31) and *stigma* (mean difference 0.28, 95% CI 0.19-0.36; *P*<.001; η^2=0.24) conditions. The effects were sustained and strengthened at the 1-week follow-up in both conditions (*combo*: mean difference 0.39, 95% CI 0.29-0.49; *P*<.001; η^2=0.31; *stigma*: mean difference 0.33, 95% CI 0.23-0.43; *P*<.001; η^2=0.24). In the *interact* condition, the effect was not significant from baseline to after the assessment (mean difference 0.03, 95% CI −0.05 to 0.12; *P*=.99; η^2=0.01) and from baseline to 1-week follow-up (mean difference 0.06, 95% CI −0.04 to 0.16; *P*=.40; η^2=0.01). In the *control* condition, the effect was also not significant from baseline to after the assessment (mean difference 0.03, 95% CI −0.06 to 0.12; *P*=.99; η^2=0.01) and from baseline to 1-week follow-up (mean difference −0.04, 95% CI −0.15 to 0.07; *P*=.99; η^2=0.01). The results indicated that the effect of the *combo* condition was stronger than that of the *stigma* condition in terms of mean difference values. No significant interaction effect between interactivity and stigma content was found (*P*=.58) after performing an additional post hoc analysis to compare the *combo* and *stigma* conditions.

Social Distance From People With Mental Illness

The results showed a nonsignificant time×condition effect (*P*=.25; η^2=0.02). The additional post hoc analysis comparing the *combo* and *stigma* conditions showed no significant interaction effect between interactivity and stigma content (*P*=.46). The details of the repeated measures ANOVA are shown in Table 2.

Table 2. Imputed values of means and SDs across conditions.

	Combo condition[a] (n=66), mean (SD)	*Stigma* condition[b] (n=65), mean (SD)	*Interact* condition[c] (n=64), mean (SD)	*Control* condition[d] (n=67), mean (SD)

Mediating Analysis

To compare the mediation effect of perceived autonomy and immersiveness between conditions with public stigma and microaggression, mediation analyses were performed by incorporating both perceived autonomy and immersiveness into PROCESS model 4. Table 3 shows the unstandardized and standardized factor loadings for the model. A mediation model of perceived autonomy and immersiveness between conditions with public stigma and microaggression is shown in Figure 2. Mediation analysis for social distance was not conducted, because no interaction effect was observed in the social distance across conditions.

We observed significant indirect effects of the *combo* (b=−0.19, bias-corrected and accelerated [BCa] CI −0.36 to −0.03), *stigma* (b=−0.15, BCa CI −0.29 to −0.02) and *interact* (b=−0.16, BCa CI −0.32 to −0.02) conditions on public stigma through perceived autonomy. The nonsignificant indirect effects of the *combo* (b=−0.13, BCa CI −0.30 to 0), *stigma* (b=−0.13, BCa CI −0.30 to 0), and *interact* (b=−0.07, BCa CI −0.16 to 0) conditions on public stigma through immersiveness were observed. The results showed that perceived autonomy was a significant mediator between the conditions and public stigma.

We observed nonsignificant indirect effects of the *combo* (b=0.07, BCa CI −0.03 to 0.17), *stigma* (b=0.05, BCa CI −0.03 to 0.14), and *interact* (b=0.06, BCa CI −0.03 to 0.15) conditions on microaggression through perceived autonomy. The indirect effects of the *combo* (b=−0.13, BCa CI −0.23 to −0.06), *stigma* (b=−0.13, BCa CI −0.23 to −0.05), and *interact* (b=−0.07, BCa CI −0.13 to −0.02) conditions on microaggression through immersiveness was significant. The results showed that immersiveness was a significant mediator between the conditions and microaggression.

Table 3. Unstandardized and standardized parameter estimates for the hypothesized model.

Parameter estimates (structural model)	Unstandardized B (SE)	Standardized β	*t* value (df)	*P* value
Combo[a]→perceived autonomy	1.20 (0.13)	1.42	9.53 (257)	<.001

Discussion

Principal Findings

This study investigated the effect of internet-based storytelling programs with a combination of stigma content and interactivity on mental illness stigma reduction. Multiple forms of mental illness stigma were accounted for, including public stigma toward people with mental illness, microaggression, and social distance from people with mental illness.

The results supported our hypothesis that an internet-based storytelling program with a combination of stigma content and interactivity was able to significantly reduce public stigma and microaggression immediately after the experiment and at the 1-week follow-up assessment. Contrary to our hypothesis, an internet-based storytelling program with a combination of stigma content and interactivity did not significantly reduce the social distance from people with mental illness. In other words, the storytelling program was more effective in improving individuals' stigmatizing cognitions, sense of personal advocacy [4], and microaggressions centering around their everyday conversations and encounters in daily life [61] than in enhancing their willingness and intention to behaviorally interact with people with mental illness in various life domains [62].

Nevertheless, the results showed that an internet-based storytelling program with stigma content alone could also lead to a reduction in public stigma and microaggression. Comparing the significant effects elicited by the 2 different internet-based storytelling programs, the one with a combination of stigma content and interactivity produced a stronger effect after the assessment and at the 1-week follow-up assessment than that with stigma content only. These results were consistent with the findings of previous studies showing that internet-based stigma reduction interventions with a combination of interactivity and stigma content can lead to more effective stigma reduction [26]. The results reinforce the importance of correcting stigmatizing misperceptions in diminishing stigma [55,63]. Interestingly, the internet-based storytelling program with interactivity only was also found to reduce public stigma after the assessment although the effect could not be maintained after 1 week. This might support our assumption of a positive relationship between interactivity and positive affect and between positive affect and reduced prejudice [37,40]. Further studies are required to examine these relationships.

Moreover, although perceived autonomy could mediate the effect of conditions on public stigma, immersiveness could mediate the effect of conditions on microaggression. In previous findings, perceived autonomy was associated with the endorsement of the selected responses and actions and cognitive changes [46]. This might demonstrate that cognitive changes are essential for reducing public stigma. On the contrary, immersiveness could facilitate cognitive and affective changes [50-52], which might expedite people to have more intended changes in ameliorating everyday microaggressions. Social distance posited the focus on one's behavioral intention toward people with mental illness in various dimensions [62], which may have more long-term implications to their life domains (eg, friendship and employment); the short-term sense of choice and immersiveness in storytelling programs may not be sufficient to bring about changes in social distance.

In addition, this study showed that a storytelling program with stigmatized content but without interactivity could also enhance perceived autonomy and immersiveness. These findings align with the literature showing that stigma content with storytelling elements, which served as an internet-based contact with people with lived experiences, was effective in inducing immersiveness [24,28,30]. The inducement of perceived autonomy with the story was outstanding, whereas the effect might be due to the application of a conversational storyline, which allowed one to feel like interacting with the protagonist even without choosing responses and actions. Thus, storytelling in the form of conversations alone might already provide an effective means for participants to immerse themselves and feel a sense of agency.

The superior effect of an internet-based storytelling program with a combination of interactivity and stigma content over the one with stigma content only was not explained by the interaction effect between interactivity and stigma content. Stigma content was a more important criterion than interactivity in inducing stigma reduction. The addition of interactivity was only supplementary to boosting the stigma reduction effect. The results confirmed previous suggestions that enhanced motivation through perceived autonomy and immersiveness would lead to enhanced stigma reduction [43,44]. This study provides empirical support for the rationale behind the use of internet-based storytelling programs, especially for those with stigma-related stories and interactivity.

Limitations and Future Directions

This study has some limitations that deserve attention. First, our sample mainly consisted of young university students. These findings may not be generalizable to other populations. In social marketing, segmentation of our target population is essential. This study showed that internet-based antistigma storytelling programs with interactivity may be an effective tool in reducing mental illness stigma for young, educated people in the community who are comfortable and skillful in accessing information over the internet. Furthermore, because of the homogeneous nature of our sample, moderation analysis was not performed. Future studies should explore possible moderators of the effect of internet-based stigma reduction interventions, such as gender, age, and education level.

Second, this study did not include a long-term follow-up. Only a 1-week follow-up assessment was included to investigate whether the mediation effect could be sustained for a week to draw possible mediating mechanisms behind the effect of internet-based stigma reduction interventions. It could capture the short-term effect of the intervention but was incapable of predicting the long-term maintenance effect of stigma reduction [64]. However, the long-term effect must be tested to provide insights into developing sustainable and effective stigma reduction interventions. It is unknown whether an internet-based storytelling program with a combination of interactivity and stigma content could impose a more prolonged stigma reduction effect when than a program with stigma content only. To examine the stigma reduction effect of various internet-based storytelling programs over time, future research should lengthen its follow-up.

Third, this study lacked behavioral measures but solely used self-report measures that tapped into the thoughts, affect, and behavioral intentions of the participants. Although the measures used have been empirically validated, future studies aiming to examine stigma change should also use behavioral measures, such as the inclusion of offering payment for completing questionnaires and the option of donating the payment to a mental health charity, in addition to self-report measures to bolster the findings.

The necessary intensity of storytelling and interactivity to strengthen the stigma reduction effect should also be investigated. Research has shown that placing individuals in a highly immersive environment might lead to worsening attitudes [65], which varies according to the degree of identification with the embodied target [66]. Therefore, the degree of immersiveness elicited should be considered. In addition, future studies can explore how individual differences, such as the baseline level of empathy, may influence intervention benefits, as internet-based interventions with different adaptations might cater to different segments of the population. People with different levels of dispositional empathy may have variable receptivity to internet-based storytelling programs, and matching their styles with this approach may maximize the outcomes.

Finally, this study suggests that increased perceived autonomy and immersiveness could strengthen the stigma reduction effect in internet-based storytelling programs with interactivity and stigma content. With the advancement in virtual reality technology and the sense of embodiment and story transportation being found to mediate public stigma reduction [67], future studies can consider comparing virtual reality–based and internet-based stigma reduction programs to shed light on which delivery methods are more effective and cost-effective in reducing mental illness stigma.

Conclusions

In sum, this study showed that internet-based storytelling programs with a combination of interactivity and stigma content are effective in reducing mental illness stigma, and perceived autonomy and immersiveness are significant mechanisms in the stigma reduction process. The findings of this study are encouraging and support the possible mechanisms behind the effects of internet-based storytelling programs. Furthermore, the study upholds the gravity of stigma content, as the strength of interactivity in reducing mental illness stigma can only be manifested in the presence of stigma content. To leverage the power of technology in reducing mental illness stigma, it is paramount for antistigma campaigns to incorporate these active ingredients into the design of antistigma interventions to create low-cost, effective, and scalable internet-based stigma reduction programs.

Abstract

Background: App-based interventions provide a promising avenue for mitigating the burden on mental health services by complimenting therapist-led treatments for anxiety. However, it remains unclear how specific systems' use of app features may be associated with changes in mental health outcomes (eg, anxiety and worry).

Objective: This study was a secondary analysis of engagement data from a stage 1 randomized controlled trial testing the impact of the Unwinding Anxiety mobile app among adults with generalized anxiety disorder. The aims of this study were 2-fold: to investigate whether higher microengagement with the primary intervention feature (ie, educational modules) is associated with positive changes in mental health outcomes at 2 months (ie, anxiety, worry, interoceptive awareness, and emotional reactivity) and to investigate whether the use of adjunctive app features is also associated with changes in mental health outcomes.

Methods: We analyzed the intervention group during the stage 1 trial of the Unwinding Anxiety mobile app. The total use of specific mobile app features and the use specific to each feature were calculated. We used multivariate linear models with a priori significance of α=.05 to investigate the impact of cumulative app use on anxiety, worry, interoceptive awareness, and emotional regulation at 2 months, controlling for baseline scores, age, and education level in all models. Significant relationships between system use metrics and baseline participant characteristics were assessed for differences in use groupings using between-group testing (ie, 2-tailed *t* tests for continuous data and chi-square analyses for categorical data).

Results: The sample was primarily female (25/27, 93%), and the average age was 42.9 (SD 15.6) years. Educational module completion, the central intervention component, averaged 20.2 (SD 11.4) modules out of 32 for the total sample. Multivariate models revealed that completing >75% of the program was associated with an average 22.6-point increase in interoceptive awareness (*b*=22.6; SE 8.32; *P*=.01; 95% CI 5.3-39.8) and an 11.6-point decrease in worry (*b*=−11.6; SE 4.12; *P*=.01; 95% CI −20.2 to −3.1). In addition, a single log unit change in the total number of meditations was associated with a 0.62-point reduction in the Generalized Anxiety Disorder-7 scale scores (*b*=0.62; SE 0.27; *P*=.005; 95% CI −1.2 to −0.6), whereas a single log unit use of the stress meter was associated with an average of a 0.5-point increase in emotional regulation scores (Five Facet Mindfulness Questionnaire; *b*=0.5; SE 0.21; *P*=.03; 95% CI 0.1-0.9).

Conclusions: This study offers a clearer understanding of the impact of engagement with app features on broader engagement with the health outcomes of interest. This study highlights the importance of comprehensive investigations of engagement during the development of evidence-based mobile apps.

Introduction

Background

As anxiety disorders (ADs) increase worldwide [1-5], app-based interventions offer evidence-based, high-fidelity treatment options [6] with incredible potential and comparable effects with traditional treatment models in efficacy trials [7]. Several recent meta-analyses that assessed app-based interventions for anxiety have indicated a growing evidence base [7-9]. A recent 2021 Nature review (k=22) [10] found significant but small effect sizes on anxiety symptomatology (Hedges g=0.2888; P<.001). These interventions can fill an important treatment gap, mitigate the growing burden on providers [11,12], and reduce barriers to care (eg, time, cost, and stigma) [13]. However, app-based interventions for AD often have low levels of user engagement, which reduces their efficacy and inhibits broader health care implementation [14]. To capitalize on the benefits of these interventions, engagement needs to be effectively understood and analyzed [10]. Specifically, research identifying the optimal levels of engagement with app-based interventions and the effects of various app features on anxiety-related outcomes is critical to realizing their full potential as treatments for AD [15-17].

To date, research on engagement remains limited and is often not assessed, as app-based interventions are still largely analyzed using conventional methods (eg, intent to treat) [18]. This method evaluates the effect of *assignment to treatment* (ie, the effect of being randomized to a group) instead of the direct effect associated with the app features that were actually used during the intervention [18]. Analyzing which features the user engages with is critical to designing personalized, effective interventions [14] and allows researchers to understand which in-app features drive changes in health outcomes [14,19]. Understanding engagement is also important for app development; specifically, it contributes fundamental information toward identifying the optimal intervention dose [17], streamlining inefficiencies [20], and tailoring apps to specific clinical populations [21]. Recognizing the importance of information on engagement, research is increasingly prioritizing the investigation of the relationship between engagement and improvements in mental health outcomes [10,16,22,23]. Encouragingly, in one of the first meta-analyses examining the effect of engagement on health outcomes, Gan et al [24] (k=25) found significant moderate improvements in postintervention symptomatology for participants categorized as having higher engagement than participants with lower levels of engagement (Hedges g=0.40; SE 0.16; 95% CI 0.097-0.705; P=.01). Although only 5 studies were designed to target AD, the effects indicated a significant positive association between engagement and anxiety (r=0.33; 95% CI 0.24-0.41; P<.001) [24]. This work is promising; however, the field remains preliminary and requires additional research to enhance the growing understanding of the associations between engagement with app-based interventions and anxiety [25-27].

Inconsistency in the definition and measurement of engagement is an ongoing challenge associated with analyzing the construct within this promising preliminary research [24]. Engagement can be broadly conceptualized as "(1) the extent (eg, frequency, duration) of usage; and (2) a subjective experience characterized by affect, attention, and interest" [28], as it relates to subsequent changes in the targeted health behavior (eg, anxiety and depression) [29,30]. However, different industries (eg, psychology and marketing) have historically focused on specific parts of this definition (eg, in-app use vs levels of engagement in the targeted health behavior), often failing to fully capture an understanding of the complex relationships that make up engagement [29,30]. To improve our understanding of app-based interventions and health outcomes, it is critical to understand the relationship between what is used during the intervention and subsequent changes in health outcomes [31]. One model proposed by Cole-Lewis et al [31] addresses this relationship and posits that engagement is multifaceted, encompassing multiple definitions from various disciplines. The model links both system-level and behavior-level engagement [31]. They defined engagement as a multidimensional construct encompassing a user's interactions with app features that influence specific behavioral determinants, resulting in increased engagement in the targeted health behavior [31]. The model posits that the use of in-app features (ie, microlevel engagement) is directly associated with changes in the desired health outcome (ie, macrolevel engagement). Understanding both microlevel and macrolevel measurements is necessary to evaluate the effects of app-based interventions on improvements in mental health symptomatology [31].

Applying this model of engagement, we conducted a secondary analysis using multivariate regression models to examine the associations between in-app engagement (ie, microengagement) and mental health outcomes (ie, macroengagement) for participants with generalized AD (GAD) using a targeted mobile app called Unwinding Anxiety (UA) [32]. Data were collected from the intervention group in a recently published randomized controlled trial (RCT) that tested UA versus treatment as usual [32]. The UA app is a theory-driven, multifaceted app that comprises both guided (ie, educational modules) and unguided features (eg, meditations and ecological check-ins) targeting novel reinforcement learning constructs [32,33]. The results from the primary RCT (N=65) were promising, with participants in the UA group reporting a median reduction in anxiety scores of 8.5 (IQR 6.5; P<.001) and the treatment as usual group reporting a median reduction of 1 (IQR 5; P=.01), representing a 67% versus 14% reduction at the 2-month follow-up [32].

Objectives

The aims of this study were 2-fold: (1) to investigate whether higher microengagement with the primary intervention feature (ie, educational modules) is associated with positive changes in mental health outcomes at 2 months (ie, anxiety, worry, interoceptive awareness, and emotional reactivity) and (2) to investigate whether the use of adjunctive app features is also associated with changes in mental health outcomes. We hypothesized that higher levels of microengagement with educational modules would be associated with significant changes in outcomes, which is consistent with improved mental health.

Methods

Overview

This study is a secondary data analysis of a previously described stage 1 parallel-group RCT [32]. As this secondary analysis is interested in system use data and their association with study outcomes, data were taken from the intervention arm only, and study procedures relevant to analyzing the intervention group are summarized in the following sections [32]. Roy et al [32] provide detailed information on the study design, procedures, and the results of the randomized trial.

Ethics Approval

The primary trial was registered at Clinicaltrials.gov (NCT0368472), and the Brown University Institutional Review Board approved the study procedures (reference number PV4802) [32].

Study Procedures

The data used for these analyses were from the baseline and 2-month time points for the intervention group only [32]. The inclusion criteria were as follows: (1) score ≥10 on the Generalized Anxiety Disorder 7-item scale (GAD-7), (2) owning a smartphone, (3) willingness to receive check-in calls, and (4) aged ≥18 years [32]. Participants were excluded from the study if they reported (1) dose changes of any psychoactive medication in the previous 2 months; (2) needed use of benzodiazepines and hypnotic sleep aids; (3) a history or current diagnosis of bipolar, schizophrenia or schizoaffective, or another psychotic disorder; (4) a significant medical condition that would affect the ability to complete study tasks; (5) cohabitation with someone already enrolled in the study; and (6) having a previous history of using other related apps, specifically Eat Right Now or Craving to Quit, which use similar reinforcement processes to UA [33-35]. Participants were recruited using social media largely through Facebook advertisements.

Eligible participants underwent informed consent procedures before enrolling in the study [32]. After enrollment, participants completed an in-person interview using the Mini International Neuropsychiatric Interview (MINI) International Neuropsychiatric Interview to confirm a diagnosis of GAD along with the assessment of other potential comorbid disorders (eg, depression, obsessive-compulsive disorder, and posttraumatic stress disorder) [32]. The participants were then asked to complete a web-based questionnaire using Qualtrics. Follow-up questionnaires were administered 2 months from treatment initiation using personalized email links specific to each participant's unique identification number [32].

Intervention

UA is an app-based intervention comprising educational modules that are considered the primary intervention features, consistent with recommendations from recent meta-analyses. The modules comprised instructional psychoeducational videos (5-15 minutes per day) teaching reinforcement learning concepts (Table 1). Modules are locked until the previous module is completed; however, participants can return to any of the already completed modules for review.

In addition, the app offers unguided adjunctive features divided into 2 categories: ecological features designed to synergize with skills learned in the modules and meditation practices. The ecological features included physiological check-ins and 2 types of stress evaluation: a meter that evaluates the strength and reason for stress or anxiety and a stress test that assists in familiarizing participants with practicing curiosity regarding stress or anxiety using interoceptive awareness skills learned in the program. Detailed descriptions of these features can be found in Table 1, a visual depiction of the main dashboard is shown in Figure 1 and an example of an adjunctive ecological feature is provided in Figure 2. The example is the psychological check-in feature, in which a participant is asked first to identify their current emotional state from an initial list and then rate their anxiety level at the moment, and it ends by offering a recommendation for a short practice to return to present moment awareness depicted from left to right.

For the adjunctive meditation features, participants had access to a series of 3 practices that they were encouraged but not mandated to use: Resting in Awareness, a body scan practice, and the Loving Kindness practice (Table 1) [36]. Each meditation had the option to choose from 4 lengths of time (7-30 minutes). The intent of offering varying lengths of time is that participants initially engage in shorter practices and progress to longer periods of sustained meditation. A dashboard with meditation features is shown in Figure 3. An example of meditation (ie, Loving Kindness) is depicted in Figure 4.

Table 1. Overview of the Unwinding Anxiety app engagement features with content.

Feature or day introduced	Description
Educational modules	
Modules 1-7, week 1	• Overview of the program, personalized goal setting for the program that is logged in the app, and an introduction to the modules • Topic areas focus on how worry and anxiety become habituated through reinforcement learning processes (ie, operant conditioning and reward-based learning), an overview of mindfulness and its application in identifying reinforcement patterns that result in negative health outcomes, and an introduction to curiosity as an attitudinal quality
Module 8-14, week 2	• Introduction to the application of reinforcement concepts (ie, trigger, behavior, and reward), specifically, learning how to recognize behaviors, identifying the "rewards" or outcomes of the behaviors (eg, cognitive, physical sensations, and emotions), and becoming disenchanted with these behaviors allowing for an alternative behavioral pattern to emerge • Novel to the program is the instruction to participants to not attempt to change behaviors immediately but to concentrate on the embodied experience (ie, interoceptive awareness and present moment awareness) of anxiety and the associated behaviors • The modules introduce the RAIN[a] practice and the role of curiosity in engaging with present moment experiences rather than judgment
Module 15-21, week 3	• Week 3 begins with troubleshooting and applying reinforcement lessons from the previous week • Participants are encouraged to gain acceptance of present moment experiences through resistance or unresistance, defined as the ability to engage with present moment experiences with curiosity, being aware of thoughts but not attached to them, and riding out waves of anxiety using the RAIN practice and other mindfulness exercises • Modules then focus on the detriments of "contracting" or identifying with thoughts (ie, anxiety) • Participants are asked to identify a variety of thought patterns (ie, anxiety, doubt, anger, and kindness) and observe rather than attach or react to these narratives
Module 22-30, week 4	• The week begins with explaining the science of resistance to habit change, specifically, participants are introduced to the association between anxiety and performance (ie, anxiety becomes associated with accomplishing tasks) • The previous modules regarding the application of mindfulness to unwind these associations are highlighted. Participants are guided through the importance of taking breaks when pursuing habit change, the advantages of alternate strategies to anxiety (ie, curiosity), and the ability to drop into the flow (ie, concentration and awareness focused on the present moment with a loss of reflective consciousness) • The week ends with the key elements of continued motivation and review of the effectiveness of the program, specifically improvements participants have observed, termed "evidence-based faith"
Ecological features	
Check-ins, day 1	• Select their current emotional state from a list provided (eg, happy, anxious, and relaxed) • Describe the strength of their anxiety on a 10-point Likert scale (1=low and 10=high) • Provided an exercise to complete (eg, hand awareness and breathe into anxiety)
Stress meter, day 1	• Identify the strength of their anxiety on a 10-point Likert scale (1=low and 10=high) • Identify from a list the reason for their anxiety (eg, uncompleted tasks and reliving past experiences) • Provided with a short exercise to complete (eg, breathe into anxiety)
Stress test, day 6	• Identify where anxiety is strongest in the body (eg, head, neck, and shoulders) • Select a description of the sensation from a provided list (eg, tightness, pressure, and burning) • Select the intensity from 0 to 100 on a scale (eg, 100=most stress ever) • Identify on which side of the body the anxiety is strongest (ie, left or right) • Provided with a short exercise to complete (eg, breathe into anxiety)
Meditations	
Resting in Awareness, day 1	• Participants offer gratitude to themselves for taking the time to take care of themselves • Subsequently, they are encouraged to shift their awareness to sounds in the room, then to thought processes by allowing thoughts to rise and pass away (ie, making a mental note of "thinking") • They are guided to directly observe thoughts as they arise and pass away on their own if not engaged with (eg, resisted) • Subsequently, they are instructed to open their eyes, engaging in awareness of sights, sounds, thoughts, and body sensations, whichever present moment experience is most prominent in their experience • Participants can choose from 9-, 15-, 20-, and 30-minute exercises

Feature or day introduced	Description
Body scan, day 3	• Participants bring their attention to physical sensations in their body (eg, touch and pressure) and how sensations are connected to feelings or emotions (eg, anxiety) and are guided on how to pay attention to thoughts and mental processes (eg, noticing how "busy" thoughts can get when connected with anxiety) • Participants can choose from 12-, 15-, 20-, and 30-minute exercises
Loving Kindness, day 5	• Participants notice the physical sensations associated with an imagined experience of anxiety then shift to an experience when they meet a dear friend or kind being (ie, person and animal) • From there, they are encouraged to investigate the different physical sensations of anxiety (eg, tightness and contraction) versus being with a kind person (eg, openness and warmth) • They are then asked to offer phrases of kindness to the person or being identified (eg, "May you be happy") using the phrases as mental anchors for present moment awareness • Participants can choose from 7-, 15-, 20-, and 30-minute exercises

[a] RAIN: Recognize and Relax, Allow and Accept, Investigate, and Note.

Figure 1. Unwinding Anxiety main dashboard.

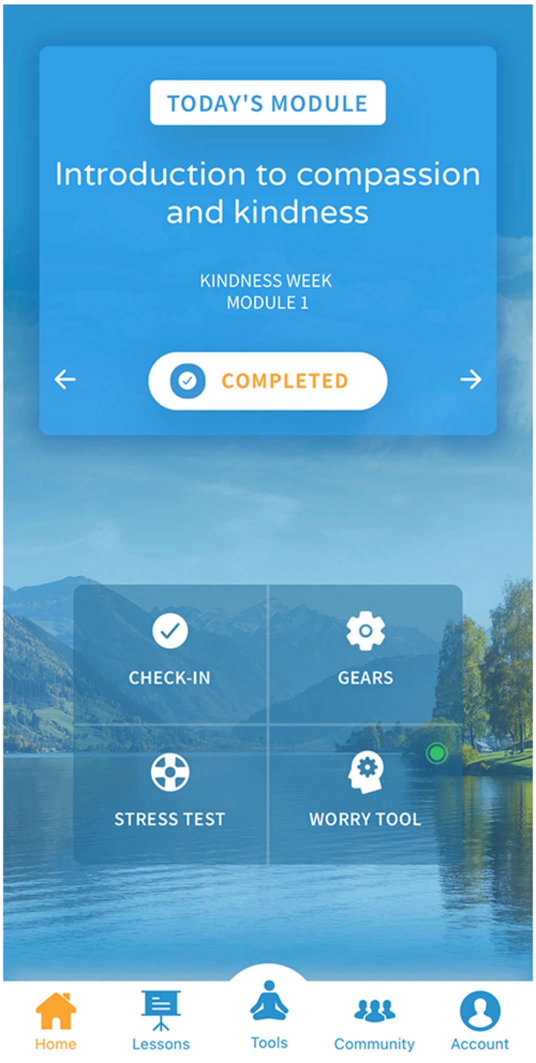

Figure 2. Adjunctive ecological feature example: check-ins.

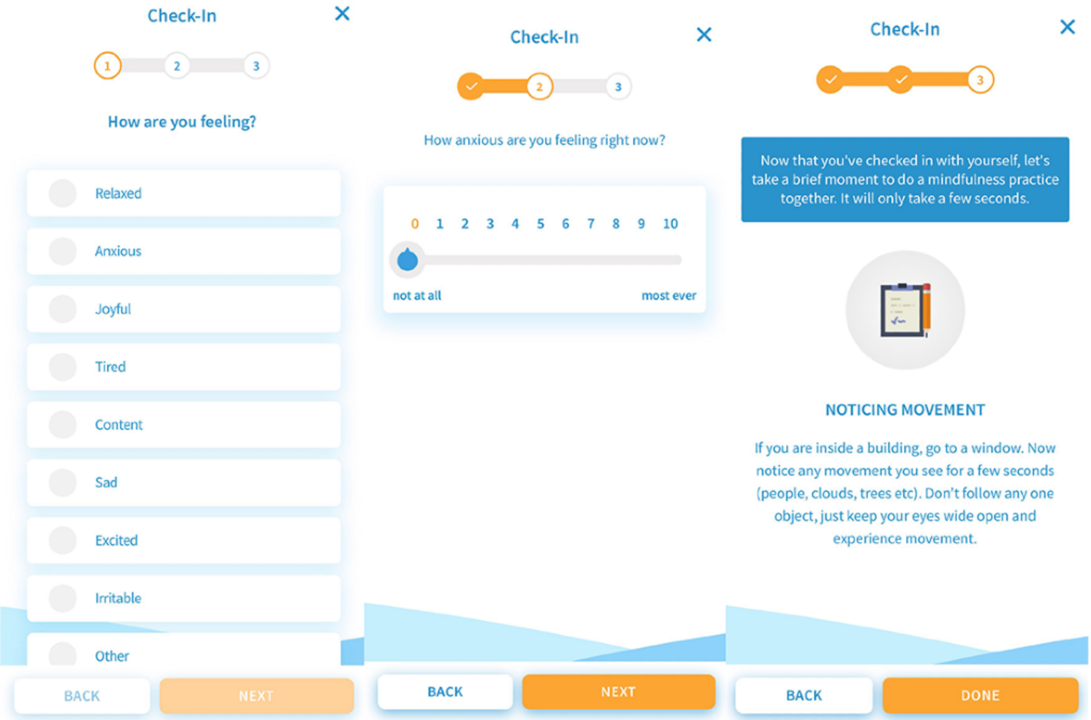

How are you feeling?

- ○ Relaxed
- ○ Anxious
- ○ Joyful
- ○ Tired
- ○ Content
- ○ Sad
- ○ Excited
- ○ Irritable
- ○ Other

How anxious are you feeling right now?

Now that you've checked in with yourself, let's take a brief moment to do a mindfulness practice together. It will only take a few seconds.

If you are inside a building, go to a window. Now notice any movement you see for a few seconds (people, clouds, trees etc). Don't follow any one object, just keep your eyes wide open and experience movement.

Measures

Demographics

Demographic variables collected at baseline included age, biological sex, education level, and current employment status.

Psychiatric Diagnoses

The MINI is a short (15-minute) structured diagnostic interview assessing 17 of the most prevalent mental health disorders, including depression and ADs [37]. Previous studies have validated the MINI against the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, and the International Classification of Diseases, Tenth Revision, and found the measure to be reliable and valid along with the added benefit of being more efficient [38].

Engagement Measures

The study measures were organized into 2 categories: microengagement and macroengagement. For clarity, in the model proposed by Cole-Lewis et al [31], engagement with the app-based intervention is referred to as the "little e" construct, which we categorize in these analyses as microengagement. The model then defines engagement with the targeted health outcome as the "Big E" construct, which we refer to as macroengagement [31].

Macroengagement: Mental Health Outcomes

Anxiety

Anxiety was assessed using the GAD-7, which comprises 7 items (eg, "feeling nervous, anxious, or on edge"). The GAD-7 is the most widely used self-report tool for clinical screening and tracking of GAD (sensitivity and specificity of 89% and 82%, respectively) [39]. Scores of ≥10 indicate a probable diagnosis of moderate GAD, whereas scores ≥15 indicate severe GAD [40]. In clinical testing, the scale demonstrated high reliability (Cronbach α=.88) and validity (r=0.69), correlated with the Beck Anxiety Index [41].

Emotional Regulation

The Five Facet Mindfulness Questionnaire (FFMQ) nonreactivity subscale was used to measure emotional regulation. The FFMQ is a validated 39-item questionnaire used to assess mindful awareness with high internal consistency (Cronbach α ≥.70) and an acceptable fit with a correlated 5-factor model (confirmatory fit index 0.914) [42]. It comprises 5 subscales, each validated for use independently [42,43]. The nonreactivity subscale comprises 7 questions (eg, "I perceive my feelings and emotions without having to react to them") from the 39-item FFMQ with acceptable internal consistency (Cronbach α=.75) [32].

Interoceptive Awareness

The Multidimensional Assessment of Interoceptive Awareness is a 32-item measure with response options provided on a

6-point Likert scale (0=never and 5=always) that has demonstrated moderate levels of internal consistency (Cronbach α ≥.70) and a good model fit (comparative fit index 0.886) [44]. The scale comprises eight subscales: (1) noticing, (2) not distracting, (3) not worrying, (4) attention regulation, (5) emotional awareness, (6) self-regulation, (7) body listening, and (8) trusting (eg, "I trust my body sensations") [44,45].

Worry

The Penn State Worry Questionnaire is a validated 16-item questionnaire used to assess worry (eg, "My worries overwhelm me"). It has high internal consistency (Cronbach α=.93) and validity compared with the Self-Analysis Questionnaire Tension subscale (r=0.36) and the Emotional Control Questionnaire (r=−0.53) [46]. Items are rated on a 5-point Likert scale (ie, 1=not at all typical and 5=very typical of me), and scoring for the scale is calculated as a total with possible ranges of 16 to 80 (eg, 60-80 indicating high worry) [46].

Microengagement: App Features Used

Microengagement (ie, system use) was defined as the total number of times each app feature was accessed [47]. The app features were organized into 3 categories for this study. The first category was engagement with the primary intervention feature and completion of the educational module. The other two engagement categories involved the use of the adjunctive app features: (1) ecological features and (2) meditations. These adjunctive or supportive features are components that participants could elect to use in combination with educational modules. Ecological features were considered adjunctive or supportive as they were designed as a short (<2 minutes in length) complement to the modules to assess participants' current emotional or cognitive state at the moment. Meditations were defined as features >5 minutes in length, which followed evidence-based guidelines consistent with researched meditation practices (eg, Loving Kindness meditation) [48]. Table 1 provides a detailed description of each app feature. Aggregated totals for each of the 3 categories, as well as the total use of individual features, were calculated.

Analysis

This was a secondary analysis of a previously conducted RCT. As such, the analysis was restricted to 32 participants who were randomized to the intervention group. A complete case analysis was conducted in this study. Of the 32 participants in the original intervention sample, 2 (6%) participants dropped out of the study before follow-up, and 2 (6%) participants did not complete the follow-up assessments, resulting in a final sample of 28 (88%) participants for this secondary analysis representing 88% of the original sample. For the primary RCT, a sample size of 52 was determined to have 80% power (1-sided Cronbach α=.05) to detect a statistically significant between-group difference in the primary outcome of anxiety (Cohen d=0.7). The final sample size was increased to 65 participants to account for 25% attrition.

Descriptive statistics, including means (SDs) for continuous variables and frequencies and percentages for categorical variables, were calculated for baseline variables, including demographics, anxiety, emotional regulation, and worry. Use data included ecological assessments (ie, check-ins, stress tests, and stress meters), mindfulness practices with the length of time completed (ie, Loving Kindness, Resting in Awareness, and body scan), and educational modules completed. Correlation analysis was used to identify potential confounders. Specifically, variables (eg, age, education, and income) were assessed using Spearman correlations, and those that met an a priori threshold of P≤.20 were included in subsequent models.

Microengagement was reported as the total number of times each app feature was accessed (ie, the total amount of use per item). Spearman rank correlation matrices were run to identify potential predictors to be included in the univariate linear regression models; predictors with a significance of P≤.20 were included [49]. Skewed engagement data were log transformed, except for the number of educational modules completed. Instead, the educational modules were dichotomized based on the completion of ≥75% (23/32) of the modules.

A series of multivariate linear regression models were constructed to investigate the dose-response relationships regarding the effect of use variables on psychosocial outcome measures. First, to determine predictors for inclusion in multivariate models, we ran a series of univariate linear models controlling for baseline scores to determine the impact of use variables on anxiety (ie, GAD-7), worry (ie, Penn State Worry Questionnaire), emotional regulation (ie, FFMQ), and interoceptive awareness (ie, Multidimensional Assessment of Interoceptive Awareness) at 2 months after treatment initiation. Predictors that were associated with outcomes at a modest P≤.20 level and met the assumptions testing criteria were then included in the subsequent multivariate linear regression models.

Final multivariate models investigated total meditation use, total ecological assessment use, individual meditation practices, and individual ecological assessments as predictors of the 4 outcomes (ie, anxiety, worry, interceptive awareness, and emotional regulation). All models controlled for baseline scores, as well as age and education level, as both have been shown to affect mobile app engagement in health behavior change in previous research [16]. Biological sex was not included as a covariate in the models to preserve parsimony because of a lack of correlation with outcomes (ie, P≥.20) in exploratory analyses and as only 7% (2/27) of the total sample identified as male versus 93% (25/27) as female. Analyses were run in R (version 4.0.3), and an a priori α level of .05 was set for the analyses. All models were evaluated to meet relevant model assumption criteria (eg, homoscedasticity and normality of residuals), and only models meeting the assumption criteria were reported. Summaries include R^2 statistics (measure of effect size), β coefficients, 2-tailed t test values, P values, and 95% CIs for all the included models.

Results

Demographics

The participant demographics are presented in Table 2. The sample was primarily female (25/27, 93%), and the average age was 42.9 (SD 15.6) years. Most participants reported completing some level of college education and self-reported as employed:

67% (18/27) reported having attained a bachelor's degree or higher, 59% (16/27) reported having full-time employment, and 74% (20/27) reported an annual income of ≥US $40,000 per year.

We explored potential differences in demographic information across high versus low engagement with the main intervention feature—education modules. High versus low engagement was quantified as those who completed >75% of the education modules (≥23 modules; high completion) and those who completed <75% (<23 modules; low completion). Both the high and low engagement groups averaged consistent numbers of participants who reported psychiatric conditions (Table 2). With one exception, the high engagement group had significantly more past depressive episodes (*P*=.02).

Table 2. Participant demographics: high versus low engagement and total sample (N=27).

Demographics	Low: <23 modules (n=13)	High: ≥23 modules (n=14)	*P* value	Total sample

[a] Significance set at a priori α level of .05 (ie, $P \leq .05$).

The baseline anxiety, emotional regulation, worry, and interoceptive awareness scores are reported in Table 3. Overall, the sample had average anxiety scores of 13.0 (SD 4.9) and high average worry scores of 65.5 (SD 7.1). The average interoceptive awareness score was 78.7 (SD 22.4), and participants had an average low emotional regulation score of 15.2 (SD 4.2). No significant differences were observed between the high and low engagement groups in the primary outcomes at baseline.

Participants completed an average of 20.2 (SD 11.4) modules of the primary intervention feature for the total sample. Of these, 52% (14/27) were considered "high completers" (ie, ≥23 modules). Use data of the adjunctive features over the 2-month intervention period are presented separately for high versus low engagement in Table 4. For the ecological features, participants' total engagement averaged 38.1 (SD 52.6) uses. Regarding specific ecological features, the average check-in use accounted for most of the use at 31.1 (SD 45), whereas stress tests and stress meters averaged <5 uses for the 2-month period. When assessing adjunctive ecological feature engagement across high versus low primary intervention engagement, the high engagement group used adjunctive ecological tools more across all types of features than the low engagement group (Table 4).

Participants averaged 7.2 (SD 7.2) mindfulness practice uses over the 2-month period. The range of uses varied for meditations, although not as broadly as ecological tool use, with some individuals never using the meditations and other participants using the meditations more frequently, with median meditation use of 7 (IQR 8). In addition, when assessing meditation use across intervention engagement categories (ie, high vs low), those who completed a high level of the primary intervention also used meditation practices more on average (Table 4). Specifically, those who had a higher engagement with the primary intervention also used significantly more meditations overall, as well as the Loving Kindness meditation and Resting in Awareness meditation (Table 4).

Summary statistics of meditation practice use for the full sample, and for high versus low engagement, are presented in Table 3. The completion of cumulative mindfulness practices across the entire sample averaged 7.2 (SD 7.2) over the 2-month period. The range of uses varied for meditations, although not as broadly as the ecological tool uses, with some individuals never using the meditations and other participants using the meditations more frequently, with median meditation use of 7 (IQR 8). In reviewing differences in average meditation use between high and low engagement, the group with high engagement also used meditation practices more on average, and significant differences were observed for cumulative meditations used, Loving Kindness, and Resting in Awareness but not for the body scan meditations (Table 4).

Table 3. Average outcome measure scores at baseline.

Measure	Low: <23 modules, mean (SD)	High: ≥23 modules, mean (SD)	*P* value	Total sample, mean (SD)
Anxiety (Generalized Anxiety Disorder-7 scale)	13.4 (5.9)	12.6 (3.9)	.60	13.0 (4.9)
Emotional regulation (Five Facet Mindfulness Questionnaire, Nonreactivity Subscale only)	14.9 (4.2)	15.4 (4.4)	.70	15.2 (4.2)
Worry (Penn State Worry Questionnaire)	66.8 (6.6)	64.2 (7.6)	.30	65.5 (7.1)
Interoceptive awareness (Multidimensional Assessment of Interoceptive Awareness)	76.5 (19.6)	80.7 (25.2)	.60	78.7 (22.4)

Table 4. Average number of tool uses by segment over 2 months: high versus low engagement and total sample.

App components	Low: <23 modules, mean (SD)	High, ≥23 modules, mean (SD)	*P* value	Total sample, mean (SD)
Cumulative ecological tool use	12.9 (14.4)	61.6 (64.1)	.02[a]	38.1 (52.6)
Check-ins	10.5 (12.0)	50.4 (55.5)	.02	31.1 (45.0)

Multivariate Regression Results

Overview

Analyses were conducted to identify associations between microengagement, quantified as specific features use tools, and macroengagement, defined as worry, anxiety, interoceptive awareness, and emotional regulation. Predictors (ie, microengagement metrics) were entered into univariate models, controlling for baseline scores on the outcome of interest, and assumption testing was performed on models that met the a priori significance threshold ($P \leq .20$). However, after review, models that violated assumptions were excluded, and those that met the criteria were consolidated for subsequent multivariate testing.

Using the results from the univariate models, multivariate linear regression models were built to answer the primary research question testing the association of (1) total meditation practice, (2) total ecological assessment, (3) individual meditation practices, and (4) individual ecological assessments with changes in psychosocial outcomes at 2 months (ie, anxiety, worry, emotional regulation, and interoceptive awareness). Only models that met a priori significance levels and all model assumptions are reported (Table 5) by system use categorization (ie, educational modules, ecological tools, and meditation practices). Parameter estimates, effect sizes (ie, coefficient of determination; R^2), 95% CIs, and additional relevant statistics for all the included models are outlined in Table 5.

Table 5. Multivariate linear regression analyses of use metrics and change in psychosocial measures at 2 months.

Use metric[a]	Outcome	R^2	*P* value	*t* test (*df*)	*b* (95% CI)
Low vs high module	Interoception[b]	0.22	.01	2.72 (26)	22.6 (5.3 to 39.8)
Low vs high module	Worry[c]	0.25	.01	−2.83 (26)	−11.6 (−20.2 to −3.1)
Total meditations[d]	Anxiety[e]	0.21	.03	−3.16 (26)	−0.6 (−1.2 to −0.6)
Stress meter[d]	Mindfulness[f]	0.29	.03	2.36 (26)	0.5 (0.1 to 0.9)

[a] All models were adjusted for age, educational attainment, and baseline outcome measure total score.

[b] Multidimensional Assessment of Interoceptive Awareness.

[c] Penn State Worry Questionnaire.

[d] Variable was log transformed, and the results are reported on a log scale.

[e] Generalized Anxiety Disorder-7 scale.

[f] Five Facet Mindfulness Questionnaire, Nonreactivity Subscale only.

Education Modules

Completion of ≥75% of the educational modules was significantly associated with increases in interoceptive awareness and decreases in worry. More specifically, it was associated with an average 22.6-point increase in interoceptive awareness (SE 8.32; *P*=.01; 95% CI 5.3-39.8) and an 11.6-point decrease in worry (SE 4.12; *P*=.01; 95% CI −20.2 to −3.1) when holding age, education level, and baseline worry and interoceptive awareness scores constant.

Meditation Practices

Total meditation practice was associated with a significant reduction in anxiety scores. For each log unit change in the total number of meditations, there was a reduction of 0.62 in anxiety scores (SE 0.27; *P*=.005; 95% CI −1.2 to −0.6) after controlling for age, educational level, and baseline anxiety scores.

Ecological Tools

Stress meter use was associated with significant changes in emotional regulation. Specifically, a difference of 1 unit (on the log scale) in the stress meter was associated with a 0.5-unit increase on average in emotional regulation scores (SE 0.21; *P*=.03; 95% CI 0.1-0.9). Both associations were adjusted for age, education level, and baseline emotional regulation scores.

Discussion

Principal Findings

Comprehensive app-based interventions offer promising, high-fidelity treatments for AD, which are critical for addressing the growing treatment needs of the health care system [7,9,10,50]. To fully realize their potential, research will need to maximize engagement through a comprehensive understanding of how microengagement with in-app features affects macrolevel engagement in the target health outcome [31]. Our analyses sought to build on existing evidence by using multivariate linear regression models to examine the associations between improvements in mental health outcomes and the use of specific features within the UA mobile app. The results indicated that microengagement with app features was associated with significant changes in macroengagement in health outcomes (ie, interoceptive awareness, anxiety, emotional regulation, and worry), consistent with the engagement model proposed by Cole-Lewis et al [31]. Consistent with our hypothesis, engagement with the primary intervention feature (ie, completing at least 75% of the modules) was associated with an average increase of 22 points in interoceptive awareness scores and an 11-point decrease in clinical measures of worry at the 2-month follow-up. Associations were also found between the adjunctive app features (ie, ecological features and meditations) and improvements in health outcomes. Total meditation use was associated with a highly significant 0.62-point average reduction in anxiety (GAD-7), and the use of the Stress Meter, a tool for recognizing and investigating stressful situations in the moment, was associated with an average increase of 0.5 points in emotional regulation.

Moving forward, this research has significant implications for testing, developing, and customizing app-based interventions that target AD. First, this study offers important evidence that engagement with in-app features is a critical mechanism for increasing treatment benefits. Specifically, our findings showed a strong association between module completion and mental health outcomes, offering important evidence within the limited field of work on engagement with app-based interventions for AD. Previous research has largely focused on module completion as the primary engagement metric, finding small but significant associations with improvements in mental health outcomes for all digital interventions (eg, internet based and app based) [51-55]. However, these studies were mostly internet-based interventions, with few apps clinically tested for the effects of engagement on AD-related outcomes [23,24].

In addition, we found that intervention effects were driven by more than module completion, with findings indicating that adjunctive features (eg, ecological check-ins) were associated with important changes in health outcomes. The adjunctive or supportive components of complex app-based interventions have rarely been investigated. Instead, to date, most research has favored the analysis of completed modules or using a total frequency metric for all features used [24]. Focusing singularly on these adjunctive components offers 2 important insights: a clear indication of how those additional features are associated with changes in outcomes and information on potentially unnecessary or ineffective tools, which may needlessly complicate the app. Future research building on this study, focusing on understanding how specific supportive features function mechanistically to affect clinical outcomes, will be important as this information allows developers to streamline digital interventions [31]. By prioritizing streamlining app-based interventions, highlighting the effective features and removing ineffective features we can increase intervention efficiency as well as the likelihood of initiating and sustaining health behavior changes [22,56].

Although our analyses offer important novel insights into engagement and health outcomes, to fully capitalize on the potential of app-based interventions for sustained behavior change engagement, research needs to move beyond considering engagement as an aggregated total. Summed user engagement metrics, such as those used in these analyses, offer important insights but provide a limited view when considering the practical reality of engagement as a dynamic interaction between the participant and the app over time [22,23,47,57]. In the case of UA specifically, the app is designed to develop knowledge (eg, retraining reinforcement learning, education on understanding anxiety, and goal-directed behavior training) and promote skills maintenance (eg, meditation and emotional regulation), which can be applied in everyday life. The eventual goal of the app is actually "off ramping" participants or effectively reducing microengagement with the app while sustaining the associated health outcome improvements (eg, reductions in anxiety and increased emotional regulation). In this case, the pattern of engagement may change; for example, a participant may start at a higher level of engagement but begin to titrate how often they use the app over time. As such, the goal for UA is that health behavior change would be sustained despite lower engagement over time, which cross-sectional or sum engagement metrics cannot reflect. Thus, future analyses will need to move beyond aggregated engagement and analyze individual time series data to capture the dynamic, longitudinal relationship between in-app engagement and sustained health behavior changes.

Comparison With Previous Work

Although the analysis presented is the first to investigate associations between the use of UA tools and mental health outcomes, the underlying reinforcement learning theory and curriculum for the primary intervention feature have been associated with behavioral reductions in our previous work on smoking cessation [58,59]. Specifically, our findings regarding module engagement build on results from an RCT (n=225) of the Craving to Quit program, a mobile platform designed to help people quit smoking, which uses a similar suite of educational modules grounded in the reinforcement learning theory and application of meditation practices on which the UA program is founded. These previous results indicated that educational module engagement, categorized as low (0-14 modules), medium (15-41 modules), and high (≥42 modules) in linear mixed models, was associated with significant reductions in the relationship between craving and cigarette smoking at 6 months ($F_{1,104}$=4.44; *P*=.04) in the intervention group (n=182) [58].

In addition, in a previous trial of an app-based intervention targeting eating behaviors and craving-related eating—Eat Right Now—the results indicated significant associations between ecological feature engagement and craving-related eating [60]. Eat Right Now also comprises ecological features, which guide participants by investigating cravings, in addition to mindful eating exercises, to reduce the reward value of overeating [60,61]. The results showed significant effects of ecological feature use on reductions in craving-related eating, anticipated reward value of craving-related eating, and the likelihood of engaging in craving-related eating within an initial sample of 46 participants, which was then replicated among a larger sample (n=1119) using Rescorla-Wagner computational modeling [61].

This study, coupled with previous work, demonstrates the important role of multiple engagement metrics associated with positive changes in health outcomes among a range of clinical populations.

Limitations

This study has some limitations. First, engagement data were calculated as the total number of uses. It is possible that a feature was opened, closed, or stopped midway. It is also possible that the participant was not actively engaged with the feature (eg, distracted or the participant was not the one using the app). In future studies, the length of use time should be considered for analysis to mitigate these limitations. In addition, this analysis considered specific features that operate singularly on health outcomes. However, this is unlikely to reflect the engagement patterns of participants who use a combination of features in pursuit of their health goals. Aggregation of microengagement patterns with the inclusion of the total time of engagement may offer windows into specific "usage profiles," which could more effectively reflect the interdependent nature of many of these features. Another important limitation was the small sample size available for analysis. In addition, the sample was overwhelmingly female, White, and highly educated, making the generalizability of these findings to broader populations questionable. The length of follow-up may also have been a limiting factor for the analysis as there was variability regarding module completion, which may not have been aligned with the 2-month assessment window. Future analyses should use larger, more diverse samples to test the impact of microengagement patterns in the broader population.

Conclusions

This secondary analysis offers evidence of associations linking the use of in-app features in UA to improvements in mental health outcomes; however, these results are preliminary and exploratory. The work presented offers a clearer understanding of the impact of how microengagement with the app features affects macroengagement with health outcomes of interest, consistent with the model proposed by Cole-Lewis et al [31]. This study highlights the importance of comprehensive investigations of engagement during the development of evidence-based app-based interventions. Future research would benefit from comprehensive, longitudinal analyses, as well as primary studies that specifically assess the effects of varying levels of engagement trials on health outcomes (eg, microrandomized trials, rapid optimization methods, and multiphase optimization strategies) [18,62-64]. As research continues, understanding the effects of engagement with app-based intervention features on clinical outcomes will be critical to designing targeted interventions needed to increase patient health and support accessible, comprehensive care.

Conflicts of Interest

JB and AR are paid advisers to Sharecare, the company that owns the mindfulness app used in this study. This financial interest has been disclosed to and is being managed by Brown University, in accordance with its Conflict of Interest and Conflict of Commitment policies, including being restricted from recruitment, being blinded to the study group until after analysis, and not having access to data or performing analyses.

Abstract

Background: Patients with digestive system cancer often experience psychospiritual distress. Life review is an evidence-based psychological intervention for patients with cancer, but the effects of digital life review programs are unclear, especially for patients with digestive system cancer.

Objective: We examined the effects of a WeChat-based life review program on the psychospiritual well-being of patients with digestive system cancer.

Methods: This study was a 3-arm parallel randomized controlled trial. Eligible patients with digestive system cancer were recruited from a university hospital in Fujian, China. They were randomized to a life review group and 2 control groups. All participants received routine care, and the life review group also received the 4-week WeChat-based life review program. Control group 1 also received a 4-week program of friendly visiting. Anxiety, depression, hope, and self-transcendence were measured at baseline and 2 days, 1 month, and 6 months after the intervention.

Results: A total of 150 participants were randomly allocated to the WeChat-based life review group (n=50), control group 1 (n=50), or control group 2 (n=50). The overall dropout rate was 10% (15/150), and 92% (46/50) of participants in the the life review group completed the intervention. Significant interaction effects for time and group membership were found for anxiety (*P*<.001), depression (*P*<.001), hope (*P*<.001), and self-transcendence (*P*<.001) at all follow-up time points. For anxiety and depression, the scores did not differ significantly between the life review group and control group 1 on day 2 (*P*=.80 for anxiety, *P*=.51 for depression), but the scores were significantly lower in the life review group at month 1 and month 6 (*P*=.02 for anxiety at both months 1 and 6; *P*=.003 and *P*<.001 for depression at months 1 and 6, respectively). Significant increases in hope and self-transcendence were revealed in the life review group compared to control group participants at all follow-up sessions.

Conclusions: The WeChat-based life review program was effective in reducing anxiety and depressive symptoms and in improving the level of hope and self-transcendence among patients with digestive system cancer. Though friendly visiting can also help to relieve anxiety, its effects are short-term.

Introduction

Cancer is one of the leading causes of mortality and morbidity in the world; approximately 19 million new cases and 10 million deaths occurred in 2020, and these numbers are predicted to increase by 50% over the next 20 years. In China, digestive system cancers, including cancers of the colon, rectum, stomach, liver, and esophagus, are ranked within the top 5 diagnoses, accounting for 41% of new cancer cases and 49% of mortality [1]. A recent systematic review and meta-analysis reported a high prevalence of anxiety and depressive symptoms among patients with digestive system cancer, ranging from 50% among patients with hepatic and pancreatic cancer to 70% among patients with colorectal, esophageal, and gastric cancer [2]. Hopelessness, meaninglessness, and despair are also reported often, along with negative emotions triggered by concerns about death, seeking meaning in life, or unresolved life events associated with regret or pity [3,4].

A systematic review revealed the importance of psychological interventions in palliative care, as they can specifically address patients' emotional difficulties and spiritual concerns [5]. Life review has been recognized as an effective psychological intervention. It is a process of recalling, evaluating, and integrating life experiences to facilitate the achievement of ego integrity [6]. Ego integrity is a state of achieving a sense of meaning and acceptance of past life events that has been found to relate to higher levels of mental health and well-being among patients in a palliative care setting [7]. Life review enables patients to express their emotions, confirm their roles in life, reassess their attitudes toward death, reorganize their perspectives toward life, and finally integrate their entire life into a more acceptable or meaningful whole [8]. Originally, life review targeted older adults' psychosocial crises, but it has since been applied to palliative care. Accumulated evidence suggests that life review could reduce anxiety and depression, elevate hope and meaning in life, and improve self-transcendence and the quality of life of patients with cancer [9-11].

Digital technologies are increasingly being used to promote life review interventions via mobile phones, computers, wearable devices, and social media or applications [12-14]. Wise et al [15] first designed a telephone-based life review and illness narrative intervention with online resources for patients with cancer to share their personal stories and establish social networks. Afterwards, Wise et al [16] further demonstrated the effectiveness of life review in increasing feelings of peace and decreasing negative mood in patients with stage III or IV cancer after 4 months of the program. However, telephone-based life review interviews did not provide the opportunity to observe nonverbal cues, such as patients' facial expressions and body language. Additionally, Wise reported a high dropout rate in a sample that was predominantly White, female, and had high income and high education. Recently, Dang et al [17] tested an avatar-facilitated life review intervention to reconstruct the self and identity of patients with cancer through performativity. Patients were given full-body movement devices that captured their motions and synchronized their voices onto an avatar in a virtual environment. Although the virtual environment induced a sense of immersion during the therapeutic interaction and, therefore, enhanced patients' engagement and self-expression, the program was expensive, and there were hardware limitations [17-19].

Social media sites, such as Facebook, Instagram, and YouTube, and mobile applications have also been used to conduct life review interventions, because they enable patients to share photos, videos, and life stories [20]. WeChat is a social media platform with high popularity in 200 countries, especially China, due to its simplicity, convenience, efficiency, and mobility [21]. It allows users to interact asynchronously with each other through text messaging, voice messaging, video conferencing, and other means, as well as obtain information and resources from various WeChat platforms at any time. In 2018, our research team developed a WeChat-based life review program for patients with cancer, consisting of e-life review interviews, memory prompts, review extraction, mind space, and e-legacy products [22]. A preliminary study found that the program was acceptable, feasible, and promising in improving the psychospiritual well-being of patients with cancer [23]. Thus, this study aimed to robustly evaluate the effectiveness of the WeChat-based life review program in improving the psychospiritual well-being of patients with digestive system cancer using a 3-arm parallel randomized controlled trial.

Methods

Study Design and Setting

A randomized, controlled, single-blinded, 3-group pretest and repeated posttest experimental trial was conducted at the oncology department of a university-affiliated general hospital in Fujian, Southeast China. This study was performed in accordance with the CONSORT-EHEALTH checklist (Multimedia Appendix 1) [24] and was registered with the Chinese Clinical Trial Registry (ChiCTR-IOR-17011998).

Participants

Participants were recruited from June 2019 to October 2020, with follow-up ending in April 2021. Inclusion criteria were as follows: (1) diagnosis of digestive system cancer, (2) age ≥ 18 years, (3) awareness of diagnosis and treatment, (4) ability to use WeChat, and (5) no cognitive or verbal communication impairments. The exclusion criteria included (1) current use of anxiolytics or antidepressants, (2) participation in other psychotherapeutic programs, and (3) severe disability or diagnosis with a rapid-deterioration disease (Karnofsky performance status <40%).

Sample Size

Power analysis was used to estimate the sample size. Assuming a power of 90%, a 2-tailed test, and an effect size of 0.33 for anxiety and 0.43 for depression, 38 and 24 participants were needed to detect changes in anxiety and depression scores, respectively [25]. For hope (effect size 0.68) and self-transcendence (effect size 0.39), sample sizes of 10 and 28 participants were needed, respectively [26]. Anticipating a 20% attrition rate, we aimed to recruit 46 participants for each study group. A final total of 50 participants was recruited for each group.

Randomization and Blinding

A research assistant who was not involved in subject recruitment, data collection, or the interventions conducted the randomization schedule. A research randomizer website [27] was used to generate 150 nonrepeating random number sequences. The numbers ranged from 1 to 150, with 1 to 50, 51 to 100, and 101 to 150 corresponding to the life review group, control group 1, and control group 2, respectively. Each number was separately packaged in a sequentially sealed, opaque envelope to ensure allocation concealment. In this study, the recruited participants and facilitator (the first author) were not blinded to the group assignment; another research assistant, who was blinded to group allocation, conducted the data collection and analysis.

Interventions

All participants received routine care from medical staff at the oncology department. In addition, participants in the life review group received the 4-week WeChat-based life review program and those in control group 1 received the 4-week friendly visiting program.

Life Review Group

The life review group received the WeChat-based life review program along with routine care. The program consisted of a synchronous e-life review interview and asynchronous communication modules (Multimedia Appendix 2). The e-life review consisted of an individual, online, 40-to-60-minute nurse interview on WeChat, including 4 sections: present life (cancer experience); adulthood; childhood and adolescence; and summary of life. The asynchronous communication involved 4 modules. “Memory prompts” presented a set of images, music, videos, and audio-picture books relevant to each life section to trigger the participants’ memories and facilitate the life review process. “Review extraction” was a summary of meaningful events in which participants could view or leave comments. “Mind space” enabled participants to express emotions, hand down wishes, or reveal their true feelings to anyone who was important at that stage. “E-legacy product” was a digital booklet reflecting participants’ significant experiences, which they could transfer to their offspring.

The WeChat-based life review program was conducted weekly and facilitated by the first author, a registered nurse with more than 25 years of experience in clinical cancer care and 50 hours of life review training. Before the intervention, participants in the life review group installed WeChat and created a personal account. They accessed the memory prompts module to obtain an overview of the current session. Then, an e-life review interview was arranged by means of a video call with additional use of instant texts, voice messages, and emoticons. During the life review process, the facilitator monitored participants’ physical condition, emotional status, and responses to the guiding questions. Participants were also encouraged to access the asynchronous communication modules, which were available 24 hours a day, to freely review their interview content, express feelings and blessings, and provide important pictures and e-legacy products.

Control Group 1

Control group 1 received 4 sessions on an individual basis that provided social contact by engaging participants in daily conversation without reviewing the past. For consistency with the life review group, the 4 friendly visiting sessions were conducted by the first author through WeChat. Each visit lasted about 40 minutes, depending on the participants’ preference.

Control Group 2

Control group 2 received routine care, including drug treatment, nutritional support, symptom management, health education, and functional exercise.

Measures

A self-designed questionnaire by the first author was used to collect participants’ sociodemographic information and clinical characteristics. Sociodemographic data included age, gender, marital status, education, monthly income, and religion. Clinical characteristics included the specific diagnosis; the presence or absence of chronic disease and metastasis; the use or nonuse of surgery, chemotherapy, targeted therapy, radiotherapy, and immunotherapy; and Karnofsky performance status. Karnofsky performance status was used to evaluate participants’ physical function on an 11-point scale, with 0 indicating death and a score of less than 40% indicating severe disability and rapidly progressing disease. This study only included participants with a score higher than 40%.

Psychological outcomes included anxiety and depression symptoms; these were measured by the Hospital Anxiety and Depression Scale [28]. This is a 14-item scale divided into anxiety and depressive subscales, with each of 7 items rated on a 4-point Likert scale (higher scores represent increased anxiety or depression). The Chinese version of this scale has good sensitivity and specificity [29].

Spiritual outcomes consisted of hope and self-transcendence. The 12-item Herth Hope Scale [30] was used to assess participants’ hope on a 4-point Likert scale (range 12-48). Higher scores indicate higher levels of hope. The scale has been extensively used for assessment of hope in Chinese patients with cancer; it has a Cronbach α of .87 and a construct validity of .85, indicating good reliability and validity [31]. The 15-item self-transcendence scale assessed participants’ self-transcendence [32]. Each item was rated from 1 (“not at all”) to 4 (“almost always”), with the total score ranging from 15 to 60 and a higher score indicating a higher level of self-transcendence. The Chinese version of the scale has shown good reliability (Cronbach α=.83-.87) [33].

Data Collection and Analysis

A trained research assistant who was blinded to group assignments conducted all data collection. Outcome data were collected at baseline (T0) and 2 days (T1), 1 month (T2), and 6 months (T3) after the intervention. Statistical analysis was performed using R for Windows (version 3.5; R Foundation for Statistical Computing), with statistical significance set at $P<.05$. Normally distributed continuous variables were expressed as the mean and SD, nonnormally distributed continuous variables were presented as the median and range, and categorical variables were expressed as numbers (percentages). The Little test was used to check whether the missing data were missing completely at random. An intention-to-treat analysis was employed. Hypothesis testing used the chi-square test, the Mann-Whitney *U* test, the Fisher exact test, or a 1-way ANOVA to compare baseline data among groups. Since hierarchical linear models have more flexible data requirements and account for individual changes relative to group differences [34], they were employed for repeated measures. Both the baseline scores (intercepts) and change in scores (linear slopes) for each outcome within the groups were estimated in this model [35]. Time was represented as a dummy-coded variable to compare the outcomes at T1 to T0, T2 to T0, and T3 to T0. The effect of life review was examined based on the 3 dummy-coded time variables and the interaction effects between groups.

Ethical Considerations

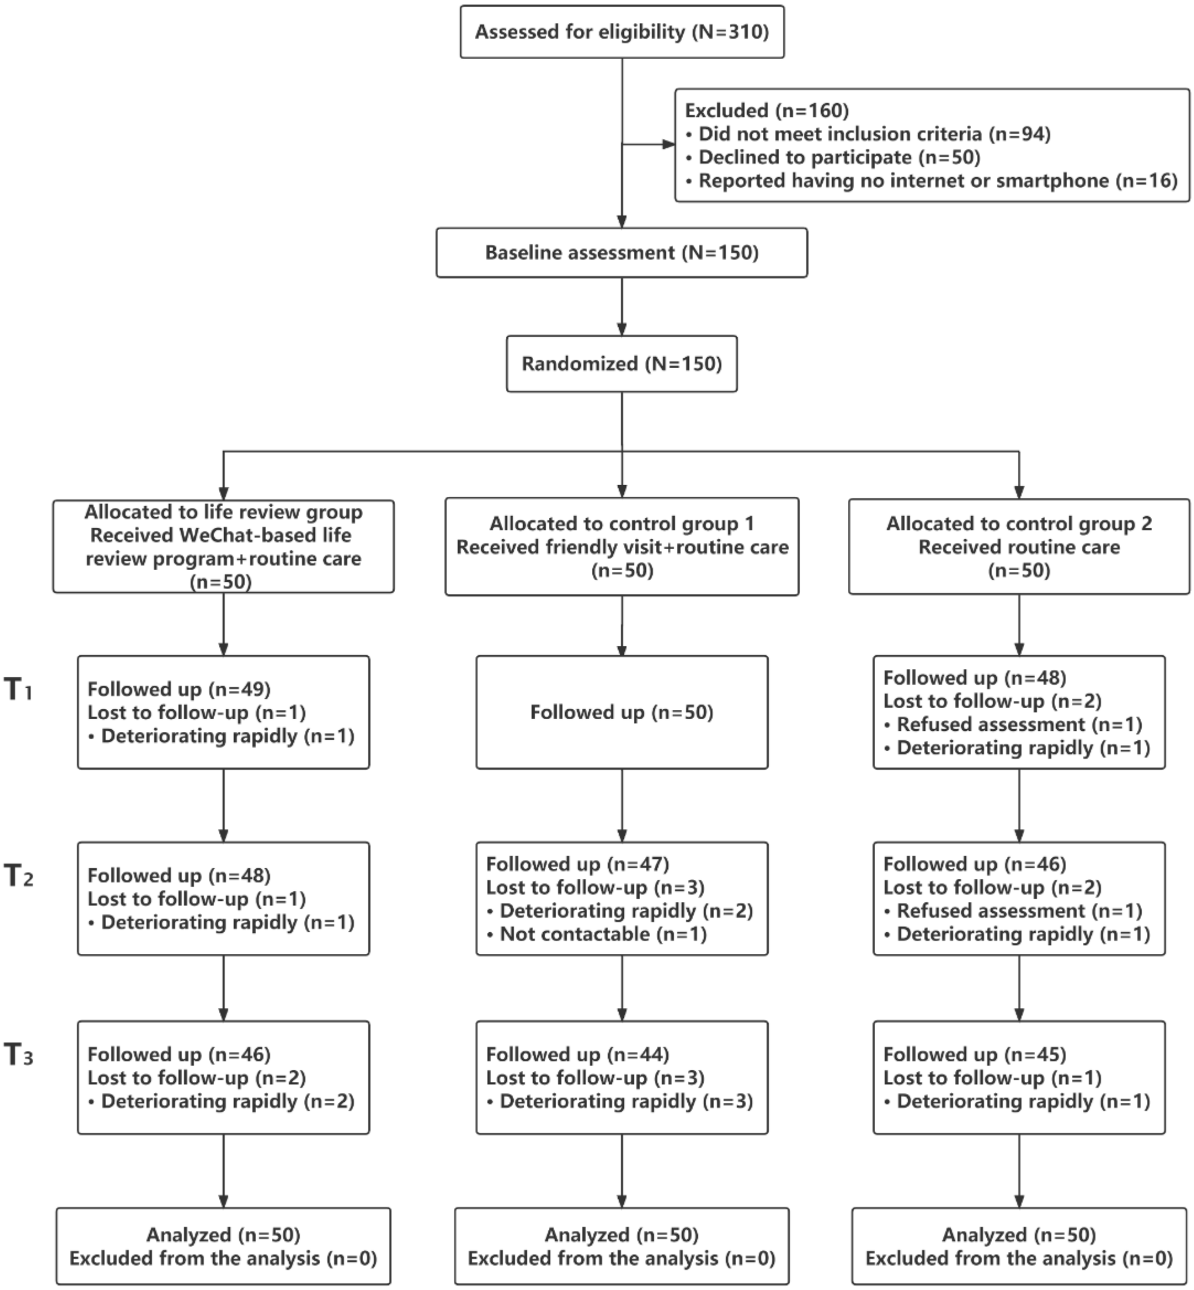
This study was approved by the Ethics Committee of Fujian Medical University (2016/00020) and the study hospital. All participants were provided with detailed information about the study, and written informed consent was obtained from each participant prior to data collection. Importantly, the data collected were kept confidential and anonymous and were used exclusively for this research.

Results

Participant Recruitment and Retention

During the period of this study, 310 patients with digestive system cancer were assessed for eligibility; only 150 patients met the inclusion criteria and consented to participate in this study. They were randomly allocated to 3 groups: the life review group (n=50), control group 1 (n=50), and control group 2 (n=50). Fifteen participants withdrew from the study because their disease progressed (n=12), they refused to participate (n=2), or because they could not be contacted (n=1). Four of these participants were from the life review group, 6 from control group 1, and 5 from control group 2. A final total of 135 participants completed the intervention and measurements. A flowchart of the study is shown in Figure 1.

Figure 1. Flowchart of the study.



Participant Characteristics

Table 1 shows the participants’ sociodemographic characteristics, clinical characteristics, and the baseline outcome variables across the study groups. The participants’ mean age was 58.48 (SD 9.96) years, and the majority were male (123/150, 82%), married (144/150, 96%), and affiliated with a religion (118/150, 78.7%). Less than half of the participants (74/150, 49.3%) had a primary school education level or lower and 57/150 (38%) had an average monthly household income per capita of RMB 1000 (US $148) or less. Among these participants, cancer in the digestive tract (114/150, 76%) was more common than cancer in the digestive glands (36/150, 24%); 48/150 (32%) patients had metastasis. Most patients had undergone surgery (124/150, 82.7%) or chemotherapy (102/150, 68%), and the average Karnofsky performance status was more than 60% (99/150, 66%). The groups’ demographic and clinical details were broadly comparable between the 3 groups. Interestingly, baseline anxiety and depression scores were up to 12% higher in control groups 1 and 2, but this difference could have arisen by chance alone (*P*=.89 and *P*=.17, respectively). Furthermore, this small difference would only have biased the overall estimate of effectiveness toward the null hypothesis, as it would have plausibly been slightly easier to reduce depression and anxiety scores in the control groups, as they started with a higher baseline.

Table 1. Baseline characteristics of participants.

Variables	Total (N=150)	Life review (n=50)	Control 1 (n=50)	Control 2 (n=50)	F/χ^2 (*df*)	*P* value

Effects on Outcome Variables

Table 2 shows the mean (SD) for the outcome variables at baseline and at the 3 follow-up sessions. A hierarchical linear model was employed to examine the change in outcome variables at each time point (Table 3). Overall, the interaction effects of the intervention on anxiety, depression, hope, and self-transcendence between groups over time were statistically significant.

Figure 2 shows the change over time in the mean (SD) scores for anxiety, depression, hope, and self-transcendence. Specific comparisons of outcome variables between groups at each time point and within groups are presented in Multimedia Appendix 3 and Multimedia Appendix 4. For anxiety, there was a significant decrease in the life review group at T1, T2, and T3 compared to baseline (*P*<.001, *P*<.001, and *P*=.002, respectively), indicating that the scores remained stable after the intervention. In the control groups, the anxiety score tended to show an overall upward trend, except for a decrease from baseline to T1 in control group 1. No significant difference in anxiety score was found between participants in the life review group and control group 1 at T1 (*P*=.80). However, the anxiety score was significantly lower in the life review group than in control group 1 at T2 and T3 (*P*=.02 for both). Compared with control group 2, the scores significantly decreased in the life review group at all follow-up sessions (*P*=.01, *P*=.02, and *P*=.01 at T1, T2, and T3, respectively).

A similar tendency was found in the depression score. There was a significant decrease in the life review group at all periods, and an increase in control group 2 from baseline (*P*=.02, *P*<.001, and *P*=.002 for T1, T2, and T3, respectively). As for control group 1, depression decreased significantly at T1 (*P*<.001) and increased at T2 and T3 (*P*=.07 and *P*=.37, respectively). The depression scores did not differ significantly between the life review group and control group 1 at T1 (*P*=.51), but depression was significantly lower in the life review group than in control group 1 at T2 and T3 (*P*=.003 and *P*<.001, respectively). There was also a significant difference in the depression score between the life review group and control group 2 at all follow-up sessions (*P*=.02 for both T1 and T2, *P*=.004 for T3).

A significant difference was observed in the hope score between the life review group and the 2 control groups at all follow-up sessions. Intragroup comparisons showed a significant increase in hope in the life review group after the intervention at T1, T2, and T3 (all *P*<.001). No significant differences were found over time in control group 1 (*P*=.55, *P*=.32, and *P*=.46 for T1, T2, and T3, respectively), while significant decreases were found in control group 2 at T1, T2, and T3 (*P*=.02 for both T1 and T2, *P*=.002 for T3).

In terms of self-transcendence, there was a significant difference between the life review group and the 2 control groups at T1, T2, and T3. Intragroup comparisons showed a significant increase in self-transcendence in the life review group after the intervention at T1, T2, and T3 (all *P*<.001). No statistically significant differences were found in self-transcendence over time for control group 1 (*P*=.46, *P*=.51, and *P*=.24 for T1, T2, and T3, respectively), while significant decreases were found in control group 2 at T1, T2, and T3 (P=.01, P=.04, P=.01 for T1, T2, and T3, respectively).

Discussion

Primary Findings

This is the first study to evaluate the effects of an online life review intervention on the psychospiritual well-being of patients with digestive system cancer; this study adopted a rigorous randomized controlled trial design with a very large sample size and long follow-up time. Our results show that the WeChat-based life review program could reduce anxiety and depressive symptoms and improve feelings of hope and self-transcendence among patients with digestive system cancer for a period of at least 6 months after the intervention. Our findings also revealed that friendly visiting might reduce anxiety symptoms in the short term; however, it did not improve depressive symptoms, feelings of hope, or self-transcendence among patients with digestive system cancer.

Participants' Adherence

Fifteen of 150 participants (10%) withdrew after 6 months of follow-up, which is an attrition rate lower than that of previous online life review studies [16,36]. Specifically, in the life review group, 46 out of 50 patients completed the whole program, indicating that the WeChat-based life review program was well implemented. A possible reason may be that life review is a naturally occurring, universal mental process among patients with cancer in the final life stage [37]. Patients with deteriorating health or low functionality can still participate in life review, even when lying in bed [38]. The low dropout rate may also be due to the simplicity, convenience, efficiency, and mobility of the WeChat-based program, especially among patients with cancer [39]. Considering the time and space limitations, it provided a range of ways to communicate, including text and pictures, voice messages, and video calls, allowing patients to participate in the program at any convenient time and location.

Patients' Outcomes

Among patients with digestive system cancer, anxiety symptoms significantly decreased from baseline up to 6 months after the life review intervention, which is consistent with previous research findings [40]. It is also worth noting that friendly visiting might help reduce anxiety symptoms in the short term, but not the long term. Scholars have put forward the idea that expression is an effective way of regulating emotions, allowing patients to feel supported by others, sort out their thoughts, and release negative emotions [41,42]. In this study, both friendly visiting and life review were conducted in a virtual, individual session where patients could feel safe and comfortable and reveal their innermost feelings in a familiar environment. Friendly visiting allowed patients to express their complaints about the disease and helped them divert their attention to other achievable things, leading to a temporary decrease in anxiety. Conversely, the WeChat life review program's long-term effectiveness may be due to opportunities for patients to retrieve positive thoughts, express and re-evaluate negative emotions, focus on the balance of positive and negative reminiscences, and integrate memories into a meaningful whole. Though painful memories may be picked up during the life review process, the facilitator offers guidance to consider these memories from other perspectives. Accordingly, patients are able to let go, accept, or even gain fresh insights into their lives, finally achieving self-integrity [8]. Meanwhile, the friendly visiting intervention focused on daily conversations without reviewing the past and with no guidance from the facilitator; thus, its effect on anxiety was unstable, with patients' anxiety scores going back to baseline or increasing 1 and 6 months after the intervention.

Our study results further confirmed the long-term benefits of the life review intervention for patients with digestive system cancer. The WeChat-based life review program significantly decreased depressive symptoms long-term, for at least 6 months after the intervention. This is in line with the findings of Lamers et al [43], who reported positive effects 6 months after the implementation of a similar program to ours among adults with moderate depressive symptoms.

The decrease in depression scores might be due to the accumulation of positive thoughts [44]. The WeChat-based life review program facilitated the retrieval of happy feelings from positive memories, prompted by means of appreciating images, music, videos, and audio-picture books. It also provided an opportunity for patients to learn from the past and affirm their contributions to families and society, which may induce positive emotions. On the other hand, reconciling negative experiences contributes to relieving depressive symptoms and improving one's emotional state [45]. In the process of life review, patients were encouraged to optimistically interpret the negative experiences in their own way to give positive meaning to the unpleasant stories, difficulties, and disappointments in their lives. From different perspectives, those negative experiences were reconstructed to bring about desired changes in the patients' views of themselves and their world. Finally, various life experiences were integrated into an acceptable whole and the patients moved toward acceptance of their lives.

Significant improvements in hope were also perceived among patients with cancer who participated in the WeChat-based life review program, consistent with previous research [11,46]. It might be that life review helps patients collate and learn from their pasts and reaffirm their contributions and accomplishments to their families and society, strengthening their awareness of their existence. During the life review process, patients may also perceive support from the facilitator and their family, since positive correlations have been observed between social support and increased hope [47]. Alternatively, patients could have set goals that matched their ability, making them more likely to be successful, thus increasing their feelings of hope. Through the life review intervention, patients become systematically aware of their life trajectory, gain a better understanding of their current situation, and take action congruent with their palliative situation. In addition, the e-legacy products may be beneficial to increase the patients' hope. A systematic review has reported that patients are in a positive state when reviewing their lives, especially when they view, touch, and appreciate the e-legacy product made in the life review process [8]; such feelings are maintained for a period of time.

Significant increases in self-transcendence were observed among patients with digestive system cancer who participated in the WeChat-based life review program, which is consistent with previous findings [23,48]. According to Reed [49], self-transcendence is an expansion of one's conceptual boundaries; inwardly, through introspective activities, outwardly, through concerns about others' welfare, and temporally, by integrating perceptions of one's past and future to enhance the present. The following reasons explain how our WeChat-based life review program could improve self-transcendence. First, during life review, patients recall and evaluate life experiences, and they are encouraged to express their feelings, reorganize their perspectives, and reconstruct the meaning of their lives, which can strengthen the inward domain of self-transcendence. Second, the WeChat-based life review program helps patients connect with their surroundings, which can improve outward transcendence by engaging in reciprocal relationships. While reviewing their lives, patients can reconsider and reflect on their connections to family and society, thereby discovering important emotional support around them. Third, the WeChat-based life review program integrates patients' past and future to improve their present, which is helpful in enhancing the temporal domain of self-transcendence. In sum, the WeChat-based life review program enabled patients to gradually focus on caring for others, transcending the present and achieving self-transcendence by introspection and gaining a harmonious view of the past, present, and future.

This study explored new possibilities for psychological interventions in oncology. The program took advantage of WeChat's increased availability and scalability to life review interventions, which is expected to overcome the obstacles of geographic distance and traffic issues, benefiting more patients, especially remotely located individuals. WeChat also promises to reduce personnel resources for delivery compared with face-to-face interventions. We recommend that future studies also examine the cost-effectiveness of this program, which could convince facilitators to engage in practice and integrate this intervention into transitional care in the community for patients with cancer.

Limitations

The limitations of this study should be noted. First, the WeChat-based life review program may not be suitable for people with poor literacy skills, because they may encounter difficulties in completing the 4 life review modules. Second, participant recruitment took place in only 1 hospital; hence, the generalizability of the findings may be limited. Multicenter and transregional research with a rigorous design is recommended in future research. In addition, this study covered multiple types of cancer diagnoses; future studies may consider selecting patients with the same cancer diagnosis.

Conclusions

Our WeChat-based life review program showed short- and long-term effectiveness in reducing anxiety and depressive symptoms and improving hope and self-transcendence among patients with digestive system cancer. By contrast, friendly visiting might reduce anxiety symptoms, but did not influence depression, hope, or self-transcendence. Accordingly, this WeChat-based life review program should be integrated into transitional care for digestive system cancer.

Acknowledgments

This study was supported by the Humanities and Social Science Fund of the Ministry of Education (grant 18YJA190017) and the Natural Science Foundation of Fujian Province (grant 2020J01644). We are grateful to all patients who participated in the study. We also thank the nurses and doctors from the study hospital's oncology department for their great support during this study.

Abstract

Background: Chronic kidney disease (CKD) is linked to major health consequences and a poor quality of life. Despite the fact that CKD is becoming more prevalent, public knowledge of the disease remains low.

Objective: This study aimed to evaluate the outcome of a health education intervention designed to enhance knowledge, health-related quality of life (QOL), and motivation about healthy lifestyle among adults with CKD.

Methods: This study was a parallel-group (1:1), randomized controlled trial in the Mirzapur subdistrict of Bangladesh that compared 2 groups of patients with CKD. Adults with CKD (stages 1-3) were enrolled in November 2020 and randomly assigned the intervention or control group. The intervention group received health education through a CKD awareness campaign and mobile health technologies and was observed for 6 months, whereas the control group received standard treatment. The primary outcome was the evaluation of improved scores on the CKD knowledge questionnaire, and the secondary outcomes were improved QOL and changes in the levels of blood pressure (BP), BMI, serum creatinine, fasting blood sugar (FBS), hemoglobin, cholesterol, high-density lipoprotein cholesterol, triglyceride, serum uric acid, blood urea nitrogen (BUN), and albumin-to-creatinine ratio.

Results: The study enrolled 126 patients (control: n=63; intervention: n=63) and performed intention-to-treat analysis. The analyses included repeated measures ANOVA, and the results were observed to be significantly different from within groups (*P*<.001), between groups (*P*<.001), and the interaction of group × time factor (*P*<.001) for knowledge score. Diastolic BP and BMI showed significant differences arising from within groups (*P*<.001 and *P*=.01, respectively) and the interaction of group × time factor (*P*=.001 and *P*=.02, respectively); food salinity and hip circumferences showed significant differences arising from within groups (*P*=.001 and *P*=.03, respectively) and between groups (*P*=.001 and *P*=.02, respectively). Moreover, systolic BP and waist circumference showed significant differences from within groups (*P*<.001 and *P*=.003, respectively). However, no significant differences were found arising from within groups, between groups, and the interactions of group × time for QOL, urine salinity, and mid-upper arm circumference. Regarding the laboratory findings, from baseline to 6 months, the mean (SD) FBS decreased by 0.51 (3.77) mmol/L in the intervention group and 0.10 (1.44) mmol/L in the control group (*P*=.03); however, blood urea nitrogen increased by 3.64 (7.17) mg/dL in the intervention group and 1.68 (10.10) mg/dL in the control group (*P*=.01).

Conclusions: The health education strategy, which included a campaign and mobile health, showed promise for enhancing CKD knowledge among patients with CKD. This strategy may also aid patients with CKD in controlling their FBS and BP. The combined health education initiatives give evidence for scaling them up in Bangladesh and possibly other low- and middle-income countries, particularly in rural and peri-urban settings.

Introduction

Chronic kidney disease (CKD) is responsible for poor health outcomes, low quality of life (QOL), and high health care expenses [1]. Globally, the rising trend of CKD is being recognized as a future public health threat [2]. The prevalence of CKD in stages 1-3 has been documented at 8.9% of the global population [3], with rates higher in low-income nations such as India (15.6%) [4] and Bangladesh (21.33%) [5]. Early stage CKD is generally asymptomatic, and diagnosis is usually made through serum creatinine and albumin-to-creatinine ratio tests [6]. If left undetected and untreated, CKD can proceed to end-stage renal disease, which requires expensive renal replacement therapy such as dialysis or kidney transplantation to save the patient's life [7]. Over the last decade, the economic burden of renal replacement therapy has increased dramatically and is substantially higher in low- and middle-income countries (LMIC) than in high-income countries [8]. Although primary renal disease causes CKD, the great majority of patients with CKD have concomitant health conditions such as diabetes, hypertension, and older age [9]. The majority of individuals with nonprimary renal disease are treated for associated risk factors such as diabetes and hypertension rather than the CKD itself [10]. Glomerular filtration rate declines slowly in most patients with CKD in stages 1-3; however, the declining trend varies among individuals and is influenced by a variety of factors such as diabetes, high blood pressure (BP), and older age, etc [6]. Individuals with CKD who receive proper information and knowledge about CKD and its risk factors are more likely to engage in health-promoting behaviors and lifestyle changes [11]. CKD early diagnosis and prevention strategies, such as a CKD preventive campaign, are currently being applied in a number of high-income countries. Increasing knowledge about CKD and its risk factors is a crucial strategy for slowing the disease' progression.

In Bangladesh, community health workers (CHWs) are health cadres who work in public-sector health facilities. In recent years, CHWs in some places have begun to provide services for noncommunicable diseases, including health education and counseling [12]. The use of CHWs to deliver an education and monitoring intervention has been found to be effective in noncommunicable diseases such as reducing BP and has the potential to be scaled up in resource-limited settings [13,14]. They can make a substantial difference in the health of patients living with CKD. CHWs can educate patients to help protect their own kidneys and improve their QOL [15]. Mobile health (mHealth) is still in its implementation phase in the field of nephrology. However, mobile phone call–based health education has great potential to provide CKD knowledge and improve QOL, because it relies on basic mobile technology and requires limited literacy or numeracy skills [15]. A nephrologist-facilitated CKD health campaign also has the potential to improve patients' knowledge and awareness [16,17].

The education of patients with CKD may increase perceived kidney disease knowledge among patients, improve QOL, and delay the progression of kidney disease [18,19]. A community-based screening revealed a high prevalence of CKD in stages 1-3, with only around 7% of the people being aware of their condition prior to the study; however, no health education intervention for these stages was investigated [5]. Most studies on the education of patients with CKD have focused on individuals with end-stage disease and shown improved outcomes [11]. However, a CKD campaign and mHealth-based health education in the early stages could be an integral part of patient management and the reduction of the related risk factors, slowing down the progression of the disease, and the need for such education is greater in rural and peri-urban areas. Thus, this study aimed to evaluate the outcome of a health education intervention designed to enhance knowledge, health-related QOL, and motivation about healthy lifestyle among rural and peri-urban adults with CKD (stages 1-3).

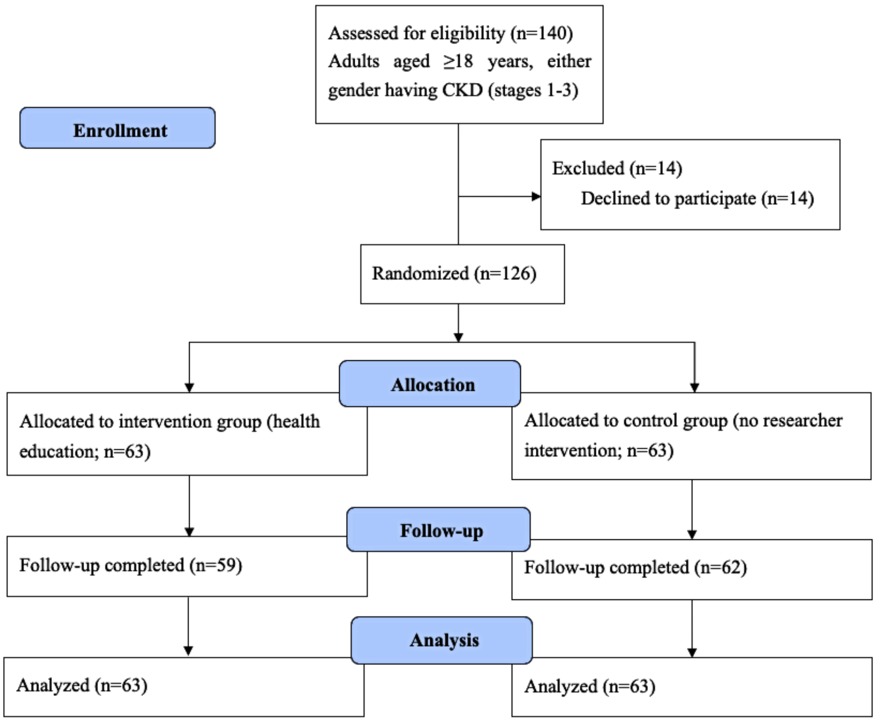
Methods

Design

This study was a community-based, single-center, prospective, open-label, parallel-group (1:1), randomized control trial (RCT) involving patients with CKD, conducted in a rural and peri-urban population of Bangladesh. This study was designed in accordance with the CONSORT (Consolidated Standards of Reporting Trials) [20] and SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) [21] guidelines.

The study flowchart is shown in Figure 1. The total study duration was 1 year; during that 1 year, the intervention duration was 6 months, starting from mid-November 2020 and completed in May 2021.

Figure 1. Flowchart of the participants throughout the study. CKD: chronic kidney disease.



Study Population and Sampling

This study was conducted in the demographic surveillance system (DSS) area of the Mirzapur subdistrict under the Tangail district, which is 60 km north of Dhaka, the capital city of Bangladesh. The details of the Mirzapur DSS have been described in a previous publication [5]. The research team completed a CKD prevalence study before implementing this RCT [5]. The Chronic Kidney Disease Epidemiology Collaboration equation was used to estimate glomerular filtration rate [22], and the National Kidney Foundation Kidney Disease Outcomes Quality Initiative guidelines were used to define and indicate the stages of CKD [23]. We randomly enrolled study patients from the residents of the DSS who have been diagnosed with CKD. The inclusion and exclusion criteria are shown in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion Criteria

- Adults (aged ≥18 years) of either gender, diagnosed with chronic kidney disease in stages 1-3 (any one of the following: estimated glomerular filtration rate = 30-59 mL/min/1.73 m^2 and albumin-to-creatinine ratio ≥30 mg/g for more than 3 months) [24]
- Lived continuously in the locality for at least 5 years
- Has a personal cell phone or access to a shared phone
- Gave written informed consent to participate in the study

Exclusion Criteria

- Individuals diagnosed with chronic kidney disease in stages 4 and 5
- Hospitalized at the time of enrollment
- Having any known, serious illness with questionable prognosis; for example, malignancy, mental illness, congenital disease, or gross physical disability (if they have prescriptions)
- Declined to give consent to participate in the study

Randomization

Permuted block randomization technique was performed using a block size of 6 based on a computer-generated random number sequence. An experienced statistician, who is not involved in the study in any way, prepared the randomization table and listed the study patients’ numbers with the corresponding intervention allocations for patients with CKD in sequentially numbered, sealed envelopes according to the randomization schedule to correspond to the serial numbers of the patients with CKD. These envelopes were kept in an office locker. Allocation was concealed in identical sealed envelopes that were only opened when the study patient was ready for enrollment under the supervision of the principal investigator. This step took place after a patient with CKD had been enrolled in the study, after obtaining voluntary informed written consent and having been assigned a study number.

Study Activities and Contents

CHWs conducted baseline home visits during the first week and received written informed consent before interviewing research patients and administering field-tested standardized questionnaires to collect information on socioeconomic and demographic characteristics, level of knowledge, and QOL. Next, they advised the study patients to visit Kumudini Women's Medical College and Hospital's laboratory for study-related investigations. After evaluating the study patients' eligibility, the statistician performed the randomization. The responsible research staff then opened the sealed envelope, revealing the patient's random allocation, and handed the patient's ID number to the CHWs. Staff in this trial were not blinded to the intervention or control groups; however, they were blinded to the baseline interview. The CHWs called the enrolled trial patients assigned to the intervention group and invited them to the CKD awareness campaign.

In addition to baseline, at 3 and 6 months, the CHWs visited the patients' homes for an interview and physical examination using the same questionnaire. After 6 months, the CHWs advised the study patients to visit the laboratory for study-related investigations.

During the home visits, the CHWs used a Portable Health Clinic box with the essential diagnostic equipment for this research (the details were described in our previous paper) [25]. At the baseline, they collected sociodemographic information such as age, gender, marital status, religion, occupation, educational background, income per month, patient's current medical history including medication use, past medical history, and family history (3 generations) including current and immediate past medical history. The same information was collected at 3 and 6 months in case of any changes from the baseline. They also administered a questionnaire on CKD knowledge and QOL. Physical examinations were performed to measure BP, pulse, height, weight, waist and hip circumferences, and mid-upper arm circumference (MUAC). In addition, blood and spot urine samples were taken to estimate the kidney function status and their related risk factors such as serum creatinine, fasting blood sugar (FBS), hemoglobin, cholesterol, high-density lipoprotein cholesterol, triglyceride, serum uric acid, blood urea nitrogen (BUN), and albumin-to-creatinine ratio (Multimedia Appendix 1).

Intervention Group

A CKD awareness campaign and mHealth technologies were used to provide health education to the intervention group.

CKD Awareness Campaign

A nephrologist conducted the CKD awareness campaign in the native language (Bengali). Important information related to CKD, such as the basics of kidney function and kidney diseases, stages, risk factors, and preventive measures were discussed during the half day campaign. Health education materials (leaflet, short textbook, and recording notebook) were provided to the study patients. The details of the CKD campaign have been discussed in the protocol paper [25].

mHealth Technology

A nephrologist trained the CHWs to conduct the mHealth education. The CHWs were trained over 3 days. The training was facilitated by a nephrologist and coordinated by the project's principal investigator. The program included lectures, discussions, question-and-answer sessions, and role-playing. We developed training materials that were tied to the study objectives to ensure that the CHWs acquired the skills needed to deliver the education to the target patients. The CHWs conducted the health education over a mobile phone call using mHealth technology once every 2 weeks during the intervention period. They discussed with the study participants in the intervention group about fundamental kidney disease, risk factors, and CKD prevention methods. Over a 10-minute session, the patients were free to discuss their health-related concerns with the CHWs. The details of the contents have been described in the protocol paper [25] (Multimedia Appendix 2).

BP Check

During the intervention phase, CHWs performed weekly home visits to the patients belonging to the intervention group and measured their BP.

Control Group

The control group received usual care and was observed without intervention throughout the trial period. At 3 and 6 months, an interview and physical examination were conducted for these patients. Furthermore, they returned to the laboratory for study-related investigations after 6 months.

Sample Size

The sample size was calculated based on the primary outcome—the enhanced knowledge of the study patients following the intervention of the health education program. We assumed that the proportion of existing knowledge among patients with CKD (stages 1-3) was 40% [26], with the percentage of predicted knowledge increasing to 70% following the intervention. As a result, with 90% power and 20% loss to follow-up, the total sample size was 126 (63 in each group). The details of the sample size calculation have been described in the protocol paper [25].

Study Outcomes

The primary and secondary outcomes were measured at baseline, 3 months, and 6 months for both the intervention and control groups (Textbox 2). The laboratory parameters were measured at baseline and 6 months.

Textbox 2. Primary and secondary outcomes.

Primary Outcome

- Evaluation of improved scores on the Chronic Kidney Disease Knowledge Questionnaire [26]

Secondary Outcomes

- Improved quality of life; measured by the EQ-5D-5L quality of life questionnaire [27]
- Changes in the levels of blood pressure, BMI, serum creatinine, fasting blood sugar, hemoglobin, cholesterol, high-density lipoprotein cholesterol, triglyceride, serum uric acid, blood urea nitrogen, and albumin-to-creatinine ratio

Measurements of Knowledge and QOL

The evaluation of knowledge was measured using the Kidney Knowledge questionnaire, a 24-item scale designed to assess the CKD knowledge of patients in stages 1-3. A more in-depth description of the method has been mentioned elsewhere [25]. QOL was measured using the standardized EQ-5D-5L questionnaire [28]. In this study, we used the Japanese region’s tariff to define the standard value (tariff) for EQ-5D-5L to assess the impact of the health care interventions on QOL.

Statistical Analysis

In this study, intention-to-treat analysis was used to compare the outcomes of the intervention and control groups. Missing data were dealt with by using the last observation carried forward method [29]. All baseline indicators at the time of registration were analyzed to ensure the comparability of the randomized samples. For the baseline assessment, continuous variables were compared by 2-tailed *t* test or Mann-Whitney *U* test, and categorical variables were compared by chi-square test. Multiple comparisons were performed by 2-way repeated measures ANOVA for the evaluation of the outcome variables such as CKD knowledge questionnaire, physical measurements, and QOL at baseline, 3 months, and 6 months. In addition, generalized estimating equations were used to estimate the effect of the health education after adjusting for relevant covariates. However, outcome variables for laboratory findings were measured at baseline and 6 months. Changes in the laboratory profiles were compared between the intervention group and control group by 2-tailed *t* test or Mann-Whitney *U* test after checking the data normality. The significance level was set at $P<.05$. The statistical analyses were conducted using SPSS statistical software (version 20.0; IBM Corp).

Consent to Participate

All study patients provided written informed consent and participated entirely voluntarily. The patients received a copy of the consent form. Each study patient received written information about the aim of the study and was informed that they could decide to leave the study at any time and for any reason. Patients in the intervention group were informed that they would get additional health education alongside the usual care, whereas patients in the control group were informed that they would not receive any interventions. Patients were assured that their information would not be disclosed, and they were informed about the use of data for analysis and the use of the results for enhancing patient care activities, conducting research, and publication without disclosing their name or identity.

Ethics Approval

Ethical approval was obtained by the Research Review Committee and Ethical Review Committee of the International Centre for Diarrhoeal Disease Research, Bangladesh (icddr,b) (PR 19081). The study was registered at ClinicalTrials.gov (NCT04094831).

Results

A total of 126 patients (control group: n=63; intervention group: n=63) were enrolled in the study. Of the 126 patients, 5 withdrew from further participation during the follow-up period—4 from the intervention group and 1 from the control group. Of the 4 patients who withdrew in the intervention group, 2 did not participate in the health campaign, and the other 2 did not continue their health education. The patient in the control group, on the other hand, left the area after enrollment into the study. The analyzable study patients, however, still comprised 126 patients, including 63 receiving mHealth education and 63 receiving usual care. Among these study patients, the mean (SD) age was 57.97 (15.03) years and 57.32 (14.37) years for the control and intervention groups, respectively. Among the 63 study patients in each group, 71% (n=45) were female in the control group, whereas 60% (n=38) were female in the intervention group; 67% (n=42) were housewives in the control group, whereas 56% (n=35) were housewives in the intervention group; and 79% (n=50) were married in the control group, whereas 71% (n=45) were married in the intervention group. Furthermore, comparisons between the control and intervention groups in 4 other categories show the following differences: being illiterate at 40% (n=25) versus 48% (n=30), income <US $100/month at 14% (n=9) versus 22% (n=14), present tobacco user at 13% (n=8) versus 16% (n=10), and current smokeless tobacco user at 43% (n=27) versus 30% (n=19). These characteristics did not differ significantly between the control and intervention groups. Except for hip circumference, no outcome indicators differed significantly at baseline. Baseline details are given in Multimedia Appendix 3, and patient flow through in the trial is shown in Figure 1.

The analyses included repeated measures such as ANOVA, and the results were observed to be significantly different for within groups, between groups, and the interaction of group × time factor in terms of knowledge score. QOL on average changed more favorably in the intervention group than in the control group, but the difference largely failed to achieve statistical significance. Diastolic BP and BMI showed significant differences arising from within groups and the interaction of group × time factor; food salinity and hip circumferences showed significant differences arising from within groups and between groups. Moreover, Systolic BP and waist circumference showed significant differences from within groups. However, no significant differences were found arising from within groups, between groups, and the interactions of group × time in terms of urine salinity and MUAC (Table 1).

Using the generalized estimating equation, knowledge score was considerably increased; however, food salinity and hip circumference were significantly decreased in the intervention group compared to the control group in both the unadjusted and adjusted models. However, waist circumference was considerably lower in the intervention group than the control group in the adjusted model (Table 2).

Regarding the laboratory findings, from baseline to 6 months, the mean (SD) FBS decreased by 0.51 (3.77) mmol/L in the intervention group and by 0.10 (1.44) mmol/L in the control group (*P*=.03); however, BUN increased by 3.64 (7.17) mg/dL in the intervention group and by 1.68 (10.10) mg/dL in the control group (*P*=.01). No other laboratory parameters showed any significant changes over the 6-month duration of the study (Table 3).

Table 1. Changes in the study outcomes between the intervention group and control group over time (2-way repeated measures ANOVA test was performed).

Characteristic, group	Baseline, mean (SD)	At 3 months, mean (SD)	At 6 months, mean (SD)	*P* value

[d] eGFR: estimated glomerular filtration rate.

[e] HDL-c: high-density lipoprotein cholesterol.

[f] BUN: blood urea nitrogen.

[g] ACR: albumin-to-creatinine ratio.

Discussion

Principal Findings

To our knowledge, this study is the first trial assessing the outcomes of a health education intervention using a nephrologist-facilitated health campaign and CHW-conducted health education using mHealth technology on patients with CKD in Bangladesh. In this single-center, randomized trial of patients with CKD in stages 1-3, health education through a nephrologist-facilitated health campaign and CHW-conducted mHealth education improved the patient knowledge status when compared with usual patient care. In addition, mHealth can significantly increase disease knowledge in patients with CKD. The effectiveness of CKD campaigns in raising CKD awareness and boosting motivation for healthy lifestyle changes to reduce

CKD-related complications seems promising. Patients can rely on nephrologists as they are a trusted channel for delivering health education on CKD and related risk factors. Most LMIC have a scarcity of nephrologists, particularly in rural areas; therefore, policy makers should prioritize this leading health problem while formulating appropriate intervention strategies. On the other hand, CHWs play an important role in delivering health education through mHealth [30], because they have the ability to develop interventions and sustain community well-being [31], especially in areas where there are a prevailing shortage of registered physicians and nurses.

It is crucial for patients with CKD to keep their BP under control as hypertension is a major risk factor for the development and progression of CKD. In our analysis, the intervention group had decreased systolic and diastolic BP at the end of the study. Weekly BP measurements, in addition to health education, might also have been influential for this study's patients. Studies have documented that regular BP monitoring reduces systolic and diastolic BP significantly when compared to usual care [32]. Our findings are comparable with other similar studies that have been undertaken in a range of settings [13,32]. An RCT in rural India showed that a 3-month health education intervention reduced BP in the intervention group compared to the control group [13]. According to a research study, one-third of Bangladeshis have never monitored their BP and have no idea how to control it [14]. Weekly BP checks may alert patients to their BP status, motivating them to better control their diastolic BP. It has also been hypothesized that if patients are aware of their weekly BP levels and know the risk of hypertension with CKD, then they may be more likely to comply with medical therapy in the longer term. In the intervention group, urine salinity remained unchanged despite considerable reductions in BP and dietary salinity. To decrease salt intake, people must regulate their daily lives once they have gained knowledge, which necessitates ongoing community education as well as changes in food business policies.

Patients with diabetes and CKD are at a higher risk of cardiovascular disease and renal failure. Comprehensive education is essential for empowering patients with diabetes and CKD to self-manage their health status [33]. Our effective health education improved patients' knowledge and awareness about bringing changes in lifestyle and maintaining healthy dietary practices in particular. We found that FBS level was significantly reduced among the intervention group at the end of the 6-month intervention period. According to a study conducted among patients with diabetes in rural China [34], health education enhanced diabetes knowledge and significantly reduced FBS in the intervention group compared to the control group. Related to the BMI, waist and hip circumferences also showed a decreasing trend at the end of 6 months.

The intervention group's BUN level increased significantly when compared to the control group, which is a notable finding in our study. In patients with CKD, BUN is a marker of the retention of nitrogenous uremic solutes, which are predominantly obtained from protein consumption [35]. Increased protein consumption is the most common extrarenal cause of BUN elevation for patients in the early stage of CKD. Nutritional health education is strongly recommended to achieve a positive outcome.

This study observed a favorable trend of QOL improvement in the intervention group compared to the control group; however, no significant improvement was observed. Health education has a strong favorable influence on all health-related QOL metrics in patients undergoing hemodialysis. However, in our analysis, patients with CKD in stages 1-3 were included, and the 6-month trial duration could be the primary explanation for these poor outcomes. Overall, our data are in line with the concept that health education may improve QOL, even though our study patients in the intervention group were illiterate. These, once again, could be linked to poor urine salinity and MUAC outcomes. Improving QOL, urine salinity, and MUAC in this population may be a challenging goal, and perhaps, multiple interventions with longer duration would be the best approach to the problem.

Limitations and Strengths

This study's limitations include a small sample size and a 6-month intervention and follow-up period, in which a longer follow-up period could generate more accurate results. Our study patients were selected randomly from the 3 unions of the Mirzapur subdistrict, and this does not represent the entire rural and peri-urban population with CKD. Moreover, data contamination by neighbors and family members was very plausible; however, the CHWs obtained a verbal agreement from the study patients not to share any study details with their neighbors or other family members. Furthermore, since the participants provided their own data, the outcome assessment was not blinded. The strengths of the study include the facilitation of the health campaign by a nephrologist, and the CHWs' provision of health education through mobile phone calls in the patients' native language (Bengali). Health education materials were developed using the same native language for better understanding even with the patients' minimum technical knowledge and skills. Furthermore, the study's strengths are the unbiased systematic sampling approach used to recruit patients and the standard laboratory facility used to identify patients with CKD.

Practical Implications

Integrating nephrologists and CHWs for health education may enhance the knowledge, glycemic control, and hypertension care of patients with CKD in rural and peri-urban Bangladesh. A CKD campaign and the use of mHealth technology would be substantial advantages for the target populations to minimize CKD risk factors. BP monitoring should be included in the routine care of patients with hypertensive CKD to control their BP.

Conclusions

The health education intervention through a campaign and mHealth technologies demonstrated the potential for improving CKD knowledge among patients with CKD. Education campaigns may have potential for improving FBS and BP among patients with CKD. Both the positive outcomes of health education and weekly BP monitoring interventions on patients with CKD provide evidence for the potential scaling up of these interventions in Bangladesh and possibly other LMIC, especially in rural and peri-urban settings.

Acknowledgments

Japan's Grants-in-Aid for Scientific Research Program has provided funding for this study (grant 18H03113). We would like to express our gratitude to the study patients for their generous support. We are grateful to Dr Yuko Ito for her enormous support and Dr Ashir Ahmed (Kyushu University, Japan) for providing the Portable Health Clinic box. We would like to express our heartfelt gratitude to the nephrologist, community health workers, and laboratory staff for their unconditional support. The International Centre for Diarrhoeal Disease Research, Bangladesh (icddr,b) is also grateful to the governments of Bangladesh, Canada, Sweden, and the United Kingdom for providing core and unrestricted support.

Authors' Contributions

MHRS, MM, and ASGF designed the study. MHRS, MM, and ASGF performed the main statistical analysis. HUR, MMR, SKS, SKD, SEA, TA, and MJC helped with the main statistical analysis and data interpretation. MM, MMR, MJC, SKS, SEA, TA, ASGF, and MHRS helped with the material support during the study. All authors contributed to the drafting and review of the manuscript and approved the final version to be published.
